PBPK-PD models calculate the time-course of PSs in the vascular and body tissues via ordinary differential equations to account for absorption, distribution, metabolism, and excretion processes. The following is an example differential equation of a metabolizing tissue:

$$
\begin{equation*}
\frac{d A_{l}}{d t}=\left(Q_{l} \times C_{a}\right)-\left(Q_{l} \times \frac{C_{l}}{P_{l}}\right)-\left(\frac{V_{M a x} \times C V_{l}}{K M+C V_{l}}\right) \tag{1}
\end{equation*}
$$

where subscripts $l$ and $a$ denote liver and arterial, respectively, $A=$ amount of chemical (mg), $Q=$ blood flow (L/hr), $C=\mathrm{mg} / \mathrm{L}, K M=$ Michaelis-Menten constant $(\mathrm{mg} / \mathrm{L}), \mathrm{P}=$ tissue/blood partition coefficient, CV is venous concentration, and $V_{\max }=$ maximum rate of parent chemical change to metabolite ( $\mathrm{mg} / \mathrm{hr)}$ ).

There are three basic critical components to PBPK-PD models: 1) species-specific physiological parameters, 2) chemical-specific parameters, and 3) experiment-specific details for the studies to be simulated. As per convention, the physiological and chemical parameter values in our model were based on prior empirical measurement (Tardif et al., 1997). Species-specific physiological parameters are the organ weights and blood flow rates for the defined compartments (e.g., organs) in the PBPK-PD model and are derived from the closest like species when not available. Chemicalspecific parameters that are unique for each chemical are the tissue solubility (partition coefficient), metabolism of the parent compound, and plasma and tissue binding characteristics. The specific experimental details pertain to the time of dosing and amount, route of dosing, and whether the subjects are physically active or quiescent. These details were obtained from Rahill et al. (1996).

Figure 1 shows the time-course of toluene concentration in the brain. Toluene increases rapidly from 135 to 150 minutes while the subject engages in exercise. Toluene concentration plateaus during rest then declines rapidly after the end of the 360-minute exposure period.

## ACT-R

ACT-R is a cognitive architecture that specifies how modular cognitive systems interact to produce cognition and overt behavior (Anderson, 2007). Models developed within ACT-R posit a common set of processes and mechanisms, which are instantiated as a computer simulation. Independent modules operate in parallel and include declarative memory, vision, attention, and motor modules. Procedural memory coordinates the behavior of the architecture through a set of production rules. Production rules follow an "IF-THEN" structure that encodes the conditions under which specific actions are taken. ACT-R provides a structure within which potential explanations for the effect of toluene on cognition can
be formalized. For example, toluene might disrupt normal functioning of declarative memory, resulting in a slowdown in the retrieval of task-relevant information. We developed CPC models that formalize three explanations: toluene affects (1) declarative memory, (2) attention, or (3) motor execution. For brevity, we will refer to each of these explanations as the memory CPC, attention CPC, and motor CPC model, respectively.

The memory CPC model formalizes the hypothesis that toluene interferes with memory retrieval. In ACT-R, each fact stored in declarative memory-called a chunk- is associated with an activation value corresponding to the frequency and recency with which it has been used. Higher activation results in faster and more accurate retrieval. The declarative memory system in ACT-R offers several potential mechanisms for toluene modulation. Our criteria for selecting a mechanism were (1) it must be theoretically grounded and (2) it must produce a transient effect. We selected the parameter $F_{d}$ because it produces a temporary decrease in activation and has been successful in accounting for the transient effect of fatigue on declarative memory (Gunzelmann et al., 2012). $F_{d}$ scales base-level activation as follows:

$$
\begin{equation*}
b_{i}=F_{d} \cdot b_{L L} \tag{2}
\end{equation*}
$$

where $F_{d}=[0,1], b_{i}$ is base-level activation for chunk $i$, $b_{L L}$ represents activation associated with life-long learning ( $\approx 2.68$; Gunzelmann et al., 2012). According to this explanation, toluene causes an acute decrease in activation, resulting in longer RTs and more errors. Decay, by contrast, has a destructive effect, which cannot be restored without additional practice.

The attention CPC model formalizes the hypothesis that the time required to attend to a stimulus is longer, resulting in a longer observed RT with no direct change in accuracy. Attentional processing time is controlled by increasing the attention latency parameter. The motor CPC model formalizes the hypothesis that toluene slows down the motor system, which increases RT without affecting accuracy. Motor execution is controlled by increasing the motor latency parameter.
Procedural Memory Model Declarative memory was populated with four chunks that encoded the response mapping. On each trial, the model attended to the number presented on the screen, retrieved a response mapping, and responded with the key specified in the retrieved chunk.
Recognition Memory Model Declarative memory was populated with chunks representing each letter in the alphabet. Once the list of six letters was presented, the model located a new letter starting on the left. After locating the letter, the model attended to the letter, and rehearsed it so as to strengthen its activation in memory. Throughout the course of the learning phase the model studied the list by repeating this cycle of productions. In Rahill et al. (1996), the learning phase was terminated by the subject when he or she was confident that the letters were memorized. However, no informa-
tion regarding the duration of the study phase was reported. We assumed participants studied the list for 10 seconds before proceeding to the test phase, which produced high accuracy found in similar studies (Levinson et al., 2005) with minimal time commitment. When a letter appeared during the test phase, the model attended to it, attempted to retrieve a chunk in memory that matched the letter and was in the study list, and executed a response. The model responded "yes" by key press if the retrieved letter matched the letter presented on the screen. If the letter did not match or no letter could be retrieved, the model responded "no" by key press.

Arithmetic Model Declarative memory in the arithmetic model was populated with chunks representing arithmetic facts. Once the problem was presented (e.g., $3+5-2$ ), the model processed each of the five components starting from left to right. First, the model located the leftmost stimulus (e.g., 3). Next, the model attended to the stimulus and then encoded the stimulus to keep track of the problem state. The model then repeated the procedure on the next stimulus (e.g., + ). After encoding the first two numbers and operator, the model retrieved and then encoded the intermediate solution (e.g., 8). The model processed the remaining stimuli and retrieved the final solution (e.g., 8-2 = 6). Lastly, the model responded whether the solution was less than or greater than 5 via key press. If a math fact could not be retrieved, the model responded randomly.

## Model Integration

The following equations provide a high-level representation of the model integration:

$$
\begin{equation*}
\operatorname{PBPK}(\Lambda, t)=\tau \tag{3}
\end{equation*}
$$

where $\Lambda$ is a set of parameters, $t$ is time since the beginning of the experiment, and $\tau$ is the predicted concentration of toluene in the brain. A high level representation of ACT-R is given by

$$
\begin{equation*}
\operatorname{ACTR}_{m}(\Theta)=(R T, A C C) \tag{4}
\end{equation*}
$$

where $\Theta$ is a set of parameters, $m \in\{$ procedual,recognition memory,arithmetic $\}$ indexes the ACT-R models, and the tuple ( $R T, A C C$ ) is the predicted mean reaction time and accuracy.

A linear link function allows specific ACT-R parameters to vary as a function of toluene level as follows:

$$
\begin{equation*}
\theta_{p}=\beta_{0_{p}}+\beta_{1_{p}} \tau \tag{5}
\end{equation*}
$$

$p \in P=\left\{F_{d}, A, M\right\} \subset \Theta$ indexes the toluene-modulated ACTR parameters, which correspond to fatigue declarative memory $\left(F_{d}\right)$, attention latency (A), and motor latency (M). The intercept $\beta_{0_{p}}$ is the value of parameter $\theta_{p}$ when the concentration level of toluene in the brain is zero. $\beta_{1_{p}}$ is the slope which represents the degree to which $\theta_{p}$ varies as a function of $\tau$. $\beta=\left\{\beta_{0_{p}}, \beta_{1_{p}}\right\}$ represents the set of link function parameters. Let $\hat{\Theta}=\Theta \backslash P$ be the subset of ACT-R parameters that are not determined from Equation 5 (e.g., latency factor).

Table 1: The slopes used in the link function of the CPC models. Slopes were varied over the ranges in brackets with 10 equal interval steps.

| CPC Model | $\beta_{1_{A}}$ | $\beta_{1_{F_{d}}}$ | $\beta_{1_{M}}$ |
| :--- | :---: | :---: | :---: |
| Attention | $[0, .015]$ | 0 | 0 |
| Memory | 0 | $[-.03,0]$ | 0 |
| Motor | 0 | 0 | $[0, .015]$ |
| Baseline | 0 | 0 | 0 |

The CPC model integrates the ACT-R and PBPK-PD models through the linear link function and can be represented as:

$$
\begin{equation*}
\operatorname{CPC}(\hat{\Theta}, \Lambda, \beta, t)=(R T, A C C) \tag{6}
\end{equation*}
$$

We imposed the following parametric restrictions on the CPC models in the interest of parsimony. First, as shown in Table 1, we assumed that toluene affected only one cognitive system: either the attention, memory, or motor system. For example, in the attention CPC model, the slope $\beta_{1_{A}}$ was allowed to vary while the other slopes were fixed to zero. As a basis for comparison, we also included a baseline CPC model in which no parameters were modulated by toluene. Second, we used the same parameterization of the link function across the three tasks. Specifically, when a slope was estimated, the estimated value applied across the three tasks. We also fixed the intercepts to $\beta_{0_{A}}=.085$ and $\beta_{0_{M}}=.05$, which are default values that have emerged as good fitting values across a wide range of studies. Because the intercept $\beta_{0_{F_{d}}}$ does not have a default value, we fixed this parameter to theoretically justified values of $.72,1$, and .83 for the procedural, recognition memory, and arithmetic tasks, respectively, to reflect differences in prior exposure to task-specific stimuli. For example, subjects had more experience with the alphabet used in the recognition memory task than the response mapping used in the procedural memory task.

Third, when possible, we fixed other parameters to default values. For example, we fixed decay to .5. Mismatch penalty and activation noise do not have default values, and as such, were set to 2.8 and .15 for all models under consideration. Fourth, task-specific parameters were fixed across toluene conditions, blocks, and the four CPC models. Specifically, we set the retrieval threshold to .78 in the recognition memory task to control the speed of negative responses. Finally, the parameters of the PBPK-PD model were fixed to values acquired through prior empirical measurement.

## Results

Human RTs (black) are displayed in Figures 2-4 for each task. Each panel represents an exposure condition, and points within each condition represent mean RT for a given block. Human RT increased in the toluene condition for the procedural and recognition memory tasks, but remained relatively constant in the arithmetic task. Although accuracy data were not reported in Rahill et al. (1996), no effect of toluene on ac-

Table 2: RMSE of best fitting models. PMT: procedural memory task, RMT: recognition memory task, AT: arithmetic task

|  |  | RMSE |  |  |  |
| :--- | :---: | :---: | :---: | :---: | :---: |
| CPC Model | $\beta_{1_{p}}$ | PMT | RMT | AT | Aggregate |
| Attention | .0015 | 10.13 | 28.04 | 92.30 | 56.00 |
| Memory | . .003 | 10.87 | 30.33 | 89.24 | 54.78 |
| Motor | .0045 | 9.59 | 23.40 | 90.17 | 54.07 |
| Baseline | 0 | 12.02 | 30.83 | 88.71 | 54.66 |

Figure 2: RT predictions for the CPC models plotted against the human mean RT for the Arithmetic Task. Bars are standard deviations.
curacy was detected. Based on other studies using the same or similar tasks, we assume that accuracy was $\geq 90 \%$ (Levinson et al., 2005; Vincent et al., 2012).

We fit the four CPC models using the parameter ranges displayed in Table 1 and selected the best fitting models using a two-stage procedure. In the first stage, we selected the subset of results for which accuracy was $\geq 90 \%$ in all blocks to ensure that the predictions were in line with previous studies. In the second stage, we selected the $\beta_{1_{p}}$ with the lowest aggregate RMSE for each model. Table 2 summarizes aggregate RMSE, RMSE broken down by task, and the best fitting $\beta_{1_{p}}$ for each model. The predictions of the best fitting CPC models are compared to the human data in Figures 2-4.

Aggregate RMSE was the lowest for the motor CPC model, suggesting that toluene slows down motor processing. Although the improvement in aggregate RMSE relative to the baseline model may appear small, it hides modest but important improvements in the procedural and recognition memory tasks. Importantly, the motor CPC model was able to capture the qualitative pattern of effects found in the human data: an effect of toluene in the procedural and recognition memory tasks with no effect in the arithmetic task.

Figure 3: RT predictions for the CPC models plotted against the human mean RT for the Procedural Memory Task. Bars are standard deviations.

Figure 4: RT predictions for the CPC models plotted against the human mean RT for the Recognition Memory Task. Bars are standard deviations.

It is also informative to discuss patterns found in some poorly fitting CPC models. For example, when $\beta_{1_{A}}$ increased for the attention CPC model, the RT predictions improved to a similar degree as the motor CPC model in the procedural and recognition memory tasks. In the arithmetic task, however, the attention CPC model greatly over-estimated RT due to the large contribution of attention to the overall RT. This finding provides further evidence against the attention CPC model.

## Discussion

We developed and tested a set of CPC models to understand which cognitive systems are affected by toluene and lead to
the performance decrements reported in the literature. The CPC model integrated the physiological dynamics of toluene concentration into the ACT-R cognitive architecture to produce dose-response predictions over a prolonged period of toluene exposure. The CPC models formally instantiated deficits in memory, attentional, and motor processing as competing explanations for detrimental effects of toluene exposure. Our model comparison provided tentative evidence that performance decrements are driven by a slowdown in motor execution. Furthermore, we also found evidence against attention as a mechanism: when attention was modulated by toluene to the same extent as the motor system, it greatly overestimated RTs in the arithmetic task. Importantly, the motor CPC model produced the pattern of toluene effects in the human data: an effect of toluene in the procedural and recognition memory tasks, and no effect in the arithmetic task.

Our CPC model adds to the growing literature showing that integrated models can yield more accurate predictions and deeper insights compared to non-integrative approaches. The CPC model has several benefits. First, it enabled us to account for data at two different time-scales: on the order of milliseconds as well as hours. Second, the CPC model was powerful yet highly constrained. With the CPC model, we were able to account for the effects of toluene exposure in three tasks using a single mechanism. Moreover, other parameters were either set to default values or otherwise highly constrained. Third, the CPC model is quite general, allowing it to be applied to any PS of interest.

## Limitations

Our findings should be interpreted in light of several limitations. First, research on PSs often has small sample sizes and small exposure manipulations due to restrictions imposed by institutional review boards to limit risk. As a result, discriminating among competing explanations is challenging and our conclusions regarding the motor CPC model remain tentative. Second, we also could not apply the model at the individual level or examine nuanced predictions (e.g., false alarms vs. misses) because only summary data were available. Third, our PBPK-PD model could not examine the possibility of region-specific effects of toluene in the brain. A model with this level of detail would provide tighter integration and more focused hypotheses about the affected mechanisms. Finally, we made assumptions about several unreported or ambiguous methodological details, such as the number of trials, the duration of the study phase in the recognition task, and the use of response deadlines. Nonetheless, when these assumptions were changed, the motor CPC still emerged with the strongest level of support.

#### Abstract

People often use spatial language to talk about time, and this is known to both reflect and shape how they think about it. Despite much research on the spatial grounding of temporal language and thought, little attention has been given to how spatial metaphors influence reasoning about real events, especially those in the future. In a large online study ( $N=2362$ ), we framed a discussion of climate change using spatial metaphors that varied on reference-frame (ego- vs. time-moving), speed of movement (fast vs. slow), and time horizon (near, medium, or far future). We found that describing climate change as approaching (time-moving frame) - versus something we approach - made the issue seem more serious, but also more tractable, at least when the rate of motion was fast (e.g., "it's rapidly approaching"). These findings offer novel insights into the relationship between spatial metaphors and temporal reasoning and how we communicate about uncertain future events.

Keywords: metaphor, space, time, framing, reasoning, future

## Introduction

People often talk about time in terms of space (Clark, 1973; Lakoff \& Johnson, 1980). Two holidays can be described as close together, and deadlines, as rapidly approaching. Spatiotemporal metaphors, which underlie such talk, are ubiquitous across cultures (Boroditsky, 2011; Núñez \& Cooperrider, 2013). What's more, much research has established that we actually mentally represent and reason about time in terms of space as well, and that this happens in a manner that is consistent with the particular language we use (Boroditsky, 2000, 2011; Boroditsky \& Ramscar, 2002; Casasanto, 2005; Casasanto \& Boroditsky, 2008; Núñez \& Cooperrider, 2013; but see Casasanto, 2016).

A popular method for assessing this claim is to manipulate how someone is thinking about space before asking them to reason about time. In one early study, for example, Boroditsky (2000) showed participants spatial primes that depicted an agent moving towards a goal or an object moving toward an agent, and then asked them to answer an ambiguous temporal question: "Next Wednesday's meeting has been moved forward two days. Which day is the meeting now that its been moved?".

English speakers use two spatial reference frames for talking about time: ego-moving, which depicts the agent as actively moving through time-space (e.g., "we are approaching retirement") and time-moving, which depicts the agent as stationary while events in time move toward them (as in, "the holiday season is approaching"). In the ambiguous 'Wednesday's meeting' question, the implied vector of motion (forward) differs depending on which frame you adopt - toward (time-moving) versus away from (ego-moving) the individual - such that the meeting could now be interpreted as falling either on Monday (timemoving) or Friday (ego-moving). Boroditsky found that egoand time-moving spatial primes reliably biased participant responses to the ambiguous question in a metaphorcongruent manner, suggesting that people were relying on active spatial representations to reason about time (see also McGlone \& Harding, 1998).

This basic pattern of results has been replicated and extended in many ways, from the use of more ecologically valid spatial primes (Boroditsky \& Ramscar, 2002), to nonlinguistic measures of temporal reasoning (Casasanto, 2005; Casasanto \& Boroditsky, 2008), to cross-cultural comparisons (Boroditsky, Fuhrman, \& McCormick, 2010). These data offer converging support for the view that people (frequently) represent and reason about time using their knowledge of space, and that the specific spatial relations that are mapped onto the domain of time are shaped by patterns of metaphor in language (along with other factors like writing direction and cultural values; Boroditsky, 2011; Casasanto, 2016; Núñez \& Cooperrider, 2013).

While research has been largely focused on showing links between space and time in the mind, scant attention has been given to whether metaphors influence how people reason about real world events in the future. Do people conceptualize impending events differently when they are described using different spatial metaphors for time?

To address this question, we conducted a large-scale linguistic framing study to assess how people think about negative outcomes associated with climate change. We chose climate change because it is a real-world problem laden with uncertainty. In general, people have a very poor
understanding of what climate change is, what the specific outcomes will be, and what to do about it (see Barnosky et al., 2017). We reasoned that this inherent ambiguity might make it easier to observe the effects of spatiotemporal metaphors on how people think and feel about the issue since people's prior beliefs may be somewhat nebulous.

In our experiment, participants first read a brief article about US efforts to tackle climate change, and then responded to questions about how serious and tractable they viewed the issue. We manipulated whether the report described climate change with the ego- or time-moving reference-frame, whether speed of movement in time-space was fast or slow, and whether US conservation goals were situated in a relatively near, medium, or far future time horizon.

We hypothesized that using a time-moving reference frame would make the effects of climate change seem more urgent and serious, since this perspective represents the individual as fixed in place, unable to control the arrival of a negative future event. This would be consistent with prior research showing that people who spontaneously adopt a time-moving perspective tend to show higher levels of state and trait anxiety and depression, which are associated with a loss in feelings of agency (Richmond, Wilson, \& Zinken, 2012).

However, this increase in feelings of urgency does not imply an increase in pessimism about the tractability of the issue. In fact, it could be the case that the time-moving frame might lead people to view climate change as a more tractable problem, given that the individual is free to engage in their own actions on this construal (since they are not occupied with the task of moving through time). This would resonate with research showing that people who spontaneously adopt the time-moving reference frame procrastinate less and are more conscientiousness than those who spontaneously adopt the ego-moving reference frame. (Duffy \& Feist, 2014; Duffy, Feist, \& McCarthy, 2014). One way of thinking about this is that the decrease in feelings of control (and increase in anxiety) that results from the time-moving frame might lead to a compensatory counter-response, such that people would now be motivated to believe that personal actions are likely to be effective in addressing the problem. In other words, when it feels like you cannot stop a future event from happening, you will feel better if you consequently believe that at least you can deal it when it arrives.

We included the speed manipulation to assess whether the "rate" at which we approach future events (or they approach us) might affect or interact with the temporal reference frame in shaping these attitudes towards climate change. It is plausible, for instance, that faster "motion" would be associated with a greater sense of urgency. The time horizon manipulation was included in part to affect perceptions of whether the US seemed likely to achieve the conservation milestones in the article, which allowed us to assess effects of the other spatial metaphors independently of this judgment (see Flusberg, Matlock, \& Thibodeau, in press).

## Experiment

## Methods

Participants A total of 2400 participants were recruited and paid through Amazon's Mechanical Turk for the study in the Spring of 2016 (Berinsky, Huber, \& Lenz, 2012; Buhrmester, Kwang, \& Gosling, 2011). We restricted our sample to people living in the US who had a good performance rating ( $>90 \%$ ) on previous Turk tasks. Data was not analyzed from 38 participants who did not complete the study (i.e. from participants who did not submit a valid completion code), leaving a sample size of $N=2362$. The sample was $46 \%$ male and had a mean age of 35.2 years ( $S D$ $=11.1$ ).

Materials \& Procedure Participants read a brief fictional article that described US efforts to reduce greenhouse gas emissions. It used (1) an ego- or time-moving frame of reference; (2) temporal language about climate change as a slow or fast process (speed), and (3) identified an outcome on a time horizon in the relatively near (2025), medium (2040), or distant future (2115).

As shown in Figure 1, the report began, "In response to the recent Paris Climate Talks, the Associated Press release the following brief statement." The title was presented below this heading in capital letters. The rest of the passage was an appeal for addressing climate change and identified a specific goal for the US: to reduce greenhouse gas emissions by more than $30 \%$ by 2025,2040 , or 2115 .

Figure 1. Participants read this report, which varied on frame of reference, speed of change and time horizon.

The body of the report for the ego-moving frame of reference condition read (differences by speed and time horizon conditions are noted in the text):

We're \{rapidly / gradually\} approaching the day when it will be too late to prevent the devastating effects of climate change. We will \{quickly / eventually\} find ourselves in a world that includes more extreme weather conditions, more public health problems, as well as severe economic challenges if we don't start \{racing / inching\} towards a solution soon. As a result, the United States has pledged to reduce its carbon footprint in the next few decades, approving dozens of projects as part of an effort to reduce greenhouse gas emissions by more than $30 \%$ by $\{2025,2040,2115\}$. The projects will leverage scientific expertise and individual engagement to improve the energy efficiency of cars and
buildings, reduce personal energy use, and increase the use of renewable energies such as wind and solar. Let's avoid the \{race / slow crawl\} towards disaster!
The body of the report for the time-moving frame of reference condition read (differences by speed and time horizon conditions are noted in the text):

The day is \{rapidly / gradually approaching when it will be too late to prevent the devastating effects of climate change. If a solution doesn't start heading our way \{quickly / eventually\}, more extreme weather conditions, more public health problems, as well as severe economic challenges will \{swiftly / slowly\} appear. As a result, the United States has pledged to reduce its carbon footprint in the next few decades, approving dozens of projects as part of an effort to reduce greenhouse gas emissions by more than $30 \%$ by $\{2025,2040$, $2115\}$. The projects will leverage scientific expertise and individual engagement to improve the energy efficiency of cars and buildings, reduce personal energy use, and increase the use of renewable energies such as wind and solar. Let's watch out for disaster as it \{quickly / slowly\} approaches!
Target and Background Questions. After reading the article, participants answered question about whether they thought the US would achieve its climate reduction goal in the stated time frame (i.e., by 2025,2040 , or 2115 ). Then they answered questions about whether they thought the problems of climate change would be solved, whether the disastrous effects of climate change were inevitable at this point, how urgent it is for the US to implement energy reduction programs, and how much risk they perceived to be associated with climate change. Participants also answered questions about their willingness to change their own behavior to reduce greenhouse gas emissions (see Figure 2).

```
Dependent Measures:
    Goal: The United States will achieve its goal of reducing greenhouse gas emissions by more than 30% by...
        1, Strongly disagree, to 5, Strongly agree
    Solvable: Humans will inevitably solve the problems associated with climate change, preserving the earth
        for future generations.
            1, Strongly disagree, to 5, Strongly agree
    Inevitable: The disastrous effects of climate change are inevitable, and there is nothing we can do to
        prevent them.
            1, Strongly disagree, to 5, Strongly agree
    Urgent: How urgent is it for the US to implement energy reduction programs right away?
            1, Not at all urgent, to 5, Very urgent
    Risk Perception: How concerned are you with the following potential consequences of climate change?
        (e.g., soil erosion, water drought, economic decline; 13 items; }\alpha=.93
            0, Not at all concerned, to 7, Extremely concerned
    Behavioral Intentions: Would you be willing to pay a carbon offset cost on future purchases of items
        derived from fossil fuels? (6 items; \alpha=.87)
            1, Definitely no, to 5, Definitely yes
Background Questions:
    Belief in Global Warming: I believe that burning fossil fuels increases atmospheric temperature to some
        measurable degree.(2 items; }\alpha=.90
            1, Strongly disagree, to 5, Strongly agree
    Political ideology (0, very liberal, 100, very conservative)
    Age, Gender, Education, Political affiliation (Democrat, Independent, Republican, or Other)
```

Figure 2. Dependent measures and background questions.

Most dependent measures were rated on a 5-point scale. One exception was the measure of risk perception, recorded on an 8-point slide bar. The measure of risk perception included 13 items (Cronbach's $\alpha=.93$ ). The measure of behavioral intentions included six items (Cronbach's $\alpha=$ .87). All other dependent measures were a single question.

Participants then answered demographic questions about their age, gender, educational history, political ideology (categorically and on a continuum), and about their belief in global warming (two items: "I believe that burning fossil fuels increases atmospheric temperature to some measurable degree" and "I believe that the burning of fossil fuels on the scale observed over the last 50 years has increased atmospheric temperature to an appreciable degree"; Chronbach's $\alpha=.90$; Lewandowsky, Oberauer, \& Gignac, 2013).

Data Reduction. As expected, the dependent measures were correlated with one another. As shown in Table 1, the six measures clustered into two groups: there was a high correlation (a) between the goal judgment, assessment of whether climate change would be solved, and whether the consequences of climate change were inevitable ( $r \mathrm{~s}>.19$ ), and (b) between the measures of urgency, risk perception, and willingness to change one's behavior ( $r \mathrm{~s} \gg .5$ ).

Table 1. Correlations between the dependent measures. Asterisk indicates statistical significance at the $* p<.001$ level.

|  | 1 | 2 | 3 | 4 | 5 | 6 |
| :--- | :---: | :---: | :---: | :---: | :---: | :---: |
| 1. Goal |  | $.38^{*}$ | $-.19^{*}$ | $.15^{*}$ | $.15^{*}$ | $.15^{*}$ |
| 2. Solvable |  | $-.29^{*}$ | -.04 | -.01 | -.01 |  |
| 3. Inevitable |  |  | $-.13^{*}$ | -.06 | $-.10^{*}$ |  |
| 4. Urgent |  |  |  | $.52^{*}$ | $.56^{*}$ |  |
| 5. Risk |  |  |  |  | $.55^{*}$ |  |
| 6. Behavior |  |  |  |  |  |  |

To further investigate the relationship among dependent measures, we did an exploratory factor analysis: a principal components analysis, using singular value decomposition (Mardia, Kent, \& Bibby, 1980). Principal components analysis (PCA) extracts the common variance in measures that are conceptually and empirically related (Dunteman, 1989). The analysis revealed, based on the Kaiser criterion and an analysis of the Scree plot, two major underlying sources of variance in the data, consistent with the pairwise correlations in Table 1. As shown in Table 2, the first factor loaded most heavily on the measures of urgency, risk perception, and willingness to change. The second loaded most heavily on the goal judgment, whether people thought climate change would be solved, and whether they thought the consequences of climate change were inevitable.

To analyze the data parsimoniously, we created two composite outcome variables based on the clustering of dependent measures found in the pairwise correlations and exploratory factor analysis. We combined the first three questions, using PCA, into a measure of how tractable participants considered the problem of climate change, and the last three questions into a measure of how serious participants considered the problem of climate change (see Table 2 for weights used to create the composite measures). The composite measures captured the majority of the variance in the raw data: the measure of how tractable
participants' considered climate change to be captured 53\% of the variance in the first three questions; the measure of how serious participants' considered climate change captured $70 \%$ of the variance in the last three questions ${ }^{1}$.

Table 2. Factor loadings of exploratory factor analysis and weights used to create composite outcome measures.

|  | PC1 | PC2 | Tractable | Serious |
| :--- | :--- | :---: | :---: | :---: |
| Goal | .27 | $\mathbf{. 5 0}$ | .58 |  |
| Solvable | .11 | $\mathbf{. 6 6}$ | .64 |  |
| Inevitable | -.20 | .$- \mathbf{4 6}$ | -.51 |  |
| Urgent | $\mathbf{5 4}$ | -.18 |  | .58 |
| Risk | $\mathbf{5 3}$ | -.19 |  | .57 |
| Behavioral intentions | $\mathbf{. 5 5}$ | -.18 |  | .59 |

There was a moderate correlation between the two composite measures (tractable and serious), $r(2360)=.12$, $p<.001$ (in contrast, $p c 1$ and $p c 2$ are orthogonal), and both were positively correlated with participants' belief in global warming: tractable, $r(2360)=.14, p<.001$; solvable, $r(2360)=.66, p<001$.

## Results

Analysis We conducted our primary hypothesis tests on the two composite measures (i.e. how tractable and serious people consider climate change to be). We also analyzed the six dependent measures separately in exploratory follow-up analyses. For each analysis, an initial omnibus betweensubjects ANOVA is presented with tests for main effects of and interactions between the three experimental manipulations. We show the results of the two ANOVAs, along with the coefficients from the corresponding linear regression models in Tables 3 and 4. Time horizon (2025, 2040, 2115) was treated as an ordinal variable; frame of

[^66]reference (ego- versus time-moving) and speed (fast versus slow) were treated as factors.

To account for the primary source of variance in the dependent measures, we included participants' belief in the anthropogenic origins of climate change as a covariate, although this did not affect the reliability of the results. To address secondary research questions (e.g., who is affected by manipulating the reference frame?), we tested for 2-way interactions between the experimental manipulations and participants' belief in global warming.

Serious The results of a model in which the Frame of reference (ego- or time-moving), speed (fast or slow), and time horizon (2025, 2040, or 2115), as well as participants' belief in global warming, were used to predict how serious people consider climate change to be (see Table 3). The strongest predictor of seriousness was participants' belief in global warming. People who recognized the anthropogenic origins of climate change thought the issue was more urgent, recognized more risk, and were more willing to change their behavior to reduce greenhouse gas emissions.

The model also revealed a main effect of the frame of reference, qualified by an interaction with participants' belief in global warming. Overall, participants were more likely to think of climate change as an urgent issue with important risks worthy of behavior change in the timemoving condition $(M=.06, S D=1.44)$, compared to the ego-moving condition ( $M=-.05, S D=1.52$ ). This was especially true for people who were skeptical about the anthropogenic origins of climate change, likely due to a ceiling effect on this measure for non-skeptics.

Table 3 Effects of experimental manipulations and belief in global warming on perceptions of the seriousness of climate change. The results of the ANOVA $\left(d f_{I}=1\right.$ and $d f_{2}=2350$ in every case) are shown in the first column; regression coefficients (and standard errors) are shown in the second column.

|  | $F(p)$ | $B(S E)$ |
| :--- | :--- | :---: |
| Intercept |  | $0.00(.02)$ |
| Time horizon | $0.63(.429)$ | $-0.03(.03)$ |
| Speed: Slow | $0.05(.818)$ | $0.00(.02)$ |
| Frame of reference: Time | $4.55(.033)$ | $0.01(.02)$ |
| Belief in global warming | $1775.65(<.001)$ | $0.95(.02)$ |
| Time horizon * Speed | $0.51(.475)$ | $0.02(.03)$ |
| Time horizon * Frame | $0.84(.359)$ | $0.03(.03)$ |
| Speed * Frame | $0.04(.839)$ | $0.01(.02)$ |
| Time horizon * Belief | $1.41(.236)$ | $0.04(.03)$ |
| Speed * Belief | $1.55(.213)$ | $-0.03(.02)$ |
| Frame * Belief | $4.66(.031)$ | $-0.05(.02)$ |
| Time * Speed * Frame | $2.06(.151)$ | $0.04(.03)$ |

Separate analyses on "raw" questions about urgency, risk perception, and behavioral intentions yielded consistent results. For example, people reported perceiving more risk in the time-moving reference frame, $B=.43, S E=.20, p=$ .032. Perceptions of risk were related to beliefs about global warming, $B=1.01, S E=.04, p<.001$. These predictors also
interacted, $B=-.12, S E=.05, p=.029$, suggesting that the effect of the reference frame most strongly affected people who reported skepticism about climate science.

Finally, the exploratory analyses of participants' responses to questions of urgency, risk perception, and behavioral intentions suggested that one effect was obscured by analyzing the composite measure: of speed on perceptions of urgency. Participants reported that global warming was a more urgent issue to address when the language suggested that the climate was changing quickly, $B$ $=.27, S E=.14, p=.049$, regardless of time horizon or frame of reference.

Tractable The results of a model in which the Frame of reference (ego- or time-moving), speed (fast or slow), and time horizon (2025, 2040, or 2115), as well as participants' belief in global warming, were used to predict judgments related to how tractable people consider climate change to be (see Table 4). Consistent with the analysis of how serious people consider the issue, the strongest predictor in the model was participants' belief in global warming. People who recognized the anthropogenic origins of climate change were more optimistic about being able to address the problem, probably due to the fact they are the ones who think it is a problem in the first place. There was also a main effect of the time horizon manipulation: people considered the issue more tractable when the specific goal was situated in the distant, as opposed to the near, future.

Table 4. Effects of manipulations and belief in global warming on perceptions of tractable-ness of climate change. ANOVA results ( $d f_{1}=1$ and $d f_{2}=2350$ in every case) are in the first column; regression coefficients (and standard errors) are in the second column.

|  | $F(p)$ | $B(S E)$ |
| :--- | :--- | :--- |
| Intercept |  | $0.00(.03)$ |
| Time horizon | $8.29(.004)$ | $0.07(.03)$ |
| Speed: Slow | $0.00(.981)$ | $0.00(.03)$ |
| Frame of reference: Time | $1.34(.247)$ | $0.02(.03)$ |
| Belief in global warming | $43.04(<.001)$ | $0.17(.03)$ |
| Time horizon * Speed | $1.94(.164)$ | $-0.04(.03)$ |
| Time horizon * Frame | $0.02(.888)$ | $0.00(.03)$ |
| Speed * Frame | $3.11(.077)$ | $0.05(.03)$ |
| Time horizon * Belief | $6.42(.011)$ | $-0.08(.03)$ |
| Speed * Belief | $0.22(.638)$ | $-0.01(.03)$ |
| Frame * Belief | $0.22(.643)$ | $-0.01(.03)$ |
| Time * Speed * Frame | $0.56(.454)$ | $0.02(.03)$ |

Finally, there was an interaction between participants' belief in global warming and the time horizon. The effect of the time horizon manipulation was driven by participants who were more skeptical about climate science. For example, among participants who reported the most skepticism about climate change (a score less than 2 on the measure of belief in global warming; $n=196$ ), there was a relatively large effect of the time horizon manipulation $\left(M_{2025}=-.75, S D=1.34 ; M_{2040}=-.57, S D=1.44 ; M_{2115}=-\right.$ $.11, S D=1.31), F(1,194)=8.652, p=.004$. In contrast,
among participants who reported the strongest belief in climate science (a score greater than 4 on the measure of belief in global warming; $n=668$ ), there was no effect of the time horizon manipulation $\left(M_{2025}=.10, S D=1.22\right.$; $\left.M_{2040}=.10, S D=1.40 ; M_{2115}=.19, S D=1.35\right), F(1,194)=$ $0.36, p=.551$. In other words, people who reported a belief in climate science tended to be optimistic about the issue, regardless of the time horizon of the goal, whereas people who were skeptical about climate science were more likely to think the issue would be solved on a more distant time horizon.

Figure 3. Participants' perception of the tractability of the problem of climate change, as a function of the reference frame and speed. Error bars denote SEMs.

The omnibus test also revealed a marginal interaction between the speed manipulation (whether the effects of climate change were described as happening quickly or slowly) and the frame of reference (ego- or time-moving). As shown in Figure 3, there was an effect of the reference frame when the report described the effects of climate change as occurring quickly (but not slowly). In the fast speed condition, participants were more optimistic about solving climate change on the time-moving reference frame compared to the ego-moving reference frame, $t(1160)=$ $2.07, p=.039$. In the slow speed condition, there was no effect of the reference frame, $t(1198)=0.38, p=.704$.

## Discussion

Time is highly abstract, but people manage to talk and think about it by drawing on spatial language and knowledge (Boroditsky, 2011). In this paper, we examined how particular spatial metaphors used to describe uncertain future outcomes would affect how people think about an important issue. So, instead of focusing on whether people reason about time using spatial representations, we looked at how different spatial construals would affect how they think about a real-world event. In a large online study, we framed a discussion of US efforts to tackle climate change using spatial metaphors that varied according to reference-frame
(ego- vs. time-moving), speed of movement (fast vs. slow), and time horizon (near, medium, or far future).

People appeared to be more optimistic about solutions for climate change with a more distant time horizon (implying there would be more time to address it). This was especially true for people who were skeptical of climate science, which probably reflects a ceiling effect for those who are more inclined to accept the scientific consensus.

More interestingly, and consistent with our initial hypothesis, climate change seemed more serious and urgent when described with a time-moving metaphor than with an ego-moving metaphor. This supports the view that talking about uncertain future events as approaching of their own accord may be associated with additional anxiety surrounding the issue. Because this effect was actually most pronounced for people who were skeptical about climate science (again suggesting a ceiling effect for non-skeptics), this finding may have important practical applications for policy makers and climate science communicators. We also observed some suggestion that metaphorical speed affects this sense of urgency, such that fast "motion" language makes people think the issue is more urgent.

Also consistent with our initial prediction, the reference frame appeared to affect perceptions of the tractable-ness of the issue of climate change, though only when the process was described as happening quickly: people felt the issue was more tractable on the time-moving reference frame when climate change was said to be occurring rapidly. This may arise from the increased sense of urgency and risk surrounding the issue on the time-moving frame - to effectively compensate for this increase in existential anxiety, people may come to view the problem as something they can actually address through concerted action.

Though preliminary, these findings have shed some new light on how metaphor can affect reasoning - both in general and for an issue with real world consequences. Taking a nuanced approach like this to investigating metaphor has the potential to advance our understanding of how metaphor works in the context of communicating about real world problems.

# Early Colour Word Learning in British Infants 

Samuel H. Forbes (samuel.forbes@psy.ox.ac.uk)<br>Department of Experimental Psychology, University of Oxford<br>United Kingdom

Kim Plunkett (kim.plunkett@psy.ox.ac.uk)<br>Department of Experimental Psychology, University of Oxford United Kingdom

#### Abstract

Colour word learning has traditionally been viewed as a difficult task. Previous accounts have focussed on infants' ability to show an adult-like understanding of colour terms. Here we examine whether infants understand colour terms at a basic level, using two different methods: first, evidence from parental reports that British infants can comprehend colour terms early, second from experimental data using eye-tracking. These finding show that colour word learning is a process that begins much earlier than previously thought, and develops slowly as infants learn where the boundaries of each term are located. Due to their abstract properties, colour words present a unique opportunity to assess category learning in infants, as well as the mechanisms that control word learning in general.

Keywords: Word learning; language acquisition; colour

## Introduction

It has long been documented that colour words are difficult for children to learn (Kowalski \& Zimiles, 2006; O’Hanlon \& Roberson, 2006; Soja, 1994; Sandhofer \& Smith, 1999). They are learned late (Heider, 1971; Franklin, 2006) and even when infants do learn to say colour words, they are riddled with errors (Pitchford \& Mullen, 2003). But just how difficult are colour words to learn? Studies to date have had difficulty establishing a time-line for when colour words are learned, leading to various theories about why colour words are more difficult to learn, such as the inability to put categorical terms on a continuous spectrum of colour (Andrick \& Tager-Flusberg, 1986), or their ability to abstract colour as a relevant domain of linguistic meaning (Kowalski \& Zimiles, 2006; O'Hanlon \& Roberson, 2006; Sandhofer \& Smith, 1999). In the present study, it is demonstrated that in fact infants have some degree of colour word knowledge much earlier than previously shown, and that they are able to recognise typical colours when named. This finding suggests that the difficulties that infants have with understanding colour terms correctly may be due more to an inability to recognise the category boundary, rather than a complete lack of understanding of the basic terms.

Research into colour word learning in infants has shown that the age of acquisition has dropped dramatically over time (Franklin, 2006; Shatz, Behrend, Gelman, \& Ebeling, 1996). While early studies had colour words learned as late as $7 ; 0$ (Heider, 1971), more recent studies have concluded that they are learned successfully around three years of age (Pitchford \& Mullen, 2002) or earlier (Mervis, Bertrand, \& Pani, 1995). While there may be an actual drop in age of colour term acquisition due to a rise in coloured plastic goods or other such
environmental influences, it is also possible that an infant's comprehension of colour terms has been underestimated.

It is clear that infants have difficulty grasping an adult-like understanding of the meaning of a colour word, but this does not necessarily imply that they have failed to grasp the meaning of the term. Research into the slow inductive process of colour word learning has shown that it is possible for toddlers from around 30 months to 40 months to comprehend basic colour terms while still making errors (Wagner, Dobkins, \& Barner, 2013; Wagner, Jergens, \& Barner, 2014). This suggests that colour words are similar to most other classes of word, in that children first acquire a partial meaning for the colour terms, and start producing the terms, before then later slowly acquiring a fuller, adult-like meaning. In this case, proper, adult-like comprehension follows only after production, further raising questions about what it is to comprehend in such an abstract category of words. While this account may provide some insight into how colour words are learned, the participants are old enough that they may have already comprehended colour words to a degree. This raises two questions: when are colour words learned, and what is meant in this instance by "learned?"

The present study employs two different means to answer these questions: a parental word-learning survey, and an eye tracking paradigm. While word-learning surveys are particularly useful for measuring production (Fenson et al., 1994), measuring comprehension in this way has been debated (Tomasello \& Mervis, 1994; Houston-Price, Mather, \& Sakkalou, 2007), despite test showing that if anything, they could even be an underestimate of the child's ability (Styles \& Plunkett, 2009). In the case of colour terms, which are a much more abstract category of word than concrete nouns, this doubt might be magnified. The aim of the present study is to investigate when colour word learning is occurring, and in doing so, establish where the process of colour term acquisition might begin. The results of the parental survey are then to be compared to eye-tracking data, in order to confirm the measures of early comprehension, and compare them to measures of production from the survey.

## Parental Reports

## Method

Participants 2692 8-30 month-old participants' details were filled out by parents either on paper or online before visiting the lab. Participants were always visiting either Ply-
mouth Babylab or Oxford BabyLab as part of an experiment. Participants for whom there was incomplete descriptive data of age and gender were not included in the analysis. As a number of participants visited more than once, the total was $N=3413$ samples ( 1653 female). Figure 1 shows participant information by age and gender.

Figure 1: Histogram of participant samples in each age group by gender.

Procedure Parents were asked to fill out the Oxford Communicative Development Inventory (Oxford CDI, Hamilton, Plunkett, \& Schafer, 2000). The Oxford CDI is a British adaptation of MacArthur-Bates CDIs (Fenson et al., 1994), which contains 416 terms. The Oxford CDI differs from the MacArthur-Bates CDIs in that it measures comprehension and production for the full age range of participants. Parents or caregivers were asked to check if their child does not comprehend, comprehends, or comprehends and produces each word. Thus an infant was marked as producing a term only if they were thought to "comprehend and produce" the term, while selecting either "comprehends" or "comprehends and produces" saw them marked as comprehending.

The Oxford CDI contains four colour terms: red, blue, green, and yellow. Only data from these four terms are included in the analysis.

Data was analysed in two separate binomial regressions, one for the comprehension data, and another for the production data, where the outcome was a binary response for the colour term in question (yes or no for either comprehension or production). Both models had fixed effects of which colour term was being recorded, as well as age of participant and the gender of the participant. Gender and colour were both dummy coded in each model.

## Results

A summary of the model coefficients of each model can be seen in Table 1 and Table 2. Effects were added into the model individually and compared by measuring reduction in deviance compared to degrees of freedom, distributed as a
$\chi^{2}$. Colour improved model fit in comprehension $\operatorname{dev}(3)=$ $15.95, p=0.0012$ and in production $\operatorname{dev}(3)=21.58, p<$ 0.0001 , as did gender, both in comprehension $\operatorname{dev}(1)=$ $43.2, p<0.0001$, and in production $\operatorname{dev}(1)=59.89, p<$ 0.0001 .

Table 1: Standardized values of comprehension model effects. Colours are as compared to Blue.

|  | Estimate | Std. Error | $z$ value | $\operatorname{Pr}(>\|z\|)$ |
| :--- | :--- | :--- | :--- | :--- |
| (Intercept) | -8.42 | 0.20 | -41.51 | 0.000 |
| Age | 0.39 | 0.01 | 41.56 | 0.000 |
| Green | -0.25 | 0.07 | -3.75 | 0.000 |
| Red | -0.04 | 0.07 | -0.68 | 0.499 |
| Yellow | -0.11 | 0.07 | -1.67 | 0.095 |
| Male | 0.66 | 0.27 | 2.42 | 0.016 |
| Age:Male | -0.05 | 0.01 | -3.61 | 0.000 |

Table 2: Standardized values of production model effects. Colours are as compared to Blue.

|  | Estimate | Std. Error | $z$ value | $\operatorname{Pr}(>\|z\|)$ |
| ---: | ---: | ---: | ---: | ---: |
| (Intercept) | -9.24 | 0.23 | -39.59 | 0.000 |
| Age | 0.40 | 0.01 | 39.07 | 0.000 |
| Green | -0.34 | 0.07 | -4.65 | 0.000 |
| Red | -0.17 | 0.07 | -2.34 | 0.019 |
| Yellow | -0.19 | 0.07 | -2.55 | 0.011 |
| Male | -0.60 | 0.34 | -1.77 | 0.077 |
| Age:Male | 0.01 | 0.01 | 0.60 | 0.549 |

The results from Table 1 show that there was a large difference between green and the other colours, both in speaking and comprehension, while yellow and red were both slightly behind blue in both areas. Male infants learned the colour words significantly slower than female infants, suggesting that the general advantage that has been seen in word learning for female infants also applies to colour word learning, although it is possible that there is an effect of the higher rates of colour vision problems in males.

The results show that the four basic colour terms measured in this report are learned at a similar age, as reported by parents. All four colour terms are learned mostly within a month of each other, however the data suggests that green may be learned significantly after the other three, with blue generally the first colour term learned. Green may in many cases be learned after the other three colours, but only by a short amount of time. Around three months on average separates learning the colour word and producing it - a gap that suggests that there is a very short time in between basic learning and production.

The colour word learning shown here suggests both comprehension and production at a much earlier age than has been previously shown. By 24 months, around $75 \%$ of infants have learned the four colour terms, and around $50 \%$ were already producing the terms. This result is in stark contrast to previous studies that suggested that at the earliest, some children

Figure 2: CDI estimates of proportion of British infants who understand colour terms at each age.
comprehended colour terms around 30 months (Sandhofer \& Smith, 1999; Pitchford \& Mullen, 2002). Here, parents report that roughly all of the children have learned the terms by this age.
The above results make startling claims about when colour word learning occurs. However, parental surveys have long been called into question, particularly in the case of measuring comprehension (Tomasello \& Mervis, 1994; HoustonPrice et al., 2007). Additionally, the parental reports only contain data from the four basic colour terms, which may not capture the full picture of colour word learning. In order to test the veracity of the claims made by the parental questionnaire, and to expand the scope of colours used from four to six, a second study was designed, using eye tracking data.

## Eye-tracking Study

## Method

Participants $N=146$ participants were recruited for this study, either online or from the local maternity ward. A further $N=23$ participants were excluded for fussiness or for failing to complete the experiment, while $N=5$ participants were excluded from the experiment for failing to complete at least one trial with each colour as both target and distractor. Full participant information can be seen in Table 3. Participants were in 5 age groups, with the oldest age group as a control group who have likely learned colour words (and thus were not selected to be a specific age), and the youngest age group a control group who likely have not yet learned colour terms. All participants were monolingual and were learning English as their first language.

Table 3: Descriptive statistics for participants in Exp 2

| Group | $N$ | Mean Age (months) | SD (months) |
| ---: | ---: | ---: | ---: |
| 12 | 30 | 11.84 | 0.70 |
| 16 | 29 | 15.96 | 0.70 |
| 19 | 31 | 19.69 | 0.73 |
| 24 | 28 | 24.30 | 0.36 |
| 48 | 28 | 53.46 | 18.78 |

Procedure Participants were seated on the lap of the caregiver, around 75 cm from the eye tracker and presentation screen. Participants first completed a nine-point calibration sequence, and following that the trials began. In each trial, participants saw an attractive attention-getter for 2 seconds, and then were presented with two objects. The objects were identical in every way, except for colour. The objects on the screen were coloured one of red, blue, green, yellow, black, or white. All colours were considered to be typical examples of that colour category by three independent observers, and not too dark or light. 2 seconds after the test objects appeared on the screen, participants heard a colour term corresponding to one of the objects, in the format of "look, red," "look at the red one" or "look at the red chair." The objects that made up the stimuli were all regular items that would be seen around the household by the infants, such as furniture or items of clothing. The trial would continue for another 5 seconds after colour label onset.

Each participant saw 18 trials, 3 of each colour, and all trials were left right randomised. Presentation was counter-

Figure 4: Fitted growth curve of looking to each colour after target word onset, separated by age group. Dotted red line indicated target word onset, dotted black line indicates chance looking.

Figure 3: A typical trial as seen by participants.
balanced so that any pairing that participants saw with one of the stimuli (e.g. the red chair) as a target, they would then see again with that as a distractor, and the stimulus that had been the distractor (e.g. the white chair) then became the target. All stimuli were presented on a neutral grey background, and trials were presented in a randomised order. Infant fixations were recorded using a Tobii eye tracker sampling at 120 Hz .

The data was modelled with a hierarchical binomial growth
curve, using the function glmmPQL, with quartic orthogonal polynomials (Mirman, 2014), with a random effect of subject. Age and time were treated as continuous numeric variables, and target colour was dummy coded. Rather than modelling the raw data, which allows infant colour preferences to override the effect of the label, trials were aggregated for each participant, such that the proportion of looks to target was defined by using the target and distractor for the same colour i:

$$
\text { Proportion }=\frac{\operatorname{TargetLooks}(i)}{\text { TargetLooks }(i)+\operatorname{DistractorLooks}(i)}
$$

## Results

The fitted model can be seen in Figure 4. The results indicate that there is very little colour word understanding at either 12 or 16 months, but by 19 months most of the participants understand all six colour words being examined. The effect of the label becomes more defined in the 24 month age group, until almost all participants react to the colour label by looking to the target in the 48 month group. The key fixation period is during the first two seconds after label onset. After that initial effect of the target label, it is likely that the infants return to random looking or looking by preference.

The results of this experiment also show that there is very little difference in the word learning of individual colour terms. Over the three month period between 16 months and 19 months, infants progress from knowing little of any of the colour terms to displaying some abilities in all of them. This shows that any differences in colour word learning must be of a smaller difference than three months.

The model output showed a significant effect of all four polynomials ( $p<0.0001$ ), of age ( $p<0.0001$ ) and of the interaction between age and each of the polynomials ( $p<$ 0.0001 ). The differences between colour terms had no significant effects on the model output (all $p>0.05$ ). This suggests that general patterns of looking at the target vary over the course of the trial by age, but do not really vary by colour.

Finally, the proportion of looks to the target was collapsed so that for each colour and each participant any participant with a proportion of looks to target over 0.55 (above chance) in the first two seconds after target word onset were coded as "looking to target," while any participant looking at a proportion lower than 0.55 were coded as "not looking." These answers were then compared with the responses given by parents in the Oxford CDI for those participants by way of a Chisquared test with Yates' continuity correction. $N=6$ participants were excluded from this analysis as they did not fill out the Oxford CDI. Results showed a significant relationship between CDI answers and infants performance in the eye-tracking task, $\chi^{2}(1, N=560)=22.974, p<0.0001$.

## General Discussion

Two experiments were presented in order to measure colour word learning, the first using parental reports of whether their children were understanding and producing the terms, the second an experimental study using eye-tracking to measure whether infants looked to the coloured object upon hearing the colour label. Both methods have shown that there is early comprehension of colour terms, before 24 months in many participants according to the CDI results. The purpose of the second study was to verify the early comprehension that was evidenced in the parental reports. In the parental reports, the majority of participants were thought to have comprehended all four colour terms in the Oxford CDI by around 24 months. At 19 months, however, only $25 \%$ of participants were reported to have understood the colour terms. It is clear from the eye-tracking data that there is some understanding of the colour terms already by 19 months. Not only does the experimental evidence confirm that colour words are learned early, but it suggests that parents may in fact be underestimating how much their children know with respect to colour terms.

The results of each study showed that although there maybe patterns in the order of acquisition of colour terms in English, the differences between those colour terms are not great - in the parental reports green was seen to be significantly behind the other three colour terms, but only by a difference of around a month, while in the eye-tracking study, none of the colours were learned by the majority of partic-
ipants at 16 months, while at 19 months all were learned. This suggests that there is a great deal of consistency as to when colour words are learned, and follow the assertion of Mervis et al. (1995) that following the learning of the first colour term, others quickly follow.

The results of the present study show that colour word learning occurs as young as 18 months, significantly earlier than has been shown by previous studies (Kowalski \& Zimiles, 2006; O’Hanlon \& Roberson, 2006; Pitchford \& Mullen, 2002; Sandhofer \& Smith, 1999; Soja, 1994). However, both elements of the present study only addressed typical examples of the colours in question, not a full adult-like understanding of colour terms. Previous studies focussed on atypical examples of the colour categories in order to examine colour word learning, but evidence presented here suggests that it is highly likely that this may have led to an underestimation, as the participants may have understood typical examples, but been unable to extend the colour categories in the same way an adult would (Wagner et al., 2013).

In the present study evidence is given for an early comprehension around 19 months of age, in contrast to this, Wagner et al. $(2013,2014)$ have shown that errors are still consistently made by participants around three years of age when presented with atypical examples of the colour category. This suggests that colour words are learned slowly over a long period of time, where an early comprehension precedes production, and that comprehension develops slowly until they have achieved an adult-like understanding (Wagner et al., 2014).

In this sense, colour words behave the same as other classes of word, including concrete nouns (Andersen, 1975), where children begin with typical examples of the word, but take time to learn the words closer to the boundary (Wagner et al., 2014; Yurovsky, Wagner, Barner, \& Frank, 2015). Often the examples closer to the category boundary could be learned after production, while the typical examples will be learned before production. Very similar examples have been seen in the case of time words (Tillman \& Barner, 2015), where children understand the order of time words, but not the exact meaning until much later.

The present study also compared the results of a parental report with those of an experimental eye-tracking study. The eye-tracking data successfully corroborates the results of the parental reports, with results suggesting a close relationship between both measures. Measuring comprehension through the use of questionnaires has long been questioned (HoustonPrice et al., 2007; Tomasello \& Mervis, 1994), despite evidence that it is a successful measure of comprehension at least in the case of object labels (Dale, 1991; Styles \& Plunkett, 2009). The data evidenced here suggests that parents estimate colour word comprehension conservatively, possibly due to comprehension of a colour term being more abstract and thus harder to observe than a more concrete term. Even in the abstract case of colour terms, parental reports provide a useful estimate of comprehension, but parents are sensitive to small improvements that children make in their vocabularies
at a young age, and as such this captures comprehension at an early stage of the process. While parental reports are found here to be largely consistent with CDI reports of their understanding of these individual terms, little is known about how the rest of the colour vocabulary will develop after they learn their first few terms.

Colour words in many respects behave like other classes of words; they are learned early, but it takes infants some time to establish where the boundaries are located, and find an adultlike definition. We have provided strong evidence that colour word comprehension occurs much earlier than thought, preceding production and slowly developing for a number of years. It is worth noting all participants in this study were British monolingual infants and toddlers, learning English. The order and timing of early comprehension of colour words at this stage is only known for British English; it remains to be seen whether the same trends apply to colour word learning globally.

## Acknowledgments

We thank the members of the Oxford BabyLab for assistance in booking participants and gathering CDI data, and to Caroline Floccia and members of the Plymouth Babylab for gathering and sharing CDI data. We are grateful to all the parents and infants who participated in this research. S.H.F. is funded by the Rhodes Trust.

# Word Identification Under Multimodal Uncertainty 

Abdellah Fourtassi<br>afourtas@stanford.edu<br>Department of Psychology<br>Stanford University

Michael C. Frank<br>mcfrank@stanford.edu<br>Department of Psychology<br>Stanford University

#### Abstract

Identifying the visual referent of a spoken word - that a particular insect is referred to by the word "bee" - requires both the ability to process and integrate multimodal input and the ability to reason under uncertainty. How do these tasks interact with one another? We introduce a task that allows us to examine how adults identify words under joint uncertainty in the auditory and visual modalities. We propose an ideal observer model of the task which provides an optimal baseline. Model predictions are tested in two experiments where word recognition is made under two kinds of uncertainty: category ambiguity and distorting noise. In both cases, the ideal observer model explains much of the variance in human judgments. But when one modality had noise added to it, human perceivers systematically preferred the unperturbed modality to a greater extent than the ideal observer model did.

Keywords: Language; audio-visual processing; word learning; speech perception; computational modeling.

Language uses symbols expressed in one modality (e.g., the auditory modality, in the case of speech) to communicate about the world, which we perceive through many different sensory modalities. Consider hearing someone yell "bee!" at a picnic, as a honeybee buzzes around the food. Determining reference involves processing the auditory information and linking it with other perceptual signals (e.g., the visual image of the bee, the sound of its wings, the sensation of the bee flying by your arm).

This multimodal integration task takes place in a noisy world. On the auditory side, individual acoustic word tokens are almost always ambiguous with respect to the particular sequence of phonemes they represent, which is due to the inherent variability of how a phonetic category is realized acoustically (e.g., Hillenbrand, Getty, Clark, \& Wheeler, 1995). And some tokens may be distorted additionally by mispronunciation or ambient noise. Perhaps the speaker was yelling "pea" and not "bee." Similarly, a sensory impression may not be enough to make a definitive identification of a visual category. ${ }^{1}$ Perhaps the insect was a beetle or a fly instead.

Thus, establishing reference requires reasoning under a great deal of uncertainty in both modalities. The goal of this work is to characterize such reasoning. Imagine, for example, that someone is uncertain whether they heard "pea" or "bee", does it make them rely more on the visual modality (e.g., the object being pointed at)? Vice versa, if they are not sure if they saw a bee or a fly, does that make them rely more on the auditory modality (i.e., the label)? More importantly, when input in both modalities is uncertain to varying degrees, do

[^67]they weight each modality according to its relative reliability, or do they over-rely on a particular modality?

In this paper, we propose a probabilistic framework where such reasoning can be expressed precisely. We characterize uncertainty in each modality with a probability distribution, and we predict ideal responses by combining these probabilities in a optimal way. Our work can be seen as an extension to previous Bayesian models of phoneme identification (e.g., Feldman, Griffiths, \& Morgan, 2009), where, instead of a unimodal input, we model a bimodal one. A few studies have explored some aspects of audio-visual processing in a probabilistic framework (e.g., Bejjanki, Clayards, Knill, \& Aslin, 2011). In these studies, the researchers focused on the specific case of phoneme recognition from speech and lip movement, however, where information is tightly correlated across modalities.

In the present work, we study, rather, the case of arbitrary mapping between sounds and visual objects. We test participants on their ability to process audio-visual stimuli and use them to recognize the underlying word. More precisely we study the case where both the word's form and the word's referent are ambiguous, and we examine the extent to which humans conform to, or deviate from the predictions of the ideal observer model. Moreover, some previous studies on audiovisual processing documented cases of modality preference, when people rely predominantly on the visual modality (e.g., Colavita, 1974) or the auditory modality (e.g., Sloutsky \& Napolitano, 2003). Thus, we will explore if participants in our task show evidence of a modality preference.

The paper is organized as follows. First, we introduce our audio-visual recognition task. We next present the ideal observer model. Then we present two behavioral experiments where we test word recognition under audio-visual uncertainty. In Experiment 1, audio-visual tokens are ambiguous with respect to their category membership. In Experiment 2, we intervene by adding noise to one modality. In both experiments participants show qualitative patterns of optimal behavior. Moreover, while participants show no modality preference in Experiment 1, in Experiment 2 they over-rely on visual input when the auditory modality is noisy.

## The Audio-Visual Word Recognition Task

We introduce a new task that tests audio-visual word recognition. We use two visual categories (cat and dog) and two auditory categories (/b/ and /d/ embedded in the minimal pair /aba/-/ada/). For each participant, an arbitrary pairing is set between the auditory and the visual categories, leading to two audio-visual word categories (e.g., dog-/aba/, cat-/ada/).

Figure 1: Overview of the task

In each trial, participants are presented with an audiovisual target (the prototype of the target category), immediately followed by an audio-visual test stimulus (Figure 1). The test stimulus may differ from the target in both the auditory and the visual components. After these two presentations, participants press "same" or "different."

This task is similar to the task introduced by Sloutsky and Napolitano (2003) and used in subsequent research to probe audio-visual encoding. However, unlike this previous line of research, here participants are not asked whether the two audio-visual presentations are identical. Instead, the task is category-based: They are asked to press "same" if they think the second item (the test) belonged to the same category as the first (target) (e.g., dog-/aba/), even if there is a slight difference in the word, in the object, or in both. They are instructed to press "different" only if they think that the second stimulus was an instance of the other word category (cat-/ada/).

The task also includes trials where pictures were hidden (audio-only) or where sounds were muted (visual-only). These unimodal trials provide us with participants' categorization functions for the auditory and visual categories and are used as inputs to the ideal observer model, described below.

## Ideal Observer Model

The basis of our ideal observer model is that individual categorization functions from each modality should be combined optimally. In each modality, we have two categories: /ada/ ( $A=1$ ) and /aba/ $(A=2)$ in the auditory dimension, and cat $(V=1)$ and $\operatorname{dog}(V=2)$ in the visual dimension. We assume, for the sake of simplicity, that the probability of membership in each category is normally distributed:

$$
\begin{aligned}
& p(a \mid A) \sim N\left(\mu_{A}, \sigma_{A}^{2}\right) \\
& p(v \mid V) \sim N\left(\mu_{V}, \sigma_{V}^{2}\right)
\end{aligned}
$$

In the bimodal condition, participants see word tokens with audio-visual input, and have to make a categorization decision. We define word tokens as vectors in the audio-visual space, $\mathbf{w}=(a, v)$. A word category $W$ is defined as the joint distribution of auditory and visual categories. It can be characterized with a bivariate normal distribution:

$$
p(\mathbf{w} \mid W) \sim N\left(M_{W}, \Sigma_{W}\right)
$$

Figure 2: Illustration of our model using simulated data. A word category is defined as the joint bivariate distribution of an auditory category (horizontal, bottom panel) and a visual semantic category (vertical, left panel). Upon the presentation of a word token $w$, participants guess whether it is sampled from the word category $W_{1}$ or from $W_{2}$. Decision threshold is where the guessing probability is 0.5 .

We have two word categories: dog-/aba/ ( $W_{1}$ ) and cat-/ada/ $\left(W_{2}\right)$. Participants can be understood as choosing one of these two word categories (Figure 2). For an ideal observer, the probability of choosing category 2 when presented with an audio-visual instance $\mathbf{w}=(a, v)$ is the posterior probability of this category:

$$
\begin{equation*}
p\left(W_{2} \mid \mathbf{w}\right)=\frac{p\left(\mathbf{w} \mid W_{2}\right) p\left(W_{2}\right)}{p\left(\mathbf{w} \mid W_{2}\right) p\left(W_{2}\right)+p\left(\mathbf{w} \mid W_{1}\right) p\left(W_{1}\right)} \tag{1}
\end{equation*}
$$

We make the assumption that, given a particular word category, the auditory and visual tokens are independent:

$$
\begin{equation*}
p(\mathbf{w} \mid W)=p(a, v \mid W)=p(a \mid W) p(v \mid W) \tag{2}
\end{equation*}
$$

Under this assumption, the posterior probability reduces to:

$$
\begin{equation*}
p\left(W_{2} \mid \mathbf{w}\right)=\frac{1}{1+(1+\varepsilon) \exp \left(\beta_{0}+\beta_{a} a+\beta_{v} v\right)} \tag{3}
\end{equation*}
$$

with $\beta_{a}=\frac{\mu_{A 1}-\mu_{A 2}}{\sigma_{A}^{2}}, \beta_{v}=\frac{\mu_{V 1}-\mu_{V 2}}{\sigma_{V}^{2}}, \beta_{0}=\frac{\mu_{A 2}^{2}-\mu_{A 1}^{2}}{2 \sigma_{A}^{2}}+\frac{\mu_{V 2}^{2}-\mu_{V 1}^{2}}{2 \sigma_{V}^{2}}$ and $1+\varepsilon=\frac{p\left(W_{1}\right)}{p\left(W_{2}\right)}$ is the proportion of the prior probabilities. If the identity of word categories is randomized, and if $W_{1}$ is the target, then $\varepsilon$ measures a response bias to "same" if $\varepsilon>0$, and a response bias to "different" if $\varepsilon<0$.

In sum, the posterior 3 provides the ideal observer's predictions for how probabilities that characterize uncertainty in
each modality can be combined to make categorical decision about bimodal input.

## Experiment 1

In Experiment 1, we test the predictions of the model in the case where uncertainty is due to similar auditory categories, and similar visual categories. Crucially, the similarity is such that the distributions overlap. To simulate such uncertainty in a controlled fashion, we use a continuum along the second formant (F2) linking the words /aba/ and /ada/, and we use a morph that links a dog prototype and a cat prototype.

## Methods

Participants We recruited a planned sample of 100 participants, recruited from Amazon Mechanical Turk. Only participants with US IP addresses and a task approval rate above $85 \%$ were allowed to participate. They were paid at an hourly rate of $\$ 6 /$ hour. Data were excluded if participants completed the task more than once ( 2 participants). Moreover, as specified in the preregistration (https://osf.io/h7mzp/), participants were excluded if they had less than $50 \%$ accurate responses on the unambiguous training trials (6), and if they reported having experienced a technical problem of any sort during the online experiment (14). The final sample consisted of 76 participants.

Stimuli For auditory stimuli, we used the continuum introduced in Vroomen, van Linden, Keetels, de Gelder, and Bertelson (2004), a 9-point /aba/-/ada/ speech continuum created by varying the frequency of the second (F2) formant in equal steps. We selected 5 equally spaced points from the original continuum by keeping the end-points (prototypes) 1 and 9, as well as points 3,5 , and 7 along the continuum. For visual stimuli, we used a morph continuum introduced in Freedman, Riesenhuber, Poggio, , and Miller (2001). From the original 14 points, we selected 5 points as follows: we kept the item that seemed most ambiguous (point 8 ), the 2 preceding points (i.e., 7 and 6 ) and the 2 following points (i.e., 9 and 10). The 6 and 10 points along the morph were quite distinguishable, and we took them to be our prototypes.

Design and Procedure We told participants that an alien was naming two objects: a dog, called /aba/ in the alien language, and a cat, called /ada/. In each trial, we presented the first object (the target) on the left side of the screen simultaneously with the corresponding sound. The target was always the same (e.g., dog-/aba/). The second sound-object pair (the test) followed on the other side of the screen after 500 ms and varied in its category membership. For both the target and the test, visual stimuli were present for the duration of the sound clip ( $\sim 800 \mathrm{~ms}$ ). We instructed participants to press "S" for same if they thought the alien was naming another dog-/aba/, and "D" for different if they thought the alien was naming a cat-/ada/. For each participant, we randomized the soundobject mapping as well as the identity of the target.

The first part of the experiment trained participants using only the prototype pictures and the prototype sounds (12 tri-

Figure 3: Average human responses in the auditory-only condition (left), and visual-only condition (right). A) represents data from Experiment 1, and B) data from Experiment 2. Error bars are $95 \%$ confidence intervals. Solid lines represent unimodal logistic fits.
als, 4 each from the bimodal, audio-only, and visual-only conditions). After completing training, we instructed participants on the structure of the task and encouraged them to base their answers on both the sounds and the pictures (in the bimodal condition). There were a total of 25 possible combinations in the bimodal condition, and 5 in each of the unimodal conditions. Each participant saw each possible trial twice, for a total of 70 trials/participant. Trials were blocked by condition and blocks were presented in random order.

## Results

Unimodal conditions this is the case where the pictures were hidden, or where the sounds were muted. Average categorization judgments and fits are shown in Figure (3, A). The categorization function of the auditory condition was steeper than that of the visual condition. The fit was done using the Nonlinear Least Squares (NLS) R package, as follows. For an ideal recognizer, the probability of choosing category 2 (that is, to answer "different") when presented with an audio instance $a$, is the posterior probability of this category $p\left(A_{2} \mid a\right)$. If we assume that both categories have equal variances, the posterior probability reduces to:

$$
\begin{equation*}
p\left(A_{2} \mid a\right)=\frac{1}{1+\left(1+\varepsilon_{A}\right) \exp \left(\beta_{a 0}+\beta_{a} a\right)} \tag{4}
\end{equation*}
$$

with $\beta_{a}=\frac{\mu_{A_{1}}-\mu_{A_{2}}}{\sigma_{A}^{2}}$ and $\beta_{a 0}=\frac{\mu_{A_{2}}^{2}-\mu_{A_{1}}^{2}}{2 \sigma_{A}^{2}}$. $\varepsilon_{A}$ is the response bias in the auditory-only trials.

For this model (as well all other models), we fixed the values of the means to be the end-points of the corresponding continuum: $\mu_{A 1}=0$ and $\mu_{A 2}=4$ (and similarly $\mu_{V 1}=0$, and $\mu_{V 2}=4$ ). To determine the values of the bias and the variance, we fit a model for each modality, collapsed across participants. For the auditory modality, we obtained $\varepsilon_{A}=-0.20$ and

Figure 4: Proportion of "different" judgments as a function of auditory distance. Solid lines represent average human responses (left), predictions of the ideal observer (middle), and the bimodal fit (right). Dashed lines represent average human responses in the unimodal conditions. Colors represent values in the visual continuum. A) represents data from Experiment 1, and B) data from Experiment 2.
$\sigma_{A}^{2}=2.04$. For the visual modality, we obtained $\varepsilon_{V}=-0.11$ and $\sigma_{V}^{2}=3.34$.
Bimodal condition We fit a model to human responses in the bimodal condition, collapsed across participants, finding $\varepsilon=-0.32, \sigma_{A b}^{2}=5.00$ and $\sigma_{V b}^{2}=7.27$. The fit explained $94 \%$ of total variance.

Ideal observer model We derived the predictions of the ideal observer model by using the values of the variances derived from the unimodal conditions, and the response bias derived from the bimodal condition, and by substituting these values into the expression of the posterior in Eq. 3. Figure $(4, \mathrm{~A})$ shows participants' responses in the bimodal condition (left), as well as the prediction of the ideal observer (middle), and the bimodal fit models (right).

Response bias We found negative values in all response bias terms, which suggests a general bias toward answering "different." This bias is probably due to the categorical nature of our same-different task: when two items are ambiguous but perceptually different, this could cause a slight preference for "different" over "same".

Modality preferences We next analyzed whether there was a preference for one or the other modality when making decisions in the bimodal condition, beyond that explained by the variance in categories implied by the unimodal responses. This preference would manifest as a deviation from the decision threshold predicted by the ideal observer model. The decision threshold is defined as the set of values in the audio-
visual space along which the posterior (Eq. 3) is equal to 0.5 . The decision threshold takes the following form:

$$
\begin{equation*}
v=-\frac{\sigma_{V}^{2}}{\sigma_{A}^{2}} a+v_{0} \tag{5}
\end{equation*}
$$

If the slope derived from the bimodal fit is greater than the slope of the ideal observer, this finding would suggest a general preference for the auditory modality (similarly, a smaller slope would suggest a preference for the visual modality). The limit cases are when there is exclusive reliance on the auditory cue (a vertical line), and where there is exclusive reliance on the visual (a horizontal line). Figure 5 (top left) shows the decision threshold in the audio-visual space with a constant intercept; the fit to human data (solid black line) was very close to the ideal observer threshold (red line). Nonparametric resampling of the data showed no evidence of a deviation from the slope of the ideal observer ( 5 , bottom left).

## Discussion

Qualitatively, participants' judgments were similar to the predictions of the ideal observer model (remember that the latter was obtained by optimally combining fits to the unimodal data). Consider, for example, the contrast between the auditory-only case (dashed black line in Figure 4, top left) and the bimodal case (solid colored lines). Higher certainty in the visual modality generally influenced responses, with greater visual distance leading to more "different" ratings and less visual distance leading to more "same" ratings. Similar ob-
servations can be made about the contrast between the visualonly case and the bimodal case.

Overall, we found that the ideal observer model explained much of the variance in judgments $\left(r^{2}=0.89\right)$. But although we see a qualitative resemblance between human data and the model, there were quantitative differences. For example, model predictions were more influenced by the visual modality at the auditory midpoint (the point of highest uncertainty) than human judgements, and were more compressed at the endpoints (the points of lowest uncertainty).

Formally, there was an increase in the value of the variance associated with each modality. Whereas the ideal observer model predicted the weights to be proportional to $1 / \sigma_{A}^{2}$ and $1 / \sigma_{V}^{2}$, for the auditory and the visual modalities, respectively (see expression 3), the fit to human data suggested that the real weights were proportional to $1 / \sigma_{A b}^{2}$ and $1 / \sigma_{V b}^{2}$. Our analysis of modality preference showed that the relative values of these variances were almost the same (Figure 5, left). Thus, 1) the bimodal presentation introduced a certain level of randomness in the participants' responses, and 2) this increased randomness did not affect the relative weighting of both modalities, i.e., participants were weighting modalities according to their relative reliability. The latter explains the qualitative resemblance between the predictions of the ideal observer and human data, and the former explains the quantitative discrepancy.

In sum, we found that participants followed the ideal observer model in that they weighted modalities according to their reliabilities. In real life, however, tokens can undergo distortions due to noisy factors in the environment. In Experiment 2, we explore this additional level of uncertainty.

## Experiment 2

Imagine that the speaker generates a target production $t$ from an auditory category $t \mid A \sim N\left(\mu_{A}, \sigma_{A}^{2}\right)$. In Experiment 1, we assumed that the observer could directly retrieve this production token. But if the observer is in a noisy environment, they do not hear exactly this produced target, but the target perturbed by noise, which we assume, following Feldman et al. (2009), that it is normally distributed: $a \mid t \sim N\left(t, \sigma_{N}^{2}\right)$. When we integrate over $t$, we get:

$$
\begin{equation*}
a \mid A \sim N\left(\mu_{A}, \sigma_{A}^{2}+\sigma_{N}^{2}\right) \tag{6}
\end{equation*}
$$

In this experiment, we explored the effect of this added noise ${ }^{2}$ on performance in our task. We tested a case where one modality was ambiguous and noisy (auditory), and where the other modality was ambiguous but not noisy (visual). We were interested to know if participants would treat this new source of uncertainty as predicted by the ideal observer model, and whether noise in one modality would lead to some systematic preference for the non-noisy modality.

[^68]
## Methods

Participants A planned sample of 100 participants was recruited online through Amazon Mechanical Turk. We used the same exclusion criteria as in the previous experiment; the final sample consisted of 93 participants.

Stimuli and Procedure We used the same visual stimuli as in Experiment 1. We also used the same auditory stimuli, but we convolved each item with Brown noise of amplitude 1 using the audio editor Audacity (2.1.2). The procedure was exactly the same as in the previous experiment, except that test stimuli were presented with the new noisy auditory stimuli.

## Results

Unimodal conditions We fit a model for each modality, collapsed across participants. For the auditory modality, our parameter estimates were $\varepsilon_{A}=-0.18$ and $\sigma_{A}^{2}+\sigma_{N}^{2}=4.70$. For the visual modality, we found $\varepsilon_{V}=-0.24$ and $\sigma_{V}^{2}=3.93$. Figure 3 (bottom) shows responses in the unimodal conditions as well as the unimodal fits. In contrast to Experiment 1, auditory responses were flatter (showing more uncertainty).
Bimodal condition We fit a model to human responses in the bimodal condition, collapsed across participants. We estimated $\varepsilon=-0.38, \sigma_{V b}^{2}=5.21$, and $\sigma_{A b}^{2}+\sigma_{N b}^{2}=9.84$. The fit explained $97 \%$ of total variance.
ideal observer model We generated the predictions of the ideal observer model by using the values of the variances derived from the unimodal conditions, and the response bias derived from the bimodal condition, and by substituting these values into the expression of the posterior in Eq. 3. Results are shown in Figure 4 (bottom).

Modality preferences Participants' decision threshold suggested a preference for the visual modality (the non-noisy modality). Indeed non-parametric resampling of the data showed a decrease in the value of the slope ( 5 , right).

## Discussion

We found, similar to Experiment 1, that participants generally showed qualitative patterns similar to the ideal observer model ( $r^{2}=.91$ ). But we also found a similar discrepancy at the quantitative level. The ideal observer model predicted the modality weights to be proportional to $1 /\left(\sigma_{A}^{2}+\sigma_{N}^{2}\right)$ and $1 / \sigma_{V}^{2}$, for the auditory and the visual modalities, respectively. The fit to human data suggested that the empirical weights were proportional to $1 / \sigma_{A b}^{2}$ and $1 / \sigma_{V b}^{2}$. An interesting difference with Experiment 1, however, was that participants had a clear preference for the non-noisy modality, as the values of the relative variances were different (Figure 5, right). This preference affected the relative weighting, where, contrary to Experiment 1, the visual modality had greater weight than what could be expected from its relative reliability alone.

It is important to understand that this preference was not the mere consequence of the added noise increasing the variance of the auditory modality, since this increase was already

Figure 5: Top: decision thresholds in the audio-visual space. Red dotted line is the prediction of the ideal observer. Blue dotted lines are cases where modality preference is twice as strong as the ideal observer. Solid line is the threshold derived from human data. Bottom: comparison of the threshold slope between the ideal observer and the fit to human data. Error bars are $95 \%$ confidence intervals computed via nonparametric bootstrap.
accounted for in the ideal observer model. The preference was, rather, a form of over-reliance on the visual modality.

## General Discussion

Understanding language requires both the ability to integrate multimodal input, and the ability to deal with uncertainty. In this work, we explored a case where both abilities were at play. We studied the case of identifying a word when both its form (auditory) and its referent (visual) were ambiguous with respect to their category membership (Experiment 1), and when the form was perturbed with additional noise (Experiment 2). We introduced a model that instantiated an ideal observer, predicting how information from each modality could be combined in an optimal way. In both experiments, participants showed the qualitative patterns of the ideal observer.

There were, however, quantitative differences. Audiovisual presentation increased the level of randomness in the participants' responses. One possible explanation is that this phenomenon was caused by the arbitrary nature of the formmeaning mapping. Previous studies suggest that while redundant multimodal information improves performance (e.g., determining the frequency of a bouncing ball from visual and auditory cues), arbitrary mappings generally tends to hinder performance (for review, see Robinson \& Sloutsky, 2010).

Interestingly, however, in Experiment 1 this increase in randomness occurred at a similar rate for both the auditory and the visual modality, and thus, it did not affect their relative weighting. The latter was primarily determined by in-
formational reliability. Only when we intervened by adding noise to one modality in Experiment 2, did participants show a systematic preference for the non-noisy modality. One possible explanation for this preference could be that people do not combine cross-modal uncertainties of a similar kind (e.g., ambiguity in both modalities) in the same way they would combine uncertainties of different kinds (e.g., ambiguity in one modality and noise in the other). For instance, it could be that the latter, but not the former, cause the over-reliance on a particular modality.

Overall, in both Experiments, the majority of the variance could be explained by an ideal observer that combined multimodal information optimally. In the light of this main result, we can revisit some previous findings in the literature. For instance, Sloutsky and Napolitano (2003) reported a dominance for the auditory modality in children. This dominance disappears or reverses in adults. Could this difference be driven by changes across development in the level of perceptual noise affecting the intrinsic relative reliability of modalities (by analogy to Experiment 2)? More work is needed to carefully examine this (and other) speculations, and more generally, to determine the extent to which the optimal combination account helps us better understand the mechanisms of word processing and learning.

# Could both be right? Children's and adults' sensitivity to subjectivity in language 

Ruthe Foushee (foushee@berkeley.edu) Mahesh Srinivasan (srinivasan@ berkeley.edu)<br>Department of Psychology, University of California, Berkeley, Berkeley, CA 94704

#### Abstract

While some word meanings, like "spotted," depend on intersubjectively accessible properties of the world, others like "pretty" invoke speakers' subjective beliefs. We explored children and adults' sensitivity to the subjectivity of a range of adjectives, including words like "spotted" and "pretty," but also words like "tall," which are evaluated relative to a standard. Participants saw two speakers who had independently experienced sets of exemplars of a novel object kind disagree about whether a critical exemplar was, e.g., "tall," "pretty," and "spotted." In Experiments 1 and 3, speakers had seen distinct sets of exemplars, while in Experiments 2 and 4, the sets were identical. Adults always judged disagreements over words like "pretty" as faultless-indicating that both speakers "could be right"-and permitted less faultless disagreement for ones like "tall" when the speakers had experienced identical sets of exemplars. Strikingly, children did not respond in an adult-like manner until age 8 or 9 , but their explanations for speakers' conflicting assertions suggested some sensitivity to the kinds of knowledge relevant for evaluating different adjectives.

Keywords: metalinguistic development; theory of mind

## Introduction

What goes into our understanding of what other people say? While comprehension of some words, like "spotted" or "striped," does not appear to rely on our knowledge of others' beliefs and experiences, comprehension of other words, like "pretty" or "tasty," does. Thus, when someone says that they saw a "spotted bird," we can understand what they mean by leveraging our understanding of what "spotted" and "bird" refer to. We understand that the bird must have some spots on it to be called "spotted," and that were we also to see the bird, we would agree with the speaker's description. The meaning of "spotted" is in this sense intersubjective, based on properties in the external world all speakers can access. In contrast, when someone says that they saw a "pretty bird," it is not immediately apparent what property of the bird she is describing, nor that we would agree that the same bird is "pretty." This is because the meanings of words like "pretty" are not intersubjective, but instead depend on the speaker's belief.

The present studies are motivated by the idea that many words-far beyond clearly subjective predicates of personal taste like "pretty," "tasty," and "funny"-are interpreted relative to their speakers. In particular, we consider the cases of relative adjectives like "big" and "cold," which have to be interpreted relative to the nouns they modify: a "big bird" is smaller than a "big lion." We test whether these predicates are also interpreted relative to the prior experiences and beliefs of speakers. Do we adjust the imagined size of a "big apartment" or temperature of a "cold day" depending on the sample of apartments and weather we believe our interlocutor has experienced? Speakers may have different thresholds for calling an apartment "big" or a day "cold" depending on their
prior experiences, such that they may not always agree about whether a specific apartment or day is "big" or is "cold."

As we review below, the fact that speakers may have different things in mind when using words like "big" and "pretty" may pose a challenge for successful communication. This is especially true in light of evidence that children (and even adults) have an overarching tendency toward naive realism; i.e., to behave as though their own perception reflects reality and their judgments are objective (Ross \& Ward, 1996).

## Background

Previous work demonstrates that children have sophisticated knowledge of relative adjectives, but leaves open whether they incorporate information about their interlocutors into their interpretations. Four-year-olds understand that the meanings of words like "big" and "tall" depend on distributions of referents within a given class. For example, they appropriately identify "tall pimwits" as ones at the higher end of the distribution of only pimwit heights, even if that means ignoring other, taller objects (Barner \& Snedeker, 2008). Five-year-olds also understand that the frame of reference for what counts as "high" or "low" varies with the class of object in question (e.g., "high" for a bird is much higher than "high" for a bunny: Smith, Cooney, \& McCord, 1986).

One reason to think that children may have difficulty interpreting the meanings of words that depend on speakers' beliefs is that they appear to begin life heavily influenced by naive realism, and behave as if their own construal of a stimulus will be shared by others. In one study, for example, children were shown an image that was then covered so only an unidentifiable quadrant of it was left visible. Four-year-olds predicted that others would still be able to identify the largely occluded image, seemingly discounting their previous subjective access to it in full (Taylor, Cartwright, \& Bowden, 1991).

In general, the literature suggests that young children might be able to understand why people say the things they say, but still have difficulty thinking that others can have different meanings for words than they do, perhaps due to their fundamental assumptions about language itself. For example, although toddlers recognize that others might want a different snack from one that they themselves find delicious (Repacholi \& Gopnik, 1997), they judge statements of unconventional snack opinions like "ice cream is yucky" as unacceptable well into the preschool years (Holubar, 2015). Thus, preschoolaged children understand that others may have different preferences, but struggle with understanding that an unqualified statement about a preference that they think is wrong can still be "right." Children's eventual success on false belief tasks (e.g., Wellman \& Liu, 2004) demonstrates their understanding that an individual's experience leads to their beliefs. But
it may be more challenging for children to understand that experience might result in speakers of the same language having different meanings for the same word (e.g., such that speakers have different temperatures in mind when they talk about a "cold day"). Consistent with this, studies on children's beliefs about conventionality in language have argued that children expect object labels to be shared by other speakers of their language, even given evidence to the contrary (e.g., when other speakers were absent when a novel object's label was taught: Diesendruck, 2005).

While adults "succeed" on some of these tasks that stump children, they are also not immune to the influence of naive realism, suggesting some form of continuity over development. For example, adults often overestimate the prevalence of their own attitudes in the general population, and are reluctant to attribute those attitudes to their own subjective experience, rather than to objective features of the world (see Ross \& Ward, 1996 for a review). When it comes to language, adults have the metalinguistic knowledge to be able to explicitly judge words and phrases like "pretty shirt" as subjective when they are presented in the absence of a referent that they could evaluate (Scontras, Degen, \& Goodman, 2016). However, to our knowledge there have been no empirical investigations of whether adults permit different word meanings for speakers when the adults themselves are confident of whether the word applies: e.g., when they are confident that a particular shirt is "pretty" or "big." Additionally, no studies have explored whether adults' tolerance of disagreement about different word uses is influenced by their knowledge of a speaker's relevant prior experience.

## The Present Studies

Here, we explore adults' and children's sensitivity to linguistic subjectivity across four experiments. In particular, we ask whether, in addition to considering the real-world distribution of a specific noun's referents along a given dimension, listeners also interpret adjectives like "tall" relative to what they know of the distribution that the speaker has experienced. To test these ideas, we manipulate whether two speakers experience different distributions of exemplars of a novel object kind (Exps. 1 and 3), or identical distributions of exemplars (Exps. 2 and 4), and assess whether this affects adults’ (Exps. 1 and 2) and children's (Exps. 3 and 4) judgments of whether the two speakers can disagree about how to describe a novel target exemplar that they can both see.

Across our studies, the disagreeing assertions that participants judge involve adjective-noun phrases that describe the same target object: e.g., "That's [not] a tall pimwit." We introduce novel nouns, but use familiar gradable adjectives (GAs) that vary in how intersubjective versus subjective they are. We categorize these adjectives into three classes. Following Syrett, Kennedy, and Lidz (2009), we call words like "spotted" absolute GAs. These adjectives require their arguments to possess some minimal degree of a property, and their meaning is largely context-independent. We refer to contextdependent adjectives like "tall" as relative GAs (Syrett et al.,
2009), and refer to adjectives like "pretty" as subjective GAs.

To assess individuals' appreciation of the subjectivity of these different kinds of adjectives, we obtain judgments of faultless disagreement: disagreements where neither person is wrong (Barker, 2013). Such judgments are closely correlated with direct measures of statements' subjectivity (Scontras et al., 2016), and offer a less metalinguistically demanding measure to use with children. In addition, we elicit qualitative explanations from participants to understand the sources of knowledge that they are drawing on when evaluating speakers' utterances. Critically, given that participants maintain visual access to the complete distribution of exemplars observed by both speakers, they are able to form their own evaluation of whether the adjective-noun phrase applies to the target exemplar that is the subject of the speakers' disagreement. Since they share this evaluation with only one of the two disagreeing speakers (e.g., one will call the pimwit "pretty" and one "not pretty"), we can interpret judgments of faultess disagreement as overcoming naive realism.

## Experiment 1

Participants Twenty-five UC Berkeley undergraduates participated in Experiment 1 (18 women, 19.65-27.37, $M=$ 21.24 years, $S D=1.68$ years). All were native speakers of English and received course credit for their participation.

## Stimuli and Methods

Speakers exposed to DISTINCT distributions (Exps. 1 \& 3)

Figure 1: Schematic of experimental setup for Exps. 1-4.

Experimental Setup The stimuli were sets of eleven objects belonging to distinct novel kinds. Critical kinds were pimwits, thin purple cylinders ranging from 0.75 to 6.25 inches in height, and from densely to sparsely spotted, and daxes, blue and yellow spheres ranging from 0.5 to 3 inches in diameter, and from heavily to lightly striped. Each set was divided into two arrays composed of the five smallest and five largest exemplars, with the exemplar in the middle of the size distribution used as the critical target exemplar (Figure 1).

Participants sat across a table from two wooden house-like structures separated by a narrow stage. The experimenter sat behind the display and animated pairs of puppets representing familiar characters from Sesame Street, who she
explained could not see or hear anything that happened beyond their "classrooms" while they were inside them.

The experiment consisted of two blocks of two training trials each, followed by two blocks of three critical trials each and a post-test. In each block, two speakers were independently introduced to distinct arrays of a novel kind in their classrooms by the experimenter, before emerging to view and disagree about a new exemplar (the target) placed by the experimenter in the middle of the stage.

Training Trials The initial training trials familiarized participants with the paradigm, and provided practice with judging disagreements as faultless and not. In them, characters saw distinct sets of exemplars labeled with the same noun, and then 'disagreed' over a target exemplar that shared properties with both sets. In a faultless training trial, Dawn might see five feps that were matte white circles, while Big Bird saw five feps that were sparkly white squares. Dawn would exclaim that the target fep, a sparkly white circle, was "sparkly," while Big Bird would assert that it was "round" (a faultless disagreement). The non-faultless complement would consist of one speaker asserting the target exemplar was "white," while the other said it was "black." Participants received feedback for their answers on only the first block of training trials, and we recorded their judgments prior to feedback.

Critical Trials In critical trials, the characters were introduced to distinct sets of exemplars belonging to the same novel kind (pimwits or daxes). For example, Zoe might see five relatively short and densely spotted pimwits, while Cookie Monster saw five relatively tall and lightly spotted ones. Upon encountering the intermediate target pimwit, Zoe would assert that it was tall, which Cookie Monster would deny. Following the disagreement, participants answered whether each speaker was "wrong" or "could be right," and explained why. Responses where participants answered "could be right" for both speakers were coded as indicating faultless disagreement. For each novel kind, speakers disagreed over an absolute, relative, and subjective GA.

The order of the blocks, which speaker asserted the positive statement, and the block-internal order of the relative versus subjective disagreements were counterbalanced across participants. Disagreements over absolute GAs were always presented last to avoid invalidating one of the speakers. To prevent speakers from being degraded across blocks for wrong assertions, new speakers were introduced each block of trials.

Qualitative Explanations In each critical trial, we collected qualitative explanations of participants' evaluations of speakers' assertions. From explanations collected during piloting, we developed three primary codes to describe participants' responses. Trained coders identified whether each explanation made reference to apparently intersubjective properties of the target exemplar (Object Property-e.g., "It is beautiful;" "There are dots on it"), the distinct arrays
of exemplars the speakers had experienced (SPEAKER EX-PERIENCE-e.g., "He saw tall pimwits and she saw short ones"), or the speaker's subjective evaluation of the object (Speaker Opinion-e.g., "He likes purple and she doesn't like spots."). Explanations could receive multiple codes.

Post-Test We directly assessed participants' own evaluation of the target exemplars in a post-test. Participants saw the entire distribution of exemplars, and answered whether the target exemplars were "spotted," "tall," "pretty," etc.

## Results

Faultless Disagreement Disagreements over relative and subjective GAs were almost always judged as faultless (spotted: $24 \%$, striped: $20 \%$, tall: $100 \%$, big: $100 \%$, pretty: $100 \%$, boring: $92 \%$; see Figure 2). There were no significant differences between the proportions of faultless disagreement for the two adjectives in each class, so we collapse them here.

Figure 2: Adult rates of faultless disagreement judgment during critical trials in Exps. 1-2 by gradable adjective type (ABSOLUTE: "spotted," "striped;" RELATIVE: "tall," "big;" SUBJECTIVE: "pretty," "boring"). Participants in Exp. 1 judged speakers exposed to distinct distributions of exemplars, while participants in Exp. 2 judged speakers who had seen identical ones. Error bars for this and all plots indicate $95 \%$ bootstrapped confidence intervals $(k=1000)$.

Relation to Post-test The relation between participants' post-test evaluations and faultless disagreement judgments qualitatively distinguished the three classes of adjectives. For absolute GAs, participants uniformly answered "yes" when asked whether the target pimwit or dax was "spotted" or "striped," and typically answered that only the speaker who asserted the same could be right. For relative GAs, in contrast, while participants again all said that the target exemplar was "tall" or "big," they also all responded that both speakers could be right. Despite variability in participants' own evaluations of the critical items' beauty ( $91 \%$ said it was "pretty") or tedium ( $17 \%$ said it was "boring"), they almost always judged disagreements over subjective GAs as faultless.

Qualitative Explanations Participants for the most part cited distinct sources of knowledge to explain their judgments of utterances from different adjective classes (Figure 3). They referred to speakers' opinions (SPEAKER OPINION) exclusively when explaining their evaluations of utterances using
subjective GAs (and did so on $80 \%$ of all subjective trials).
We fit separate logit models to the data for the two remaining codes (Object Property and Speaker Experience) that were used in explanations regarding more than one adjective class, using GA type as our sole predictor. Participants were more likely to refer to object properties to explain absolute GA utterances ( $\beta=1.266, p<0.001$ ), and less likely to cite them when explaining subjective GA judgments ( $\beta=-3.462, p<0.001$ ). Participants cited speakers' unique experiences most in explaining judgments of relative GA utterances, and were unlikely to do so to explain judgments of absolute GAs $(\beta=-1.153, p<0.001)$.

Explanation Code ■Object Property 【Speaker Experience■Speaker Opinion

Figure 3: Adult reference to properties of the target exemplar (Object Property), speakers' distinct experiences of the object kind (SPEAKER EXPERIENCE), and speakers' subjective opinions (Speaker Opinion), in explaining their evaluations of assertions. Panels reflect proportions of each code for explanations regarding a given GA type (in columns) in a given experiment (in rows).

## Experiment 2

Having demonstrated that adults readily judge disagreements over relative and subjective GAs as faultless when speakers have experienced distinct distributions of exemplars, we explored the limits of listeners' acceptance of subjective meanings by equating the disagreeing speakers' experiences.

Participants 33 undergraduate adults ( 26 women, 18.1039.83 years, $M=20.91, S D=3.52$ ) participated.

## Stimuli and Methods

The experimental paradigm was identical to that of Experiment 1 with two changes: 1) speakers saw identical distributions of exemplars in their respective classrooms, and 2) we introduced an additional, plain (i.e., not spotted or striped) target exemplar for each novel kind about which the speakers only disagreed using our subjective GAs. ${ }^{1}$

## Results

Faultless Disagreement We fit a logit model to the faultless disagreement judgment data with GA type as a predictor. Par-

[^69]ticipants were highly likely to permit faultless disagreement for subjective $(\beta=7.377, p<0.001)$ and relative $(\beta=3.061$, $p<0.001)$ GAs. They were unlikely to permit faultless disagreement over absolute ones ( $\beta=-2.501, p<0.001$ ).
Relation to Post-test As in Experiment 1, we see differences among the adjective classes in the relation between participants' own assertion of each GA and their permission of faultless disagreement over it. In the post-test, all participants judged the target pimwit with spots "spotted," "tall," and "pretty." $94 \%$ answered "yes" when asked if the plain target pimwit was "pretty." For the dax with stripes, $97 \%$ judged it "striped." $64 \%$ said it was "big," and only $9 \%$ said it was "boring," while $55 \%$ said that the plain dax was. Despite substantial variation in their own evaluations of the critical items, participants almost always permitted faultless disagreement for the subjective GAs. For the absolute GAs, which the vast majority of participants accepted as true of the critical items, participants permitted very little faultless disagreement, but judged disagreements over the relative GAs as faultless between half and three-quarters of the time (Figure 2).

Even when listeners do not have an explanation for speakers' differing standards for relative GAs, they may permit faultless disagreement due to the standard's uncertainty. Participants permitted more faultless disagreement over "big" ( $72 \%$ of participants), which a lower proportion (64\%) agreed was true of the critical dax, and less over "tall" ( $56 \%$ ) which all participants agreed was true of the pimwit.
Qualitative Explanations Fitting logit models to the data for each explanation code and GA type, participants again were likely to refer to object properties in explaining judgments over absolute GAs $(\beta=1.541, p<0.001)$, but not relative $(\beta=-4.616, p<0.001)$ or subjective $(\beta=-4.616$, $p<0.001$ ) ones. Participants were most likely to refer to speakers' experiences-even though they were identical-in their explanations for relative ( $\beta=3.960, p<0.001$ ) and subjective ( $\beta=2.060, p<0.01$ ) GAs, and least likely for absolute ones ( $\beta=-3.466, p<0.001$ ). Finally, participants were unlikely to refer to speakers' opinions in explaining disagreements over absolute GAs ( $\beta=-2.501, p<0.001$ ), but were likely to do so in explaining disagreements over relative GAs ( $\beta=1.096, p<0.05$ ), and highly likely for subjective ( $\beta=3.521, p<0.001$ ) ones as well (Figure 3).

Compared to Experiment 1, adults permitted less faultless disagreement for relative and absolute GAs when speakers had experienced identical distributions of exemplars (Figure 2). This was not the case for subjective GAs, which participants continued to permit faultless disagreement over.

## Experiment 3

Experiment 3 followed up on the previous experiments with adults by exploring the developmental trajectory of linguistic subjectivity. We tested a large age range to span a broad swath of theory-of-mind and metalinguistic development.

Participants Seventy-one children across three age groups participated (24 4-5.5 years: 15 girls, $M=4.83, S D=0.34$; $235.5-7$ years: 8 girls, $M=6.05, S D=0.470 ; 248-9.5$ years: 14 girls, $M=8.90, S D=0.34$ ). Four children were excluded due to experimenter error or broken stimuli $(n=2)$.

## Stimuli and Methods

Experiment 3 used the same method as Experiment 2, except that speakers experienced distinct exemplar distributions as they did in Experiment 1. We also only included one object kind, pimwits, to keep it a more manageable length for children.

## Results

Figure 4: Child rates of faultess disagreement judgment in Exp. 3. Train:AbS and Train:FD trials were training intended to elicit non-faultless and faultless judgments, respectively. Participants made two judgments over the subjective GA "pretty," regarding a spotted as well as a plain pimwit, but there was no significant difference between rates of faultless disagreement between the two.

Faultless Disagreement We fit a logit model to the critical trial faultless disagreement data with GA and age. Children were significantly less likely to permit faultless disagreement for absolute GA "spotted" ( $\beta=-7.646, p<0.001$ ), and significantly more likely for relative and subjective GAs "tall" and "pretty" ("tall": $\beta=2.047, p<0.001$; "pretty" for spotted pimwit: $\beta=1.170, p<0.05$; "pretty" for plain pimwit: $\beta=1.831, p<0.001$ ). In general, they permitted faultless disagreement more with age ( $\beta=0.764, p<0.001$ ).

We can think of children's initial judgment rates on the faultless disagreement training trials as baselines (Figure 4). Even in our oldest age group, rates of faultless disagreement on the critical trials are significantly below those of the faultless training trials (for relative trials: $t=-2.164$, $d f=31.373, p<0.05$; for subjective trials: $t=-3.820$, $d f=70.616, p<0.001$ ). While capable of judging disagreements as faultless, children were reluctant to do so when they themselves agreed with only one of the speakers.

Relation to Post-test $96 \%$ of children judged the target pimwit "spotted." More children judged it "pretty" (85\%) than "tall" ( $49 \%$ ). $55 \%$ answered that the plain pimwit was "pretty." For the absolute and relative GAs, we see roughly
the same qualitative relation between post-test response and faultless disagreement judgments as with adults: greater posttest consensus meant less faultless disagreement.
Qualitative Explanations There appear to be some children across our age range who understood the source of knowledge most relevant for each GA, though children referred to object properties most frequently for all types until our oldest age group (Figure 5). We fit logit models to the data for each explanation code separately, with GA type, age, and their interaction as predictors. Children were highly likely to refer to properties of the objects in explaining absolute $(\beta=2.543, p<0.05)$ and relative $(\beta=3.758$, $p<0.05)$ GA utterances, and less likely to do so for relative $(\beta=-0.800, p<0.01)$ and subjective ones with age ( $\beta=-0.642, p<0.01$ ). They were least likely to refer to speakers' experiences in explaining absolute utterances ( $\beta=-6.608, p<0.01$ ), though more likely to refer to them at all with age $(\beta=0.586, p<0.05)$. Finally, they became more likely to refer to speakers' opinions to explain subjective utterances as they got older ( $\beta=0.872, p<0.05$ ).

Figure 5: Proportion of children's explanations in Exp. 3 receiving each qualitative code, by GA type and age group (in panels).

## Experiment 4

Experiment 4 used the same method as above, with children at the older end of the age range. As in Experiment 2, the distributions that the two speakers saw were identical.

Participants Participants were 24 children 8-9.5 years of age (12 girls; $M=9.09, S D=0.44$ ).

## Results

Faultless Disagreement Children permitted faultless disagreement on $98 \%$ of faultless training trials, and on none of non-faultless training trials. They did so most on subjective trials ( $67 \%$ of the time, $95 \%$ CI:53-80), followed by relative $(38 \%, C I: 21-54)$ and absolute $(1 \%, C I: 0-4)$.

Children were least likely to permit faultless disagreement over absolute GA "spotted" ( $\beta=-3.135, p<0.01$ ), and highly likely for all other adjectives ("tall": $\beta=2.625$, $p<0.05$, "pretty" for spotted pimwit: $\beta=4.052, p<0.001$, "pretty" for plain pimwit: $\beta=3.829, p<0.001$ ).
Relation to Post-Test While all children judged the target pimwit "spotted" and "tall," they resembled adults by still permitting faultless disagreement over "tall" about half the time (and almost never over "spotted"). $79 \%$ and $92 \%$ participants judged the spotted and plain pimwits "pretty," respectively. Despite general consensus over their beauty, children responded more like adults in nonetheless permitting faultless disagreement over them at relatively high, equivalent rates.
Qualitative Explanations Children's explanations for absolute GA "spotted" were highly likely to receive the Овject Property code ( $\beta=2.398, p<0.01$ ), while explanations of relative ( $\beta=-2.734, p<0.01$ ), and subjective ( $\beta=-3.267, p<0.001$ ) utterances were unlikely to. Explanations of absolute GA utterances were also unlikely to be coded as referring to Speaker Experience ( $\beta=-3.135$, $p<0.01$ ), which was highly likely for relative GA utterances ( $\beta=2.625, p<0.05$ ). Lastly, explanations of subjective GAs were likely to be coded as citing Speaker Opinion ( $\beta=4.005, p<0.001$ ), in contrast to explanations about absolute GA utterances ( $\beta=-3.135, p<0.01$ ).

## General Discussion

We tested theoretical claims about faultless disagreement arising when there is uncertainty about how and whether to assess something as, e.g., "pretty" or "tall" (Barker, 2013). We asked in particular whether individuals consider the reference distribution of their interlocutors in interpreting relative gradable adjectives. Adults reliably permitted faultless disagreement over relative and subjective GAs when two speakers had had distinct personal experiences. Rates of faultless disagreement decreased for relative GAs when speakers had experienced identical distributions, but did not disappear altogether, suggesting that adults were instead permitting faultless disagreement out of an understanding of the standard's uncertainty. Together, these findings provide evidence for the consideration of speaker at the level of semantics, as well as adults' sensitivity to the potential for differing standards of more than just explicitly context-dependent adjectives.

The development of sensitivity to linguistic subjectivity appears to be exceptionally prolonged: for the most part, children 'sided' with the speaker who voiced their own evaluations. Two factors might explain the apparent gap between adults and children in our studies. First, previous work sug-
gests that children better grasp subjectivity when they are able to reason about an individual's goals (Holubar, 2015), a dimension that was absent from our experiments. To this end, our ongoing studies explore the effect of goal-oriented contexts (e.g., choosing who you would want to be friends with or learn from), which might be more sensitive to children's nascent understanding of the different implications of being "wrong" about whether something is "spotted" as opposed to "pretty." Second, there may be more continuity between adults and children than it appears. Adults' permission of faultless disagreement and explanation of different GA utterances may reflect social pressures and metalinguistic knowledge, rather than a core belief that their own evaluation is subjective. When it comes to predicates of personal taste, although adults may readily say that the meaning of "good" is subjective, such that both speakers can be right, we have all had the experience of disagreeing about whether a movie or song is "good." Future studies will test for possible continuity between children and adults by examining the contexts in which children may behave more like adults in their metalinguistic judgments of subjectivity, and the contexts in which adults may react similarly to children in their implicit commitment to intersubjectivity.

# Word Embedding Distance Does not Predict Word Reading Time 

Stefan L. Frank (s.frank@let.ru.nl)<br>Centre for Language Studies, Radboud University<br>P.O. Box 9103, 6500 HD Nijmegen, The Netherlands

#### Abstract

It has been claimed that larger semantic distance between the words of a sentence, as quantified by a distributional semantics model, increases both N400 size and word-reading time. The current study shows that the reading-time effect disappears when word surprisal is factored out, suggesting that the earlier findings were caused by a confound between semantic distance and surprisal. This absence of a behavioural effect of semantic distance (in the presence of a strong neurophysiological effect) may be due to methodological differences between eye-tracking and EEG experiments, but it can also be interpreted as evidence that eye movements are optimized for reading efficiency.

Keywords: reading; eye tracking; N400; distributional semantics; semantic distance; word surprisal

## Introduction

An open question in the study of human language processing is to what extent mere semantic similarity among words within a sentence or text affects the comprehension process. Results from controlled experiments are inconclusive. On the one hand, there is ample evidence for effects on the N400 event-related brain potential (ERP) component: Reading a word that is semantically related to words in the preceding context decreases N400 size, relative to when the context words are not meaning related (Camblin, Gordon, \& Swaab, 2007; Metusalem et al., 2012; Paczynski \& Kuperberg, 2012). A number of behavioural experiments, however, failed to find corresponding effects on word-reading time (Gordon, Hendrick, Johnson, \& Lee, 2006; Traxler, Foss, Seely, Kaup, \& Morris, 2000). In contrast, two studies that analysed reading times on naturalistic texts (instead of taking a controlled experimental approach) did find that words are read faster when they have stronger semantic relatedness to earlier words in the text (Mitchell, Lapata, Demberg, \& Keller, 2010; Pynte, New, \& Kennedy, 2008). In those studies, semantic relatedness measures were obtained from a distributional semantics model, which assigns numerical vectors to words on the basis of the words' co-occurrence patterns in large text corpora. These vector representations are known as word embeddings in the computational linguistics literature. Words that tends to occur in similar contexts receive similar embeddings. Consequently, distances between the words' embedding vectors correspond to semantic distances between the corresponding words.

If semantically related words tend to co-occur, a word's occurrence can (to some extent) be predicted from the presence of related words. Consequently, if one wants to claim that the reading process on word $w_{t}$ is affected by the word's semantic relatedness to the preceding words $\left(w_{1}, \ldots, w_{t-1}\right)$, it is crucial to factor out any effect of the predictability of
$w_{t}$ from its previous context. Otherwise, apparent effects of relatedness could in fact be due to word predictability instead. Frank and Willems (in press) recently showed that N400 effects of semantic distance (as quantified by a distributional semantics model) remain when factoring out the words' (un)predictability as quantified by their surprisal (i.e., $-\log P\left(w_{t} \mid w_{1}, \ldots, w_{t-1}\right)$ ), leaving no room for a confound between predictability and semantic distance. The current paper will show that the same is not true for reading times: Effects of semantic similarity on reading times for naturalistic materials, of the type reported by Mitchell et al. (2010) and Pynte et al. (2008), disappear when surprisal is factored out, provided that surprisal is computed by a powerful enough language model. Hence, semantic similarity between the words of a sentence or text affects N400 size but not reading time.

## Method

## Eye-tracking Data

Word-reading times were extracted from two published sets of eye-tracking data: The UCL corpus (Frank, Monsalve, Thompson, \& Vigliocco, 2013) and the English Dundee corpus (Kennedy \& Pynte, 2005). The UCL corpus comprises data from 42 native English speakers reading 205 individual sentences sampled from three unpublished novels; the Dundee corpus has 10 participants reading newspaper editorials. Frank and Willems (in press) demonstrated strong N400 effects of semantic distance (over and above the effect of surprisal) for the sentences of the UCL corpus. Mitchell et al. (2010) reported reading-time effects of semantic distance in the Dundee data, and similar results by Pynte et al. (2008) were based on the French part of the Dundee corpus, also comprising newspaper texts.

Four measures of reading time will be investigated: firstfixation duration, first-pass duration (the sum of fixation durations on a word before the first fixation on any other word), right-bounded reading time (the sum of fixation durations on a word before the first fixation on a later word), and go-past reading time (the sum of fixations on all words from the first fixation on the current word until the first fixation on a later word). These four measures, in this order, have been argued to reflect increasingly late cognitive processes (Clifton Jr., Staub, \& Rayner, 2007; Gordon et al., 2006).

## Models

Each content word of the UCL and Dundee corpora was assigned a measure of semantic distance to preceding content words, as well as five estimates of word surprisal. The distributional semantics and surprisal models were trained on
the first slice of the ENCOW14 web corpus (Schäfer, 2015), comprising 644.5 M word tokens of 2.81 M types.

Semantic Distance Word embeddings were generated by the word2vec skipgram model (Mikolov, Chen, Corrado, \& Dean, 2013), which is basically a feedforward neural network with one hidden layer. The network learns to associate each input word $w_{t}$ to the $k$ words immediately preceding and following (i.e., the sequence $w_{t-k}, \ldots, w_{t-1}, w_{t+1}, \ldots, w_{t+k}$ ). After training the network, the vector of connection weights from each input unit to the 300 -unit hidden layer forms the embedding for the word corresponding to the input unit. The 'window size' parameter was set to $k=5$ in the current application of the model.

As explained in the Introduction, the distance between two word vectors quantifies the semantic distance between the two words. A common distance measure used in distributional semantics is the cosine of the angle between the vectors. Here, we require a measure for the distance between the current word's embedding $\vec{w}_{t}$ and its entire previous context (not just a single word). The vector representing the combination of content words from the previous context is defined as simply the sum of the words' individual vectors. Thus, the relevant distance measure becomes

$$
\begin{equation*}
\operatorname{semdist}(t)=-\cos \left(\vec{w}_{t}, \sum_{w \in A_{t}} \vec{w}\right) \tag{1}
\end{equation*}
$$

where $A_{t}$ is a collection of content words that precede $w_{t}$ in the sentence or text. For the individual sentences of the UCL corpus, $A_{t}$ contains all content words preceding $w_{t}$ in the sentence. For the full texts of the Dundee corpus, $A_{t}$ contains the four content words immediately preceding $w_{t}$ in the text (if $w_{t}$ is among the text's first four content words, $A_{t}$ will contain correspondingly fewer words). If $A_{t}$ is empty, word $w_{t}$ has no semantic distance. Semantic distance values on the UCL corpus were identical to those used by Frank and Willems (in press) to analyse N400 ERP effects.

Surprisal Word surprisal was computed by $n$-gram language models, which simplify the full conditional probability $P\left(w_{t} \mid w_{1}, \ldots, w_{t-1}\right)$ to $P\left(w_{t} \mid w_{t-n+1}, \ldots, w_{t-1}\right)$, that is, only the $n-1$ previous words are taken into account when estimating the occurrence probability of $w_{t}$. Model order $n$ was varied from $n=2$ to $n=5$, and the model was generated by SRILM (Stolcke, 2002) with modified Kneser-Ney smoothing (Chen \& Goodman, 1999).

The semantic distance measure defined above is sensitive to content words beyond the $n-1$ previous words that matter to an $n$-gram model. If semantic distance correlates with surprisal, this could yield apparent effects of semantic distance that are in fact due to unpredictability resulting from words outside of the $n$-gram window. To control for this, a 'skipbigram' language model (SBLM) was used to obtain a fifth set of surprisal values:

$$
P_{\mathrm{sblm}}\left(w_{t} \mid A_{t}\right)=\frac{1}{\left|A_{t}\right|} \sum_{w_{i} \in A_{t}} P\left(w_{t} \mid w_{i}\right)=\frac{1}{\left|A_{t}\right|} \sum_{w_{i} \in A_{t}} \frac{P\left(w_{i}, w_{t}\right)}{P\left(w_{i}\right)}
$$

with $A_{t}$ as defined as in Equation 1 and $\left|A_{t}\right|$ the number of words in $A_{t} . P\left(w_{t} \mid w_{i}\right)$ denotes the probability that $w_{t}$ occurs within a distance of 15 words after occurrence of $w_{i}$. That is, the preceding content words $w_{i} \in A_{t}$ are taken as independent cues to the occurrence of $w_{t}$, whose skip-bigram probability is computed by averaging over these individual cues.

The required word-pair probabilities $P\left(w_{i}, w_{t}\right)$ are estimated from co-occurrence frequencies in the training corpus, using the Simple Good-Turing smoothing method (Gale \& Sampson, 1995) to estimate the total probability of all unseen pairs. This total probability $P_{0}$ is divided over the unseen pairs $(v, w)$ in proportion to $P(v) P(w)$, that is, the probability of each particular unseen pair $(v, w)$ is given by:

$$
P(v, w)=\frac{P_{0} P(v) P(w)}{1-\sum_{\left(v^{\prime}, w^{\prime}\right) \in S} P\left(v^{\prime}\right) P\left(w^{\prime}\right)},
$$

where $S$ is the set of all ordered word pairs observed in the training data within a 15 -word distance from each other.

Relation between semantic distance and surprisal Table 1 shows there indeed exists a positive confound between surprisal and semantic distance, which grows stronger as the language model is able to use words from further back in the context.

Frank and Willems (in press) interpolate the 5-gram and skip-bigram models to minimize average surprisal over the UCL corpus and show empirically that the semantic distances do not contain information that can be used to further improve this interpolated language model. Hence, if the semantic distances account for variance in human reading difficulty measures over and above what is already explained by the surprisal values, this cannot be attributed to a confound between semantic relatedness and predictability but must be due to the effect of semantic relatedness itself.

## Data Analysis

Linear mixed-effects regression models were fitted to the logtransformed reading times using as covariates: word position in the sentence, word length (number of characters), word log-frequency in ENCOW14, and a binary factor indicating whether or not the previous word was fixated. To account for the possibility that reading-time effects appear shortly after the point at which they originate (so-called spillover effects), the previous word's length and log-frequency were also included. All two-way interactions between these six factors were also present.

Table 1: Correlation coefficients between semantic distance and surprisal values.

|  | Language model |  |  |  |  |
| :--- | ---: | ---: | ---: | ---: | ---: |
| Data set | 2-gram | 3-gram | 4-gram | 5-gram | SBLM |
| UCL | .19 | .26 | .27 | .27 | .29 |
| Dundee | .05 | .18 | .20 | .21 | .26 |

The main factor of interest was the word's semantic distance measure. Separate analyses were run using the current and previous word's semantic distance; the latter capturing potential spillover. ${ }^{1}$ In addition to a control condition without any surprisal measure in the regression, five separate analyses were run including $n$-gram surprisal with $n=2,3,4,5$, or both 5-gram and SBLM surprisal (always for both the current and previous word).

Random effects in the regression model were the bysubject and by-word intercept, and by-subject slopes of semantic distance and any surprisal measure that was included as a fixed effect.

Regression models were fitted to each of the four reading time measures from both data sets, making a total of 96 analyses: 4 reading time measures $\times 2$ corpora $\times 2$ semantic distance measures (of current or previous word) $\times$ ( 5 surprisal measures +1 control). Words were excluded from analysis if they were not fixated, were attached to punctuation, contained any non-letter or more than one capital letter, or were the first or last word on a line.

## Results

Figure 1 displays the estimated regression coefficient (i.e., effect size) of the semantic distance predictor in each of the 96 fitted regression models. Note that effect sizes cannot be compared between the analyses investigating the current versus previous word's semantic distance. This is because these analyses apply to different sets of words: All content words when the current word's semantic distance is used, but the words directly following content words (including many function words) when the previous word's semantic distance is the variable under investigation. The same holds for the estimated regression coefficients of the surprisal predictors, plotted in Figure 2. ${ }^{2}$

For the UCL corpus, none of the semantic distance effects reach statistical significance. For the Dundee corpus, there is a clear effect of semantic distance in the expected (i.e., positive) direction when surprisal is not factored out, and it remains present for later reading time measures when surprisal takes only very local context into account (i.e., under a bigram model).

As is clear from Figure 2, words with higher surprisal take longer to read, as is well known from the literature (e.g. Monsalve, Frank, \& Vigliocco, 2012; Smith \& Levy, 2013). Surprisal computed by the novel SBLM language model has an effect over and above 5-gram surprisal, at least for the Dundee corpus, which means that it is not merely the local,

[^70]4-word context that is is taken into account when generating expectations about upcoming words. Rather, long-distance co-occurrence patterns between content words matter as well.

There are a few noticeable difference between the results for the UCL and Dundee data sets, which mirror differences in the text materials of these two corpora. Surprisal effects appear to be more reliable in the Dundee data, in that the zero point falls further outside the confidence intervals. This can simply be explained by the Dundee data set being much larger than the UCL data set ( 134,203 versus 18,178 data points). Interestingly, the UCL corpus results show larger effect sizes (i.e., larger coefficients) which is probably due to these materials having been specifically designed for language model evaluation. Compared to the Dundee corpus texts, the UCL corpus sentences contain fewer low-frequency words (for which surprisal is hard to estimate reliably) and can comprehended more easily without relying on world knowledge (which the language models do not incorporate). Finally, the fact that the SBLM model explained unique variance in reading times from the Dundee corpus only can be explained by the fact that this corpus consists of full texts as opposed to the UCL corpus's individual sentences. Compared to individual sentences, full texts will contain more content words outside of the 5-gram window, making the SBLM model more influential.

## Discussion

Results on the Dundee corpus showed significant, positive effects of semantic distance on all four reading time measures when surprisal was not taken into account. However, factoring out surprisal as computed by anything more powerful than a bigram model made the effects of semantic distance disappear. Apparently, these effects were due to a confound between semantic distance and surprisal, that is, a word is less likely to appear if it has weaker semantic relatedness to earlier words. It was actually a word's unpredictability, rather than its semantic content per se, that resulted in increased reading time.

Indeed, the findings by Pynte et al. (2008) and Mitchell et al. (2010), on the French and English Dundee corpus, respectively, can be attributed to confounds between semantic relatedness and predictability. Pynte et al. (2008) did not factor out surprisal (or even simple transitional probabilities between words) in their analysis of the effect of semantic distance. Mitchell and Lapata's (2009) goal was to show that incorporating semantic distance measures from their own 'simple semantic space model' (as well as from a Latent Dirichlet Allocation Topics model; Griffiths, Steyvers, \& Tenenbaum, 2007) reduces perplexity of a combined $n$-gram and probabilistic phrase-structure grammar. That is, taking these semantic measures into account improves the language model. Consequently, the improved fit to reading time could be due merely to more accurate next-word prediction rather than to semantic similarity per se.

The UCL corpus results showed no effect of semantic dis-

Figure 1: Regression coefficients (with $95 \%$ confidence intervals) of semantic distance predictor, when factoring out different measures of surprisal. The leftmost two panels display results on the UCL corpus; the Dundee corpus results are shown in the rightmost panels. The 2nd and 4th panel show the coefficient of the previous word's semantic distance. Reading time measures are indicated by FF (first fixation), FP (first pass), RB (right-bounded), and GP (go-past).

Figure 2: Regression coefficients (with $95 \%$ confidence intervals) of surprisal predictor, when factoring out semantic distance. "5-gram*" refers to the effect of 5-gram surprisal when SBLM-surprisal is also included as a regressor, and "sblm" refers to the effect of SBLM-surprisal over and above 5-gram surprisal. The leftmost two panels display results on the UCL corpus; the Dundee corpus results are shown in the rightmost panels. The 2nd and 4th panel show the coefficient of the previous word's semantic distance. Reading time measures are indicated by FF (first fixation), FP (first pass), RB (right-bounded), and GP (go-past).
tance on reading times whatsoever, even when surprisal was not taken into account. This is remarkable considering that Frank and Willems (in press) found that N400 effects of the very same semantic distance values are of similar size as and independent from - the effect of surprisal as computed by an interpolated 5-gram and skip-bigram language model. This discrepancy between neurophysiological and behavioral effects is consistent with findings from the controlled experimental studies mentioned in the Introduction. But how can it be explained?

One possible cause is the difference in stimuli presentation method. The eye-tracking methodology allows a natural reading processes whereas in most EEG reading studies, words are presented one at a time for an unnaturally long duration. The EEG data used by Frank and Willems (in press) came from a study with word-length dependent presentations durations of at least 627 ms (Frank, Otten, Galli, \& Vigliocco, 2015), which is much longer than fixation durations in natural reading. Wlotko and Federmeier (2015) showed that using more natural word presentation rates in an ERP reading study can remove particular effects of semantic relatedness on the N400. If semantic distance effects are delayed relative to surprisal effects, this could explain their absence in reading times: By the time they would have appeared, any effect has already been washed out by the processing of several other words. Although Figure 1 indeed shows a trend for the semantic distance effect to be somewhat stronger for the later reading time measures (as was also found by Pynte et al., 2008), the same is true for the surprisal effect (Figure 2) so this cannot explain why reading times are insensitive to semantic distance. Moreover, Frank and Willems (in press) found fMRI effects of semantic distance (as quantified by distributional semantics) during normal speech comprehension, indicating that the presence of a measurable neural response does not rely on unnaturally slow presentation rates.

An alternative, and possibly more interesting explanation of the difference between N 400 and reading time effects is that reading is optimized for speed (Smith \& Levy, 2013). Being faster on more predictable (i.e., lower surprisal) words increases overall efficiency, whereas there is no reason to be faster on merely semantically related words. Hence, we would expect reading times to display effects of surprisal but not of semantic distance. Other dependent variables from eye-tracking, however, could show sensitivity to semantic distance, and this is exactly what Van den Hoven, Hartung, Burke, and Willems (2016) found in a recent analysis of data from a Dutch narrative text reading eye-tracking study: Semantic distance correlated with saccade distance and regression probability but not with reading time after factoring out trigram surprisal. In contrast, the reason why the N400 shows effects of both surprisal and semantic distance could be that it forms an index of the difficulty of retrieving lexical information from long-term memory (Brouwer, Fitz, \& Hoeks, 2012; Kutas \& Federmeier, 2000). As Frank and Willems (in press) argue, this difficulty is reduced both by probabilis-
tic word prediction (surprisal) and by semantic similarity to earlier words (word embedding distance).

## Conclusion

The current results failed to replicate earlier findings of a positive correlation between reading times on naturalistic data and semantic relatedness between words, as quantified by a distributional semantics model. This apparent effect of semantic relatedness appeared to be due to a confound with word predictability. Of course, it is possible that an effect of semantic distance reappears when using a different distributional semantics model, or a more sophisticated technique for combining single word vectors into a sentence context vector (Equation 1). However, it is equally true that improved surprisal models may undo the work of more sophisticated word embedding models. And crucially, the current distributional semantics modelling choices were appropriate for predicting reading times when surprisal was not taken into account, as well as N400 sizes over and above surprisal, so they should also have sufficed for revealing reading time effects of semantic distance that are independent from surprisal, if there had been any.

# Is Conflict Detection in Reasoning Domain General? 

Darren Frey (darren@post.harvard.edu)<br>Paris Descartes University, Sorbonne Paris Cité CNRS UMR 8240, LaPsyDÉ, Paris, France

#### Abstract

A great deal of reasoning research indicates that individuals are often biased by intuitive heuristics. However, contemporary results indicate that individuals seem sensitive to their biases; they seem to detect conflict with reasoning norms. One of the key remaining questions is whether this conflict sensitivity is domain general. To address this question, we administered a battery of five classical reasoning tasks to a large sample of subjects and assessed their conflict detection efficiency on each task by measuring their response confidence. Results indicate that conflict detection is, in most senses, not domain general, though there are compelling exceptions.

Keywords: conflict detection; reasoning; bias; domain generality; decision making

## Introduction

That human reasoning is prone to error comes as no surprise to most everyone. Upon reflection, we discern blunders in our own reasoning in the most ordinary of circumstances: we realize we miscalculated how long a trip would take us; we come to acknowledge our snap judgment of a colleague was mistaken. Likewise, we often witness mistakes in others and throughout history, some of which aggregate in the most atrocious of ways: an innocent man is convicted, judged, tried, and sentenced to more than forty years of solitary confinement based on the shakiest possible evidence, the testimony of a single untrustworthy witness (e.g., the case of Albert Woodford, see Aviv, 2017).

Although mistakes like this seem, at first, entirely unrelated, one could argue they often issue from a uniform set of underlying tendencies. Exploring these tendencies has motivated much of the research in reasoning and decision making throughout the past four decades. One compelling and especially generative account of reasoning mistakes contrasts two types of thinking: fast, associative, heuristic thinking and slower, more demanding, rule-based reasoning (Kahneman, 2011). Returning to the example of misjudging a colleague, the fast type of reasoning (System 1) seems to account for our initially misguided impression, which is then revised upon reflection-and after gathering more evidence-by the slower, more deliberate type of thinking (System 2).

The family of dual process theories that rely on contrasting these two forms of reasoning has provided
countless testable hypotheses and a diverse set of approaches and methods. While most parties agree that heuristics are useful, efficient, and often optimal means of navigating complex environments, investigators disagree about how often and in what contexts they conflict with logical and mathematical principles. Evans (2003, 2010), Kahneman (2011), and Stanovich and West (2000) insist that individuals regularly make reasoning mistakes because of unchecked heuristic inferences, while Gigerenzer (2008), Katsikopoulos (2013) and others emphasize that heuristics are generally ecologically rational and truth preserving. ${ }^{1}$

Until recently, one of the cardinal doctrines of the dual process account of reasoning mistakes relied on the imperceptibility of reasoning conflicts. Prominent scholars have argued that our reasoning mistakes masquerade beneath our awareness, which is, at least partially, what accounts for their ubiquity. Surely-the argument goes-if reasoners were aware of their mistakes they would correct them. However, many contemporary empirical analyses of reasoning bias suggest that individuals are often sensitive to conflicts between heuristics and normative principles even when they err (e.g., Bonner \& Newell, 2010; De Neys \& Glumicic, 2008; Pennycook, Fugelsang, \& Koehler, 2015; Handley \& Trippas, 2015).

Researchers have demonstrated this across a number of diverse reasoning tasks using many different methods. Much of the work relies on contrasting tasks that contain conflicts between intuitively cued heuristics and normative principles with structurally identical tasks containing no such conflict. Standard behavioral markers that index conflict on lower level tasks, like response times (RT) and confidence levels (Yeung \& Summerfield), also indicate people are sensitive to conflict in higher level reasoning tasks (Bonner \& Newell, 2010; De Neys \& Glumicic, 2008; Pennycook, Fugelsang, \& Koehler, 2012). Additionally, people tend to fixate visually on the conflicting elements of the tasks, as evidenced in eye and gaze tracking experiments (De Neys \& Glumicic, 2008; Ball, Phillips, Wade, \&

[^71]Quayle, 2006), and they register heightened levels of arousal on skin conductance recordings (De Neys, Moyens, \& Vansteenwegen, 2010). There is neuropsychological evidence of conflict sensitivity as well, derived from both fMRI (De Neys, Vartanian, \& Goel, 2008; Simon et al,. 2015) and EEG analyses (De Neys, Novitskiy, Ramautar, \& Wagemans, 2010). Despite the diversity of methods and tasks supporting these effects, there are many who find the research problematic, largely because its results seem to imply that individuals have fairly immediate access to logical and probabilistic principles (Mata, Schubert, \& Ferreira, 2014; Pennycook et al., 2012; Singmann, Klauer, \& Kellen, 2014; Travers, Rolison, \& Feeney, 2016). Even the most ardent proponents of the work acknowledge that it is still developing and in need of greater clarification (De Neys, 2012, 2014).

Although conflict detection has been explored with a variety of methods and across various tasks, no previous research examines individuals' tendencies to detect conflict across a range of tasks, giving researchers no clear sense of how or whether conflict sensitivities interact. It is unclear, for example, whether a given person's ability to detect a conflict between an intuitively cued heuristic and a reasoning rule on a particular kind of task is related to her ability to do so on different tasks. In essence, a key open question is whether conflict detection is domain general or task specific.

By further clarifying the precise nature of conflict detection, research of this sort will help characterize emergent dual process theories, especially those that explicitly rely on conflict detection mechanisms. For example, Pennycook et al's (2015) three-stage dual-process model relies on differentiating between successful conflict detection and "cognitive decoupling," which is the more resource intensive process of rejecting a conclusion at odds with reasoning rules even when it has been facilitated by a certain heuristic. Crucially, although conflict detection failures are a prominent feature of this model, it is unclear if conflict sensitivity is a stable individual difference. If conflict detection is domain general, then one would expect the prominence of these failures to extend fairly globally. Apart from further specifying the theory, such a conclusion would offer a partial account of the prevalence of cognitive biases. However, if conflict detection is task specific, then one can suppose that empirically observed detection on a given task is largely unrelated to others, and the prevalence of bias needs to be accounted for in other ways.

To address this issue, we presented a battery of the most intensively studied tasks in the field to a large number of reasoners. This enabled us to assess their conflict detection efficiency by measuring their response confidence. Examining the relationship of detection efficiency across the tasks gives us evidence with which to evaluate whether conflict detection is domain general or task specific.

## Method

## Participants

A total of 318 undergraduates (260 female; average age = 22.32, $\mathrm{SD}=6.11$ ) at Paris Descartes University completed the experiment.

## Materials

The experiment consisted of adaptations of five classic reasoning tasks. For each of the five tasks, participants received two conflict items, two no-conflict items, and one abstract control, resulting in 25 items. The tasks were as follows.

Bat and Ball Items (BB) The conflict items in this set were modeled after the canonical CRT problem (Frederick, 2005): "A bat and a ball together cost $\$ 1.10$. The bat costs $\$ 1$ more than the ball. How much does the ball cost?" The answer that often comes to mind is 10 cents, though the correct answer is 5 cents $(\$ 0.05+\$ 1.05=\$ 1.10)$. Participants likely intuitively substitute the "costs $\$ 1$ more than" phrase with "costs \$1," so to generate no-conflict variants one simply removes this phrase (see De Neys, Rossi, \& Houdé, 2013).

Ratio Bias Items (RB) Also called "denominator neglect" problems, these items consist of asking participants to choose between two trays, a small tray and a large one, containing a mixture of gray and white marbles. The participants' goal is to get a gray marble, but the marble will be drawn from the tray they select at random. In a conflict item, the absolute value of gray marbles in the large tray is greater than the absolute value of gray marbles in the small tray, but the relative value of gray marbles is greater in the small tray (e.g., $19 / 100$ vs. $2 / 10$, $19 \%$ vs. $20 \%$ ). Since the marble is being selected at random, one should choose the tray that maximizes the relative likelihood of getting a gray marble (the small tray), but participants are often intuitively and immediately drawn to the larger tray. To generate noconflict items one aligns the relative and absolute values in a tray, so that the tray most likely to have a gray marblethe one with the highest relative value-is also the most perceptually salient one-the one with the highest absolute value (e.g., 21/100 vs. 2/10, see Bonner \& Newell, 2010).

Syllogism Items (SYL) Syllogisms are fundamental arguments in classical logic that consist of two premises and a conclusion, which necessarily follows from the premises when the argument is valid. When the conclusion is at odds with common beliefs, participants tend to deem it logically invalid even when explicitly told just to evaluate the argument's validity (Markovits \& Nantel, 1989). A conflict item consists of a logically valid (or invalid) argument structure with an unbelievable (or believable) conclusion. Here is an example of an unbelievable but valid argument: All mammals can walk. Whales are mammals. $\therefore$ Whales can walk. No-conflict items are those in which common beliefs and the argument's logical structure both cue the
same response. All problems were based on Markovits and Nantel's material (1989).

Base Rate Items (BR) Base rate items consist of statistics describing a sample from which an individual is randomly selected along with a description of the individual. Here is an example of a conflict item: "In a study 1000 people were tested. Among the participants there were 5 sixteen-yearolds and 995 forty-year-olds. Lisa is a randomly chosen participant of the study. Lisa likes to listen to techno and electronic music. She often wears tight sweaters and jeans. She loves to dance and has a small nose piercing. What is most likely? (A.) Lisa is sixteen. (B.) Lisa is forty." This item creates a conflict by calling to mind a stereotype that is at odds with the statistically most likely outcome. To generate no-conflict items, one aligns the statistics and the intuitively cued heuristic. For example to turn the above item into a no-conflict example, switch the base rates so the the sample consists of 995 sixteen-year-olds and 5 forty-year-olds. All problems were based on De Neys and Glumicic's (2008) material.

Conjunction Items (CON) Modeled on the classic Linda problem, participants received descriptions about individuals that either intuitively prompt a single statement (no-conflict) or a conjunctive statement (conflict), and they are asked to decide which statement is most likely. Since a single statement is always more likely than a conjunctive statement, subjects should always choose the single statement regardless of whether it coheres with the stereotype. Here is an example of a conflict item: "Jon is 32. He is intelligent and punctual but unimaginative and somewhat lifeless. In school, he was strong in mathematics but weak in languages and art. Which one of the following statements is most likely? (A.) Jon plays in a rock band. (B.) Jon plays in a rock band and is an accountant." Since the description generally cues an accountant stereotype, subjects often wrongly choose the less likely option, B. Noconflict items simply isolate the heuristically cued option. All problems were based on De Neys, Cromheeke, and Osman's (2011) material.

## Procedure

The participants were tested in groups of no more than thirty students in a silent classroom at the beginning of a course. In addition to the conflict and no-conflict items illustrated above, participants answered one abstract neutral problem per task. These were designed to query abstract knowledge of relevant reasoning rules and were variants of the above tasks with no clear, consistent intuitive or heuristic prompts. Accuracy on the neutral control items was high (mean accuracy $81.6 \%$, $\mathrm{SD}=0.18$ ). All analyses were run filtering for controls and they made no significant impact on any of the results. Thus, we will present only our unfiltered data in what follows and will not discuss the control items further.

The overall structure of the experiment, a within subject design, was manipulated in three ways: it was balanced for
conflict content, task order, and conflict presentation order. The conflict and no-conflict contents were balanced across participants, such that half the participants received, for example, the conflict conjunction item above, while the other half received its no-conflict analogue, and vice versa. Additionally, the order in which a given task was presented varied, as did whether an individual first saw a conflict or no-conflict item. A partial Latin square of these factors generated 10 different experiment formats, which were distributed evenly across the participant sample.

All items were presented on their own page. At the bottom of which there was a scale where participants indicated how confident they were in their response on a range from $0 \%$ (not at all confident) to $100 \%$ (completely confident).

## Results

## Accuracies

Table 1 (first two rows) presents averages of accuracy levels on each of the tasks, separated by conflict status. Replicating classical findings, performance on no-conflict items was consistently higher than performance on conflict items. In all cases except for RB, contrasts between performance on conflict and no-conflict items was significant (all BB/SYL/BR/CON t > 10.07, $\mathrm{p}<0.001$; RB: $\mathrm{t}(315)=1.10, \mathrm{p}=0.28)$.

Table 1: Accuracies and Conflict Detection Effects

|  | Conflict |
| :---: | :---: | :---: | :---: | | No-Conflict |
| :---: |$c$| Conflict |
| :---: |
| Task |
| Accuracy (SD) |
| Accuracy (SD) |
| Detection (SD) |

## Conflict Detection

To get a sense of how widely conflict detection efficiency is distributed across tasks, it is useful to look at what proportion of the sample tended to detect conflict on the entire battery. At the aggregate level, averaged across tasks, we observe most individuals (74.70\%) tend to a lowered confidence level on conflict vs. no-conflict items. Across all tasks, this difference amounts to a $9.50 \%$ diminution in confidence on incorrectly solved conflict items compared to correctly solved conflict items, $\mathrm{t}(307)=12.01$, $\mathrm{p}<0.001$. This is roughly reflected in the task by task contrasts, though it is highly variable. For example, in the case of the BB items the confidence diminution was $23.15 \%$, while most others hovered around $10 \%$, and, in contrast with previous findings (Stupple, Ball, Evans, Kamal-Smith, 2011), there was little difference between confidence levels on SYL items ( $0.37 \%$ ). In all cases except for SYL, $\mathrm{t}(177)$
$=0.50, \mathrm{p}=0.61$, the task specific confidence decrease was significant: $\mathrm{BB} / \mathrm{RB} / \mathrm{BR} / \mathrm{CON}$ : all $\mathrm{t}>2.65$, all $\mathrm{p}<0.01$.

## Task Specificity and Domain Generality

With a view to evaluating whether conflict detection is task specific or domain general, we ran four primary kinds of analyses: correlations between conflict items across tasks; correlations between conflict detection effects across tasks; analyses of the distribution of conflict detection effects by individual; and regressions to predict conflict detection effects with a composite meant to uncover diffuse evidence of domain generality.

Table 2 summarizes the results of the first two analyses. The statistics above the diagonal are correlations between conflict detection effects across biased individuals on each of the tasks. The correlations below the diagonal are between accuracies on each of the conflict items across tasks for all participants $(\mathrm{N}=318)$. Accuracies on conflict items were significantly correlated between all tasks (all p < 0.04 ), although most correlations are fairly modest, ranging from 0.12 to 0.32 .

Table 2: Conflict Accuracy and Detection Correlations

|  | BB | RB | SYL | BR | CON |
| :---: | :---: | :---: | :---: | :---: | :---: |
| BB |  | $0.06{ }_{56}$ | -0.09 ${ }_{114}$ | $0.07{ }_{142}$ | $0.04{ }_{145}$ |
| RB | 0.24** |  | $0.22_{55}$ | $-0.02_{76}$ | $0.15{ }_{75}$ |
| SYL | 0.26 ** | $0.23 * *$ |  | $0.14_{150}$ | $0.06_{158}$ |
| BR | $0.17{ }^{* *}$ | 0.12* | 0.11* |  | $0.16{ }^{*}{ }^{27}$ |
| CON | 0.12** | 0.13* | 0.13* | 0.32** |  |

As a reminder, a conflict detection effect is, in this context, a diminution of confidence on an incorrectly solved conflict item relative to a correctly solved no-conflict item. Given the notorious noisiness and subjectivity of confidence measures and the difficulty of interpreting conflict detection effect sizes (Frey, Johnson, \& De Neys, 2017), this is measured in a binary way: one either shows the effect or one does not. In stark contrast to the pattern below the diagonal, correlations between conflict detection effects-those above the diagonal-are almost uniformly insignificant. The only exception is CON \& BR, which was correlated at 0.16 ( $p$ 0.02 ). The correlation between BR \& SYL was marginally significant, $\mathrm{r}=0.144, \mathrm{p}=0.078$. Additionally, Bayes Factors for the correlations were all below 0.52, except CON \& BR, which was 1.59.

The binary correlations of conflict detection effects provide no real evidence of domain generality. However, if there is a general and diffuse signal, why should that be captured by simple, pairwise correlations? Perhaps it is the case that conflict detection on a particular task is better predicted by a non-specific and global sensitivity to conflict across tasks. We ran a regression analysis to address this hypothesis, using the combined predictive power of a participant's responses across all tasks. In particular, we used logistic regressions to determine whether conflict
detection on a given task was predicted by one's tendency to detect conflict on all of the other tasks. For example, to see if we can predict whether an individual shows an effect on the BB items, we tallied how often she showed an effect on all the other items (RB, SYL, BR, and CON) and used the latter as our predictor variable.

Table 3: Predicting Conflict Detection Effects

| Model | Beta | Z | P | Pseudo $\mathrm{R}^{2}$ |
| :---: | :---: | :---: | :---: | :---: |
| BB | 1.02 | 5.46 | $<0.01$ | 0.17 |
| RB | 0.37 | 1.34 | 0.18 | 0.02 |
| SYL | 0.07 | 0.40 | 0.69 | $<0.01$ |
| BR | 0.23 | 1.99 | 0.05 | 0.01 |
| BR2 | 0.12 | 0.61 | 0.55 | $<0.01$ |
| CON | 0.33 | 2.08 | 0.04 | 0.01 |
| CON2 | 0.20 | 1.00 | 0.32 | $<0.01$ |

As is clear from Table 3, the goodness of fit of these first models (BB, RB, SYL, BR, CON) was generally quite low. The pseudo $\mathrm{R}^{21} \mathrm{~s}$ (McFadden's) range from $<0.001$ to 0.02 , except for the BB model which was at the limit of what is considered reasonably good (0.17). The relative goodness of this model is reflected in its higher beta coefficient (1.02), which is significant ( $\mathrm{p}<0.001$ ).

The only other models with significantly predictive coefficients were the BR and CON models. However, given the tight correlation between these items discovered in the first analysis, we wondered if this was driving the effect. Indeed, if one runs a restricted model, omitting the correlate of the predictor (leaving out CON in the BR case, and vice versa), the models (BR2 and CON2 in Table 3) have inferior goodness of fit and coefficients that are both smaller and no longer significant. ${ }^{2}$

## Individual Differences

So far, we have uncovered little evidence of domain generality in conflict detection. However, most of the previous findings rely on averaging effects across reasoners. It might well be the case that there are individuals who show evidence of fairly generalized conflict detection. The concern we address in this section is that important differences between individuals might be lost by aggregating as we have, a concern that echoes theorists who emphasize the importance of examining individual differences in reasoning and decision making (Baron, 2010).

[^72]To address this issue, we present a final means of characterizing the sample's overall conflict sensitivity, which is summarized in Figure 1. We scored every biased participant individually in order to get a sense of the distribution of conflict detection effects. For a given individual, the total number of tasks on which she showed a conflict detection effect was divided by the total number of tasks on which she was biased, giving us a range of detection levels spanning from 0 (showing no effect on any of the tasks on which an individual is biased) to 1 (showing an effect on all of the tasks on which an individual is biased).

Figure 1: Frequency of Reasoners by Detection Level
There are concentrations of individuals who consistently detect (Detection Level 1: $18.09 \%$ of the sample), detect half the time (Detection Level 0.50: 21.28\% of sample), and who consistently do not detect (Level 0: $12.77 \%$ of the sample), with all other participants distributed between these three groups. The observation that up to $13 \%$ of the sample shows a Detection Level 0 is in line with previous findings that suggest there are subsets of reasoners who consistently fail to detect conflict (Frey, Johnson, \& De Neys, 2017, Pennycook et al., 2015). The additional observation that $18 \%$ of the sample shows perfect detection across all tasks also implies that there might be exceptions to the overall trend toward task specificity. Although this distribution is compatible with the few studies that have explored individual differences in conflict detection previously, we cannot confirm the representativeness of this kind of a distribution given our methods, as we could have arrived at it by chance.

## Discussion

While performance on conflict items was consistently correlated, we found no clear indication that conflict detection is similarly correlated. Even using a more liberal measure, one that leverages the predictive power of the entire panel of tasks to anticipate conflict detection on a single task, there was only the faintest signal of generality. Nevertheless, base rate (BR) and conjunction (CON) items
were correlated, and the more liberal regression models relying on them were minimally predictive, as was the model predicting the bat and ball (BB) problems. So we found, additionally, no clear evidence of hard and fast task specificity.

One might classify our findings as "domain specific," where a domain is defined as a set of problems that share similar reasoning rules subject to comparable competing intuitive heuristics. From such a perspective, base rate and conjunction items would be considered to fall within the same domain, as they share similar underlying reasoning structures (statistics and probabilities, respectively) that are in conflict with comparable intuitively prompted heuristics (social stereotypes in both cases), and in indeed both were developed to evaluate biases resulting from the representativeness heuristic.
This hybrid outcome has a number of exciting theoretical features and practical applications. For example, Teovanović, Knežević, \& Stankov (2015) argue against a single, explanatory factor underlying cognitive biases that one can easily relate to general intelligence. The account we present here is commensurate with those findings, as it seems indicative of multiple, often dissociable loci of conflict detection failures. Additionally, one of the implications of our findings is that a conflict detection failure on a given task may be largely dissociable from a conflict detection failure on a distant task. This is a hopeful conclusion, especially given the evidence that at the individual level such failures are a non-negligible source of reasoning bias (e.g., Pennycook et al., 2015). The prominence of conflict detection failures on a certain task need not paint a grim picture of reasoning globally. However, the association within what we are calling a domain indicates that at points detecting on a given task will be related to detection on a different task, a relationship that could be exploited educationally. For example, a reasonable pedagogical strategy might begin by allocating resources to the easier of two related tasks, relying on the shared conflict prompting structures to aid in instructional transfer and facilitate instruction on the second task.
These findings raise many additional questions. Since confidence measures are inherently noisy, our results are necessarily tentative. It will be important to revisit the question of the domain generality of conflict detection with additional measures, especially response times. Additionally, given that we were interested in performance across many tasks, we were only able to use a few items per task, so our findings need to be interpreted cautiously. Another particularly promising research project will be to further characterize those individuals who detect conflict in a domain general manner. For example, it would be particularly instructive to determine whether they share similar general cognitive capacities or tend have related thinking dispositions.

#### Abstract

We studied a simple binary prediction task and discovered that, when making predictions, humans display sequential effects similar to those in reaction time. Moreover, we found that there are considerable individual differences in sequential effects in prediction, again similarly to reaction time studies. We discuss our results in light of the view that sequential effects are the trace of an attempt at detecting a pattern in the sequence, as well as the possible influence of randomness perception in our results. We conclude that the same pattern detection mechanism is likely to underlie sequential effects in reaction time and prediction.

Keywords: sequential effects; prediction
When responding to a sequence of stimuli, human performance depends on the past sequence of stimuli, often to a larger extent than on the properties of the stimuli (e.g. Bertelson, 1961; Cho et al., 2002). This phenomenon, known as 'sequential effects', is commonly interpreted as the product of an attempt at detecting a pattern in the sequence of trials, and in particular whether it is a repeating or alternating sequence. Take for instance a random sequence with two possible elements: after a repeating run, people tend develop an expectation that the next event will be the same; similarly, after an alternating run, an expectation will develop that the next event will alternate relative to the last one. This is reflected in human reaction times (RTs) which tend to be faster for those events which are expected and shorter for those that are not. For instance, let ' $R$ ' and ' $A$ ' stand for repetitions and alternations of stimuli: after seeing RRRR people react faster if the next event was $R$, and slower if it was $A$; conversely, after seeing AAAA they will react faster to another A and slower to an R. If we plot mean RT for all possible histories of events we obtain a 'profile' of sequential effects. Figure 1 shows a commonly obtained profile of sequential effects, often referred to as 'cost-benefit' in order to highlight the trade-off in RT after a given sequence.

But what if, instead of reacting to each element, a prediction must be made about what the next one will be? It follows from the expectation-based account expounded above that those events which are expected should be predicted the most (i.e,. prediction frequency should be negatively proportional to RT). However, the longer a repeating run is, the more people have been found to predict that the sequence will alternate (Jarvik, 1951), an effect known as the 'gambler's fallacy' (Oskarsson, Van Boven, McClelland, \& Hastie, 2009). At first sight, results from prediction experiments where the gambler's fallacy is observed are incompatible with those of RT experiments - where it is found that RT decreases as a
function of run length (Bertelson, 1961) - since, together, the findings from the two paradigms paradoxically imply that humans predict more and more that which they predict less and less. Also, note that, since people react faster when a pattern is confirmed, they are going with the pattern - i.e. behaving as if the pattern will continue - whereas, when predicting, they seem to be going against the perceived pattern.

One possible explanation for the differences observed between prediction and RT is that people might perceive the sequence to be random in some cases and not random in others (Nickerson, 2002). It stands to reason that if a sequence is random, then any regular pattern encontered must be shortlived; if, on the other hand, a sequence is judged to be structured, then a pattern might be more likely to continue. Differences in randomness perception might influence results, but there is evidence that both phenomena - decreasing RT and increasing proportion of prediction with increase in run length - occur simultaneously, as both have been observed in experiments where subjects were made to predict - as well as react to - each stimulus (Hale, 1967; Perruchet, 1985). At first sight, this finding does not seem compatible with the randomness perception account, since that account would suggest that whether or not the sequence is percieved as random changes within the same trial. Thus, while randomness perception cannot be ruled out as a possible explanation for some results, it is not the full story.

Before a decision can be made to go with or against a pattern, the pattern must be detected in the first place. Parsimony suggests that the pattern detection mechanism underlying sequential effects in both prediction and reaction is the same, but that the information it conveys is being used in different ways, and this forms our first hypothesis. As evidence for this hypothesis, we will take any similarities in the profiles of sequential effects in prediction and reaction time. For instance, should the proportion of times people predict the next event to repeat or alternate (i.e., the prediction probability) be found to resemble the cost-benefit pattern in Figure 1, this would be taken as evidence that the same type of sequential effects can be found in RT and prediction. However, we do not know beforehand whether humans are going with or against the pattern in the sequence when making predictions. If going against the pattern we would expect prediction probability to be proportional to RT, and negatively proportional if going with the pattern. In the latter case the profile of sequential effects in prediction would look like an inverted copy of its RT counterpart (see Figure 1, right panel). Previous evidence points to the fact that humans are going against the pattern

Figure 1: Illustration of working hypotheses. Sequences at the bottom are shown in terms of repetitions (R) and alternations (A) of stimuli and should be read from top to bottom with the last event in bold. Left panel shows reaction time data of a single individual included in the analyses performed by Gökaydin et al. (2016), illustrating the ideal profile of sequential effects, also known as 'cost-benefit'. Right panel illustrates what would be expected if prediction also displayed sequential effects similar to those observed in RT. The solid line on the right panel shows what would be expected if humans were going against the pattern in a prediction task, i.e. predicting more often that the pattern will continue; the dashed line shows what would be expected if subjects were going with the pattern.
when predicting, so our second hypothesis is that prediction probability will be proportional to RT, and that the respective profile of sequential effects will show the same 'polarity' as that of RT (Jarvik, 1951; Hale, 1967; Perruchet, 1985).

## The structure of sequential effects

In order to test our hypotheses we must assess whether sequential effects in reaction and prediction are the same. However, this is not a simple matter of comparing results of two sets of subjects performing a reaction and a prediction task, as it is well known from reaction time studies that there is extensive variation in the profile of sequential effects depending on experimental parameters such as the interval between the stimuli (Soetens, Boer, \& Hueting, 1985; Gökaydin et al., 2016), as well as for different individuals performing the same experiment. In fact, the 'typical' profile of sequential effects shown in Figure 2 (left panel) is the exception rather than the rule (Gökaydin et al., 2016). Therefore, in order to demonstrate that sequential effects in prediction are the same as those in reaction time we will try to show they have the same structure.

There is growing evidence that sequential effects in reaction time can be explained in terms of two separate components, one perceptual and related to the sequence of stimuli and the other motor in origin and related to the sequence of responses (Jentzsch \& Sommer, 2002; Maloney, Dal Martello, Sahm, \& Spillmann, 2005; Wilder, Jones, Ahmed, Curran, \& Mozer, 2013; Gökaydin et al., 2016). Crucially, the relative

Figure 2: Perceptual and motor sequential effects. Both panels show data collected by Jentzsch and Sommer (2002). Left panel shows the evidence for a perceptual component of sequential effects (S-LRP) and the right panel for a motor component (LRP-R). See main text for an explanation of the meaning of these two components.
contributions of the two components of sequential effects are known, and take the form of the profiles shown in Figure 2. Moreover, sequential effects in reaction time - across different participant and experimental conditions - are known to be well approximated by a linear combination of the two components, giving us a simplified working model of sequential effects in reaction time. Applying this model to results from a prediction task gives us a way of testing whether sequential effects in reaction time and prediction are similar.

Figure 2 shows the best evidence available about the two components of sequential effects, from an EEG study conducted by by Jentzsch and Sommer (2002). The authors measured the time between stimulus onset and the occurrence of the lateralised readiness potential (LRP), termed S-LRP; and the time between the LRP and the moment a response occurred, or LRP-R. Since the LRP is thought to separate temporally pre-motor from motor processing, S-LRP and LRP-R are considered to give a measure of pre-motor and motor processing respectively. By measuring both S-LRP and LRP-R as a function of the sequence of stimuli, Jentzsch and Sommer (2002) sought to capture the pre-motor and motor contributions towards sequential effects (see Figure 2). Further evidence from other studies shows that what Jentzsch et al. referred to as pre-motor processing can safely be assumed to be perceptual in nature and associated with the processing of stimuli (Maloney et al., 2005; Wilder et al., 2013). For this reason, we will refer to the two components of sequential effects simply as perceptual and motor, denoting them, respectively, as $P$ and $M$.

## Different ways of looking at the data

Sequential effects are usually studied in the context of twoalternative forced-choice tasks ( 2 AFCs ) where one has to react to each stimulus as quickly as possible (e.g., pressing one button if the stimulus appears on the left and another if the stimulus appears on the right). Error rates in this type of task
tend to be quite low, which means that the sequences of stimuli and responses are very similar and that organising results as a function of one or the other yields the same results. By contrast, in a prediction task with two equiprobable stimuli, the error rate is $50 \%$ by design, and this means that the sequence of responses and of stimuli become uncoupled. This raises the question: should the sequence of stimuli or that of predictions be used in order to study the way in which predictions depend on the sequence? And what information is each type of analysis conveying? One possibility is that analysing predictions as a function of the history of predictions - which involve a motor action - we will recover the motor component of sequential effects in prediction; conversely, predictions as a function of the history of stimuli might yield the perceptual component.

## Method

## Participants

21 subjects ( 11 female, 10 male) participated in the experiment. Subjects were recruited using Amazons Mechanical Turk (Mturk) system. Only participants with at least 500 HITS completed on Mturk and with an approval rate of $95 \%$ or above were accepted and paid $\$ 5$ USD for taking part in the experiment.

## Stimuli

Stimuli consisted of two white dots of radius equal to 30 pixels, horizontally separated by a distance in pixels equal to $20 \%$ of the width of the screen. The dots were white and displayed against a grey (RGB 0.5/0.5/0.5) background. During each trial, the two possible positions of the dots were indicated by two black squares equal in width to the diameter of the dots.

## Procedure

Each trial began with a 2000 ms -long text display above the two black squares: 'Is the next dot on the left or on the right?'. Predictions were made with the ' f ' key for 'left' and ' j ' for 'right'. If a prediction was made during the 2000 ms period, the corresponding black square's border would thicken and further key presses had no effect. Once 2000 ms elapsed, the next dot appeared for 600 ms , together with feedback (green tick for a correct prediction or a red cross for incorrect). If no prediction was made, a warning message 'Don't forget to guess' was displayed before the appearance of the next dot. If no prediction was made for five consecutive trials, the experiment stopped, and the message 'Please remember to respond' was displayed until the space bar was pressed. Each subject performed 500 trials separated into five blocks of 100 each, with an additional 10 practice trials. The sequence of dots was random, with the constraint that the frequency of left and right dots was equal for each block.

## Data analysis

In the sequential effects literature it has been customary to show results as an average of a few participants. However,
recent work has uncovered that individual differences are not only substantial but also meaningful in that they reflect different contributions - perceptual and motor - towards sequential effects (Gökaydin et al., 2016). Thus, average results are not conclusive with respect to demonstrating that sequential effects in prediction are similar to those in reaction time.

In order to calculate the probability of repeating/alternating as a function of the history of stimuli for each participant, each participant's trials were separated according to five-long histories of predictions, with prediction probabilities being calculated simply as the relative frequency with which a repetition or alternation was predicted as the fifth event in each of the 16 possible five-event-long histories presented on the $x$-axis of Figure 1. For instance, denoting frequency by $f($.$) ,$ the probability of alternating after predicting ARA was calculated as $p(A R A A)=f(A R A A) /(f(A R A A)+f(A R A R))$.

We will use $X_{s}, Y_{s}$ to denote the left/right dots and $X_{p}, Y_{p}$ the left/right predictions. In order to calculate the probability of repeating/alternating as a function of the history of stimuli, sequences such as $A R A R$ consisted of $X_{s} Y_{s} Y_{s} X_{s} X_{p}$ and $Y_{s} X_{s} X_{s} Y_{s} Y_{p}$. Probabilities of repeating/alternating were then calculated as above.

As discussed above, in order to assess whether sequential effects in prediction are similar to those in reaction time, we will use a simple model which is known to provide a good description of sequential effects in reaction time and apply it to sequential effects in prediction. Our model will consist of a simple linear combination of the perceptual elements of sequential effects. Our model then reads as $a P+b M$, where $a$ and $b$ are scalar free parameters and $P$ and $M$ are the perceptual and motor components of sequential effects - effectively just the profiles shown in Figure 2.

## Results

We will look primarily at individual results given that we know from reaction time studies that individual differences can be substantial (Gökaydin et al., 2016). Moreover, as discussed above, looking at averaged results is inconclusive with respect to assessing whether prediction and reaction time show the same type of sequential effects. We will discuss two types of analysis: prediction probability as a function of the history of predictions - prediction history profiles for short - and prediction probability as a function of the history of stimuli - or stimulus history profiles. Results from both types of analysis will be shown in turn. Overall, prediction history profiles emerged as having a larger number of individuals with a better fit to the combination of the components model: 17/21 prediction history profiles had an $R^{2}$ greater than 0.5 , compared to $8 / 21$ for stimulus history profiles. Note that a clear profile of sequential effects on one type of analysis was no guarantee that a clear profile emerged for the other type: several subjects displayed clear sequential effects on their prediction history profile but not in their stimulus history profile; conversely, one subject displayed strong sequential effects on the stimulus history profile but not on

Figure 4: Individual sequential effects in prediction as a function of stimulus history. Blue solid lines- empirical mean prediction probability. Red dashed lines - best fitting linear combination of the form $a P+b M$ where $P$ is represented by S-LRP and $M$ is represented by LRP-R. Inset bar plots show coefficients $a(P)$ and $b(M)$. Also shown is the $R^{2}$ value of the fits.

The remaining profiles in Figure 4 (bottom two) show two profiles which are consistent with a mixture of the two components of sequential effects, where the motor component is inverted but not the perceptual, and vice-versa. These types of profile, resembling an almost two-tiered dependence on the last event and whether this was a repetition or an alternation, are common at the individual level in RT studies despite only recently having been described (Gökaydin et al., 2016). Interestingly, no single participant exhibited a good fit to a combination of the two components where both had positive coefficients. Note that the two sets of subjects shown in figures 4 and 3 are different, with the exception of the lower-left panel of both figures, which show both types of analysis for the same individual.

Recall that, based on previous results, we hypothesized that prediction probability would be proportional to reaction time, reflecting the fact that humans predict less that to which they respond the fastest, and vice-versa. In the context of our model, this would imply that the coefficients of perceptual and motor components have the same sign on average in reaction time and prediction. Figure 5 shows the coefficient values of both components for all the individuals with very good fit to the model $\left(R^{2}>0.7\right)$. At first sight our re-

Figure 5: Coefficients of the best fitting linear combination $a P+b M$ for those subjects with $R^{2} \geq 0.7$. Blue triangles show the coefficients of the fit to results as a function of prediction history; red squares show fits to results as a function of stimulus history. The large blue triangle and red square show the respective means.
sults differ from RT experiments in one respect: in prediction profiles at least, the motor component often varies from a strongly positive to a strongly negative sign, whereas in RT it has almost always a positive sign (see Gökaydin et al. (2016), supplementary information). With respect to differences between prediction history profiles and stimulus history profiles - squares and triangles in Figure 5 - there is a hint that perhaps stimulus history shows one or the other component in isolation, whereas prediction history shows a more balanced mixture of the two components, but it is too early to draw any firm conclusions.

## Discussion

Our first hypothesis posited that we would find sequential effects in prediction similar to those in reaction time. The evidence presented here - while falling short of demonstrating that sequential effects in reaction and prediction are the same - does strongly suggest that sequential effects in prediction are similar to those in RT insofar as they are well captured by a combination of the two components of sequential effects in reaction time - perceptual and motor. That such clear profiles of sequential effects were obtained (Figures 3 and 4) was somewhat surprising given the smaller number of trials relative to typical RT tasks, as well as the less constrained nature of the task. Still, results were visibly noisier when compared to reaction time experiments, and many subjects failed to exhibit any appreciable fit to the two-component model. Nevertheless, we cannot rule out that those individuals who did not exhibit a good fit to the model exhibit a new type of sequential effect which is meaningful. In order to firmly establish the nature of sequential effects in prediction an experiment with larger numbers, followed by latent variable analysis - such as principal components analysis (PCA) (Gökaydin et al., 2016) - is necessary. This would allow us to match the structures of sequential effects in prediction and reaction time, rather than just a few individual results.

We also hypothesized that prediction probability would be
directly proportional to RT, rather than negatively proportional as is more intuitive. Again in this case conclusions can only be drawn on average, since there is considerable variation in the sign of the two components in both RT (see Gökaydin et al. (2016)) and prediction (Figure 5). Despite the small sample size, one difference did emerge: the sign of the motor component in prediction profiles ranges from strongly negative to strongly positive, whereas in RT studies the motor component seems constrained to be positive. Another interesting observation is that the motor component with a negative sign and in relative isolation - i.e. not in combination with the perceptual component - occurred in half $(4 / 8)$ of the stimulus profiles with an $R^{2}$ greater than 0.5 . In other words, when analysing results as a function of the history of stimuli, half of the participants were using only the motor component of sequential effects. Moreover, when analysing results as a function of the history of predictions, we obtained clear contributions from both the motor and perceptual components. At first sight, these results at odds with the interpretation of the components of sequential effects as associated with the perceptual and motor systems since - in a task where the sequence of responses and stimuli are de-coupled - we should recover the motor component when looking at the sequence of responses and the perceptual component when looking at the sequence of stimuli. Therefore, our results may force a reinterpretation of the motor/perceptual association of the two components of sequential effects.

There is some debate regarding the computational nature of sequential effects. Some authors argue that sequential effects reflect the tracking different types of statistics in the environment (Wilder, Jones, \& Mozer, 2009), whereas others argue that sequential effects are instead the product of the separate detection of alternating and repeating patterns (Maloney et al., 2005). We will use the latter interpretation in order to guide our discussion, but the different explanations are not incompatible and the ensuing discussion would hold if we interpret sequential effects as tracking different statistics. In the context of the pattern-detection interpretation, the perceptual component is the natural candidate for an alternation detector, whereas the motor component would play the role of a repetition detector (see (Gökaydin et al., 2016) for an explanation of this mapping). A change in sign of either coefficient would therefore imply a change in whether a particular subject is going for or against the respective pattern. For instance, when predicting, a positive sign of the motor component would mean that the the participant is going against a perceived repeating pattern, and the opposite is true for a negative coefficient. ${ }^{1}$ In light of this, we can now see that the variation in the sign of the coefficients of both components of sequential effects (Figure 5) may reflect a differential treatment of repeating and alternating patterns: in some cases subjects are going against both types of pattern - repeating or alternating - and other times against one but with the

[^73]other. The only combination we did not obtain was a negative sign on both coefficients, which would imply going with both patterns.

Earlier we proposed that the subjective perception of randomness might influence the polarity of sequential effects, since whether or not a pattern will continue depends on whether the sequence is random or not. At first sight, the randomness perception account would seem to imply that humans either go against both types of pattern - repeating and alternating - or with both. After all, if we perceive the sequence as being random we should bet against both repeating and alternating sequences continuing, and the opposite if we believe the sequence to be structured. However, it is conceivable that the perception of randomness has a differential effect on repeating and alternating patterns or, somewhat equivalently, that individuals give different weight to repetitions and alternations when judging a sequence to be random. In fact, it is well known from RT studies that there are substantial individual differences with respect to sensitivity to repetitions and alternations (Soetens et al., 1985; Gökaydin et al., 2016). In our experiment we did not bias the participants either way, and it is therefore natural to assume that individual perception of the random nature of the sequence would vary depending on endogenous factors. One way to test the influence randomness perception on sequential effects in prediction would be to conduct the same experiment giving participants a strong hint that the sequence is random, and contrasting these results with a situation where it is implied that the sequence has a pattern.

Some of the participants in our study exhibited a clear prediction history profile, some a clear stimulus history profile, and some both. The implication is that some humans are tracking the sequence of predictions, others the sequence of stimuli, and others both, in order to try and make predictions. What is it that makes some people more sensitive to one or the other type of information? The perception of randomness may yet again play a role in this respect, since a belief that the sequence is random should lead to a dismissal of the sequence of stimuli as uninformative. If participants believe the sequence is random they might try to generate the most random possible sequence of responses by using their repetition and alternation detectors 'in reverse' in order to create a sequence of responses that is poor in repeating and alternating patterns. If this were the case, we should expect to see a positive coefficient on both components in those participants with a clear prediction history profile (blue triangles in Figure 5), which seems to be the case for a few subjects, but not all. Again, we cannot discard the possibility that individual differences in sensitivity to repetitions and alternations might play a role in this case, and that some individuals might put more or less emphasis on repetitions or alternations when generating the most random sequence possible.

## Conclusion

We have shown for the first time that prediction tasks display sequential effects similar in nature to those observed in reaction time. This work goes some way towards unifying the areas of prediction and reaction time in binary decision tasks.

# Empirical tests of large-scale collaborative recall 

Monica A. Gates (mgates@berkeley.edu)<br>Jordan W. Suchow (suchow@berkeley.edu)<br>Thomas L. Griffiths (tom_griffiths@berkeley.edu)<br>Department of Psychology, University of California, Berkeley, Berkeley, USA

#### Abstract

Much of our knowledge is transmitted socially rather than through firsthand experience. Even our memories depend on recollections of those around us. Surprisingly, when people recall memories with others, they do not reach the potential number of items they could have recalled alone. This phenomenon is called collaborative inhibition. Recently, Luhmann and Rajaram (2015) analyzed the dynamics of collaborative inhibition at scale with an agent-based model, extrapolating from previous small-scale laboratory experiments. We tested their model against human data collected in a large-scale experiment and found that participants demonstrate non-monotonicities not evident in these predictions. We next analyzed memory transmission beyond directly interacting agents by placing agents into networks. Contrary to model predictions, we observed high similarity only within directly interacting pairs. By comparing behavior to model predictions in large-scale experiments, we reveal unexpected results that motivate future work in elucidating the algorithms underlying collaborative memory.

Keywords: collaborative memory; collaborative inhibition; network transmission; crowdsourcing; agent-based modeling

Our memories often rely on the people around us: every day we communicate with our colleagues and friends, forming and editing memories in each interchange. People learn to access each other's memories within long-term couples (Wegner, Erber, \& Raymond, 1991), and groups collectively form memories that define their values (e.g., Hirst \& Echterhoff, 2012). As people connect within increasingly larger networks, collaborative memory becomes ever more relevant.

In psychology, collaborative memory has historically been investigated in small-scale, lab-based experiments. Much work on group memory has thus focused on dyads or triads. However, our worlds are more richly connected than can be replicated in a lab setting, and many of the findings from this work may not be applicable to the larger systems of our everyday lives. To address this lack of understanding of large groups, recent efforts have focused on investigating memory abilities using agent-based modeling (Luhmann \& Rajaram, 2015). By analyzing human performance in past memory experiments, researchers can derive putative algorithms that describe human memory recall and embed these algorithms in artificial agents. These "agents" can then participate in novel memory paradigms with hundreds of agents interacting at a time. Agent-based modeling provided a solution to the difficulty of recruiting large numbers of participants and arranging them in the networks required by memory experiments.

However, we have recently developed a novel approach that allows us to overcome the previous impossibility of analyzing collaborative memory abilities at scale. Using new technology interfacing with web-based crowdsourcing tools such as Amazon Mechanical Turk, we can now recruit and
organize hundreds of online participants into real-time interactive chatrooms. Moreover, by considering participants as "nodes" in a network graph, we can assemble participants into arbitrary network structures.

The plan of the paper is as follows. We first validate our approach by replicating established collaborative memory effects in small groups, then investigate collaborative memory at unprecedented scale (Experiment 1). We then explore how memories spread beyond direct communication by examining memory transmission across networks (Experiment 2). We compare our human results to those predicted by agent-based modeling (Luhmann \& Rajaram, 2015) to determine the models' accuracy in describing behavior. We find that participants show memory effects not predicted by the model, illustrating the difficulty of extrapolating findings to larger groups. Within networks, participants also diverge from model predictions, showing reduced similarity in the words they recall beyond direct interactions. These results highlight the importance of large-scale studies in developing predictive models of human interaction, and further our understanding of the complexity of real-world network transmission and memory.

## Collaborative Inhibition

Imagine a group of people recalling a list of words collaboratively. The group would generate more words than any individual trying alone. However, the key comparison is not between the number of words on the group's list and the number of words on any one individual's list- it is between the group's list, and the cumulative list of what all the individuals could have done had they worked alone. This comparison is often made in the well-established "collaborative memory" task. In this task, participants listen to a long list of items (often words) and then recall as many items as possible, either as a group or individually. The number of words recalled by the group is compared to the number of words recalled by the "nominal group": the summed list of an equivalent number of individuals (redundant words removed). In the collaborative memory paradigm, nominal groups routinely outperform collaborative groups, a finding called collaborative inhibition. This effect has been replicated across many studies and variations on the paradigm (see Rajaram \& Pereira-Pasarin, 2010).

The leading theory describing collaborative inhibition is the retrieval disruption hypothesis (e.g., Basden, Basden, Bryner, \& Thomas, 1997; Rajaram \& Pereira-Pasarin, 2010). This hypothesis states that when initially listening to a wordlist, people form idiosyncratic representations of the words. When recalling words alone, participants effectively use their idiosyncratic organizations to recall the words.

However, when placed in groups, other participants can disrupt a participant's recall, leading to reduced performance. This hypothesis predicts that when participants are encouraged to organize information in similar ways, collaborative inhibition will disappear. In fact, when participants are experts in their domain (Meade, Nokes, \& Morrow, 2009) or are exposed to similarly ordered information (Finlay, Hitch, \& Meudell, 2000), inhibition does not occur. In generating model predictions, Luhmann and Rajaram (2015) incorporated the assumptions of the retrieval disruption hypothesis. In Experiments 1 and 2, we design empirical studies to compare behavioral results to these predictions.

## Agent-Based Model

In the model described by Luhmann and Rajaram (2015), agents encode $N$ items (words), where $N=40$. Agents have two representations. The first is an activation vector $\mathbf{A}$ of length $N$. Each entry $\mathbf{A}_{j}$ gives the probability that the given item $j$ will be retrieved. The second representation is an inter-item association matrix $\mathbf{S}$ of size $N \times N$. Each entry $\mathbf{S}_{i j}$ gives item $j$ 's association with item $i$ (associations were not necessarily reciprocal). This matrix would normally contain agents’ prior knowledge about word associations; however, Luhmann and Rajaram (2015) assigned values of $\mathbf{S}$ randomly between -2 and 2 to reflect agnosticism about the semantic relationships between words. (The $\mathbf{S}$ matrix was not used in our empirical studies.)

Each agent in this model has two behaviors. The first is encoding an item $i$. The first step in encoding an item is to reduce the activation of the maximally active item in vector $\mathbf{A}$, where $\beta$ is the learning rate:

$$
\begin{equation*}
\Delta \mathbf{A}_{\max }=-\beta \mathbf{A}_{\max } \tag{1}
\end{equation*}
$$

Next, the agent reduces the activations of items semantically associated with the maximally active item:

$$
\begin{equation*}
\Delta \mathbf{A}_{j}=-\beta \mathbf{S}_{j, \max } \mathbf{A}_{j} \tag{2}
\end{equation*}
$$

Finally, the agent increases the activation of the to-beencoded item $i$, with $\alpha$ acting as the learning rate:

$$
\begin{equation*}
\Delta \mathbf{A}_{i}=\alpha\left[1-\mathbf{A}_{i}\right] . \tag{3}
\end{equation*}
$$

The activation $\mathbf{A}$ vector is then normalized to ensure that its entries can be interpreted as probabilities: $\sum_{i} \mathbf{A}_{i}=1$.

An agent can also retrieve (and "orally state") an item. Agents take turns retrieving items, and on each turn, an agent retrieves an item with probability $\gamma$. The item $i$ that is retrieved is chosen according to the proportions in $\mathbf{A}$, such that items with higher activations are more likely to be retrieved. Then the activation vector is modified. First, the agent decreases activation of items semantically associated with the retrieved item $i$, in line with the theory of retrieval disruption:

$$
\begin{equation*}
\Delta \mathbf{A}_{j}=\beta \mathbf{S}_{j i} \mathbf{A}_{j} \tag{4}
\end{equation*}
$$

Next, if $i$ is not the maximally activated item, the agent reduces the activation of the maximally active item according
to Equation 1, and the activations of items semantically associated with the maximally active item according to Equation 2. Item $i$ is then encoded according to Equation 3. $\mathbf{A}$ is then normalized such that $\sum_{i} \mathbf{A}_{i}=1$. Just as the retrieving agent encodes the item after retrieving it, "listening" agents also then encode the item according to the encoding process described previously. Luhmann and Rajaram (2015) used the following parameter settings: $\alpha=0.2, \beta=0.05$, and $\gamma=0.75$.

In the first set of simulations in Luhmann and Rajaram (2015) comparing collaborative and nominal recall (our Experiment 1), model predictions were generated by presenting agents with wordlists and then having agents recall words via the described procedure. When an agent generated a word, it was shared with every other agent in the network. Agents participated in 20 rounds of retrieval within each simulation. A total of 1000 simulations (comparing 1000 collaborative and 1000 nominal results) were run for each group size.

In their second set of simulations analyzing agent interaction over networks (our Experiment 2), agents participated in 800 "timesteps" rather than rounds. In contrast with the large-scale collaborative simulations, in each timestep, every agent interacted with one other randomly chosen agent who was directly connected to them in the network. These interactions were pairwise, in contrast to previous simulations, during which the agent and their partner both had the opportunity to retrieve a word. This pattern of one-on-one interaction captures a form of organic social interaction in which someone may run into a friend and chat, and then continue on until they happen upon someone new.

Agents were placed in two types of networks: one empirically derived network, Zachary's karate club (Zachary, 1977), and one algorithmically derived network, a small-world network (Watts \& Strogatz, 1998). The karate club network describes the 78 links between 34 members of a club. Smallworld networks are based on the 6-degrees-of-separation phenomenon, the theory that it often takes around 6 links to connect any two individuals (Travers \& Milgram, 1969). To generate small-world networks, Luhmann and Rajaram (2015) used the Watts-Strogatz algorithm with the following parameters: 100 nodes, an average degree of 4 (participants were on average connected to four others), and a rewiring probability of 0.1 . A total of 1000 simulations were run for each network type. Small-world networks were randomly generated for each simulation.

In the network experiments, the measure of interest was similarity across agents. Agent similarity was compared by computing correlations across participants' activation vectors A. To capture the notion that agent similarity should be high both when agents mutually forgot or remembered a word, the absolute value of Pearson's correlation coefficient was used.

## Testing Model Predictions at Large Scale

In Experiments 1 and 2, we design empirical behavioral experiments that align with the specifications of the modeling work as closely as possible. However, the modeling work differed in that agents were allowed to submit any word that
they had not previously retrieved, whereas in the behavioral work, participants were not allowed to recall words that they or any other group members had previously recalled.

In Experiment 1, we first replicate findings from smallgroup experiments, then empirically explore the impact of large group size on collaborative inhibition. Previous work has suggested that collaborative inhibition increases as group size increases from 1 to 4 participants (Basden, Basden, \& Henry, 2000; Thorley \& Dewhurst, 2007), but Luhmann and Rajaram (2015) were the first to scale up to a hundred agents with their agent-based model. Their model predicts that collaborative inhibition rises with group size, peaks at around 8 individuals, and then begins decreasing (Figure 1a). Specifically, collaborative recall continues increasing with group size, but nominal recall hits ceiling at around 8 people as the disruption of idiosyncratic recall strategies is compensated by sheer group size. Since collaborative inhibition is the difference between nominal and collaborative recall, from this point collaborative inhibition begins to decrease. This prediction represents an extrapolation of results from small group sizes, and we tested the assumptions underlying this agentbased model by comparing human performance in the collaborative memory experiment to the model predictions.

In Experiment 2, we turn to memory transmission across networks. One person's behavior can have effects far beyond their direct connections, and viruses, information, and behaviors like smoking can spread over social networks. This transfer of information beyond direct interactions is called "hyperdyadic spread" (Christakis \& Fowler, 2009). Consistent with hyperdyadic spread, memory researchers have found that indirectly connected pairs have more similar memories than unconnected pairs (Yamashiro \& Hirst, 2014) and that distal partners can influence word recall (Choi, Blumen, Congleton, \& Rajaram, 2014). The model from Luhmann and Rajaram (2015) accordingly predicts that agents who never directly interacted, but share neighbors, will be similar (Figure 2a). Moreover, the model also predicts that agent similarity will depend on the networks that agents participate in. Agents in small-world networks were expected to be more similar than agents in karate club networks if they had directly interacted, but the opposite was expected for agents further apart. In Experiment 2, we implemented the agent-based network models with real participants to test these predictions.

## Experiment 1: Small and Large Groups

## Methods

Participants 1138 participants were recruited through Amazon Mechanical Turk. Participants were excluded from the experiment if they did not complete the pre-experiment arithmetic task and they did not contribute words in the main experiment. Sixteen participants were removed from the collaborative experiments for a total of 561 participants. Nominal groups were matched; thus 561 participants participated in the nominal experiments. The average ( $\pm \mathrm{SD}$ ) number of participants in collaborative experiments was 15.2
$\pm 0.7$ for groups of size $16,7.6 \pm 0.7$ for groups of size 8 , $4.0 \pm 0$ for groups of size $4,3.0 \pm 0$ for groups of size 3 , and $2.0 \pm 0$ for groups of size 2.

Participants would occasionally repeat the task, as they could choose to complete the task again on Amazon Mechanical Turk despite written advisement against this. Of the participant data included in this paper (other pilot task versions were also executed), in Experiment 1, 134 participants repeated the experiment more than once ( $14.6 \%$ of participants), and $30.03 \%$ of the data was generated by these participants. Participants participated an average of 1.22 times. The mean proportion of repeaters across group sizes (both nominal and collaborative) was as follows: group size of 2: $0.33 \pm$ 0.35 (SD), group size of $3: 0.39 \pm 0.31$, group size of $4: 0.27$ $\pm 0.21$, group size of $8: 0.27 \pm 0.20$, and group size of 16 : $0.27 \pm 0.09$. The participants who repeated the nominal experiments did not show improvement over time, despite having seen the same wordlists: the correlation between number of repetitions and number of words recalled was $r=-0.03$ (91 data points). Participants did improve across repetitions in the collaborative experiments ( $r=.47,89$ data points). However, the proportion of repeaters within experiments was anticorrelated with group size: the correlation between experiments of group sizes $2,3,4,8$, and 16 and the proportion of repeaters was $r=-0.086$.
Stimuli Participants saw 60 unrelated words, each selected from a different category from Overschelde, Rawson, and Dunlosky (2004). In collaborative experiments, words were presented roughly simultaneously across all participants. The average time ( $\pm \mathrm{SD}$ ) between presentation of a wordlist to the first participant compared to the last participant was as follows: $0.4 \pm 0.5$ seconds for groups of size $2,0.2 \pm 0.3$ secs for groups of size $3,0.9 \pm 0.9$ secs for groups of size $4,2.5 \pm 1.1$ secs for groups of size $8,4.2 \pm 2.6$ secs for groups of size 16 .

Procedure Participants observed wordlists: each word was presented for two seconds. After seeing the list, participants completed a 30 -second-long arithmetic filler task before advancing to the recall task. Participants were placed in chatrooms alone or with other participants, and were encouraged to type as many of the words they had seen as possible. Participants were not told how many other participants were in the chatroom: their responses appeared in blue font, and responses from all others appeared in black. They saw all previous words entered and were not permitted to submit any word that had already been submitted. This choice- that any words already present on the group list were not redisplayed- was made to encourage participants to read others' submitted words, and because it more closely matched the lab-based version of the collaborative memory paradigm, where verbal recall creates social pressure to not repeat words. There was no time limit for the recall task.

Experiments contained group sizes of $2,3,4,8$, or 16 participants. For each recall method (nominal or collaborative),

Figure 1: Effect of group size on collaborative inhibition. (a) Model results, reproduced from Luhmann and Rajaram (2015). (b) Behavioral results. The mean proportion of words ( $\pm \mathrm{SE}$ ) recalled in the nominal (red) and collaborative (blue) conditions are shown; collaborative inhibition (yellow) is the subtraction of these two values. Note that the horizontal axis is logarithmic.

48 groups of 2 were analyzed; 32 groups of 3 were analyzed; 24 groups of 4 were analyzed, and 12 groups of 8 and 16 were analyzed. This was a $2 \times 5$ design, crossing recall method by group size. In the nominal recall condition, participants recalled words alone, and their recall lists (with redundant words removed) were added together according to the appropriate group size. In the collaborative recall condition, groups of participants were placed in chatrooms and recalled together. Recalled words that had not been on the original lists were marked as incorrect and not included.

## Results

The collaborative inhibition effect is most reliably observed in triads (Rajaram \& Pereira-Pasarin, 2010), and we replicated this effect in our behavioral data at group size 3: $t(62)$ $=2.34, p=0.02, d=.60$, independent 2 -sample $t$-test. $(\alpha=$ .05 for all planned comparisons to follow. Unlike previous studies, we investigate the collaborative inhibition effect at multiple group sizes. Had we run separate studies, we would have used $\alpha=.05$, justifying its use here.) Collaborative inhibition in the literature is frequently but not always observed in pairs (Rajaram \& Pereira-Pasarin, 2010), but we did not observe this effect in this group size $(t(94)=0.78, p=0.44$, $d=.16$ ). In the two studies known to the authors examining tetrads (Thorley \& Dewhurst, 2007; Basden et al., 2000), a collaborative inhibition effect was observed, but we did not observe this effect at group size of $4(t(46)=-0.42, p=0.67$, $d=.13$ ).

Given previous results at group sizes of 2,3 , and 4 , it is reasonable to extrapolate and hypothesize that the trend of collaborative inhibition may be expected to continue or even widen at larger group sizes (Luhmann \& Rajaram, 2015). Intriguingly, this was not the pattern of results observed: participants did not show a collaborative inhibition effect at group size of 4 , and continued to not show a collaborative inhibition effect at group size of $8(t(22)=0.25, p=0.80, d=.11)$, contrary to model predictions. A collaborative inhibition effect did reoccur at group size $16(t(22)=2.17, p=0.04, d=.93)$, but variance for the nominal group is likely decreased due to
ceiling effects.
Overall, using a between-participants two-way unbalanced ANOVA, we surprisingly failed to observe a main effect of recall method $\left(F(1,246)=2.03, p=0.16, \eta^{2}=.0045\right)$ : nominal and collaborative groups did not recall significantly different numbers of words when results from all groups were combined (Figure 1b). We did observe the expected main effect of group size, $F(4,246)=49.08, p<0.0001, \eta^{2}=.44$, in that larger group sizes increased word recall. There was no interaction effect between recall method and group size $(F(4,246)$ $=1.15, p=0.33, \eta^{2}=.010$ ).

Contrary to the model predictions from Luhmann and Rajaram (2015), the collaborative inhibition effect became less strong at group sizes greater than 3 . This observation motivates the use of large-scale studies and further experiments testing whether the retrieval disruption and related hypotheses are enough to explain these results, or whether new models of human collaborative recall are necessary.

## Experiment 2: Networks

While people occasionally come together to work in shortterm groups, we often function in long-lasting social networks, communicating occasionally with far-flung friends. These networks are complex and can spread information at a prodigious rate: a secret you tell a close friend one day might be known by the whole community the next. In Experiment 2, we sought to investigate how people share and generate information when communicating across complex networks.

## Methods

Participants After removing inattentive participants, 383 participants were sorted into one of 12 karate club networks; the mean number of participants per network was $31.9 \pm 1.4$ (SD). 390 participants were sorted into 12 different smallworld networks; the mean number of participants per network was $32.5 \pm 0.7$. Removing participants changed the structure of the networks, and path lengths increased accordingly. 81 participants repeated the network experiments more than once ( $12.7 \%$ of participants), and $27.8 \%$ of the data was

Figure 2: Similarity of agents within networks. (a) Model results, reproduced from Luhmann and Rajaram (2015). (b) Behavioral results. Mean similarity ( $\pm \mathrm{SE}$ ) across agents is plotted as a function of the minimum distance between each agent node. Participants were arranged in karate club networks (red) or small-world networks (yellow).
generated by these participants. Participants participated an average of 1.21 times. The mean proportion of repeaters in the karate club experiments was $0.23 \pm 0.10$ (SD) and in the smallworld experiments was $0.32 \pm 0.11$. The participants who repeated the network experiments did not improve in the task: the correlation between number of repetitions and words recalled was $r=-0.18$ (159 data points).

Small-world networks were randomly generated for each experiment. The average time ( $\pm \mathrm{SD}$ ) between presentation of a wordlist to the first participant compared to the last participant was as follows: $6.9 \pm 7.4$ secs for the karate networks and $3.3 \pm 1.2$ secs for the small-world networks.

Procedure To compare our results with model predictions, we sought to replicate the model's paradigm as closely as possible with human participants. Each participant was assigned as a node in a graph with the option to communicate only with individual neighbors, where "neighbor" is defined as nodes participants were directly connected to. Every time a participant generated a word, their word was shared with a randomly chosen neighbor, rather than broadcast to the entire group as in Experiment 1. Networks were generated as described in the model, except that 34 agents were included in the small-world network, to match the karate club numbers.

## Results

Hyperdyadic Spread We first asked whether participants would show evidence of hyperdyadic spread. Luhmann and Rajaram (2015) computed agent similarity by comparing their agents' activation vectors $\mathbf{A}$, but in the non-modeling world we were restricted to externally observable correlates of participants' representations. Thus, we computed the absolute value of correlations for the list of words that participants recalled in the task as our measure of hyperdyadic spread.

Using recalled lists of words, we calculated the similarity between every two agents, and sorted the correlations based on agents' proximity in the network. Specifically, we used "hops" to describe how many connections were necessary to
link an agent node to another. If agents were connected and could directly communicate with each other, they were separated by a hop distance of 1 . If the closest path between agents included one other node, they were separated by a hop distance of 2. In this study, hyperdyadic spread would be observed if there was a non-zero similarity between agents at a hop distance of 2 or greater.

Though modeling predictions suggest agents will show hyperdyadic spread, participants who did not interact (participants separated by more than 1 hop) did not show evidence of hyperdyadic spread. We may have expected agents with shared neighbors to be similar, analogous to the spread of smoking habits (Christakis \& Fowler, 2009). However, habits develop over long time periods and are perhaps more transmissible than individual words, especially in social networks crafted from personal relationships. The advantage of using simplistic stimuli like wordlists is that if effective, we gain access to a reductionist, explainable system for investigation: in this case how memory representations are related. To this end, perhaps if semantically related words had been selected (rather than an unrelated wordlist presented in random order), we would have observed hyperdyadic spread in a new model system. This result highlights the effectiveness of iterating on model-based predictions and behavioral comparison.

Network Structure We next asked whether choice of network affects agent-pair similarity. In this case the model predictions closely align with behavioral results at a distance of 1 hop, though at greater distances the behavioral results exhibit unpredicted non-monotonicities. Specifically, at a distance of 1 hop, participants in small-world networks were more similar than in karate club networks $(t(22)=-6.24, p<0.0001, d$ $=2.66$, independent $t$-test), likely due to the increased local connections in small-world networks compared to the karate club network. Behavior at hop distances greater than 1 exhibited non-monotonicity: networks did not affect agent similarity ( 2 hops: $t(22)=-2.42, p=0.024, d=1.03 ; 3$ hops: $t(22)$ $=-1.17, p=0.26, d=.50 ; 4$ hops: $t(22)=-0.84, p=0.41, d$
$=.36 ; 5$ hops: $t(22)=1.45, p=0.16, d=.62 ; 6$ hops: $t(12)$ $=1.04, p=0.49, d=1.45 ; \alpha=.008$ to account for multiple comparisons).

Accordingly, the behavioral results did not show a main effect of network type across hop distance 1-6 $(F(1,122)=$ $1.44, p=0.23, \eta^{2}=0.0014$, between-participants 2-way unbalanced ANOVA), indicating that overall similarity between agents in karate club networks compared to small-world networks was not significantly different across all hop distances (Figure 2 b ). We observed an expected main effect of hop distance $\left(F(5,122)=163.86, p<0.0001, \eta^{2}=0.81\right)$, describing that agents were less similar when they were further apart. There was an interaction effect between recall method and hop distance $\left(F(5,122)=15.01, p<0.0001, \eta^{2}=0.075\right)$, describing the non-uniform decrease in agent similarity as hop distance increased. In sum, though behavioral results failed to show hyperdyadic spread, similarity between directly interacting agents was dependent on the network structure.

## General Discussion

In an increasingly interconnected world, understanding how our memories are impacted by interacting with others will influence how we organize ourselves, think and remember. In two studies, we examined collaborative memory: how remembering words in groups changes performance compared to recalling alone. We investigated collaborative memory in small and large groups and across network structures, comparing empirical results to the agent-based model predictions developed by Luhmann and Rajaram (2015).

We first replicated the collaborative inhibition effect in triads, the most reliable group size in exhibiting this effect. We then observed that in real participants, collaborative inhibition does not uniformly persevere at larger group sizes, despite what was suggested from small-scale studies (Luhmann \& Rajaram, 2015). One suggestion for why this could be is that factors outside of retrieval disruption affected participants. For example, post-experiment questionnaires indicated that in large groups where participants raced to submit nonrepeated words, some participants felt competitive pressure rather than the cooperation evident in smaller groups. While this issue might have been reduced by using a turn-taking structure rather than free recall, waiting for each participant in a large group to take a turn would introduce a new set of problems. Future models of collaborative memory should incorporate the intrinsic difficulties of organizing large groups of people, especially as people perhaps develop different strategies and algorithms to cope. To this end, large-scale quantitative work would be well complemented by fine-grained analysis of individual differences in strategies, and closer study of the interactions between individual cognition and the medium of interaction.

Model predictions suggested that the collaborative memory paradigm would be a good candidate for examining hyperdyadic spread, but empirically only participants who had directly interacted showed increased similarity. However, this
failure to observe hyperdyadic spread could perhaps be improved if semantically related wordlists were used or if a more sensitive measure than "words recalled" were used as the comparison metric. Moreover, if the behavioral task had been structured such that agents could re-submit words that their neighbors had submitted to other neighbors, we likely would have observed greater spread: future work will have to determine which paradigm structures will best inform our understanding of collaborative recall.

The unexpected results from these studies, in extrapolation to larger group sizes and in network structure, motivate and can inform future models describing the mechanisms underlying memory representations and collaborative interaction.

#### Abstract

In this paper we introduce the hypothetical simulation model (HSM) of physical support. The HSM predicts that people judge physical support by mentally simulating what would happen if the object of interest were removed. Two experiments test the model by asking participants to evaluate the extent to which one brick in a tower is responsible for the rest of the bricks staying on a table. The results of both experiments show a very close correspondence between hypothetical simulations and responsibility judgments. We compare three versions of the HSM which differ in how they model people's uncertainty about what would happen. Participants' selections of which bricks would fall are best explained by assuming that hypothetical interventions only lead to local changes while leaving the rest of the scene unchanged.

Keywords: causality; counterfactual; hypothetical; mental simulation; intuitive physics; physical support.

## Introduction

When we look at a physical scene, such as the towers shown in Figure 1, we don't just see a pile of bricks. We also have a sense for how stable the different towers are and what is causing that stability (Battaglia, Hamrick, \& Tenenbaum, 2013; Hamrick, Battaglia, Griffiths, \& Tenenbaum, 2016). In this paper, we look at how people judge the extent to which different bricks carry the responsibility for a tower's stability. We argue that people judge responsibility by imagining what would happen to the tower if the brick were removed, and develop a hypothetical simulation model (HSM) of physical support which captures this process.

We build on previous work in which we have shown how a counterfactual simulation model (CSM) explains people's causal judgments about dynamic collision events (Gerstenberg, Goodman, Lagnado, \& Tenenbaum, 2012, 2014, 2015; Gerstenberg \& Tenenbaum, 2016). In these experiments, participants saw collisions between billiard balls, and were asked to evaluate to what extent one ball had caused another ball to go through a gate in a wall (or prevented the ball from going through). The CSM assumes that people reach this judgment by comparing what actually happened with what would have happened in a counterfactual situation in which the candidate cause had been removed from the scene. As predicted by the model, participants' cause and prevention judgments increased the more certain they were that the outcome would have been different if the candidate cause had been removed from the scene. The CSM also captures the cognitive processes by which participants reach their judgments: participants' eye movements reveal how they spontaneously anticipate what would have happened in the relevant counterfactual situation (Gerstenberg, Peterson, Goodman, Lagnado, \& Tenenbaum, in press).

The CSM makes the strong prediction that counterfactual simulation forms a necessary part of how people make causal judgments, and that no adequate account of people's causal judgments about particular events can be developed that does

Figure 1: Experiment 1. Example stimuli. Note: Red bricks that would fall off the table if the black brick were removed (according to ground truth) are marked with a white dot at their center. The dots were not displayed in the actual experiment.
not rely on counterfactuals (cf. Wolff, 2007). Thus far, however, the CSM has only been applied to modeling causal judgments about dynamic collision events. Here, we demonstrate the generality of the account by showing how a model of hypothetical simulation naturally handles judgments about physical support.

Judging physical support is different from judging causation in several ways. First, hypotheticals are different from counterfactuals in that they are future-oriented and don't require going back in time (Beck, 2015). When making causal judgments about dynamic collisions, the observer needs to remember what actually happened, and contrast this with what would have happened in the relevant counterfactual situation. However, when making judgments of physical support in static scenes, like the tower configurations in Figure 1, there is no need to go back in time. We merely need to simulate what a possible future would look like in which certain aspects of the scene were changed.

Second, the mental simulations that are required to imagine the relevant counterfactual or hypothetical are different (cf. Freyd, Pantzer, \& Cheng, 1988; Holmes \& Wolff, 2010). When simulating counterfactuals, we want to stay as close as possible to what actually happened, and only modify the world as little as possible to make the counterfactual true (Gerstenberg, Bechlivanidis, \& Lagnado, 2013; Lewis, 1973; Pearl, 2000). But what do we keep constant in the causal model of the situation, and what do we change? When judging whether a ball would have gone into the goal, we need to simulate what the trajectory of the ball would have been if the collision hadn't taken place. To model people's uncertainty, we can add noise to the simulation of the ball's trajectory (cf. Smith \& Vul, 2013) and keep everything else that we know about the scene as it was (e.g. we wouldn't change the size

Figure 2: Schematic illustration of how different versions of the hypothetical simulation model apply noise when considering what would happen if the black brick were removed.
of the goal in the counterfactual simulation). However, when judging responsibility for a tower's stability, it is less clear what aspects of the scene we should hold constant. We will compare several implementations of the HSM that differ in how they capture people's uncertainty about what would happen.

The road map for the rest of the paper is as follows: We first present in detail how the HSM predicts judgments of physical support. We will test the model in two experiments in which we ask one group of participants to make hypothetical judgments, and another to evaluate causal responsibility. As predicted by the HSM, there is a very close correspondence between hypothetical and responsibility judgments. Heuristic strategies that focus on features of the scene (such as a tower's height, or the number of bricks on top of the brick of interest) cannot explain people's judgments as well. We end by discussing limitations of the current approach and by offering directions for future research.

## Hypothetical simulation of physical support

In our experiments, we ask participants how responsible the black brick is for the red bricks staying on the table. To derive predictions from the HSM we need to determine (1) what hypothetical situation to consider, and (2) how to simulate what would happen in that situation. We assume that when judging responsibility, participants consider a hypothetical situation in which the black brick is removed. Participants then use their intuitive understanding of physics to mentally simulate what would happen in that situation.

Recent work has argued that some aspects of people's intuitive understanding of physics are well-described by assuming we have an approximate simulation engine in our mind that is akin to a physics engine (Battaglia et al., 2013; Lake, Ullman, Tenenbaum, \& Gershman, 2016). Part of what makes these simulation engines "approximate" is that they assume that people's representation of a physical situation is uncertain. This uncertainty can come in many forms, such as perceptual uncertainty about the exact location of objects (Battaglia et al., 2013), dynamic uncertainty about how exactly an object will move (Smith \& Vul, 2013), and uncertainty about latent physical parameters such as friction and mass (Sanborn, Mansinghka, \& Griffiths, 2013).

To investigate whether people's mental simulations incorporate the assumption that only some aspects of the physical scene would directly be affected by the hypothetical intervention, we contrast three implementations of the HSM. These implementations differ in how they capture people's uncertainty about what would happen if the black brick were removed. All models apply noise in the same way: as a small impulse to some of the red bricks immediately after the removal of the black brick. The models differ, however, in which bricks they apply noise to. Figure 2 illustrates how the three different models work. The global noise model applies a small impulse to all the bricks and thus captures a general uncertainty about the scene (cf. Battaglia et al., 2013). The local noise model applies the impulse only to the red bricks that are directly in contact with the black brick. This model captures the assumption that participants will be most uncertain about what would happen in the area around the black brick. The above noise model applies noise only to bricks that are above the black brick and "connected" with it. Any brick that directly contacts and has its center of mass above that of the black brick counts as connected. This definition is then applied recursively. For example, brick 2 in Figure 2c is connected since brick 1 is in contact with and above the black brick, and brick 2 is in contact and above brick 1. This model captures that removing the black brick will affect the other bricks in an asymmetric way. Similar to when we lift a wooden block playing Jenga, this version of the model assumes that we have uncertainty particularly about those parts of the scene that would be affected by this kind of manipulation.

## Experiment 1

In the experiment, participants saw towers of bricks like the ones shown in Figure 1. Depending on the experimental condition, participants were asked to consider what would happen if the black brick weren't there, or evaluate the extent to which the black brick is responsible for the red bricks staying on the table. In line with the HSM, we predicted that there would be a close relationship between hypothetical and responsibility judgments.

## Methods

Design \& Procedure The experiment had three conditions that differed only in terms of the dependent measure. ${ }^{1}$ In the selection condition, participants were asked to "Please click on the red bricks that would fall off either side of the table if the black brick wasn't there." In the prediction condition, participants were asked to answer the question: "How many of the red bricks would fall off the table, if the black brick wasn't there?" Participants provided their answer on a sliding scale ranging from 0 to the number of red bricks present in the scene in steps of 1 . In the responsibility condition, participants were asked to answer the question: "How responsible

[^74]

Figure 3: Experiment 1. Scatter plots showing the relationship between the empirical probability with which each brick was selected and (a) the ground truth as well as the predictions of the best-fitting (b) global noise model, (c) local noise model, and (d) above noise model.
is the black brick for the red bricks staying on the table?" Responses were provided on a sliding scale ranging from "not at all" (0) to "very much" (100).

The procedure for all three conditions was identical. Participants first received instructions about the task. They then saw a number of warm-up animations that showed 20 bricks being dropped on the table. These animations were shown to familiarize participants with the relevant properties of the physical scene such as gravity, the friction between the bricks, as well as the table friction. Participants were only allowed to proceed to the next stage once they had watched at least five animations.

After the warm-up, participants saw 42 images of different towers of bricks in randomized order (see Figure 1 for examples). The stimuli varied the number of bricks on the table (range $=7$ to $20, \mathrm{M}=13.7, \mathrm{SD}=3.3$ ), as well as the number of red bricks that would fall off the table if the black brick were removed (range $=0$ to $6, \mathrm{M}=2, \mathrm{SD}=1.9$ ). Participants' tasks differed depending on the condition as described above. Finally, participants were asked to provide open-ended feedback about the task, and provided demographic information.

On average, the experiment took 15.71 ( $\mathrm{SD}=6.49$ ), 9.86 ( $\mathrm{SD}=6.49$ ), and 8.88 minutes $(\mathrm{SD}=8.90)$ in the selection, prediction, and responsibility condition, respectively.

Figure 4: Relationship between the predicted number of red bricks that would fall if the black brick weren't there (prediction condition) and number of selected bricks that would fall (selection condition). Note: The letters refer to the examples shown in Figure 1 for Experiment 1, and Figure 6 for Experiment 2. Error bars in all figures denote bootstrapped $95 \%$ confidence intervals.

Participants 121 participants $\left(\mathrm{M}_{\text {age }}=34, \mathrm{SD}_{\text {age }}=12,47 \mathrm{fe}-\right.$ male) were recruited via Amazon Mechanical Turk using psiTurk (Gureckis et al., 2016) with $N=38$ in the selection condition, $N=42$ in the prediction condition, and $N=41$ in the responsibility condition. We excluded participants from further analysis based on their responses to the catch trial shown in Figure 1a. Eleven participants in the prediction condition were excluded because they predicted that at least one red brick would fall. Six participants in the responsibility condition were excluded because they gave a responsibility rating greater than 15 . No participants were excluded from the selection condition because no participant selected any of the bricks on the catch trial.

## Results

We will discuss the results from the selection, prediction, and responsibility conditions in turn.
Selection condition We tested how well the three different noise models captured participants' selections of which bricks would fall off the table if the black brick weren't there (see Figure 2). For each model, we used maximum likelihood fitting to find the noise parameter which predicts participants' selections best. For each setting of the noise parameter, we ran 100 simulations per stimulus and used the proportion of samples that each brick fell off the table in the noisy simulations to predict the probability that a given brick will be selected to fall by participants. (Figure 8 gives an example for what these predictions look like for stimuli used in Experiment 2.) Overall, the above noise model accounted best for the data (cf. Table 1).
Prediction condition Figure 4a shows the relationship between the number of bricks predicted to fall and the average number of bricks that participants selected in the selection condition. Overall, the two ways of probing participants' hypothetical simulations lead to very similar results. However, participants in the prediction condition predicted that more bricks would fall than participants in the selection condition selected (most of the data points are below the diagonal). The noise model which best accounted for participants' selections, also accurately predicts participants' average judgments about how many bricks would fall with $r=.88, \mathrm{RMSE}=0.84$.

Figure 5: Relationship between the predicted proportion of bricks that would fall if the black brick weren't there and responsibility judgments. Note: The letters refer to the examples shown in Figure 1 for Experiment 1, and Figure 6 for Experiment 2.
Responsibility condition Figure 5a shows the relationship between the proportion of bricks that participants in the prediction condition believed would fall off the table if the black brick weren't present in the scene, and participants' responsibility judgments. As predicted by the HSM, there was a very close relationship between prediction and responsibility judgments $r=.84, \mathrm{RMSE}=6.55$. This suggests that participants evaluated a brick's responsibility by considering what proportion of bricks would fall off the table if the brick weren't there. When we use the proportion of bricks selected in the selection condition to predict participants' responsibility judgments, we get a similarly good fit with $r=.78$, RMSE $=7.65$. A noise-free model that uses the proportion of bricks that actually fall off the table does not account well for participants' responsibility judgments $r=.35$, RMSE $=11.42$.

As an alternative to the HSM, we compared a heuristic model which predicts participants' responsibility judgments based on features of the physical scene. Table 2 shows how well the different features correlated with participants' judgments individually, as well as when combined via a linear regression model. We included features about the whole scene such as the number of bricks, the tower height, the average distance of each brick to the nearest edge of the table, as well as the average height and angle of each brick. We also included features specific to the black brick such as its distance to the nearest edge, its height and angle, as well as the number of bricks above it. To define the number of bricks above, we used the same criterion as the above noise model (cf. Figure 2c). As Table 2 shows, the best individual predictor for participants' responsibility judgments is the average height of each brick in the scene, followed by the number of bricks above the black one. Neither individual feature describes participants' responsibility judgments as well as the predictions
Table 2: Correlation coefficients between features and participants' responsibility judgments in Experiments 1 and 2. Note: The scene features, brick features, and all features columns show how well regressions that combine these features correlate with participants' judgments.

|  | $\begin{gathered} \mathrm{n} \\ \text { bricks } \end{gathered}$ | scene features |  |  |  | black brick features |  |  |  |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |

| Exp 1 | . 16 | . 55 | . 39 | . 73 | . 21 | . 81 | . 02 | -. 19 | -. 05 | . 61 | . 62 | . 88 |
| Exp 2 | -. 05 | . 21 | -. 10 | . 07 | . 01 | . 26 | . 12 | -. 74 | -. 04 | . 69 | . 79 | . 85 |

Note: $\mathrm{n}=$ number, avg = average.

Figure 6: Experiment 2. Example stimuli. Note: White dots indicate which bricks would fall if the black brick weren't there. There were 6 different configurations of towers ( I through VI), and 7 different positions for the black brick in each tower, see c), d), and h).
(and selections) that participants made in the other two conditions of the experiment. A regression model that combines all features correlates well with participants' responsibility judgments ( $r=.88, \mathrm{RMSE}=5.89$ ), as does a model that only considers the scene features $(r=.81, \mathrm{RMSE}=7.14)$. A model which only includes features about the black brick doesn't fare as well $(r=.62, \mathrm{RMSE}=9.6)$. Even though a model that includes all features explains slighlty more of the variance that the HSM, this is likely due to overfitting; using model selection criteria, we find that the HSM performs better $(\mathrm{AIC}=276.52, \mathrm{BIC}=281.66)$ than the heuristic model ( $\mathrm{AIC}=283.72$, $\mathrm{BIC}=302.57$ ).

## Discussion

The results of Experiment 1 support the predictions of the HSM. Most importantly, there was a very close relationship between the responsibility judgments of one group of participants, and the number of bricks that another group of participants predicted would fall if the black brick weren't there. A heuristic model that does not rely on physical simulations but uses features that can be directly extracted from the scene fared worse when taking into account both variance explained and model complexity. We contrasted three implementations of the HSM which differ in the way in which they capture people's uncertainty about what would happen if the brick were removed. The results show that the above noise model correlates best with participants' selections. This model assumes that participants are particularly uncertain about what would happen to the bricks that are located above the black one.

## Experiment 2

Experiment 1 elicited participants' judgments for a wide array of different situations. In Experiment 2, we chose a more tightly controlled stimuli set, a selection of which is shown in Figure 6. We generated six different tower configurations. For each configuration, we chose seven positions for the black brick such that removing it would result in 0 to 6 red bricks falling off the table. While a heuristic model that used

Figure 7: Experiment 2: Scatter plots showing the relationship between the empirical probability with which each brick was selected and (a) the ground truth as well as the predictions of the best-fitting (b) global noise model, (c) local noise model, and (d) above noise model.
global scene features explained responsibility judgments well in Experiment 1, we expected this model to perform poorly here since it doesn't take into account where the black brick is positioned.

In order to better tell apart the different implementations of the HSM, we included tower configurations with disjointed sets of bricks (Tower III and Tower IV). For example, consider the configuration of bricks shown in Figure 6c. While a global noise model predicts that some of the red bricks on the right would fall off the table, the local versions of the model predict that only the bricks on the left side will fall.

## Methods

Design \& Procedure The design, procedure, and questions were identical to those of Experiment 1. Participants saw 43 trials in randomized order whereby one trial served as a catch trial. On average, the experiment took $13.04(\mathrm{SD}=6.87)$, $11.57(\mathrm{SD}=5.24)$ and 7.86 minutes $(\mathrm{SD}=3.48)$ in the selection, prediction, and responsibility condition, respectively.
Participants 129 participants $\left(\mathrm{M}_{\text {age }}=36, \mathrm{SD}_{\text {age }}=11.3,59\right.$ female) were recruited via Amazon Mechanical Turk with $N=42$ in the prediction condition, $N=44$ in the selection condition, and $N=43$ in the responsibility condition. We used the same exclusion criteria as in Experiment 1 based on the same tower shown in Figure 1a. 1 participant was removed in the selection condition, 3 participants in the prediction condition, and 3 in the responsibility condition.

## Results \& Discussion

Selection condition Figure 7 shows the correspondence between participants' brick selections and the predictions according to the ground truth as well as our three noise models as illustrated in Figure 2. Overall, the above noise model accounted best for participants' selections, as in Experiment 1 (cf. Table 1).

Let us look at the two situations shown in Figure 8 in some

Figure 8: Empirical selection percentages for two different stimuli together with the predicted selection probabilities according to the different noise models. The numbers (and color fill) indicate what percentage predicted that a particular brick would fall off the table if the black brick were removed. Red and black frames around a brick indicate that the brick would fall or stay on the table, respectively.
more detail. For the example shown in the top row, participants' selections corresponded closely to the ground truth. Since the global noise model applies an impulse to all the bricks, it incorrectly predicted that participants would select bricks on the right. The local noise model incorrectly predicted selections of bricks underneath the black one. The above noise model best predicted participants' selection in this case. It only assigned a small probability that any of the bricks on the right would be selected (because sometimes the bricks on top of the black brick will fall towards the right), or bricks that are underneath the black one.

The example in the bottom row shows a situation where participants' selections didn't correspond to the ground truth. Here, the majority of participants believed that none of the bricks would fall if the black brick weren't there. When the black brick is removed, the two bricks directly underneath it fall to the left and right, and the one falling to the right pushes the stack of bricks on the right off the table. None of our noise models was able to capture participants' selections in this case. The above noise model did a particularly poor job for the simple reason that it doesn't apply any noise in this case. Since the black brick is on top, its predictions correspond to the ground truth. What this clearly shows is that our noise models don't yet completely capture participants' hypothetical simulations. We will discuss some ideas about how the improve the models in the General Discussion below.
Prediction condition Figure 4 b shows the relationship between the number of bricks predicted to fall and the average number of bricks that participants selected in the selection condition. As in Experiment 1, there was a very close relationship between predictions and selections, and, again, participants predicted that more bricks would fall on average than they selected. The above noise model again best explained participants' predictions with $r=.76, \mathrm{RMSE}=1.41$.
Responsibility condition Figure 5b shows the relationship between participants' predictions and responsibility judgments. Like in Experiment 1, participants' responsibility judgments were well-accounted for by the proportion of
bricks that would fall off the table if the black brick were removed $r=.91$, RMSE $=8.66$. Again, we can also account for participants' responsibility judgments based on the proportion of bricks that were selected in the selection condition $r=.91$, RMSE $=8.67$. A noise-free model again fails to account well for participants' responsibility judgments with $r=.36, \mathrm{RMSE}=19.99$.

Table 2 shows how well different features of the physical scene correlate with participants' responsibility judgments in Experiment 2. Expectedly, global scene features did not correlate well with participants' responsibility judgments this time because these features do not capture the actual position of the black brick. For example, they don't distinguish the configuration shown in Figure 6 c from the one shown in Figure 6h. However, a good predictor of participants' responsibility judgments was the height of the black brick. The lower the black brick was located, the more responsible it was. Unlike in Experiment 1, the average height of the bricks in the tower did not correlate with responsibility judgments. Unsurprisingly, the number of bricks above the black brick was again a good predictor. However, there was no single predictor that accounted as well for participants' responsibility judgments as participants' predictions or selections in the other two conditions did. Even a regression that combines both scene and black brick features ( $r=.85, \mathrm{RMSE}=11.17$ ) does not explain participants' responsibility judgments as well as the HSM does.

## General Discussion

How do people judge physical support? In this paper, we develop and test a hypothetical simulation model (HSM) of physical support. Based on a model of counterfactual simulation which was originally developed to explain causal judgments about collision events (Gerstenberg et al., 2012, 2014, 2015; Gerstenberg \& Tenenbaum, 2016), the HSM predicts that we judge physical support by imagining what would happen if the object were removed. An individual brick is responsible for other bricks staying on a table to the extent that these bricks would fall off the table if that brick were removed. The results of two experiments show that the greater the proportion of bricks that participants predict would fall of the table, the more responsible that brick is seen for the other bricks staying on the table. Simple features of the physical scene such as the height of the tower, or the position of the brick of interest, as well as combinations of these features cannot explain participants' judgments as well.

The central claim of the HSM is that people judge physical support by simulating what would happen to the scene if the object of interest were removed. We contrasted three different implementations of the HSM which differ in how they model participants' uncertainty about what would happen in the relevant hypothetical situation. Similar to how people spontaneously consider counterfactuals when judging causation (Gerstenberg et al., in press), people naturally play "mental Jenga" when judging responsibility for physical support. Participants' selections of which bricks would fall were
best explained by a model that adds noise to the bricks located above the removed brick. While this model does a good job overall, there remain situations that it cannot capture adequately (cf. Figure 8).

We believe that there are at least three sources of uncertainty that affect participants' judgments: first, there is perceptual uncertainty about the exact spatial location of the different bricks (cf. Battaglia et al., 2013). Second, there is uncertainty about the hypothetical intervention itself: would the black brick simply disappear, or would it be removed, thereby affecting the bricks above it. Third, there is dynamic uncertainty about what would happen once the brick is removed (cf. Smith \& Vul, 2013). While the current implementation of the HSM uses a physics engine as a proxy for participants' mental model, we are eager to explore how an approximate simulation model (which doesn't represent each brick individually) might be able to capture participants' judgments (cf. Davis \& Marcus, 2016). Ideally, such a model would help explain when it is that people's physical intuitions are faulty and deviate from the ground truth.

#### Abstract

Learning to read is often considered the most important skill taught in school because reading is a gateway to other learning. Many children struggle to acquire this fundamental skill. Suboptimal design of books for beginning readers may contribute to the difficulties children experience as close proximity between text and illustrations could promote attentional competition hampering literacy skills. The present work utilized eye-tracking technology to examine how beginning readers allocate attention and whether these patterns are related to fluency (Experiment 1) and comprehension (Experiment 2). Results suggest when reading books in which text and illustrations are in close proximity, children frequently shift attention away from the text. This pattern of attention was negatively associated with fluency, but not associated with comprehension. This line of research aims to provide theoretical insights about design principles for reading materials that can be employed to optimize instructional materials and promote literacy development in young children.

Keywords: attention; reading; reading fluency; reading comprehension; illustrations; eye tracking

## Introduction

Reading is often considered the most important skill taught in elementary school: it is not only important in its own right, but it is a key gateway to other learning within and outside of school. Failing to 'learn to read' early in life is followed by failure to 'read to learn' later in life (National Association for the Education of Young Children, 1998). Many children struggle to acquire this fundamental skill for a variety of reasons, including but not limited to neurodevelopmental disorders (e.g., Dyslexia and ADHD), poor pre-reading skills (e.g., phonological awareness), and vulnerabilities in general cognitive functioning (e.g., working memory, processing speed, etc.) (e.g., Armbruster, Lehr, \& Osborn, 2009; Biederman et al., 2004; Dykman, \& Ackerman, 1991; Jacobson et al., 2011). In addition to these factors, empirical and theoretical work in the field of cognitive science may offer insights into how subtle changes in reading materials can affect the process of learning-to-read. It is important to understand how the properties of reading materials may affect children's emerging literacy skills because these factors are
considerably more malleable than factors intrinsic to the child, and thus can be leveraged to improve learning.

The typical layout of books for beginning readers intermix text with illustrations in close proximity (see Figure 1). In many cases illustrations are detailed, colorful, and engaging. There are a number of reasons for including illustrations in books for beginning readers, including: defining the setting and characters, contributing to text coherence, reinforcing the text, providing additional information, or motivating the reader (Carney \& Levin, 2002; Fang, 1996). However, the close proximity of text and illustrations may create competition for attentional resources, a situation that could be particularly problematic for beginning readers.

Figure 1. Examples of books for beginning readers where text and illustrations are in close proximity (i.e., embedded within the illustration).

There are theoretical reasons and related empirical findings that support the notion of competition between illustrations and text. According to the Dual-channel Theory of Multimedia Learning (Mayer et al., 2001), combining text with graphical representations can lead to split attention between the two sources of information. Similarly, the Cognitive Load Theory suggests that illustrations in close proximity to text may increase extraneous cognitive load on the learner thereby reducing the amount of cognitive resources available for text decoding (Torcasio, \& Sweller, 2010; Chandler \& Sweller, 1992).

A number of studies examined the effects of supplementing text with illustrations on a variety of
outcome measures (e.g., comprehension, retention, and problem-solving) relating to the goal of reading-to-learn in college students (presumably, a population of fluent readers). Some studies found that competition between text and graphical representations lead to reduced performance (e.g., Kalyuga, Chandler, \& Sweller, 1998; Mayer et al., 2001), whereas other studies reported facilitatory effects (e.g., Bétrancourt \& Bisseret, 1998; Ginns, 2005; Moreno \& Mayer, 1999). On the basis of this large body of evidence, researchers have formulated a number of principles regarding how to combine text with illustrations in a way that facilitates the process of reading-to-learn depending on the nature of the illustrations (e.g., illustrations that are well or poorly aligned with the text content), the level of difficulty of the text, and individual characteristics of the learners (e.g., learners possessing or lacking background knowledge relevant to the text content) (Carney \& Levin, 2002; Levin \& Mayer, 1993; Mayer, 2014).

However, the multimedia principles of effectively combining text and illustrations for the purpose of reading-to-learn in fluent readers may have limited applicability to the design of reading materials for young children whose goal is learning-to-read. Conceivably, the detrimental effects of competition for attentional resources between difficult-to-decode text and easy-to-interpret illustrations on emerging literacy skills may be more pronounced in beginning readers in whom reading has not yet become an automatized skill.

In contrast to the large body of research investigating the effects of combining illustrations with text for the purpose of reading-to-learn, few studies examined this question in the context of learning-to-read. The ubiquitous practice of combining illustrations and text in materials for beginning readers was first questioned in a handful of studies nearly five decades ago (Braun, 1969; Samuels, 1967). In these studies children were taught to read sight vocabulary with words either presented in isolation or next to corresponding illustrations during the training phase. During the testing phase, printed words were presented without pictures. The results of these studies showed performance was better during the training phase for words that were accompanied by pictures than for words presented in isolation; however, the opposite was true during the testing phase, suggesting that pictures presented alongside printed words interfered with the acquisition of sight vocabulary. In another study, kindergarten-age children were given reading instruction using a storybook in which text was either accompanied by illustrations or presented without illustrations (Samuels, 1970). For more skilled readers, there was no difference in learning gains whether children received reading instruction using a storybook with or without illustrations; however, less skilled readers showed higher gains in the no-pictures condition. More recently, Torcasio and Sweller (2010) reported that reading proficiency in 6- to 7 -year-old children improved more when children practiced reading a story without illustrations compared to reading the same story with illustrations.

The studies above provide suggestive evidence that close proximity of text and illustrations in books for beginning readers may interfere with learning-to-read. However, these studies have two critical shortcomings that limit their impact. First, although prior studies have proposed a mechanism by which illustrations in storybooks may disrupt reading fluency, they have not assessed this mechanism directly. Specifically, Samuels (1970) suggested that pictures may distract children from printed text. Similarly, Torcasio and Sweller (2010) suggest that when text is accompanied by illustrations, children devote working memory resources to processing the illustrations thus having less resources for processing the text. While this possibility is plausible, there is no direct evidence showing that children devote less resources to processing text in the presence of illustrations.

Second, prior studies focused on children's ability to read words quickly and accurately (i.e., a component of reading fluency) but largely did not consider reading comprehension. However, it is possible that the detrimental effect of illustrations for decoding could be offset by the potential beneficial effects of illustrations on reading comprehension. Indeed, instructing children to refer to illustrations to aid comprehension as well as decoding is a common instructional strategy in elementary school (Samuels, 1970) (although we should note the paucity of research on the effectiveness of this strategy). Alternatively, it is possible that by interfering with fluency, illustrations also interfere with comprehension, as Torcasio and Sweller (2010) suggested. When considering possible effects of illustrations on learning-to-read it is essential to assess both reading fluency and comprehension in order to obtain evidence that can have an impact on educational practice.

The present research investigates how beginning readers allocate their attention while reading and explores the possibility that gaze shifts away from the text (hypothesized to be due to the close proximity of text and illustrations) are negatively correlated with reading fluency (Experiment 1) and comprehension (Experiment 2). As noted previously, while we hypothesize that children's gaze shifts are a result of attentional competition induced by the close proximity between text and illustrations, it is also possible that these gaze shifts are an explicit strategy children deploy to aid decoding and comprehension. The present study does not rule out this alternative interpretation, a point we return to in the Discussion section.

## Experiment 1

## Method

## Participants

The sample consisted of 24 children $\left(M_{\text {age }}=7.20\right.$ years, $S D=$ 0.35 years, 10 females, 14 males). Participants were recruited from schools in and around Pittsburgh Pennsylvania. Children were tested individually by trained hypothesis-blind research assistants.

## Design and Procedure

## Book Selection

To maintain a high level of ecological validity, children read commercially available books designed for beginning readers from the I Can Read book series (Children read either Biscuit Wants to Play (2002), or Biscuit Goes to School (2003) written by Alyssa Satin Capucilli).

Children read aloud a commercially available book for beginning readers in which the text and illustrations are in close proximity. A Tobii X2-60 portable eye tracker was used to measure children's patterns of attention allocation indexed by gaze shifts. Prior to reading the story an independent measure of reading fluency was administered (i.e., Word Recognition in Isolation Test). Reading fluency was also assessed while children were reading the story using a Running Record. Additional details regarding each measure are provided below.

## Measures

## Gaze Shifts

Eye gaze is a common measure of attention in a variety of settings and is a particularly appropriate measure in the context of reading, a complex cognitive task in which eye gaze location and the focus of attention are difficult to dissociate as they are thought to overlap (for review see Rayner, 2009). The Tobii X2-60 portable eye tracker was utilized to measure children's eye movements while reading. On each page of the book, text, picture, and white space Areas Of Interest (AOI's) were created. A python script was then used to calculate the number of times a child shifted fixation away from the text AOI's (i.e., to illustrations or white space AOI's) and the average number of gaze shifts per page was then calculated.

## Reading Fluency Measures

Fluency is defined as "accurate and automatic decoding of the words in the text, along with expressive interpretation of the text" (Rasinski, 2004, p. 2). In the present experiment one component of reading fluency, decoding accuracy, was assessed. Two measures of reading fluency were utilized: the Word Recognition in Isolation test and a Running Record. Both measures are described below.
Word Recognition in Isolation Test. Children completed a modified Word Recognition in Isolation (WRI) test, which is a common measure of reading fluency (Morris, 2013). In the WRI, participants were shown leveled lists of words presented individually on a computer screen. The participant is tasked with reading as many words as they can within the allotted time limit (in order to avoid frustration, a ceiling was imposed such that testing ceased if a participant failed to read at least $50 \%$ of the words correctly on a given word list). The child's score was based on the number of words the participant correctly read aloud within the time limit (i.e., number of words read correctly out of 100 total possible words).

Running Record. While participants read the story aloud, the experimenter completed a Running Record (Clay, 1972) in which the experimenter recorded the child's decoding accuracy for each word in the story. The percentage of correct responses was then calculated.

## Results

On average, children switched their point of fixation away from the text 3.68 times (range $=1.50$ to 11.29 times) per page. The average number of words per page was 6.94 ; thus even when the text length was relatively short many children frequently shifted their attention away from the text (see Figure 2).

Figure 2. A sample gaze plot showing multiple gaze shifts away from the text.

Furthermore, children's tendency to switch their point of fixation away from the text while reading was negatively associated with the WRI ( $M=.41, S D=.27$ ), an independent measure of reading fluency, as shown in Figure 3 (Panel A); $r=-.60, p=.002$. Additionally, Running Record accuracy was obtained for a subset of participants ${ }^{1}(\mathrm{n}=13 ; M=.97, S D$ $=.04$ ). Critically, this online measure of fluency was also negatively (and strongly) correlated with the number of gaze shifts away from the text (Figure 3, Panel B); $r=-.96$; $p<.0001$. Thus, less fluent readers (as measured by both the WRI and the Running Record) tended to make more frequent gaze shifts away from the text.

The present results indicate gaze shifts away from text are negatively associated with reading fluency; however, it is an open question as to whether gaze shifts away from the text are also associated with reading comprehension. Experiment 2 begins to explore this possibility.

## Experiment 2

## Method

## Participants

The sample consisted of 17 children $\left(M_{\text {age }}=7.15\right.$ years, $S D=$ 0.59 years, 6 females, 10 males, and 1 child whose sex was not reported by the parents). Due to technological issues, for 1 child no eye tracking data was available. Participants were

[^75]recruited from schools and camps in and around Pittsburgh

Figure 3. Association between gaze shifts away from text and performance on two measures of reading fluency: WRI (Panel A) and Running Record (Panel B). Note only a subset of the sample had Running Record data available; thus, the gaze shift range differs across the two panels.

Pennsylvania. Children were tested individually by trained hypothesis-blind research assistants.

## Design and Procedure

## Book Selection

In order to test the generalizability of the results from Experiment 1, a new book was selected for Experiment 2. We selected a book that had a more complex story line in order to address the question of whether gaze shifts away from the text are also negatively associated with reading comprehension. As in Experiment 1, children read a commercially available book designed for beginning readers in order to maintain a high level of ecological validity. Children read a book from the Hooked on Phonics Learn to Read series entitled Good Job Dennis written by Amy Kraft.

Akin to Experiment 1, children read aloud a commercially available book in which the text and illustrations are in close proximity. A RED250 mobile eye tracker was used to measure children's patterns of attention allocation indexed by gaze shifts. Prior to reading the story an independent measure of reading fluency was administered (i.e., Word Recognition in Isolation Test). Reading fluency was also assessed using a Running Record. After reading the story
children's reading comprehension was assessed. Additional details regarding each measure are provided below.

## Measures

Gaze Shifts
A RED250 mobile eye tracker (SensoMotoric Instruments, Inc.) was used to measure children's patterns of attention allocation. We used the RED250 mobile eye tracker in Experiment 2 (opposed to the Tobi X2-60 utilized in Experiment 1) due to its higher sampling rate which makes it better suited for reading studies. On each page of the book, text, picture, and white space AOI's were created. The SMI BeGaze Eyetracking Analysis Software was then used to calculate gaze shifts away from the text AOI's (i.e., to illustrations or white space AOI's) and the average number of gaze shifts per page was then calculated.

## Reading Fluency Measures

The reading fluency measures (WRI and Running Record) were identical to those described in Experiment 1.

## Reading Comprehension Measures

Retelling Prompt Retelling is a common measure of reading comprehension in elementary school (Nilson, 2008). Children were asked to orally recount the story. Retelling accuracy was scored by calculating the number of key events correctly recounted (out of 5 possible events). Scores are reported as the proportion of correct responses.

Story Questions At the end of the story children were asked 3 questions probing their memory for details from the story. For example, in the story various animals escape from a pet store including cats, dogs, birds, rabbits, and frogs. Children might be asked to recall which pets escaped. Children could receive full credit if in their response the child identified 4 or more animals that escaped and 0 points if they failed to recall the animals that escaped or provided an incorrect response. Children could also receive partial credit if the child recalled correctly a subset of the animals. Accuracy on the Story Questions was scored as the proportion of correct responses (out of 7 possible points).

## Results

On average, children switched their point of fixation away from the text 8.03 times per page (range $=1.75$ to 15.5 times). The average number of words per page was 42.67 . As in Experiment 1, there was a significant correlation between the number of gaze shifts and both measures of reading fluency (WRI and Running Records). Children's tendency to switch their point of fixation away from the text while reading was negatively associated ( $r=-.78, p<.0004$ ) with the WRI $(M=.69, S D=.19)$ as shown in Figure 4 (Panel A) and with their Running Record accuracy ( $M=96 \%$, $S D=5 \%$; Panel B; $r=-.63, p=.009$ ). This pattern of results provides corroborating evidence that gaze shifts away from the text are related to poorer reading fluency scores.

Figure 4. Association between gaze shifts away from text and two measures of reading fluency (Panel A-B) and reading comprehension (Panel C) in Experiment 2.

A composite variable was created for the reading comprehension measures. Retelling score ( $M=.45 S D=.23$ ) and Story Question score $(M=.59, S D=.29)$ were standardized using Z-scores and averaged together to create the composite variable, Comprehension Composite Score. Thus, the comprehension composite score reflects how many standard deviations the child is away from the overall mean. A score of 0 would indicate the child's performance is equal to the overall mean (an average performer on the Story Question and Retelling measures). There was no significant correlation between gaze shifts and the Comprehension Composite, $r=-.13, p=.62$ (See Figure 4

Panel C). In contrast to the results for fluency, the observed pattern of results for comprehension are not consistent with the hypothesis that the close proximity between illustrations and text could impede reading skills. Interestingly, the results also seem to suggest that children are not utilizing illustrations (or perhaps not utilizing illustrations in an effective manner) to aid comprehension, as one might expect to observe a positive correlation between gaze shifts and reading comprehension if referencing illustrations was in fact scaffolding children's reading comprehension. Future research is needed to expound upon this initial work, a point we return to in in the discussion section.

## Discussion

Although the practice of using illustrations in materials for teaching children to read has undergone little change in over 250 years (Samuels, 1970), no research has systematically examined the possible costs and benefits of this practice for children's attention, reading fluency, and comprehension. By leveraging mobile eye tracking technology, the present research found that gaze shifts away from the text (hypothesized to be due to the close proximity of text and illustrations) are negatively associated with reading fluency, an important component of literacy. This work highlights the importance of investigating experimentally more optimal book designs for beginning readers. This work also addresses an important gap in the prior literature, which focused almost exclusively on components of reading fluency. The present work adds to the prior literature by investigating the relationship between attention allocation (indexed by eye gaze) and both reading fluency as well as reading comprehension.

Our working hypothesis is that the majority of gaze shifts away from the text occur as a result of the competition between text and illustrations being resolved in favor of the latter. The findings reported above are consistent with this hypothesis: across two experiments with different samples of children and different reading materials we observed a strong and negative relationship between the frequency of gaze shifts away from text and measures of reading fluency. However, given the correlational nature of the study, other interpretations of these findings are of course possible. For example, it is possible that less proficient readers attempt to use illustrations to help with decoding and comprehension. Future experimental work is necessary to adjudicate between these possibilities. Towards this goal, we are currently collecting data in which we assess children's reading fluency and comprehension while children are reading stories in which the placement of illustrations relative to the text is experimentally manipulated.

Overall, the present study provides evidence that gaze shift patterns are associated with reading performance, and thus highlights the need for further research into the nature of this association. Future research should also expound upon these findings to ascertain whether, illustrations in close proximity to text allow children to bypass the important work of decoding as this "shortcut" may have
cumulative effects on children's literacy acquisition and subsequent learning. Additional research is also needed to systematically examine the role of individual differences. One future direction we are currently pursuing is whether the negative association between illustrations and reading fluency can be offset by modifying the design of books to reduce the competition between text and illustrations through increased spatial separation, a layout we hypothesize to be more optimal for beginning readers.

This work begins to build an important foundation of research that has direct implications for educators and publishers and that aims to ultimately improve children's literacy acquisition.

## Acknowledgments

We thank Kristen Boyle, Lindsay Gorby, Ashli-Ann Douglas, Rebeka Almasi, Hyunji Do, Graciela Garcia, and Clara Lee for their help collecting data and Marcus Godwin for creating the Python script to compute participants' gaze shifts. We also thank the children, parents, and teachers at the CMU Children's School, St. Edmund's Academy, and Sacred Heart Elementary School in Pittsburgh (PA) who made this project possible. This work was partially supported by the ProSEED/Simon Initiative Seed grant from Carnegie Mellon University and by the James S. McDonnell Foundation $21^{\text {st }}$ Century Science Initiative in Understanding Human Cognition - Scholar Award (220020401) to A.V.F.

# A Cognitive Model of Strategic Deliberation and Decision Making 

Russell Golman (rgolman@andrew.cmu.edu)<br>Carnegie Mellon University, Pittsburgh, PA.

Sudeep Bhatia (bhatiasu@sas.upenn.edu)<br>University of Pennsylvania, Philadelphia, PA.

#### Abstract

We study game theoretic decision making using a bidirectional evidence accumulation model. Our model represents both preferences for the strategies available to the decision maker, as well as beliefs regarding the opponent's choices. Through sequential sampling and accumulation, the model is able to intelligently reason through two-player strategic games, while also generating specific violations of Nash equilibrium typically observed in these games. The main ingredients of accumulator models, stochastic sampling and dynamic accumulation, play a critical role in explaining these behavioral patterns as well as generating novel predictions.

Keywords: Decision making; Game theory; Sequential sampling; Preference accumulation

## Introduction

Game theory studies the behavior of idealized decision makers. The standard solution concept for a strategic game is Nash equilibrium, which relies on common rationality and accurate expectations. Given expectations of others' choices, players behave rationally, and the resulting play conforms to these expectations (Luce \& Raiffa, 1957).

Not surprisingly, human decision makers display numerous systematic departures from Nash equilibrium (see Camerer, 2003 for a review). We present a cognitive model of strategic deliberation and choice in one-shot, two-player games, that is able to accommodate these departures. Our model proposes that decision makers dynamically and stochastically accumulate both their own preferences for available strategies, as well as beliefs about the opponent's preferred strategies. There are bidirectional relationships between preferences and beliefs, so that beliefs about what the opponent will choose influence the decision makers' preferences, and these preferences in turn influence beliefs about the opponent's choices. Ultimately, decision makers can respond to what they think the opponent will do, and also revise these beliefs as they deliberate.

Our model can be seen as an extension of decision field theory (Busemeyer \& Townsend, 1993; also Bhatia, 2014 and Rieskamp, 2006), an existing accumulator-based theory of non-strategic risky choice. Accumulator models rely on two main ingredients: stochastic sampling and dynamic accumulation (see Busemeyer, 2015 for a review). These ingredients are critical in our model for making deliberation subject to intrinsic variability and requiring it to play out over time, and we show that both ingredients have a central
role in capturing the behavioral patterns observed in strategic choice. By demonstrating the relationship between our model and established preference accumulation models, we demonstrate that a single framework can be used to understand choice behavior across a variety of non-strategic and strategic settings.

## Game Theoretic Decision Making

In strategic games, two or more players make choices over a set of strategies. Crucially, the strategies chosen by the players collectively determine the outcomes of the game, so that each player's utility depends on the other's choice as well as on their own. We define a finite-strategy two-player game with a set of pure strategies for each player, $S_{1}=$ $\left\{s_{11}, \ldots s_{1 N}\right\}$ and $S_{2}=\left\{s_{21}, \ldots s_{2 M}\right\}$ respectively, and a pair of payoff functions $u_{1}$ and $u_{2}$ that give each player's utility for each profile of pure strategies $\left(s_{1 i}, s_{2 j}\right)$. Thus if player 1 selects $s_{1 i}$ and player 2 selects $s_{2 j}$ the utility for player 1 is $u_{1}\left(s_{1 i} ; s_{2 j}\right)$ and the utility for player 2 is $u_{2}\left(s_{2 j} ; s_{1 i}\right)$, with $\boldsymbol{u}_{i j}=\left(u_{1}\left(s_{1 i} ; s_{2 j}\right), u_{2}\left(s_{2 j} ; s_{1 i}\right)\right)$. We define the set of best responses for player $\mu$ to an opponent's strategy $s_{-\mu}$ as $\operatorname{BR}\left(s_{-\mu}\right)=\arg \max u_{\mu}\left(s_{\mu} ; s_{-\mu}\right)$. Then a pure strategy Nash equilibrium can be defined as a strategy profile $\left(s_{1 i}, s_{2 j}\right)$ such that $s_{1 i} \in \operatorname{BR}\left(s_{2 j}\right)$ and $s_{2 j} \in \operatorname{BR}\left(s_{1 i}\right)$.

There are a number of settings where Nash equilibrium fails to accurately describe human behavior. For example, Nash equilibrium predicts unraveling when players have incentives to undercut each other. Consider the traveler's dilemma game (Basu, 1994), in which two travelers have lost identical items and must request compensation. The airline accepts the lower claim as valid and pays that amount to both players, and, additionally penalizes the higher claimant with a fee and rewards the lower claimant with a bonus. We represent this game with the strategy sets $S_{1}=S_{2}=\{20,30, \ldots, 90\}$, where $x_{1 i}$ and $x_{2 j}$ correspond to the amounts (in dollars) associated with strategies $s_{1 i}$ and $s_{2 j}$, and we have utilities $\boldsymbol{u}_{i j}=\left(0.01\left(x_{2 j}-\gamma\right), 0.01\left(x_{2 j}+\gamma\right)\right)$ if $x_{1 i}>$ $x_{2 j}, \boldsymbol{u}_{i j}=\left(0.01 x_{l j}, 0.01 x_{2 j}\right)$ if $x_{l i}=x_{2 j}$, and $\boldsymbol{u}_{i j}=\left(0.01\left(x_{l j}+\gamma\right)\right.$, $\left.0.01\left(x_{2 j}-\gamma\right)\right)$ if $x_{1 i}<x_{2 j}$. Here $\gamma$ corresponds to the reward/penalty offered by the airline, and is set so that $10<$ $\gamma \leq 20$. For comparability with other games, we have scaled utilities to lie between 0 and 1 .

The airline's scheme rewards undercutting the other traveler. The best response is always to claim exactly 10 less than the other traveler does (if it is feasible to do so).

As a result, the only Nash equilibrium strategy for both players is to claim 20. In experiments average claims actually are well above the lower bound that Nash equilibrium predicts (e.g. Capra et al., 1999).

Experiments on the traveler's dilemma game also find that claims are higher when the reward/penalty, $\gamma$, is lower. This payoff sensitivity is hard to reconcile with players choosing best responses to the strategies they expect their opponent to play. Nash equilibrium predicts that responses in the traveler's dilemma should be independent of $\gamma$, as changing payoffs without changing best responses should have no effect on choice behavior.

Another setting in which Nash equilibrium fails to appropriately describe behavior involves coordination games. These are games with multiple pure strategy Nash equilibria, in which players are incentivized to choose the same strategy. Due to the presence of multiple equilibria, Nash theory cannot make precise predictions. However, human decision makers are often fairly predictable. Consider the Hi-Lo coordination game, in which decision makers have to choose between two strategies: Hi and Lo. In this game we have: $\boldsymbol{u}_{i j}=(1.0,1.0)$ if both players both choose $\mathrm{Hi} ; \boldsymbol{u}_{i j}=(\gamma, \gamma)$, with $0<\gamma<1.0$, if both plays choose Lo; and $\boldsymbol{u}_{i j}=(0,0)$ if they choose different strategies. Not surprisingly, decision makers almost always successfully coordinate on Hi-Hi to obtain the highest possible rewards in this game (Colman, 2003).

In some games, decision makers do not choose any of the Nash equilibrium strategies when the potential costs of miscoordination are too great. This can be observed in the boobytrap game, which is a standard prisoner's dilemma augmented with a third option that allows decision makers to purchase a "boobytrap" to punish their opponent if he or she defects (Misyak \& Chater, 2014). Particularly, we have $\boldsymbol{u}_{i j}=(0.9,0.9)$ if both players cooperate, $\boldsymbol{u}_{i j}=(0.8,0.8)$ if both players defect, and $\boldsymbol{u}_{i j}=(0.89,0.89)$ if both players choose boobytrap. Additionally, $\boldsymbol{u}_{i j}=(0.7,1)$ if player 1 cooperates and player 2 defects, $\boldsymbol{u}_{i j}=(0.9,0.89)$ if player 1 cooperates and player 2 chooses boobytrap, and $\boldsymbol{u}_{i j}=(0,0.69)$ if player 1 defects and player 2 chooses boobytrap (and vice versa, as the game is symmetric). Nash equilibrium predicts that decision makers should ignore the boobytrap choice, however the presence of the boobytrap greatly increases the rate of cooperation in the game, contradicting the prediction of Nash equilibrium.

Yet another set of findings not accounted for by Nash equilibrium theory involves strategy salience. In many games, strategies with salient labels are more likely to be chosen. This is the case in coordination games offering multiple payoff identical strategies, with one of the strategies circled, underlined, or made salient using some other technique. Here players can coordinate successfully by selecting the salient strategy (Mehta et al., 2004).

## Bidirectional Accumulation

We propose an extension to a preexisting accumulator model of risky choice, decision field theory (Busemeyer \&

Townsend, 1993). As in decision field theory, decision makers use two layers of nodes: one to accumulate preferences in favor of the available choice options, and one to represent the probabilistic events involved in the decision. In the strategic context, the choice options are the strategies available to the decision maker and the events are the possible strategies the opponent may use. Thus, the strength of the connection from the node representing a strategy $j$ for the opponent to the node representing preference for a decision maker's strategy $i$, is proportional to the utility of strategy $i$ for the decision maker, given that the opponent plays strategy $j$. Decision makers sample the events according to the subjective probabilities they assign to their occurrence. Thus, strategies that are more likely to be played by the opponent are sampled more frequently and thereby play a larger role in determining the decision makers' preferences.

Decision field theory assumes that decision makers' beliefs about events (and subsequently sampling probabilities for these events) are fixed. For the most part this is reasonable: decision makers' preferences do not influence the actual probability with which different events occur. This assumption is less reasonable in strategic settings. Sophisticated opponents, who can anticipate decision makers' choices, will adjust their own choices to maximize their reward. We thus assume a bidirectional accumulation process to represent strategic deliberation. At each time period, decision makers sample one of their opponent's strategies based on the activations of the nodes corresponding to these strategies, and update their preferences over their own strategies based on this sample. Decision makers then sample one of their own strategies based on the activation of the nodes, and use this sample to update their beliefs about their opponent's choices. In essence, decision makers have dynamically changing mental representations for not only their own preferences, but also their beliefs about their opponents' preferences, allowing them to deliberate intelligently using perspective taking and a sophisticated theory of mind.

Figure 1: Illustration of bidirectional accumulation model

Figure 2: Simulated distribution of choices in the traveler's dilemma.

Formally, if the decision maker has to choose from the set of strategies $S_{1}=\left\{s_{11}, \ldots s_{1 N}\right\}$, then the preference layer in our model consists of $N$ nodes, with node $i$ representing strategy $s_{1 i}$. The activation of node $i$ at time $t, A_{l i}(t)$ corresponds to the decision maker's preference for strategy $i$ at time $t$. Correspondingly if the opponent has the set of available strategies $S_{2}=\left\{s_{21}, \ldots s_{2 M}\right\}$, then the belief layer in our model consists of $M$ nodes, with node $j$ representing strategy $s_{2 j}$. The activation of node $j$ at time $t, A_{2 j}(t)$ corresponds to the beliefs that the decision maker has about the opponent's preference for strategy $j$, at time $t$. We also denote the salience bias of any strategy $i$ (for the decision maker) or $j$ (for the opponent) as $\sigma_{1 i}$ or $\sigma_{2 j}$. These salience biases $\sigma_{1 i}$ and $\sigma_{2 j}$ are independent of the decision process and are determined by various exogenous factors.

At each time period $t$, the decision maker draws one sample of the opponent's strategies. We assume that a softmax (logit) function, with stochasticity parameter $\lambda>0$, determines the effect of activation strength and the exogenous salience bias on sampling probability. Thus, the probability of sampling strategy $j$ at time $t$ is given by: $p_{j}=$ $e^{\lambda\left(A_{2 j}(t-1)+\sigma_{2 j}\right)} / \sum_{k=1}^{M} e^{\lambda\left(A_{2 k}(t-1)+\sigma_{2 k}\right)}$. If the opponent's strategy $j$ is sampled, then the decision maker observes the utility for each strategy $i$ conditional on the opponent playing this sampled strategy: $u_{1}\left(s_{1 i} ; s_{2 j}\right)$. The decision maker's preferences are then updated based on this calculated utility, so the activation for each strategy $i$ becomes: $A_{1 i}(t)=A_{1 i}(t-1)+u_{1}\left(s_{1 i} ; s_{2 j}\right)$.

As discussed, beliefs about the opponent's strategies are themselves updated based on the utility the opponent would derive conditional on a sample of the decision maker's
strategies. Thus, after updating activation states $A_{l i}(t)$, decision makers draw one sample of their own strategies. The probability of sampling strategy $i$ at time $t$ is given by: $q_{i}=e^{\lambda\left(A_{1 i}(t)+\sigma_{1 i}\right)} / \sum_{k=1}^{N} e^{\lambda\left(A_{1 k}(t)+\sigma_{1 k}\right)}$. After sampling strategy $i$, the updated activation for each opponent strategy $j$ is $A_{2 j}(t)=A_{2 j}(t-1)+u_{2}\left(s_{2 j} ; s_{1 i}\right)$.

The deliberation process begins with nodes having no initial activation: $A_{l i}(0)=0$ for all $i ; A_{2 j}(0)=0$ for all $j$. Activation accumulates according to these equations until a time $t=T$. At this time, the most preferred strategy --that is, the one whose node has the highest activation-- is the strategy that is chosen by the decision maker. The parameter $T$ corresponds to an exogenous time limit on the deliberation process, and represents the amount of time taken by the decision makers to make their choices. The proposed model is illustrated in Figure 1.

## Explaining Behavioral Findings

In order to demonstrate how our model works, we use it to simulate choices in the games we introduced earlier. Our simulations use the same strategy and reward profiles as in examples in the previous section. For each of the games and each set of parameter values, we simulate our model 3000 times and report aggregate choice probabilities. We find that the model is fairly robust to parameter variation in the range $\lambda \in[0.25,4]$ and $T \in[10,30]$, and any combination of parameter values in this range produces behavior consistent with the empirical findings we have reviewed. When not explicitly specified, we set salience to $\sigma_{1 i}=\sigma_{2 j}=0$.

Traveler's Dilemma. In the traveler's dilemma our model predicts a failure of unraveling. This is demonstrated in Figure 2 which plots the probability of selecting
strategies in the set $\{20,30, \ldots, 90\}$ for $\gamma=11$ and $\gamma=19$, with varying values of $\lambda$ and $T$. Instead of predicting that players always claim the lowest possible amount, as in Nash equilibrium, here the model generates a distribution of choices that spreads across the range of strategies available to the decision maker. The model also displays payoff sensitivity. For a larger value of the reward/penalty parameter $(\gamma=19)$, the distribution of choices is smaller.

The intuition behind the model's predictions is appealing. For low rewards/penalties, i.e. low values of $\gamma$, the payoffs when both players make high claims are significantly higher than the payoffs when there is a low claim. The potential cost of missing out on this high payoff dwarfs the cost of making a higher claim than the opponent or the benefit of making a lower claim than the opponent. So, a few samples (or even a single sample) of the opponent playing a high claim will lead to high activation for one's own high claims. As beliefs about the opponent's strategy are updated, there will be more samples of high claims, and strategies involving an additional step of undercutting can accumulate the most utility. The number of steps of undercutting that does occur depends on payoff magnitudes. Increasing the parameter $\gamma$ encourages undercutting. Although it does not affect best responses (that is, the ranking of payoffs in any given sample of play), it does affect the accumulation of payoffs over time, so strategies involving more undercutting can accumulate activation more quickly.

Stochastic sampling plays an important role in the emergence of payoff sensitivity. The magnitudes of payoff differences affect the probabilities of sampling each strategy. The degree of responsiveness to the payoff parameter $\gamma$ that we observe in the predicted choices for this game depends on the logit sampling parameter $\lambda$. Comparing across the columns of Figure 2, we see larger shifts in the distribution of choices from a change in the reward/penalty parameter $\gamma$ as the parameter $\lambda$ increases.

Our model also makes new predictions about the relationship between decision time and the strategy chosen in the traveler's dilemma. Each step of undercutting takes time, and thus both the decision maker's preferred claim and the beliefs about the opponent's claim should thus decrease over time. Comparing across the rows of Figure 2, we observe lower claims when the decision time $T$ is larger. Indeed, experiments have revealed that decision makers take longer to choose the lowest claim than the highest claim (Rubinstein, 2007).

Overall, with reasonable parameter values, the model predicts a failure of unraveling. Indeed, full unraveling, consistent with Nash equilibrium would only occur with very large values of $\lambda$ and $T$, i.e., when poorly performing strategies are rarely sampled and there are many periods of sampling and iterative updating. Assuming deterministic sampling of best responses or unlimited decision time would thus lead to poor behavioral predictions for the traveler's dilemma. Conversely, assuming uniformly random sampling would lead to unreasonably high odds of choosing 80 relative to 70 , underestimating people's ability to put
themselves in their opponents' shoes and think strategically about their responses.

The Hi-Lo Game. Although the Hi-Lo game has two Nash equilibria, our model favors the $\mathrm{Hi}-\mathrm{Hi}$ equilibrium. This is shown in Figure 3, which plots the probability of choosing Hi as a function of the payoff for coordinating on Lo $(\gamma)$ for varying values of $T$ and $\lambda$. Across all parameter values we consider, Hi is the modal choice. When the payoff asymmetry is extreme, i.e., $\gamma=0.1$, Hi is almost certain to be chosen. Still, as the Lo-Lo payoff $\gamma$ increases, so does the probability of choosing Lo.

Predictable coordination in the Hi-Lo game is intuitive. The Hi strategy, which offers higher payoffs in the case of successful coordination, accumulates more activation when it is sampled from the other layer of the network than the low strategy does. This creates a feedback effect, so the model is more likely to think about Hi when forming beliefs about the opponent's choices. Believing that the opponent will choose Hi further reinforces the model's preference Hi .

The positive feedback loop, along with stochastic sampling, actually facilitates the occasional choices of Lo. If Lo is sampled first, it gains an advantage, and it becomes more likely to be sampled again. As the logit sampling parameter $\lambda$ increases, it becomes somewhat more likely (albeit still not very likely) that the model repeatedly samples Lo early on, gets fixated on this strategy, and eventually chooses it. In the extreme case that the sampling parameter $\lambda$ gets unrealistically large, the strategy sampled in the first time period may be sampled forever thereafter, completely determining the path of the deliberation. Since both strategies have the same probability of being sampled in the first period of the deliberation, the model's choice distribution approaches a 50-50 split between Hi and Lo independent of $\gamma$ for very large values of $\lambda$. As can be seen, decision time has little effect on the choice distribution, with longer deliberation only slightly reducing noise and increasing the probability of selecting the modal choice, Hi .

The Boobytrap Game. Our model deviates far from Nash equilibrium in the boobytrap game as well. For $\lambda \in$ $[0.25,4]$ and $T \in[10,30]$, it predicts that players will almost certainly cooperate (cooperation with a greater than $90 \%$ chance for all parameters). Here, a non-Nash strategy is favored due to the high magnitude of its advantage when the other player does not best respond compared to the low magnitude of its cost when the other player does respond rationally. Against the boobytrap strategy, defection is extremely undesirable. The model predicts that players will never choose the boobytrap strategy, because it is dominated by cooperation. However, the model predicts that decision makers usually will contemplate this boobytrap strategy as part of their deliberation, and this causes their preferences for defection to drop strongly.

Again, our model's behavior would be very different with an assumption of deterministic sampling of the most highly activated strategy. With deterministic sampling, the model is confident that the boobytrap strategy will not be played, so it chooses to defect.

Figure 3: Simulated probability of choosing Hi in the Hi-Lo game.

Figure 4: Simulated probability of heads in the simple heads-or-tails coordination game.

Salient Labels. Our model recognizes salience effects, too. In the simple heads-or-tails coordination game with heads being especially salient, such that $\sigma_{1 \mathrm{H}}=\sigma_{2 \mathrm{H}}=\varsigma$ and $\sigma_{1 \mathrm{~T}}=\sigma_{2 \mathrm{~T}}=0$, we find that the probability of choosing heads is increasing in its salience $\varsigma$, as shown in Figure 4. This figure plots the probability of choosing heads in this game as a function of the salience of heads, $\varsigma$, for varying values of $T$ and $\lambda$. As we should intuitively expect, when sampling is less noisy, i.e., when $\lambda$ is greater, the players are more sensitive to salience. Specifically, when near the high end of our range, i.e., $\lambda=4$, if heads is sufficiently salient, it is almost certain to be chosen. (In contrast, with an assumption of uniformly random sampling, our model would not account for any salience effect at all.) Convergence occurs quickly, so we see few effects from increasing the decision time $T$. Higher values of $T$ only slightly reduce noise and increase the choice probability of heads when the logit sampling parameter $\lambda$ is small.

## Discussion

We have proposed a cognitive model of strategic deliberation and decision making. Our model is able to account for violations of Nash equilibrium involving failures of unravelling, payoff sensitivity, predictable coordination, and salience, and we illustrate this by simulating our model on four different games. Note that these violations have also been documented in a number of additional games, including the minimum-effort coordination game, the stag hunt game, the battle of sexes game, the discoordination game, the 11-20 game, the hide and seek game, the matching pennies game, and the Kreps game. Elsewhere we show that our model makes realistic behavioral predictions for all of these games, for $\lambda \in$
$[0.25,4]$ and $T \in[10,30]$, however we exclude these findings from this paper, due to space constraints.

Our model is closely related to existing accumulator theories choice, and we suggest that it can be seen as a direct extension of decision field theory (Busemeyer \& Townsend, 1993; also see Busemeyer, 2015 for a review). The novel element in our model involves the representation of beliefs regarding opponent's choices and the bidirectional updating of both preferences and beliefs over the time course of the decision process. Intuitively, bidirectional feedback in the accumulation process allows decision makers to base their choices on their beliefs about the opponent's choices, but also to update their beliefs as their own preferences evolve. As this updating happens gradually over time, the decision makers' intended choices (and beliefs about the opponent's choices) get increasingly more sophisticated the longer they spend deliberating. Eventually the nodes for the opponent's strategies develop unequal activation, with strategies that are appropriate responses to the decision maker's preferences having higher activation. Highly activated opponent strategies are more likely to be sampled, and the decision maker is subsequently more likely to develop preferences that intelligently respond to the opponent's anticipated choices.

Note that there is considerable evidence that decision makers are able to represent the preferences and beliefs of others separately from their own. Although the nature of these representations is not typically studied in the context of game theoretic deliberation, some experimental work on theory of mind in strategic games does support our proposed model. Hedden and Zhang (2002), for example, find that players in sequential move games have sophisticated beliefs about the opponent's preferences, and that these beliefs are
dynamically modified based on the evidence presented to the decision maker during the decision process. Goodie et al. (2012) also find that players' beliefs about their opponent's preferences are fairly complex, and are formed in response to the players' own preferences.

Our approach is also closely related to cognitive decision modeling (in non-strategic settings) that uses neural networks with recurrent connectivity (Glöckner et al., 2014; Holyoak \& Simon, 1999). Recurrence in these networks is often bidirectional; the activation of cues and decision attributes may influence and be influenced by beliefs and preferences. The bidirectional feedback in the above models and in ours is very similar, implying that our model could be adapted for other cognitive decision modeling applications.

Our bidirectional accumulation model also bears some resemblance to models of behavioral game theory, such as level-k reasoning and logit quantal response equilibrium (McKelvey \& Palfrey, 1995; Nagel, 1995). In both our model and in level-k reasoning, individuals engage in an iterative process of deliberation that terminates before reaching a point of self-consistency. Likewise, in both our model and in logit quantal response equilibrium, individuals use a stochastic logit response rule to consider responses, thereby generating payoff sensitivity. However, unlike these models, our approach implements the deliberation process within a well-established psychological framework. This allows our model to describe salience effects, while also predicting the effects of time pressure and response time. Our model also makes more realistic stochastic choice predictions than either of these two existing theories: It permits trial-to-trial variability in choice, while also avoiding the selection of dominated strategies.

Our approach is also quite parsimonious. There are two parameters in our model: the decision time parameter, $T$, and the stochastic sampling parameter, $\lambda$. Decision time $T$ can be seen as controlling the extent of bidirectional processing one can engage in during deliberation and thus determining one's level of strategic sophistication. Quick decisions involve fairly limited reasoning, with choices responding to simplistic beliefs about the opponent. Decisions that are a product of extended deliberation, in contrast, generate choices based on a more sophisticated theory of mind. As in all accumulator models, decision time also influences the amount of variability in the decision.

The stochastic sampling parameter $\lambda$ can also be seen as affecting the extent of bidirectional processing one engages in. When $\lambda$ is small, strategies are sampled with close to uniform probability, and activation in one layer of the network has little or no effect on the accumulation of activation in the other layer of the network. As $\lambda$ increases, the decision maker becomes more and more likely to sample the most preferred strategies. When $\lambda$ is very large, the most highly activated strategies are almost deterministically sampled, so preferences and beliefs interact more strongly during the deliberation.

Ultimately, the model's key behavioral properties depend critically on its dynamic and stochastic processes. Many
scholars have suggested that behavioral theories of decision making can, with incorporation of these fundamental cognitive processes, describe a wide range of behavior (e.g. Busemeyer, 2015). Our results reinforce these claims by demonstrating the explanatory power of stochastic sampling and dynamic accumulation in strategic choice.

# How Can Memory-Augmented Neural Networks Pass a False-Belief Task? 

Erin Grant, Aida Nematzadeh, and Thomas L. Griffiths<br>University of California, Berkeley<br>\{eringrant, nematzadeh, tom_griffiths\} @berkeley.edu

#### Abstract

A question-answering system needs to be able to reason about unobserved causes in order to answer questions of the sort that people face in everyday conversations. Recent neural network models that incorporate explicit memory and attention mechanisms have taken steps towards this capability. However, these models have not been tested in scenarios for which reasoning about the unobservable mental states of other agents is necessary to answer a question. We propose a new set of tasks inspired by the well-known false-belief test to examine how a recent question-answering model performs in situations that require reasoning about latent mental states. We find that the model is only successful when the training and test data bear substantial similarity, as it memorizes how to answer specific questions and cannot reason about the causal relationship between actions and latent mental states. We introduce an extension to the model that explicitly simulates the mental representations of different participants in a reasoning task, and show that this capacity increases the model's performance on our theory of mind test.

Keywords: language understanding, question answering, theory of mind, false-belief test

## Introduction

Question answering poses difficulties to artificial intelligence systems because correctly answering a query often requires sophisticated reasoning and language understanding capacities, and so simply memorizing the answer or searching in a knowledge base is not enough. Despite this challenge, recent neural network models that make use of attention mechanisms in combination with an explicit external memory can successfully answer questions that require more complex forms of reasoning than before (e.g., Sukhbaatar, Weston, Fergus, et al., 2015; Henaff, Weston, Szlam, Bordes, \& LeCun, 2017). The benchmark dataset for such tasks has become the Facebook bAbi dataset (henceforth, bAbi) (Weston, Bordes, Chopra, \& Mikolov, 2016), which is a collection of question-answering tasks in the form of simple narrative episodes - termed stories - that are accompanied by questions about the state of the world described in the stories. (See Figure 1 for an example story from this dataset.)

Although bAbi is a start towards enumerating the requirements for human-like reasoning capabilities, it lacks tasks for testing the ability to reason about mental states, which is also necessary for correctly answering questions of the sort that humans encounter regularly. Consider the following:

> Sally and Ann are in the kitchen.
> Sally placed the milk in the pantry.
> Sally exited the kitchen.
> Ann moved the milk to the fridge.

For a model to correctly answer questions such as Where would Sally/Ann search for the milk? it need not only recognize that Sally and Ann have mental representations of the
state of the world but also that these representations are inconsistent: Sally believes that the milk is in the pantry while Ann thinks it is in the fridge.

Psychologists have used a task similar to this scenario termed the false-belief task - to examine children's development of theory of mind: the capacity to reason about the mental states of oneself and others (Premack \& Woodruff, 1978). Most 3-year-old children, after observing such a scenario, answer that Sally would search for the milk in the fridge because they cannot infer Sally's belief about the location of the milk, which is inconsistent with their own knowledge (e.g., BaronCohen, 1989; Baron-Cohen, Leslie, \& Frith, 1985). However, most older children are able to identify, correctly, that Sally's belief is different from theirs in that she thinks that the milk is the pantry.

To answer questions about situations like those that occur in a false-belief task, a model needs to use the observed actions in the scenario to infer the mental states of Sally and Ann. In this work, we investigate whether the End-toEnd Memory Network (henceforth MemN2N), a recent neural question-answering model (Sukhbaatar et al., 2015) that solves most of the bAbi tasks, is able to answer questions of the same structure as a false-belief task. We formulate scenarios to capture different possible causal relations among actions and beliefs, and examine the performance of the model therein. We find that the MemN2N model performs well only in the presence of strong supervision - when the training and test data share the same casual structure. This result suggests that the model is able to memorize the training data but is unable to learn to reason about mental states and how they cause and are caused by actions.

Furthermore, to simulate the (perhaps inconsistent) beliefs of the participants in a story, we extend the MemN2N model to include a separate memory representation for each participant. We show that this extension improves model performance, suggesting that explicitly modeling agents' knowledge in a disentangled manner is in part sufficient for more human-like reasoning on a false-belief task.

## Theory of Mind and the False-Belief Task

A theory of mind is integral for an agent to predict and explain the behavior that is caused by the mental representations of other agents, and therefore succeed on tasks such as the false-belief task. For children, this capacity is acquired gradually over the course of development. In particular, children undergo several milestones before they develop an adult-like theory of mind: By age two, they can distinguish between external states of the world and internal mental states possessed by cognitive agents (e.g., Meltzoff, Gopnik, \& Repacholi,

Mary got the milk there.
John moved to the bedroom.
Sandra went back to the kitchen.
Mary traveled to the hallway.
Q: Where is the milk? A: hallway
Figure 1: An example task from the bAbi dataset.
1999). By age four, they can distinguish between consistent and inconsistent mental states (e.g., Perner, Leekam, \& Wimmer, 1987), which allows them to identify a false belief.

Previous computational works have modeled human performance on the false-belief task. Some focus on modeling the development of theory of mind by instantiating a model that initially fails but eventually passes the false-belief test (Van Overwalle, 2010), while others study the settings in which a model can succeed on the task by varying the input data or the model architecture (O'Laughlin \& Thagard, 2000; Triona, Masnick, \& Morris, 2002; Goodman et al., 2006). However, none of these models use natural language sentences, despite the fact that the psychological false-belief task is usually administered verbally in the form of a natural language reasoning problem.

Furthermore, natural language is known to interact with the development of theory of mind. For example, use of mental state terms in child-directed speech (e.g., Slaughter \& Gopnik, 1996), engagement in pretend play (Youngblade \& Dunn, 1995), storybook reading (Rosnay \& Hughes, 2006), and reflection on events in the child's past (Nelson, 2007) serve to accelerate its developments, while, in turn, a greater grasp of theory of mind leads to increased linguistic ability (Milligan, Astington, \& Dack, 2007). In this work, we examine whether a model can learn from natural language about the causal relationship between actions and beliefs, in order to be able to answer questions that require reasoning about mental states.

## Memory Networks

The MemN2N model of Sukhbaatar et al. (2015) comprises an external memory cache and mechanisms to read and write to this memory. The model is trained to write a sequence of stories into its external memory and to answer questions about the stories by reading its memory and emitting the correct vocabulary item. At test time, the model is evaluated by the extent to which it can correctly answer questions about a held-out set of test stories.

Formally, the model ingests a sequence of input sentences $\left(x_{1}, \ldots, x_{n}\right)$ and produces, for each input item $x_{i}$, both a memory representation $m_{i}$ and a context representation $c_{i}$, which are stored in memory. The model is then presented with a question $q_{k}$ about the story, for which it produces an internal representation $u_{k}$. To answer the question, the model computes a normalized association score $p_{i k}$ between the question representation and each of its stored memory representations:

$$
\begin{equation*}
p_{i k}=\frac{\exp \left\{u_{k}^{\mathrm{T}} m_{i}\right\}}{\sum_{j} \exp \left\{u_{k}^{\mathrm{T}} m_{j}\right\}} \tag{1}
\end{equation*}
$$

This weight can be interpreted as an attention mechanism that defines where in memory the model will look for information relevant to the given question.

The model then produces an output representation by way of a linear combination of its context representations, weighted by the attention computed in Equation (1):

$$
\begin{equation*}
o_{k}=\sum_{i} p_{i k} c_{i} \tag{2}
\end{equation*}
$$

The output representation is combined with the query representation and decoded by some function $f$ to produce the predicted answer $\hat{a}$ :

$$
\begin{equation*}
\hat{a}=f\left(o_{k}+u_{k}\right) . \tag{3}
\end{equation*}
$$

Learning model parameters at training time is done by way of stochastic gradient descent in cross entropy error.

## Simulation 1: MemN2N Model

We evaluate the model introduced in the previous section on a set of novel textual reasoning tasks inspired by the falsebelief task. Our tasks take the form of a sequence of natural language sentences - termed a story - and an associated question about the story.

Since we aim to create tasks that, for humans to solve, involve reasoning about other agents' beliefs, we design various story templates that simulate how different actions give rise to different beliefs, and conversely how different beliefs result in different actions. These stories differ in whether or not the agent who is the subject of the question has observed a change in the state of the world (i.e., the agent has a true belief), or has not (i.e., has a false belief). The stories further differ in whether the belief is observable (i.e., the story explicitly contains sentences such as Sally believes the milk is in the pantry) or whether only actions are observable. When the agent harbors a false belief, and the model is asked to predict the action of the agent without explicit reference to the beliefs of the agent in the story, we recover a simulation of the classic false-belief task.

With this experimental design, we aim to determine whether the MemN2N model can reason about how actions cause beliefs and vice versa, and how much information needs to be revealed to enable the model to succeed.

## Data Generation

To generate stories and corresponding questions, we emulate the bAbi (Weston et al., 2016) dataset generation procedure. We define a world of entities, which are the people and objects described in the stories, and possible predicates that take entities as subject and, optionally, object. Each entity has properties that define the predicates of which it can be subject or object. For example, a world may contain Sally with

## BA

Anne moved the milk to the fridge.
True Sally believes the milk is in the fridge.
Belief Q: Where did Sally search for the milk?
A: fridge
Sally believes the milk is in the pantry.
Sally exited the kitchen.
False Anne moved the milk to the fridge.
Belief Sally entered the kitchen.
Q: Where did Sally search for the milk?
A: pantry

Sally placed the milk in the pantry.
Anne moved the milk to the fridge.
Q: Where does Sally believe the milk is?
A: fridge
Sally placed the milk in the pantry.
Sally exited the kitchen.
Anne moved the milk to the fridge.
Sally entered the kitchen.
Q: Where does Sally believe the milk is?
A: pantry

Sally placed the milk in the pantry. Anne moved the milk to the fridge.
Q: Where did Sally search for the milk? A: fridge

Sally placed the milk in the pantry. Sally exited the kitchen. Anne moved the milk to the fridge. Sally entered the kitchen. Q: Where did Sally search for the milk? A: pantry

Figure 2: Examples of the training data, with the predicates of interest underlined. Note that the true-belief and false-belief test tasks are of the same form as the top and bottom items, respectively, in the last column.
the property is agent and apple with the property is object. Our rules permit Sally to perform the action displace on the apple.

In this work, we consider a restricted set of action and belief predicates. Our actions define simple interactions of an agent with the world (e.g., place, move, enter, exit) and our beliefs correspond to mental state terms (e.g., believe, think), inspired by the terms that children gradually learn to understand and use correctly over the course of development (e.g., Bretherton \& Beeghly, 1982; Johnson \& Wellman, 1980). Our templates manipulate the order of action and belief predicates to test how the model reasons about the causal relations between them.

## Experimental Conditions

Story Template We define a set of templates that correspond to the type of story that we wish to generate. Each template fixes a sequence of predicates and therefore puts constraints on the entities that may fill the template. For example, a template could be the sequence (drop, pick up, exit). Completion of the template entails sampling valid entities from the world to fill the subject and object positions of the predicates, producing, for example, the story (Sally dropped the ball, Sally picked up the ball, Sally exited the room).

We consider three different template types:

- BA: observable beliefs (e.g., Sally believes the milk is in the pantry) give rise to observable actions (e.g., Sally searches the pantry);
- AB: observable actions (e.g., Sally places the milk in the pantry) give rise to observable beliefs (e.g., Sally believes milk is in the pantry); and
- $\mathbf{A}(\mathbf{B}) \mathbf{A}$ : observable actions (e.g., Sally places the milk in the pantry) give rise to observable actions (e.g., Sally searches the pantry) by way of unobserved beliefs (e.g., Sally believes the milk is in the pantry).

Note that the $\mathbf{A B}$ and $\mathbf{A}(\mathbf{B}) \mathbf{A}$ conditions are different in that in $\mathbf{A B}$, the question explicitly asks about Sally's belief; in
$\mathbf{A}(\mathbf{B}) \mathbf{A}$, on the other hand, the question is about Sally's action, which has been brought about by Sally's unobserved belief.
True vs. False Belief In addition to the type of template, for each story we manipulate whether the agent about whom the question is asked (i.e., Sally) has a true belief or a false belief about the state of the world. In the case that the agent has a true belief, the agent observes all changes in the state of the world and thus their beliefs are consistent with the world. On the other hand, in the case that the agent has a false belief, the agent does not observe one or more changes in the state of the world (because, for instance, Sally may exit the room), and thus has a belief that is inconsistent with the world.
Training Conditions We have six possible story types as a results of crossing the template types with the true and false belief story types; examples of each of the story types are given in Figure 2. We sample from these story types to produce our training conditions, in the following manner:

- When the training condition is such that $p($ false belief $)=$ 0 or 1 , we sample only stories with true beliefs or false beliefs, respectively, and when $p($ false belief $)=0.5$, we sample half of our stories with true beliefs and half with false beliefs.
- We sample stories from five different possible groups of templates: $\mathbf{B A}, \mathbf{A B}, \mathbf{A B}+\mathbf{B A}, \mathbf{A}(\mathbf{B}) \mathbf{A}$ and $\mathbf{A B}+\mathbf{B A}+\mathbf{A}(\mathbf{B}) \mathbf{A}$.

The $\mathbf{A B}+\mathbf{B A}$ and $\mathbf{A B}+\mathbf{B} \mathbf{A}+\mathbf{A}(\mathbf{B}) \mathbf{A}$ conditions provide the model with training data that better approximates the variety of possible scenarios in the world. In these cases, the model observes more ways in which actions and beliefs interact, and thus we would expect it to be able to better generalize to new scenarios. Moreover, $\mathbf{A B}+\mathbf{B A}$ provides the model with the opportunity to learn transitive inference - given that an action (e.g., placing milk in the pantry) results in a belief (e.g., the milk is in the pantry), and a belief (e.g., the milk is in the pantry) can cause an action (e.g., searching for milk in the pantry), a model that reasons about actions and beliefs could learn that an action (e.g., searching for milk in the pantry) is

Figure 3: Accuracy in Simulation 1. Test accuracies for the true-belief (TB) and false-belief (FB) tests across training conditions in Simulation 1. We report results for $p($ false belief $)=0.5$, since varying this parameter did not affect results except in the few cases discussed in the text.

Figure 4: Accuracy in Simulation 2. Test accuracies for the true-belief (TB) and false-belief (FB) tests across training conditions in Simulation 2. As in Figure 3, we report results only for $p($ false belief $)=0.5$.

Figure 5: Attention in Simuation 2. Visualisation of the attention weighting over memory caches for the true-belief (TB) and false-belief (FB) tests. We omit the visualization for the $\mathbf{B A}+\mathbf{A B}$ and $\mathbf{B A}+\mathbf{A B}+\mathbf{A}(\mathbf{B}) \mathbf{A}$ training conditions because the test accuracy distribution in Simulation 2 for these conditions is very similar to the $\mathbf{A}(\mathbf{B}) \mathbf{A}$ training condition (see Figure 4).
a consequence of an unobservable belief brought about by a preceding action (e.g., placing milk in the pantry).

Crossing template types $\mathbf{B A}, \mathbf{A B}, \mathbf{A}(\mathbf{B}) \mathbf{A}, \mathbf{A B}+\mathbf{B A}$, $\mathbf{A B}+\mathbf{B A}+\mathbf{A}(\mathbf{B}) \mathbf{A}$ with $p($ false belief $)=\{0.0,0.5,1.0\}$ produces our 15 training conditions. We run 10 simulations for each training condition and for each configuration of parameter settings of the MemN2N model. ${ }^{1}$
Test Conditions We aim to evaluate the model on tasks that require reasoning about latent mental states, in analogy to the classic false-belief task; however, such a capacity should apply not only in cases when an agent has a belief that is inconsistent with the state of the world (i.e., a false belief) but also when they have a true belief about the world. We therefore consider two test conditions: a true-belief (TB) and a falsebelief (FB) task. All examples in both of these test conditions share the $\mathbf{A}(\mathbf{B}) \mathbf{A}$ template type, but the conditions differ in that the true-belief task contains only examples with true beliefs (i.e., $p($ false belief $)=0$ ), and the false-belief task contains only false belief examples (i.e., $p($ false belief $)=1$ ).

[^76]
## Results

As noted by Sukhbaatar et al. (2015), the MemN2N model exhibits large variance in performance across simulations, and so we show performance by plotting the distribution of test accuracies in boxplot format. In Figure 3, we report accuracy on both test conditions (the true-belief (TB) and falsebelief (FB) tasks) across the training conditions, for $p$ (false belief) $=0.5$. The results for $p($ false belief $) \in\{0,1\}$ were similar except in the case of the $\mathbf{A B}$ story template; we compare this case with the BA condition in Figure 6 and discuss in the following. Note that success at test time corresponds to achieving 1.0 accuracy in both the TB and FB test conditions.
Training Condition BA: Beliefs to Actions The model fails on the TB task in the BA training condition, while succeeding on the FB task. This is true no matter the value of $p$ (false belief) (as depicted in Figure 6). To understand why this occurs, consider the following example of a BA training story when the false belief occurs:
Sally believes the milk is in the pantry. Sally exited the kitchen. Anne moved the milk to the fridge. Sally entered the kitchen.

Additionally, consider the BA training story when the false belief does not occur:

Anne moved the milk to the fridge. Sally believes the milk is in the fridge.

To answer the training question Where did Sally search for the milk? the model seems to learn that it should look for the sentence containing Sally and a container entity (i.e., Sally believes the milk is in the fridge).

This strategy works for the false-belief test (see Figure 2, last column, bottom row), because Sally believes that the milk is in the pantry - the location in which she originally placed it - and thus the sentence containing Sally and the identity of a container always proviedes the correct answer. However, this strategy fails on the true-belief test (again, see Figure 2, last column, top row), because Sally observes that the milk has been moved, and so no longer believes that the milk is in fridge. This suggests that the model is unable to infer that an observable action changes the mental state of Sally.
Training Condition AB: Actions to Beliefs The model is unable to achieve good performance on both the TB and FB tests in the AB condition. When the model performs better, it is in cases where the test is very similar to the training condition, i.e., the false-belief test with $p($ false belief $)=1$ in training and true-belief test with $p$ (false belief) $=0$ in training.
Training Condition AB+BA: Transitive Inference The model fails on both test tasks in the $\mathbf{A B}+\mathbf{B A}$ training condition. This is evidence that the model cannot reason about the causal relationships between actions and beliefs to perform transitive inference.
Training Condition $\mathbf{A}(\mathbf{B}) \mathbf{A}$ : Equivalent to TB/FB Test The model achieves best performance on $\mathbf{A}(\mathbf{B}) \mathbf{A}$ in the $p$ (false belief) $=0.5$ condition. This again happens because the test and training conditions are similar: the model observes examples of both the FB and TB test tasks in training, and thus receives supervision to give the correct answer at test. However, the model performs well only on the TB task in the $p$ (false belief $)=0$, and on the FB task in the $p($ false belief $)=1$ condition. This is because the model does not observe examples like one or the other test condition at training time.

Notably, the performance is not high even in the $p$ (false belief) $=0.5$ condition (the median is approximately $55 \%$ on both test tasks), despite the fact that the model is given testlike examples at training time. It is therefore not clear that the model is robustly able to solve a conditional reasoning task in which the correct answer is dependent on whether or not the observer sees the movement of the object and thus has a false or true belief. This, along with the model's failure in the other training scenarios, motivates an extension to the model, which we consider in the next section.

## Simulation 2: Multiple-Observer Model

We now propose a model that is given information about whether each agent in the story observes each sentence in the story. In general, this must also be inferred from context, but here we assume such annotations are available to the model as we simply attempt to investigate the effect of this information on the model's predictions.
(a) $\boldsymbol{p}($ false belief $)=0$ in training.

Figure 6: From Simulation 1. The test accuracy in the AB condition is dependent on the value of $p$ (false belief), but not in the BA condition.

Formally, for a story of $N$ input items that describes a situation with $M$ agents, we provide the model with an $N$-by$(M+1)$ observer annotation matrix $S$ such that $S_{i j}=1$ if input item $x_{i}$ is observable to agent $j$ and 0 otherwise, where we assign the oracle observer (who observes all input items) to the first index. These annotations are used to mask the input such that $M+1$ (possibly different) stories are produced, each of which corresponds to the story that a particular agent observes. Memory representations, attention over each memory cache, and output representations are computed separately for each observer, and so $M+1$ output representations are computed, each corresponding to the output of a distinct observer's memory.

The model then computes an attention weighting over each of the observer memory caches ( $c f$. Equation (1)):

$$
\begin{equation*}
r_{k \ell}=\frac{\exp \left\{u_{k}^{\mathrm{T}} o_{k \ell}\right\}}{\sum_{n} \exp \left\{u_{k}^{\mathrm{T}} o_{k n}\right\}} . \tag{4}
\end{equation*}
$$

This attention over memory caches is used to compute a weighted combination of the output representations that correspond to the memory cache for each agent (cf. Equation (3)):

$$
\begin{equation*}
\hat{a}=f\left(u_{k}+\sum_{\ell} r_{k \ell} o_{k \ell}\right) . \tag{5}
\end{equation*}
$$

Note that the model considered in Simulation 1 is exactly this model extension with $r_{k 0}=1$ and $r_{k m}=0, \forall m \neq 0$ (i.e., attention is given only to the oracle memory cache).

In this extension, the model is given explicit information about which observations in a story are available to each agent, by way of the annotation matrix $S$. However, it must learn to reason about this information in order to arrive at the correct answer, as before with how to write to memory and read from memory, and now with how to select over which observer's knowledge of the story is relevant to answer the question.

## Results

We report results of the model extension on the TB and FB tests in Figure 4, as well as a visualization of the attention weights in Figure 5. Our simulated data is composed of scenarios with only two agents, and therefore the extended model attends over three memory caches (one for the oracle that observes everything, one for Anne, and one for Sally, about whom the question is asked).

The extended model achieves higher accuracy across all training conditions. Notably, the model performs near perfectly (i.e., both TB and FB are close to 1 ) in the $\mathbf{A B}+\mathbf{B A}+\mathbf{A}(\mathbf{B}) \mathbf{A}$ case, meaning that the model can learn to ignore irrelevant training stimuli. This suggests that awareness of agent's knowledge about the state of the world helps in a task of reasoning about latent mental states.

Furthermore, the attention plots show that the model learns to attend to the memory representation of Sally in the FB test, which contains the information about how to answer questions about Sally's actions and beliefs. On the other hand, in the TB test, the model does not attend differently to the different memory caches, because the observations stored in all caches are the same.

## Conclusions

We investigated whether a recent language learning model that succeeds on a suite of textual reasoning tasks is able to succeed in a task that requires reasoning about latent mental states. We found that the model is unable to succeed in a set of simulated true-belief and false-belief tasks unless it has observed at training time situations that have the same structure as the test tasks, even if the diversity of the data is increased. This strongly suggests that the model is not reasoning about the state of the world, nor about mental representations thereof, but is simply memorizing its input. As a consequence, the model will not be able to succeed in a task of reasoning that differs greatly from the situations that it has observed at training time. This is in contrast to the the novelty of situations that people encounter regularly, in which they must reason about the causal relationship between events in the world and latent mental states.

However, incorporating a simple mechanism that informs the model that there may be multiple observers with differing representations of the story allows the model to achieve higher performance on the simulated false-belief and truebelief tasks. Under this modification, the model does not simply memorize the training data but also learns to use
knowledge that agents have (perhaps conflicting) observations about the story in order to answer the question. We could interpret this as analogous to the development of theory of mind in that, when a child is able to reason about others' knowledge of and beliefs about the world, the child succeeds on tests of theory of mind such as the false-belief task. A further direction of research could investigate whether manipulating variables in the training data (e.g., frequency of mental state terms) affects the model's performance in a manner similar to how a child's developmental trajectory would be affected.

# Evidence for a facilitatory effect of multi-word units on child word learning 

Robert Grimm, Giovanni Cassani, Walter Daelemans and Steven Gillis<br>Computational Linguistics and Psycholinguistics (CLiPS) Research Center Department of Linguistics, University of Antwerp, 13 Prinsstraat<br>B-2000 Antwerpen, Belgium<br>\{name.surname\}@uantwerpen.be

#### Abstract

Previous studies have suggested that children possess cognitive representations of multi-word units (MWUs) and that MWUs can facilitate the acquisition of smaller units contained within them. We propose that the formation of MWU representations precedes and facilitates the formation of single-word representations in children. Using different computational methods, we extract MWUs from two large corpora of English childdirected speech. In subsequent regression analyses, we use age of first production of individual words as the dependent and the number of MWUs within which each word appears as an independent variable. We find that early-learned words appear within many MWUs - an effect which is neither reducible to frequency or other common co-variates, nor to the number of context words contained in the MWUs. Our findings support accounts wherein children acquire linguistic patterns of varying sizes, moving gradually from the discovery of MWUs to the acquisition of small-grained linguistic representations. ${ }^{1}$

Keywords: multi-word units; age of first production; word learning; language acquisition; computational modeling

## Introduction

Frequently co-occurring word combinations have been investigated in studies examining both child (Bannard \& Matthews, 2008; Arnon \& Clark, 2011; McCauley \& Christiansen, 2014) and adult processing (Arnon \& Snider, 2010), with mounting evidence that children and adults represent such sequences separately from their constituent words. Indeed, given that many English word sequences have idiosyncratic meanings which cannot be derived from the meaning of their constituent words (e.g. pay attention to, leave of absence, you're welcome), it is reasonable to expect language users to store such semantically opaque sequences in memory. Findings from the literature, however, extend beyond this: in addition to non-compositional constructions, people are likely to also lexicalize frequent but semantically transparent formulaic sequences (Wray, 2008). Here, we use the term multi-word unit (MWU) to refer to any sequence of words - compositional or not - which is likely to be lexicalized, and we investigate the role of MWUs in the acquisition of individual words.

More concretely, we expect a facilitatory interaction between the acquisition of MWUs and the acquisition of their constituent words. Provisional evidence for a beneficial impact of MWUs on the acquisition of smaller Linguistic units was collected by Arnon and Clark (2011), who showed that children make fewer inflectional errors on known words if

[^77]the words are contained within frequent MWUs. Usagebased approaches to language acquisition, meanwhile, suggest that children acquire a repertoire of both lexically specific and more abstract multi-word constructions (Tomasello, 2009; Behrens, 2009). Based on this, we propose that children sometimes possess MWU representations before they form representations of the words contained within them, and that these MWU representations then facilitate the acquisition of single-word representations. We dub this the $M W U$ acquisition hypothesis.

With the availability of a growing number of corpora of child-caregiver interactions on the one hand (MacWhinney, 2000) and the development of methods for the extraction of MWUs from corpora on the other hand (McCauley \& Christiansen, 2014; Brooke, Tsang, Hirst, \& Shein, 2014), we are in a position to investigate the kinds of MWUs children are likely to acquire. Concretely, we extract MWUs from two large corpora of transcribed child-directed speech, using (a) a computational model employed by McCauley and Christiansen (2014) to account for findings from the language acquisition literature and (b) an algorithm, developed by Brooke et al. (2014), intended to build a comprehensive lexicon of psychologically plausible MWUs. We view extracted MWUs as an approximation of the types of MWUs children might discover and use the number of MWUs within which a given word is contained as an independent variable.

Throughout, we use the age at which children first produce words (age of first production / AoFP) as an index of word learning: if a word is first produced relatively early in development, we assume that this is in part because it is easy to learn when and how to use it. Given the MWU acquisition hypothesis, we expect a facilitatory effect of the number of MWUs in which a word appears on its AoFP. This effect, moreover, should be uniquely attributable to MWUs - and not to individual word frequency, semantic co-variates, or the number of context words contained in MWUs. Number of cooccurring context words has previously been shown to predict age of acquisition for words (Hills, Maouene, Riordan, \& Smith, 2010); but if our proposal is correct, such an effect should disappear once MWUs are taken into consideration.

## Related Work

## Language Acquisition

MWUs have emerged as an important theoretical concept in usage-based approaches to Language Acquisition (Tomasello, 2009). Within this broad theoretical framework,
learners' linguistic representations are conceived of as continually complexifying entities, with the developed cognitive system containing both lexically specific and more abstract patterns. At early stages in development, most representations are lexically specific, and child language is "(partially) formulaic and item-based" (Behrens, 2009, p. 393). That is, child language development is thought to involve representations which are lexically specific and span multiple words.

Experimental evidence for the existence of children's MWU representations comes from Bannard and Matthews (2008), who presented 2 and 3 year-olds with frequent MWUs like a drink of tea and matched infrequent MWUs like a drink of milk that differed in the last word. 2 and 3 year-olds were faster to repeat frequent MWUs, and 3 year-olds were also faster to repeat the first three words if they formed a frequent MWU with the fourth word. Since the final word and the final bigram (e.g. of tea and of milk) were matched for frequency, the processing advantage for frequent MWUs can only be attributed to the frequency of the entire MWU, rather than to the frequencies of its component words, suggesting that children have access to cognitive representations of MWUs. Bannard and Matthews (2008) argue, furthermore, that their subjects were likely familiar with the words comprising the MWUs, which implies the existence of (partially) independent MWU and single-word representations. ${ }^{2}$

In addition, Arnon and Clark (2011) found that MWUs interact with the acquisition of morphemes: 4;6 year-olds produced more correct irregular plurals after familiar lexically specific frames than after general questions. Subjects were presented with depictions of several objects. The object name was elicited either with a labeling question or with a lexically specific frame. For example, on one particular trial the objects were sheep, the lexically specific frame was Count some - , and the labeling question was What are all these called? $4 ; 6$ year-olds were more likely to complete the lexically specific frame with sheep and would provide relatively more incorrect plural forms - like the over-regularized sheeps - in response to the labeling question. This suggests that MWUs like count some sheep affect the way in which some of the smaller units contained within them are learned.

## Computational Modeling

The above-cited results by Arnon and Clark (2011) and Bannard and Matthews (2008) have been modeled by McCauley and Christiansen (2014). In a comprehension phase, their model segments a corpus of child-directed speech into MWUs. In a production phase, it generates childproduced utterances based on stored MWUs. Given a corpus, MWUs are extracted by comparing the conditional probability of the current word given the preceding word to a running average of all such probabilities, for all words so far encoun-

[^78]tered one position to the left of the current word. If this backward transitional probability (BTP) is larger than the running average, the current and preceding word are part of an MWU. The process continues until the BTP falls below the average, at which point the current MWU is stored in memory.

Extracted MWUs can then be used to re-construct childproduced utterances. McCauley and Christiansen (2011) compared model-derived to child-produced utterances across 13 corpora from the CHILDES database (MacWhinney, 2000). On average, about $60 \%$ of utterances were successfully re-produced - illustrating that a purely MWU-based system can account for a majority of child-produced utterances. Importantly, MWUs discovered by the model can also be used to model results from Bannard and Matthews (2008) and Arnon and Clark (2011). In both cases, stimuli were sequences of words - constructions like a drink of tea in the former and count some sheep in the latter study. McCauley and Christiansen (2014) assigned a chunkedness score to each stimulus by calculating the product of BTPs between the MWUs used by the model to re-produce each stimulus. In each study, differences in scores reflected differences in subjects' performance: stimuli with lower reaction times in Bannard and Matthews (2008)'s study were assigned a larger chunkedness score, as were stimuli which elicited a larger proportion of correctly inflected nouns in Arnon and Clark (2011)'s study.

## Natural Language Processing

McCauley and Christiansen's $(2011,2014)$ model can be situated in a tradition that measures association strength between pairs of words; words are then grouped together if their association strength exceeds a particular threshold. McCauley and Christiansen $(2014,2011)$ use BTP as the measure of association. Other options include pointwise mutual information or log likelihood (cf. Pecina, 2010, for an overview). All association-based methods require an arbitrary threshold for inclusion of words in MWUs. In addition, there is no consensus on which association measure is best. An alternative approach is to identify frequent n -grams - called lexical bundles -, but this requires very high frequency thresholds (Biber, Conrad, \& Cortes, 2004). There is, then, no generally accepted way of extracting MWUs from corpora, nor is it common practice to evaluate whether extracted MWUs correspond to psychologically real entities.

Work by Brooke et al. (2014) has recently begun to address these issues. Their method operates at the token level, identifies MWUs of varying sizes, and relies on two parameters: a frequency threshold and a maximum MWU size. Broadly speaking, the algorithm considers all possible segmentations of a given sentence into $n$-grams that meet a pre-specified frequency threshold. Then, that segmentation is selected which maximizes the predictability of each word within its n-gram. The stated goal of this work is to develop a method for the extraction of an MWU lexicon that would correspond to knowledge of MWUs possessed by native speakers. The system has since been refined by Brooke et al. (2015), who also in-
troduced first steps towards evaluating MWU lexicons.

## Hypothesis

According to the MWU acquisition hypothesis, children sometimes acquire MWU representations before they acquire representations of the individual words contained in MWUs, and access to MWU representations then facilitates acquisition of the words contained in them. ${ }^{3}$ While this hypothesis is grounded in the literature, it is not clear via which mechanisms MWUs might aid the word learning process. Consequently, our goal is to provide evidence that MWUs uniquely facilitate word learning, and not how this process unfolds. Below, we nevertheless sketch two possible scenarios.

One possibility is that children initially acquire MWUs as unanalyzed units. This could result from an initial undersegmentation of the input: words, before their meaning is established, need to be identified from a continuous stream of sound. Early in development, children might sometimes segment multi-word chunks before they begin to segment individual words from within those chunks. Thus, some early fossilized MWUs are likely to be (partially) undersegmented chunks. In this scenario, the more initially undersegmented MWUs contain it, the earlier a given word is going to be segmented. We would then expect this early segmentation to translate into early induction of meaning.

A second possibility is that children discover some words before establishing their meaning. They would then go on to discover MWUs containing those words, at which point they have access to fully-fledged MWU representations without having access to the meaning of each individual word. The more MWUs contain a given word, the more words it is going to be linked to - and the more words will prime its retrieval, making it more salient for the learner. On average, a word with many links will be more easily retrieved than a word with few links. Because of this, we would expect fewer necessary exposures to establish the meaning of a word which forms part of relatively many MWUs, compared to words contained in fewer MWUs.

As mentioned, we do not distinguish between these two and other such possibilities. Instead, we aim to broadly corroborate the $M W U$ acquisition hypothesis by showing that MWUs uniquely facilitate word learning: if, all else being equal, words contained in many MWUs are learned earlier than other words, this would be indicative of a developmental pattern which begins with the formation of MWU representations and then proceeds to the acquisition of individual words.

## Method

Our method is the following: first, we extract MWUs from two corpora of English child-directed speech (CDS) and estimate age of first production (AoFP) for the words produced by the children addressed in the CDS corpora. We then use

[^79]the number of MWUs within which each target word appears (\#MWUs) as an independent variable - next to several covariates - in a linear regression analysis, with AoFP as the dependent variable. If the $M W U$ acquisition hypothesis is true, we expect a unique facilitatory effect of $\# M W U s$ on AoFP.

## Child-Directed Speech

We use two corpora of CDS, which both consist of the adultproduced utterances from several corpora on the CHILDES database (MacWhinney, 2000). Some corpora are based on cross-sectional studies, while others are longitudinal. In addition, subjects vary in age. Regardless, each corpus consists of standardized transcripts, based on recordings of childcaregiver interactions. In order to maximize the amount of data, we ignore possible fine-grained differences between age cohorts and compile a North-American corpus (NA-CDS) from 45 American English corpora ${ }^{4}$ and a British English corpus (BE-CDS) from eight British corpora ${ }^{5}$. Table 1 summarizes statistics.

Table 1: Relevant corpus statistics.

| measure | CDS-BE | CDS-NA |
| :--- | :--- | ---: |
| nr. tokens | $4,681,925$ | $6,389,963$ |
| nr. types | 24,929 | 37,128 |
| median length of utt. | 4 (IQR: 4) | 4 (IQR: 4) |
| nr. adult speakers | 201 | 774 |
| nr. children addressed | 134 | 441 |
| mean child age (months) | 33 (SD: 9) | 41 (SD: 23) |

## Extraction of Multi-Word Units

To extract MWUs from the CDS corpora, we use McCauley and Christiansen's (2014) model as well as Brooke et al.'s (2014) method. McCauley and Christiansen's (2014) model called Chunk-Based Learner (CBL) - processes a given corpus utterance by utterance and word by word. Processing an utterance $u$ is initiated by incrementing the frequency count of the first word $w_{1} \in u$ by 1 and creating a new MWU with $w_{1}$ as its only member. For each subsequent word $w_{i}$ at utterance position $1<i \leq$ length $(u)$, the model keeps track of the number of times $w_{i}$ has been encountered so far, as well as how often the immediately preceding word $w_{i-1}$ has occurred one position to the left of $w$. The model then calculates the backward transitional probability (BTP) of $w_{i}$ and $w_{i-1}$ : $p\left(w_{i-1} \mid w_{i}\right)$. If this probability is larger than the average BTP across all words which have occurred one position to the left

[^80]of $w$ in all utterances so far considered, $w_{i}$ is added to the current MWU. Else, the current MWU is added to a set $M$, and a new MWU is created - again with $w_{i}$ as its only member. In this way, the model discovers MWUs of size 2 or larger, as well as single-word units, collected in $M$. In our analyses, we use all MWUs which occur at least twice in the input corpus.

As a second model, we use the method from Brooke et al. (2014) ${ }^{6}$. We refer to it as Prediction Based Segmenter (PBS), as it splits utterances into n-grams whose component words are maximally predictable. The basic idea is that given an n-gram $w_{1} \ldots w_{n}$, the conditional probability of any word $w_{i}$ given the remaining subsequence $w_{1} \ldots w_{i-1}, w_{i+1} \ldots w_{n}$ should be maximal. In essence, the algorithm splits utterances into $n$ grams such that each word's predictability is maximized, capturing the intuition that words within MWUs are more predictive of one another than words outside of MWUs - but see Brooke et al. (2014) for a more in-depth explanation. Specifying a maximum n-gram length of ten - longer than most utterances in the corpus - , we use the PBS to segment utterances into either single-word units or MWUs with a minimum size of two and a maximum size of ten. As with the CBL, we retain all MWUs which occur at least twice.

Running the models on the two CDS corpora results in four different sets of MWUs, whose distributions are summarized in Table 2. The CBL results in a larger number of shorter MWUs, while the PBS identifies MWUs that are a bit longer. There are generally more MWU types than word types (compare Table 1).

Table 2: Relevant statistics about the distribution of MWUs.

| corpus | measure | CBL | PBS |
| :---: | :--- | ---: | ---: |
| CDS- | MWU tokens | $1,073,037$ | 978,804 |
|  | MWU types | 465,447 | 387,391 |
|  | median length | $4(\mathrm{IQR:} \mathrm{3)}$ | 5 (IQR: 4) |
| CDS- | MWU tokens | $1,40,8614$ | $1,338,173$ |
|  | MWU types | 628,252 | 492,863 |
|  | median length | $4(\mathrm{IQR:} \mathrm{3)}$ | 5 (IQR: 4) |

## Age of First Production

To induce AoFP, we start from a corpus of child-produced utterances, treating a word as having been learned at the earliest developmental stage at which any child within the corpus can produce it. Developmental stage is defined in terms of mean length of utterance (MLU) - the average child utterance length, in tokens, within a transcript. Since transcripts have varying lengths, we estimate MLU for each transcript via statistical bootstrapping, wherein the sampling distribution of the population is approximated by drawing random samples from the data (Davison \& Hinkley, 1997). Each bootstrap is based on 1000 random samples with replacement, with the sample size equal to the number of child utterances

[^81]per transcript. We thus induce MLU rather than AoFP estimates, since MLU is a more robust estimator of development (Parker \& Brorson, 2005): children who are close in age may nevertheless be far apart in terms of language development. For simplicity, we still refer to a word's MLU value as its AoFP. To induce a value for any word, we calculate the set of MLUs $\gamma$ for all transcripts within which the word appears and assign it the smallest value in $\gamma$.

We perform this procedure for each word produced by the children addressed in the two CDS corpora - once for the NA data and once for the BE data, meaning that we end up with two AoFP data sets: 441 children are addressed in the CDSNA corpus and together produce 29,188 different words, each of which is assigned an AoFP value; and 134 children are addressed in the CDS-BE corpus, producing 14,747 different words, again each with its own AoFP value.

## Regression Analyses

In the regression models, we use AoFP as the dependent variable. The first key independent variable is the number of different MWUs within which a given target word appears (\#MWUs). For example, assuming our corpus is CDS-NA and our target words are girl and sit, we count the unique MWUs which contain these two words. To illustrate this, Table 3 shows the five most frequent MWUs, in CDS-NA, containing the two words. Counting all such MWUs, we end up with 113 (PBS) and 230 MWUs (CBL) for girl, and 253 (PBS) and 488 (CBL) MWUs for sit. The second key independent variable is the number of unique context words appearing in all MWUs within which a given target word is contained (\#ctxt). If MWUs aid word learning, we should see a facilitatory effect of \#MWUs on AoFP, and this effect should not be reducible to \#ctxt. If a target word appears within a large number of MWUs, it will also tend to co-occur with a large number of context words. We posit, however, that MWUs - not individual words - are the cognitively relevant units; and we predict, therefore, that it is the number of MWUs - not the number of co-occurring context words which affects learning.

Further, we include the following co-variates: the corpusfrequency of each target word (freq), number of syllables (syl), phonological neighborhood density (phon), and concreteness ratings (con). Given a target word, phon is defined as the number of homophones, plus the number of words that can be derived from the target by either adding, deleting, or substituting a single phoneme. phon, together with $n s y l$, is derived from the CMU pronunciation dictionary ${ }^{7}$. Concreteness ratings for 40,000 lemmas are taken from Brysbaert, Warriner, and Kuperman (2014) ${ }^{8}$, who collected them from over four thousand participants via Mechanical Turk. Since ratings were collected for lemmas, whereas we work with word forms, we assigned the lemma rating to all word forms which correspond to the lemma. Regression analyses are based on

[^82]Table 3: The five most frequent MWUs, found in CDS-NA, for the target words girl and sit. Frequency counts for the MWUs are give in parentheses.

| word | CBL | PBS |
| :--- | :--- | :--- |
| girl | good girl (410) | good girl (440) |
|  | little girl (110) | that's a girl (101) |
|  | a girl (68) | little girl (175) |
|  | that's a good girl (98) |  |
|  | sit down (627) | that's a good girl (59) |
| the little girl (51) |  |  |
| sit | sit up (88) | sit down (846) |
|  | sit here (46) | sit up (141) |
|  | sit over here (46) | you sit (117) |
|  | sit down please (41) | you wanna sit (87) |
| come sit (85) |  |  |

all words for which phon, syl and con estimates are available: 7,265 words in CDS-BE and 5,724 words in CDS-NA. Table 4 shows three example data points.

To increase the generality of this study's implications, we use AoFP from children who were not addressed in the corpus used to estimate \#MWUs, \#ctxt, and frequency. In other words, we use AoFP from the children addressed in the CDSNA corpus for regression models which include \#MWUs, \#ctxt and frequency counts from CDS-BE; and we use AoFP from the children addressed in CDS-BE for regression models which include independent variables from CDS-NA.

Table 4: Example data points from the CDS-BE corpus, with \#MWUs and \#ctxt estimated via the PBS. The phon and nsyl predictors are not shown due to space constraints.

| word | freq | con | \#ctxt | \#MWUs | AoFP |
| :--- | :--- | :--- | :--- | :--- | :--- |
| goes | 3,183 | 2.19 | 430 | 156 | 0.51 |
| lunch | 1,175 | 4.31 | 168 | 57 | 1.29 |
| running | 853 | 4.27 | 86 | 46 | 1.16 |

## Results

Table 5 presents results of four linear regression analyses (2 methods for MWU extraction $\times 2$ CDS corpora). All variables are log-transformed, and \#ctxt as well as \#MWUs are increased by 1 , in order to avoid problems from zero counts. The baseline models with all co-variates (second column) explain between 38 and 44 percent of the variance in AoFP. Freq and con have facilitatory effects, while there are no statistically significant effects for phon and nsyl. Given that increased frequency of exposure is associated with early word learning (Ambridge, Kidd, Rowland, \& Theakston, 2015), the effect of freq is not surprising, while the effect of con implies that words associated with concrete concepts tend to be earlyacquired.

Adding \#ctxt to the baseline models (third column) leads to
a significant increase in $R^{2}$, with a facilitatory effect of \#ctxt. Adding \#MWUs to the baseline models (fourth column) also improves the fit, with a facilitatory effect of \#MWUs. Interestingly, the effect of $\# M W U s$ is stronger than the effect of \#ctxt. Neither effect is reducible to the frequency of target words, their concreteness, their phonological complexity, or the density of their phonological neighborhoods. In models which include the covariates plus \#ctxt and \#MWUs (fifth and sixth columns), \#MWUs continues to exert a facilitatory effect; but importantly, \#ctxt now has an inhibitory effect on AoFP. This pattern suggests that the initial facilitatory effect of \#ctxt is due to collinearity with \#MWUs.

Our results imply that it is involvement in a large number of MWUs - not co-occurrence with a large number of context words - which drives word learning. Furthermore, the effect of MWUs may be limited to MWUs consisting of relatively few words. Hence, when factoring out \#MWUs, co-occurrence with a large number of context words inhibits acquisition of the target words; and when factoring out the effect of context words, the positive effect of \#MWUs persists.

## Conclusions and Future Work

We began this paper with a review of studies which suggest that children acquire representations of MWUs and that MWUs could facilitate the acquisition of smaller linguistic units contained within them. Based on this, we proposed the MWU acquisition hypothesis, according to which the formation of MWU representations precedes and facilitates the formation of individual word representations. The facilitatory effect of $\# M W U s$ on AoFP supports this hypothesis. More broadly, it supports accounts of language development wherein children acquire linguistic units at various levels of granularity, transitioning gradually from MWUs to more small-grained units.

Our results also have implications for a previous finding: Hills et al. (2010) found that the sum of unique context words occurring within a window of five words to the left and right of each target word predicts age of acquisition of the targets. We also observed a facilitatory effect of \#ctxt. However, an inhibitory effect of \#ctxt emerged once \#MWUs was controlled for. Thus, given that their measure is similar to \#ctxt, it is possible that Hills et al. (2010)'s result is due to collinearity with the number of MWUs within which target words appear.

In formulating the hypothesis, we purposefully remained agnostic with respect to the specific mechanisms involved in the facilitatory interaction between the acquisition of MWU and single word representations. Accordingly, our results support a general class of theories wherein MWUs are acquired before single words. These could be usage based approaches to language acquisition (Tomasello, 2009), but also proposals such as Peters' (1983), according to which earlyacquired MWUs are undersegmented chunks which are gradually segmented into smaller units - units which are themselves stored in memory, where they are again subject to segmentation. In future work, we plan to experiment with differ-

|  | Effect ( $\Delta R^{2}$ in \%) |  |  |  |  |
| :--- | :---: | :---: | :---: | :---: | :---: |
| Data set and corpus | Covariates <br> baseline | Log-\#ctxt | Log-\#MWUs | Log-\#ctxt <br> unique | Log-\#MWUs <br> unique |
| CBL |  |  |  |  |  |
| CDS-BE | $44.85^{* * *}$ | $1.23^{* * *}$ | $1.73^{* * *}$ | $0.34(\mathrm{I})^{* * *}$ | $0.85^{* * *}$ |
| CDS-NA | $38.33^{* * *}$ | $0.87^{* * *}$ | $1.35^{* * *}$ | $0.13(\mathrm{I})^{* * *}$ | $0.61 * * *$ |
| PBS |  |  |  |  |  |
| CDS-BE | $44.85^{* * *}$ | $0.78^{* * *}$ | $1.52^{* * *}$ | $0.55(\mathrm{I})^{* * *}$ | $1.29^{* * *}$ |
| CDS-NA | $38.33^{* * *}$ | $0.47^{* * *}$ | $1.09^{* * *}$ | $0.18(\mathrm{I})^{* * *}$ | $0.79^{* * *}$ |

Table 5: Effects of log-transformed \#ctxt and log-transformed \#MWUs. The effects of \#ctxt and \#MWUs were calculated after those of the co-variates had been included. Unique effects are those with the indicated variable entered last (i.e. \#ctxt after covariates + \#MWUs, or \#MWUs after \#ctxt + covariates). I = inhibitory effect of indicated variable.
ent operationalizations of MWUs, in order to examine what types of MWUs have the strongest potential effect on word learning. This, in turn, may allow us to more closely specify the mechanisms whereby MWUs facilitate word learning.

# The nature of quantities influences the representation of arithmetic problems: evidence from drawings and solving procedures in children and adults 

Hippolyte Gros (hippolyte.gros@cri-paris.org) ${ }^{(1,2,3)}$<br>(1) Université Paris Descartes, Sorbonne Paris Cité, 12 Rue de l'École de Médecine, 75006 Paris, France.<br>Jean-Pierre Thibaut (jean-pierre.thibaut @u-bourgogne.fr)<br>(2) LEAD-CNRS, UMR 5022, UB, Université de Bourgogne Franche-Comté, Pôle AAFE - Esplanade Erasme, 21065 Dijon. #### Abstract

When solving arithmetic problems, semantic factors influence the representations built (Gamo, Sander \& Richard, 2010). In order to specify such interpretative processes, we created structurally isomorphic word problems that could be solved with two distinct algorithms. We tested whether a distinction between cardinal and ordinal quantities would lead solvers, due to their daily-life knowledge, to build different representations, influencing their strategies as well as the nature of their drawings. We compared $5^{\text {th }}$ grade children and adults in order to assess the validity of this hypothesis with participants of varying arithmetic proficiency. The results confirmed that the distinction between cardinal and ordinal situations led to different solving strategies and to different drawings among both age groups. This study supports the ontological distinction of cardinal versus ordinal quantities and calls for the consideration of the role of daily-life semantics when accounting for arithmetic problem solving processes.

Keywords: arithmetic problem solving; interpreted structure; semantic encoding; strategy choice.

## Introduction

What are the steps taken from reading an arithmetic word problem to implementing a set of mathematical operations, and how can they be studied? It is well established, since Riley, Greeno and Heller (1983) proposed their typology of additive word problems, that different problem statements lead to different performances. Yet, the reasoning processes and representations accounting for such differences remains controversial.

The schema theory (Kintsch \& Greeno, 1985) proposes that solving a word problem requires to select and to instantiate a schema fitting the problem at hand. For example, any comparison problem will require to retrieve the corresponding schema and to implement it with the available values (Riley et al., 1983). However, it has been argued that this approach underestimates interpretative effects. For instance, Hudson (1983) showed that young children had much more trouble solving a problem stating "there are 5 birds and 3 worms, how many more birds is there than worms?" than they had solving a problem in which the question was "how many birds won't get a worm?". This
result shows that two problems which share the same schema can lead to different performances.

A contrasting approach comes from Johnson-Laird's (1983) theory of mental models. It posits that, during reading, a mental representation is constructed in working memory, and that its structure is analogous to that of the situation depicted in the problem statement (Reusser, 1990). This representation depicts the meaningful relations between the elements of the problem. The idea of a problem-specific representation, integrating conceptual information from the problem statement, can account for the interpretative effects described in the literature. De Corte, Verschaffel and De Win (1985) showed that rewording a problem statement by making the semantic relations more salient facilitates the solving process. Similarly, introducing daily-life situations in the cover stories of word problems contributes to better performance (Stern \& Lehrndorfer, 1992; Vlahović-Štetić, 1999). The use of specific words or sentences can modify the representation constructed by the solvers (Cummins, Kintsch, Reusser \& Weimer, 1988). In a study challenging the predictions of mental model and schema views, Thevenot, Devidal, Barrouillet and Fayol (2007) showed that placing the question at the beginning instead of at the end of a problem statement provided more benefit to the less experienced solvers. This result supported the mental model theory, whereas the schema theory would have predicted the reverse pattern.

## Semantic determinants of problem solving

The semantic determinants of a solvers' mental representations are an important issue. Bassok, Wu and Olseth (1995) showed that the semantic relations which connect a problem's entities influence analogical transfer. They contrasted problems where objects were given to people (OP) and problems were people were assigned to objects (PO). They found that, since in real life objects are usually given to people rather than people being assigned to objects, OP training examples led to better performance with OP transfer problems than PO training examples did with PO transfer problems.

Along this line, Bassok, Chase and Martin (1998) asked participants to create addition or division problems involving specific sets of objects that were provided. They showed that when the objects shared a functionally asymmetric semantic relation (e.g. apples and baskets evoke the contain relation), participants tended to create division problems, whereas they created addition problems when using functionally symmetric sets of objects (such as oranges and apples, that belong to the same superordinate fruit category). These biases are not driven by arithmetic properties but rather by the world semantics. Bassok (2001) developed the semantic alignment framework proposing that solvers abstract an interpreted structure that depends on their world knowledge about the entities described in the problem statement. This interpreted structure integrates the structural role of the entities mentioned in the problem, and can thus lead to an appropriate use of abstract formal knowledge when the relations it describes are semantically aligned with the mathematical relations of the problem (Bassok et al., 1998; Bassok, 2001). Both behavioral (Bassok, Pedigo \& Oskarsson, 2008) and physiological (Guthormsen et al., 2015) measures confirmed that problem solving is easier when daily-life knowledge (world semantics) and knowledge about mathematical concepts (mathematical semantics) are aligned with each other.

## Investigating participants' representations

The semantic alignment framework predicts that representations abstracted from problem statements influence the solver's solving strategies. Yet, the key semantic dimensions influencing the representations and explaining the lack of transfer remain to be elucidated in order to promote methods to help students overcome the incompatibilities posed by a problem.

In this regard, problems with multiple solving strategies are of particular interest to study representations, since the selection of one strategy over another is informative about the representation constructed by the solvers (De Corte, Verschaffel \& De Win, 1985). For instance, Thevenot and Oakhill (2005) worked on a multiple-step problem solving task in which the cognitive load was manipulated through values size (large or small). They showed that depending on the size of the values, participants used different solving algorithms. The issue of the semantic determinants of problem representations can be tackled by using such a paradigm in which different solving strategies are available, and the solver's ability to pick and use one informs us about the abstracted interpreted structures (Hakem, Sander, Labat \& Richard, 2005). For example, Coquin-Viennot \& Moreau (2003) showed that the presence of a grouping element in a problem statement (such as flowers presented within a bouquet instead of separately) could incite participants to use a factorizing rather than a development algorithm.

Another way to study the participants' mental representations is the use of drawings. Vosniadou and Brewer (1992) elicited drawings from $3^{\text {rd }}$ and $5^{\text {th }}$ grade children so as to study the development of their representations of the earth. As for problem solving, studies have highlighted the link
between problem representations and drawings of the situations (Barrios \& Martinez, 2014; Edens \& Potter, 2007). Drawings are thus an accurate way to gather information regarding the solvers representations.

## Encoding ordinal and cardinal quantities

In the following experiment, we will capitalize on problems that can be solved with two different strategies. Previous studies have suggested that an ontological distinction can be drawn between two types of situations involving numerical values: cardinal situations, consisting of sets of unordered elements, and ordinal situations, where units are endogenously ordered and can be represented along an axis, such as a timeline (Gamo et al., 2010; Hakem et al., 2005; Sander \& Richard, 2005). When solving an arithmetic word problem, the authors posited that solvers abstract an interpreted structure that is aligned with either a cardinal or an ordinal representation.

These two types of representations elicit different solving strategies: in ordinal representations, subtractions are seen as calculations performed on a one-dimensional ordered scale, whereas in cardinal representations they are encoded as a difference between a whole and a component part (Hakem et al., 2005). Thus, according to Gamo et al.'s hypothesis, a subtraction could either be perceived as a comparison or as a complementation, depending on the situation described in the problem statement. The paradigm developed by Hakem et al. consisted in problems that admitted two distinct solving strategies implementable for both cardinal (number of people) and ordinal (duration) quantities. Problem statements 1 and 2 below embody this distinction between cardinal problems and ordinal problems:

- Problem 1: "There are 5 people in the Richard family. When the Richards go on holiday with the Roberts, they make a total of 14 people at the hotel. The Roberts are joined on holiday by the Dumas family. In the Dumas family, there are 3 people less than in the Richard family. The Roberts are going on holiday with the Dumas. How many will they be at the hotel?"
- Problem 2: "Antoine took painting classes for 5 years, and stopped at the age of 14 . Jean started at the same age as Antoine, and went to classes 3 years less than him. How old was Jean when he stopped attending painting classes?"

Figure 1: Structure of the problems. This structure can depict both problems and is compatible with both strategies.

Problems 1 and 2 are isomorphs sharing the same deep structure (Figure 1), and can both be solved using either of two strategies: either a 3-step complementation strategy ( 14 $5=9 ; 5-3=2 ; 9+2=11$ ) or a 1 -step matching strategy ( $14-3=11$ ). Yet, the authors hypothesized that (i) because the quantities used are different, the interpreted structures are too, each problem statement consequently favoring the use of one strategy over the other; and that (ii) the unequal distribution of strategies used may be accounted for by the nature of the abstracted representations: problem 1 encoded as a cardinal problem (Figure 2) and problem 2 encoded as an ordinal problem (Figure 3).

Figure 2: Cardinal representation of problem 1. This interpreted structure fosters the calculation of the intersection (part 2) between whole 1 and whole 2, thus favoring the 3 -step complementation strategy.

Figure 3: Ordinal representation of problem 2. This interpreted structure puts forward the fact that the difference between whole 1 and whole 2 is equal to the difference between part 1 and part 3 . The shorter 1 -step comparison algorithm thus becomes available to solve the problem.

In accordance with the authors' hypothesis, the participants who were asked to solve the problems using as few operations as possible found the 1 -step matching strategy on problem 1 in less than $5 \%$ of the cases. On the other hand, problem 2 led to the use of the 1 -step matching strategy in over $60 \%$ of the cases, suggesting that comparisons are indeed made salient in ordinal representations. Hakem et al.'s (2005) study of the solving strategies showed that the two types of problems were underlain by different representations. Yet, the claim that ordinal and cardinal quantities evoke the corresponding ordinal and cardinal representations warrants further empirical support.

## Present study

Our study builds on the work of Hakem et al. (2005) in order to highlight the role of general semantic features on the representations abstracted by the solvers and on the implemented solving strategies. We aimed at providing converging measures of the impact of the cardinal/ordinal distinction on the solvers' ability to solve the problems, and to provide the first empirical test of these effects on children and adults simultaneously. To this end, $5^{\text {th }}$ graders as well as adults were asked to perform two tasks: solving problems involving different types of cardinal and ordinal variables using as few operations as possible, and making a drawing for each problem.

The goal of the experiment was twofold: first, we intended to confirm with both age groups the validity of the ordinal versus cardinal distinction with new material including new types of quantities and using systematically controlled problem statements. This was intended to show that strong semantic effects affect both younger and older - more proficient - participants in arithmetic problem solving. Second, we wanted to show that those effects originate in the representations abstracted from the problems, and translate into the algorithms implemented by the solvers. We predicted that within each group, the mean percentage of the 1 -step matching strategy would be significantly lower on cardinal problems than on ordinal problems, despite the adults achieving a globally higher solving performance than the children. Also, we predicted that for each age group the drawings would reveal a higher ordinal versus cardinal ratio of distinctive features for ordinal than for cardinal problems.

## Experiment

## Participants

We recruited samples from two populations for this study: a group of 59 children in $5^{\text {th }}$ grade ( 27 females, $M=11.00$ years, $S D=0.36$ ), and a group of 52 adults ( 36 females, $M=$ 26.86 years, $S D=9.72$ ). All participants were recruited from the Paris region and spoke French fluently. None had previously participated in any similar experiment.

## Materials and procedure

Each participant was presented with a set of 12 problems, 6 using ordinal values (duration, height or number of floors), and 6 using cardinal values (number of elements, price or weight), according to Hakem et al.'s definition. We considered duration, height and number of floors as ordinal values because their ordinal component is salient in daily life, putting emphasis on successorship relation and on comparison. Similarly, number of elements, price and weight were used as cardinal values because the world semantics attached to such quantities evoke the unordered grouping of elements assigned to values and the partition of a whole into its component parts.

All the problems had the same number of sentences. The numerical values were provided in the same order and both numerical values and problem order were randomized between participants. The problems were printed on 13-page
booklets with the instructions detailed on the first page. The participants were asked (1) to solve the problems using as few arithmetic operations as possible, (2) to write down every operation they made, even those they solved using mental calculation, and (3) to make a drawing for each problem statement that could help someone else understand and solve the problem. Each page was divided into four parts: problem statement, 'draft' area, 'response' area and 'drawing' area. The booklets and instructions were strictly identical for both age groups.

## Coding

The successful strategies were categorized either as correct 1 -step matching strategy, or as correct 3 -step complementation strategy. A problem was considered correct when the expected result was obtained and accompanied by calculations ${ }^{1}$. Regarding the drawings, we designed an 8-item rating scale evaluating to what extent the drawings possessed ordinal versus cardinal characteristics. The scale included 4 cardinal items (Figure 4.a) and 4 ordinal items (Figure 4.b). The items were chosen so that they would either depict unordered elements being grouped in sets, or ordered elements being described as positions on an axis and compared along this axis.

Figure 4: Coding grids for cardinal (a) and ordinal (b) features.

[^83]Each drawing, including those of failed problems, was scored by two independent raters who were not familiar with the theories at play and ignored the hypotheses being tested. They were asked to rate the drawings according to the 8 items scale resulting from the aggregation of Figures 4.a and 4.b. After an initial rating phase, the percent agreement between the two raters was of $91.87 \%$. An inter-rater reliability analysis using Cohen's Kappa statistic showed substantial agreement between raters. $(\kappa=0.61, S E=0.14)$, according to Landis \& Koch's typology (1977). After discussion, the raters reached $100 \%$ agreement. For each drawing, a score was then calculated by subtracting the number of cardinal items to the number of ordinal items, thus creating a scale ranging from -4 (the most cardinal) to +4 (the most ordinal).

## Results

Our first hypothesis was that problems with ordinal quantities should facilitate the use of the matching 1-step strategy compared to problems with cardinal quantities.

Figure 5: Children's and adults' mean rate of use of the two solving algorithms depending on the type of quantity used.

Figure 5 details the participants' use of each strategy depending on the type of quantity featured in the problems. A paired t -test revealed that the mean rate of use of the 1 -step matching strategy was higher on ordinal $(M=0.39, S D=$ 0.31 ) than on cardinal ( $M=0.08, S D=0.17$ ) problems $(t(58)=8.36, p<0.001)$. The same analyses were performed for the adults and showed that the mean rate of use of the 1step matching strategy was also higher on ordinal ( $M=0.457$, $S D=0.33)$ than on cardinal $(M=0.253, S D=0.35)$ problems $(t(51)=4.99, p<0.001)$. This confirmed that the choice of a solving algorithm is influenced by the cardinal versus ordinal nature of the quantities, and that this effect is robust among
adults. Additionally, the 1-step algorithm was significantly less used by children than by adults on cardinal $(t(109)=$ $3.48, p<0.001$, unpaired t-test) but not ordinal $(t(109)=1.10$, $p=0.27$, unpaired t-test) problems, meaning that children had significantly more difficulty than adults using the 1 -step strategy on cardinal, but not on ordinal problems.

To test our second hypothesis, we focused on the drawings made by the participants. Figure 6 details the rating of the drawings depending on the type of quantity used in the problems. The drawing score was significantly lower for drawings depicting problems with cardinal quantities ( $M=-$ $0.55, S D=0.78$ ) than for those describing problems with ordinal quantities $(M=0.06, S D=0.87, t(58)=5.61, p<$ 0.001 , paired t-test), indicating that problems using ordinal quantities led young participants to draw ordinal features (axes, intervals, etc.) at a higher ratio over cardinal features (sets, groups of elements, etc.) compared to the ordinal problems.

Figure 6: Children's and adults' mean drawing score depending on the type of quantity used in the problems. Vertical bars denote 0.95 -confidence intervals.

Similarly, among adult participants, problems with cardinal quantities $(M=-1.48, S D=0.79)$ led to a significantly lower drawing score than problems with ordinal quantities ( $M=$ $0.89, S D=0.86, t(51)=12.44, p<0.001$, paired t-test). In sum, the presence of ordinal (resp. cardinal) quantities seems to result in representations featuring a higher number of ordinal (resp. cardinal) features, in both children and adults. Of note, drawing score was significantly higher among children than among adults on cardinal problems $(t(109)=$ $6.24, p<0.001$, unpaired t -test) but significantly lower among children than among adults on ordinal problems $(t(109)=5.00, p<0.001$, unpaired t -test $)$; in other words, children included significantly less cardinal features than adults while representing cardinal problems, and significantly less ordinal features than adults when representing ordinal problems.

## Discussion

The fact that the cardinal versus ordinal distinction in problem statements influenced both children's and adults' solving strategies confirmed the robustness of these interpretative effects, even with experienced solvers who should not meet any difficulty in solving such simple problems. Indeed, children performed about half as well as adults, yet the distinction between cardinal and ordinal problems remains significant in both populations. Additionally, adults' performances were significantly higher on cardinal, but not on ordinal problems, indicating that when semantically congruent with the 1 -step strategy, world semantics help children achieve adult-like performance on the task.

The elicited drawings provided an empirical confirmation of the importance of the ordinal versus cardinal distinction in both populations. The fact that children produced drawings that had significantly fewer ordinal or cardinal features on ordinal or cardinal problems, respectively, may be attributed to a global lack of details in their drawings, which nevertheless did not prevent a significant distinction between cardinal and ordinal drawings to be revealed among children. Additionally, children may have more difficulties to produce a graphic implementation of ordinal situations, which would explain their poor ordinal score ( 0.06 ) for ordinal problems. This calls for further research on the topic.

Overall, the results of both the drawing and the solving tasks show that the participants' semantic knowledge about the quantities used in the problems (i.e. their experience with counting the number of apples in a bag, adding the price of every item on a bucket list, calculating the arrival time of their train or using the elevator) influence the encoding of arithmetic word problems. The distinction introduced between ordinal and cardinal problem statements was reflected in the representations constructed (as shown by the drawings made by the participants) and led solvers to use different solving algorithms, even when asked specifically to use the shorter strategy they could find. Furthermore, the fact that those effects could be highlighted both with young pupils and adults indicates the robustness of such encoding constraints. The ontological distinction hypothesized between ordinal and cardinal representations was thus confirmed on two complementary tasks.

The use of a double measure of the influence of the solvers' world knowledge allowed us to gather converging clues shedding light both into the abstracted representations and into the subsequently implemented algorithms. By focusing on the role of semantic properties on the initial encoding of a problem, we hope to gain a finer understanding of arithmetic problem solving in its whole, and to pave the way for accounting for the interactions between world semantics, mathematical semantics and algorithms. Understanding the determinants of problem representations is a crucial step to identify the potential pitfalls and dead ends born from semantic incongruence (Gros, Sander \& Thibaut, 2016) as well as to help develop analogical transfer between isomorphic problems by promoting semantic recoding among
the learners (Gamo, Sander \& Richard, 2010; Gros, Thibaut \& Sander, 2015). Doubtlessly, the educational opportunities resulting from a better understanding of the conditions necessary for semantic recoding and analogical transfer between problems are promising.

# Does Mandarin Spatial Metaphor for Time Influence Chinese Deaf Signers＇ Spatio－Temporal Reasoning？ 

Yan Gu ${ }^{1}$（yan．gu＠tilburguniversity．edu）<br>Yeqiu Zheng ${ }^{2}$（yeqiu．zheng＠tilburguniversity．edu）<br>Marc Swerts ${ }^{1}$（m．g．j．swerts＠tilburguniversity．edu）<br>${ }^{1}$ Tilburg center for Cognition and Communication（TiCC），Tilburg University，the Netherlands<br>${ }^{2}$ Department of Econometrics and Operations Research，Tilburg University，the Netherlands

#### Abstract

In Mandarin Chinese，the space－time word＂前／qian＂is used to express both the spatial concept of front／forward and the temporal concept of early／before（e．g．，＂前天／qian－ tian＂，literally front day，meaning the day before yesterday）． This is consistent with the fact that Mandarin speakers can gesture to the front of the body to refer to a past event，and more generally can have past－in－front space－time mappings． In Chinese Sign Languages，however，the spatial front／forward and the temporal early／before are signed differently as the sign for spatial front is only used for the spatial concept of forward，and the sign for before／past is directed to the back．In this study we investigate whether the Mandarin sagittal spatial metaphors for time influence Chinese deaf signers＇spatio－temporal reasoning．In two experiments，we found that Chinese deaf signers with higher Mandarin proficiency were more likely to interpret the Mandarin word＂前／qian＂as the temporal conception of past（Study 1），and to perform past－in－front space－time mappings（Study 2）as opposed to signers with lower Mandarin proficiency．The findings of the study not only provide within－culture evidence for the influence of language on thought，but also demonstrate that even cross－ modal space－time metaphors can have an impact on deaf－ signers＇spatio－temporal reasoning．

Keywords：space and time；Chinese deaf signers；language and thought；conceptual metaphor

## Introduction

Across cultures people use spatial representations to think about time（Bottini，Crepaldi，Casasanto，Crollen，\＆ Collignon，2015；Boroditsky，2000；Casasanto \＆ Boroditsky，2008；see reviews Bender \＆Beller，2014； Núñez，\＆Cooperrider，2013）．Most Europeans feel that the future is in front of them and the past is at their back （e．g．，Miles，Nind，\＆Macrae，2010；Ulrich et al．，2012）． Such an intuition matches the human＇s experience of walking in a certain direction，which is usually forwarding to the front，so that the passed－by path is the past and the place ahead represents the future．Interestingly，the future－ in－front and past－at－back mappings are also expressed as such in many languages．For instance，in English，one can say＂We look forward to the New Year ahead，and look back to the hard times behind（e．g．，Clark，1973；Lakoff \＆ Johnson，1980）．
However，the way of conceptualizing the past at the back and the future in the front does not generalise to all languages．For example，speakers of Aymara exhibit the opposite sagittal space－time mappings，with past things in front of them，and the future as yet unseen events behind
them．This conceptual mapping is consistent with the way they produce co－speech gestures，and with the spatial metaphors in their language，as front year in Aymara has the meaning of last year（Núñez \＆Sweetser，2006）． Interestingly，Moroccans also have a strong tendency to place past events in front，even though in Arabic the front／back time metaphors are similar to most future－in－ front languages such as English．It has been argued that the reason for Moroccans＇past－in－front space－time mapping is that，in their culture，tradition and old generations are more valued．Thus space－time mappings in people＇s minds are conditioned by their cultural attitudes towards time（e．g．，with a strong focus on past times and old generations）．It is claimed that the mental space－time mappings are dependent on attentional focus and can be independent from the space－time mappings expressed in language（de la Fuente，Santiago，Román， Dumitrache，\＆Casasanto，2014）．Moreover，a recent study on Mandarin speakers shows that there are both long－term effects of cultural attitudes on the spatialization of time，and immediate effects of lexical cues to space－ time metaphors which can probe people＇s mental representations（Gu，Zheng，\＆Swerts，2016）．

Despite the fact that a growing number of studies have shown that linguistic，cultural and bodily experiences have separate influences on people＇s spatial representation of time（e．g．，Boroditsky，2001；Casasanto，\＆Bottini， 2014；Fuhrman \＆Boroditsky，2010；Núñez \＆Sweetser， 2006；Núñez，Cooperrider，Doan，\＆Wassmann，2012；Saj， Fuhrman，Vuilleumier，\＆Boroditsky，2014；Torralbo， Santiago，\＆Lupáñez，2006），our knowledge on why some communities adopt a future－in－front mapping whereas others a past－in－front mapping for time is still incomplete． For instance，very few studies have researched deaf signers＇spatio－temporal reasoning．

Sign language speakers also tend to use spatio－temporal metaphors to express time．For instance，signers＇bodies are often referred to as a deictic reference of now，and the future is signed to the front（e．g，the American Sign Language，Emmorey，2001）relative to the signer＇s body， and the past to the back（e．g．，the French Sign Language， Maeder \＆Loncke，1996；the Spanish Sign Language Pereiro \＆Soneira，2004）．At first sight，it would seem reasonable to assume that the metaphorical timelines in those sign languages would agree with the way these are used in the corresponding spoken languages．

Interestingly，there are dramatic differences in the deictic sagittal timelines between the Chinese Signed Language（CSL）and Mandarin Chinese．In Mandarin

Chinese，the sagittal space－time word＂前／qian＂indicates both the spatial concept of forward／front and the temporal concept of early／before（Yu，2012）（e．g．，＂前天／qian tian＂， literally：front day，meaning：the day before yesterday）．A case study on gestural behaviour has shown that Mandarin speakers can point to the back or front of their body to refer to the conception of before，depending on whether the language suggests an ego－moving perspective（e．g．， We are running to the future ahead．）or a time－moving perspective（e．g．，The future is coming．）（Chui，2011）． Recent quantitative research，on the other hand，finds that Mandarin speakers are more likely to gesture the past to the front when referring to temporal expressions with the sagittal space－time word（前／qian）（Gu，Mol，Hoetjes，\＆ Swerts，in prep）．Partially due to this lexical effect，some Mandarin speakers even explicitly report to believe the past to be positioned behind and the future in front of them（Gu，Zheng，\＆Swerts，2016）．
In CSLs，however，the spatial forward and the temporal early／before are signed differently，i．e．，the sign of front is only used for the spatial concept of forward，whereas the concept of before／past is signed towards the back（e．g．， Zheng，2009；Wu \＆Li，2012）．In other words，in their lexicon，deaf signers only have the past－at－back space－ time mappings，which is different from Mandarin speakers who additionally have past－in－front mappings （Table1）．As deaf signers learn the spatial concepts earlier than the abstract concepts of time，it is plausible that if a signer has not acquired the Mandarin space－time word（前 ／qian）as a temporal past conception，s／he is likely to interpret the word as a spatial concept of forward，which is consistent with that in CSL（front in the space）．By contrast，if a signer has acquired the space－time word as a temporal past conception，s／he is likely to map the past to the back as suggested by the CLS past－at－back mappings， or s／he may also establish new space－time mappings with the past in the front，similar to Mandarin speakers．

Table 1：Differences between Mandarin Chinese and Standard CSL in sagittal spatio－temporal metaphors．

| Mandarin | Front（space） | The day before <br> yesterday（time） |
| :--- | :--- | :--- |
|  | 前面（front surface） | 前天（front day） |
|  | One hand with the <br> index finger extended， <br> point to the very front． | The ingers point to the |

Note：The spatial concept of front in Mandarin is consistent with that in CSL．Figures of signs are reproduced from the CSL， 2003

Given the cross－linguistic differences in space－time metaphors between Mandarin Chinese and CSL，and given that learning a new category of spatial metaphors for time may influence one＇s mental representation of time（Boroditsky，2001），this paper aims to study（1） whether the differences in space－time metaphors between Mandarin Chinese and CSL influence Chinese deaf signers＇understanding of time；（2）in the context of

Chinese culture，whether the acquisition of Mandarin sagittal spatial metaphors leads Chinese deaf signers to a change in space－time mappings．To this end，we have conducted two studies：study 1 used a clock question to test how Chinese deaf signers interpret the sagittal space－ time word 前／qian（spatial front or temporal before）；study 2 used a temporal diagram task to explicitly examine Chinese deaf signers＇space－time mapping．

## Study 1：The Clock Question

## Method

## Participants

15 deaf signers $(\mathrm{F}=8)$ from Rizhao Special Education School participated in the experiment．They were fluent users of Standard CSL．They studied in different grades at school，ranging from the $4^{\text {th }}$ grade to $9^{\text {th }}$ grade（ $M=7.5$ ）． Their mean age was 17.6 years（ $S D=2.9$ ）．The average hearing loss was moderate－severe，as reported by the signers themselves and their teacher（ $M=3.8,1$－Slight，2－ Mild，3－Moderate，4－Moderately Severe，5－Severe，6－ Profound）．Permission was granted to the investigators to have access to the participants＇Mandarin Chinese exam scores from the record of their last end－term exam．

## Materials and Procedure

Singers were given a questionnaire to fill in personal information and family background．The instructions were not in sign language but in written Mandarin．In the middle of the questionnaire，there was a clock question （Table 2）．The sagittal space－time word 前qian（literally front／forward or temporally before）in this question is somewhat ambiguous in meaning though mainly used as a temporal expression．Most Mandarin speakers will interpret the question as moving the clock one hour beforelearlier，thus answering the question as 12 AM （Lai \＆Boroditsky，2013）．However，if deaf signers think of the space－time word（前／qian）as a spatial front，then they are likely to move the clock one hour forward，thus giving 2 PM as an answer．It is also assumed that deaf signers of higher Mandarin proficiency levels are more likely to interpret the space－time word as a temporal past，as opposed to signers of lower Mandarin proficiency levels．

Table 2：The clock question in Mandarin and English．

## Data Analysis

Data of two participants were excluded from the analysis， as they did not fully complete the questionnaire．As a dependent variable，we counted participants＇responses to the clock question（answer： 12 AM or 2 PM ）．

We would discuss below how those responses were moderated by possible factors．The first and most important factor was participants＇Mandarin proficiency level．It was mainly measured by the school grade level in which a deaf signer was studying（grade），as a deaf signer studying in a higher grade was expected to have a higher Mandarin proficiency level than a signer studying in a lower grade．Second，signers＇Mandarin exam score（exam score）was used to supplement the proficiency measurement，albeit that the exam papers and intrinsic difficulty of tests were different across grades．

Additionally，given that age can influence individual＇s sagittal spatial－temporal reasoning（de la Fuente et al．， 2014），we controlled for age as a possible factor． Participants＇hearing loss and their parents＇deafness （deaf parents）were also considered to be factors that may influence participants＇space－time mappings．

## Results and Discussion

About $70 \%$ of participants（ 9 out of the 13 deaf signers） responded according to the spatial understanding of the word＂前／qian＂（forward），giving 2 PM as an answer．In comparison to the $13 \%$（ 3 out of 24）of Mandarin monolinguals in Lai \＆Boroditsky（2013）＇s study， Chinese deaf signers were significantly more likely to give an answer of 2 PM than Mandarin monolinguals （Fisher exact test，$p=.001$ ，Odds Ratio $=15.75,95 \% \mathrm{CI}=$ ［2．91，85．22］）．Given that these deaf signers have already learned Mandarin temporal conceptions in low grades， this indicated that participants may still be influenced by the spatial sign of front from their CSL．

Furthermore，we tested whether Mandarin proficiency influenced signers＇understanding of the space－time word （前／qian）．The results showed that the factor grade was significant $(\beta=.387, t=3.01, p=.020,95 \% \mathrm{CI}=$ ［．083，．691］），while controlling for the other factors exam score，age，deaf parents and hearing loss（Table 3）．This indicated that those higher graders were more inclined to interpret the space－time word（前／qian）as temporal before （ 12 AM）．Assuming that higher graders are likely to have higher Mandarin proficiency levels than lower graders， the effect of grade suggests that signers＇Mandarin proficiency levels play a role in shaping their understanding of the conceptions of the space－time word （前／qian）．A seemingly contradictory finding is that exam score was not significant $(\beta=-.0002, t=-.020, p=.985$ ， $95 \% \mathrm{CI}=[-.019, .019])$ ，keeping all other variables constant．This might be due to the fact that there was only limited variation in Mandarin proficiency within a grade．

Table 3：Results of the clock question．

| clock | Coef． | $\mathbf{t}$ | $\mathbf{P > t}$ | ［ 95\％CI ］ |  |
| :--- | :--- | :--- | :--- | :--- | :--- |
| grade | .387 | 3.01 | $\mathbf{. 0 2} * *$ | .083 | .691 |
| exam＿score | -.0002 | -.02 | .985 | -.019 | .019 |
| age | -.029 | -0.69 | .515 | -.129 | .071 |
| deaf＿parents | -.176 | -0.75 | .479 | -.731 | .380 |
| hearing＿loss | -.231 | -1.84 | .108 | -.528 | .066 |
| ＿cons | -1.20 | -1.76 | .122 | -2.83 | .413 |
| Note：${ }^{*} p<.1,{ }^{* *} p<.05$ |  |  |  |  |  |

The fact that signers with lower Mandarin proficiency levels were more likely to give an answer of 2 PM may be caused by their use of spatial reference of front（primarily be triggered by lexical cues），though this does not necessarily imply that they also explicitly conceptualise the future as in front of them．Study 2 investigated the Chinese deaf signers＇sagittal space－time mappings using a more explicit temporal diagram task．

## Study 2：A Temporal Diagram Task

## Method

## Participants

All participants in study 1 took part in study $2 .{ }^{1}$

## Materials and Procedure

Participants performed a temporal diagram task（de la Fuente et al．，2014，Experiment 1），which has been adapted and used in Gu，Zheng，and Swerts（2016）＇s study． They sat at a table and saw a toy doll（named Xiaoming） with one box behind and one box in front of it． Participants and the character faced the same sagittal direction（Fig．1）．Participants were provided with a written instruction in which they could read that the day before yesterday（前天／qian－tian，tr．front day）Xiaoming went to visit a friend who liked eating apples，and the day after tomorrow（后天／hou－tian，tr．back day）he would be going to visit a friend who likes eating pears．Participants were given an apple and a pear and were instructed to put the apple in the box that corresponded to the past（以前 ／yi－qian，tr．to front）and the pear to the box that corresponded to the future（今后／jin－hou，tr．now back）． The mentioning order of the apple and pear and the way they were paired with the day before yesterday or the day after tomorrow were counterbalanced．Note that there was no ambiguity in the interpretation of the space－time words in this instruction（cf．study 1），e．g．，the concept of the space－time expression＂前天／qian－tian＂，tr．front day can only be interpreted as the day before yesterday．

Figure 1：Schematic setting up of the Experiment reproduced from Gu，Zheng，\＆Swerts（2016）．

Following Gu，Zheng，\＆Swerts（2016）＇s procedure，we asked participants to perform the task with real entities rather than doing it on paper（cf．de la Fuente et al．，2014）．

[^84]This can minimise the potential projection of vertical timelines into the sagittal axis (as Chinese can conceptualise time vertically, mapping the $u p$ and down to the time conceptions of early and late, e.g., Boroditsky 2001; Gu, Mol, Hoetjes, \& Swerts, 2017). Participants were tested individually in Rizhao, China, and all instructions were not in sign language but in written Mandarin Chinese. After all tasks, they were given a small token of appreciation and signed a consent form.

## Data Analysis

In total, data of fourteen participants were used in the analysis (Data from a $4^{\text {th }}$ grader was excluded as she was helped during the task). The dependent variable was participants' responses towards space-time mappings (past-in-front or past-at-back).

As was the case with the previous experiment, we again controlled for possible factors such as participants' exam score, grade, age, hearing loss and deaf parents.

## Results and Discussion

$42.9 \%$ of participants responded according to the past-infront mapping, placing the past event in the box in front of the character and the future event in the box behind it. Although this rate was not significantly different from $50 \%, p=.79$, Odds Ratio $=.75,95 \% \mathrm{CI}=[.18, .71](N=$ 14), we expect it to be significant with a larger sample size. It is unlikely that deaf signers randomly performed the space-time mappings by chance, as shown below.

As we further examined the relationship between signers' Mandarin proficiency and their responses towards space-time mappings, controlling for deaf parents, age and hearing loss, the results showed that grade and exam score were significantly positive (Table 4). Specifically, first, higher graders had a stronger tendency to perform past-in-front mappings ( $\beta=.34, t=2.61, p=.031,95 \%$ $\mathrm{CI}=[.039, .641])$, keeping all other variables constant. Second, those who had higher Mandarin exam scores were more inclined to respond towards past-in-front mappings ( $\beta=.008, t=2.04, p=.075$ (two-tailed), $95 \%$ $\mathrm{CI}=[-.001, .017])$, ceteris paribus. The results indicated that Mandarin proficiency has an effect on signers' spacetime mappings, both between different grades and within a grade. In other words, despite the fact that there are only past-at-back spatio-temporal signs in CSL, deaf signers can gradually establish the Mandarin past-in-front spacetime mappings during their learning process of Mandarin.

Table 4: Results of the temporal diagram task.

| pastfront | Coef. | t | $\mathrm{P}>\mathrm{t}$ | [ 95\% CI ] |  |
| :--- | :--- | :--- | :--- | :--- | :--- |
| grade | .340 | 2.61 | $\mathbf{. 0 3 1 * *}$ | .0391 | .641 |
| exam_score | .008 | 2.04 | $\mathbf{. 0 7 5} *$ | -.001 | .017 |
| age | -.047 | -1.53 | .163 | -.119 | .024 |
| deaf_parents | -.477 | -2.04 | $\mathbf{. 0 7 5} *$ | -1.015 | .062 |
| hearing_loss | -.051 | -.37 | .724 | -.372 | .270 |
| _cons | -1.52 | -4.38 | .002 | -2.32 | -.722 |
| Note: ${ }^{*} p<.1, * * p<.05$ |  |  |  |  |  |

Additionally, those signers whose parents were deaf
were less likely to perform past-in-front mappings ( $\beta=$ $.48, t=-2.04, p=.075$ (two-tailed), $95 \% \mathrm{CI}=[-$ $1.015, .062]$ ), ceteris paribus. The results suggested that deaf parents may influence deaf children's space-time mappings. This is plausible, as deaf children may often be exposed to the past-at-back temporal signs performed by their deaf parents. Consequently, they may be more likely to have past-at-back space-time mappings than their counterparts with non-deaf parents.

## General Discussion

In study 1 , we used a clock experiment to examine how Chinese deaf signers interpreted Mandarin spatial metaphor of time. We observed effects of both CSL and learning Mandarin Chinese on their understanding of time. There is a co-activation of signs even in the non-signing linguistic contexts, whereas within the signers' group, those with higher Mandarin proficiency levels were more likely to interpret the space-time word 前/qian as temporal before (like Mandarin speakers). Our results suggest that language transfer occurs across modalities (i.e., a spoken language and a sign language, cf. bimodal bilinguals, Emmorey, Borinstein, Thompson, \& Gollan, 2008).

Alternatively, the results can also be explained in terms of differences in time perspective-taking (e.g., Gentner, Imai, \& Boroditsky, 2002; Moore, 2011; Núñez, Motz, \& Teuscher, 2006; Walker, Bergen, \& Núñez, 2017), which would be consistent with claims of a previous study on Mandarin-English sequential bilinguals (Lai \& Boroditsky, 2013). Similar as in CSL, in English the spatial front usually does not have a meaning of temporal before. That study found that Mandarin-English speakers were influenced by English when answering the clock question in Mandarin, such that Mandarin-English speakers were less likely to answer the clock question as 12 AM , in comparison with what Mandarin monolinguals did According to Lai and Boroditsky (2013), Mandarin speakers mostly take the time-moving perspective (12 AM), whereas English speakers mostly take the egomoving perspective ( 2 PM ). If monolingual signers of CSL mainly take the ego-moving time perspective in deictic time, it is possible that they gradually gain the time-moving perspective after learning Mandarin Chinese.

In study 2, we used a temporal diagram task to explicitly test deaf signers' sagittal space-time mappings. We found that some singers performed past-in-front space-time mappings. Given that Mandarin speakers also have past-in-front mappings (Gu, Zheng, \& Swerts, 2016), the pattern of signers' space-time mappings may be due to a characteristic of the Chinese culture, in which people give more importance to tradition and focus more on the past (Guo, Ji., Spina, \& Zhang, 2012), analogous to what appears to be true for Moroccans. However, within the Chinese culture, we found that the extent to which signers performed past-in-front mappings was positively related to their Mandarin proficiency. Similar to the results of the clock question, we found effects of Mandarin proficiency on Chinese signers' spatio-temporal reasoning, which suggests that learning a novel linguistic spatial metaphor for time may foster a new way of thinking about time (Boroditsky, 2001; Hendricks \& Boroditsky, 2015).

Future studies can further examine this using a non－ linguistic task（e．g．，Fuhrman \＆Boroditsky，2010）．

Alternatively，according to the temporal－focus hypothesis（de la Fuente et al．，2014），cultural attitudes towards time exert an important influence on people＇s space－time mappings．One may argue that the typical Chinese culture is more past－focused than that of the Chinese deaf culture，although this needs a further survey． Given such an assumption，signers may gradually adjust themselves into the mainstream Chinese culture and hence become more similar to the Mandarin speakers．Future study can additionally control for signers＇temporal－focus of attention to corroborate the present findings．
Note that in Standard CSL，there are no sign metaphors that reflect past－in－front space－time mappings but only signs for past－at－back mappings．It would therefore be ideal if we could supplement the current set of results with those obtained from a control group of monolingual deaf signers of CSL to provide stronger evidence that deaf signers indeed think of the past as being situated at the back，though，practically，we can hardly find a group of deaf signers who do not know Mandarin Chinese．Future research may also study illiterate hearing Mandarin speakers to at least examine the effects of written Mandarin proficiency on people＇s spatial－temporal conceptualisations．By contrast，in our study，we found that a certain proportion of Chinese deaf signers put the entity corresponding to the past in the front．Additionally， the effects of exam score and study grade clearly suggest that Chinese deaf signers can gradually＂learn＂to have past－in－front mappings as a function of an improved Mandarin proficiency．This is an intriguing finding as it shows that within the Chinese culture，learning a spatial metaphor in a different modality can still influence people＇s mental representations of time．
Furthermore，the past－in－front mappings performed by the deaf signers in the temporal diagram task can be argued to be a consequence of a direct translation of the spatial conception of front in the Standard CSL，thus characterising the results as merely an effect of language interferences without reference to the differences in spatio－temporal reasoning．For example，participants may simply interpret the sagittal space－time word（前／qian）as front in space rather than understanding the concept of space－time expression（前天／qian－tian，front day）as the past conception of the day before yesterday，though the conception of front day is not ambiguous at all．This is， however，quite unlikely．First，the instructions were checked beforehand by their teacher to ensure that those participants have previously learned all the vocabulary and would be able to understand the sentences and the concept of front day．Second，if deaf signers would have done a direct translation，those signers of lower Mandarin proficiency levels should be more likely to translate the space－time word（前／qian）as front，thus would produce a larger proportion of past－in－front mappings．However， quite on the contrary，we found that deaf signers of lower Mandarin proficiency levels or studying in lower grades were actually more inclined to perform past－at－back mappings，which was consistent with the CSL where the past is signed towards the back．This indicates that
participants even with a low Mandarin proficiency can already understand that front day is a temporal concept． Therefore，needless to say for the higher proficient group， the tendency of having past－in－front space－time mappings likely reflects their spatio－temporal reasoning．

Moreover，it is possible that deaf signers have to rely on their vision heavily as a result of the hearing loss． Consequently，this may trigger a stronger effect to consider things that they have seen in front of them as the past whereas the events that have not seen as the future behind them（cf．Aymara speakers，Núñez \＆Sweetser， 2006）．Apparently，this explanation does not hold for deaf people universally，as deaf users of many other sign languages（e．g．，ASL，FSL）do not exhibit a tendency towards past－in－front space－time mappings．

Additionally，we conducted both studies in Mandarin Chinese rather than in CSL．It would be interesting to ask the deaf signers to fulfil the temporal diagram task with a sign language instruction，the results of which probably can also reveal the effect of Mandarin Chinese on deaf signers＇spatio－temporal reasoning，even when signers think in CSL．Possibly，participants may be visually primed by the spatial movements of the signs in the instruction，for example，for the clock question the CSL will give a strong hint where the clock hand is moving in the signs（either a clockwise or an anti－clockwise movement）．This will not allow us to examine signers＇ authentic interpretation of the sagittal space－time word． Furthermore，the sign for front day（the day before yesterday）is signed as two fingers pointing to the back of the body，hinting a past－at－back space－time mapping．

## Conclusions

In the current study we investigate whether the Mandarin sagittal space－time metaphors influence Chinese deaf signers＇spatio－temporal reasoning．In two experiments， we found that signers with higher Mandarin proficiency were more likely to interpret the Mandarin space－time word（前／qian）as temporal before（Study 1），and to perform past－in－front space－time mappings（Study 2），in comparisons to signers with lower Mandarin proficiency． These findings not only provide within－culture evidence for the influence of language on thought（cf．Boroditsky， 2001；Hendricks \＆Boroditsky，2015），but also demonstrate that even cross－modal space－time metaphors can have an impact on signers＇spatio－temporal reasoning．

# Language and Spatial Memory in Japanese and English 

Harmen Gudde<br>University of East Anglia

## Kenny Coventry

University of East Anglia

#### Abstract

Demonstratives are among the most frequent words in all languages, but demonstrative systems vary considerably between languages. In two experiments, we tested demonstrative use and the influence of demonstratives on spatial memory in Japanese and English - languages with purportedly very different demonstrative systems. Participants engaged in a 'memory game', tapping their use of demonstratives to describe objects located on a sagittal plane (Experiment 1 ) and the influence of demonstratives on memory for object location (Experiment 2). In addition to distance from speaker, the experiments also manipulated the position of a conspecific (next to or opposite participants). Distance and position of conspecific both affected demonstrative choice and memory in Japanese, with similar effects in English even though English does not explicitly encode the position of a conspecific. We discuss possible universals underlying demonstrative systems and the influence of language on memory.

# A Computational Model for the Dynamical Learning of Event Taxonomies 

Christian Gumbsch (christian@gumbsch.de)<br>Sebastian Otte (sebastian.otte@uni-tuebingen.de)<br>Martin V. Butz (martin.butz@uni-tuebingen.de)<br>Chair of Cognitive Modeling, Department of Computer Science and Department of Psychology, Faculty of Science, Eberhard Karls University of Tübingen, Tübingen, Germany

#### Abstract

We present a computational model that can learn event taxonomies online from the continuous sensorimotor information flow perceived by an agent while interacting with its environment. Our model implements two fundamental learning biases. First, it learns probabilistic event models as temporal sensorimotor forward models and event transition models, which predict event model transitions given particular perceptual circumstances. Second, learning is based on the principle of minimizing free energy, which is further biased towards the detection of free energy transients. As a result, the algorithm forms conceptual structures that encode events and event boundaries. We show that event taxonomies can emerge when the algorithm is run on multiple levels of precision. Moreover, we show that generally any type of forward model can be used, as long as it learns sufficiently fast. Finally, we show that the developed structures can be used to hierarchically plan goaldirected behavior by means of active inference.

Keywords: event models; object interaction; predictive encoding; event segmentation; free energy; active inference; event taxonomy; concept learning

## Introduction

Event segmentation theory (EST) (Zacks \& Tversky, 2001; Zacks, Speer, Swallow, Braver, \& Reynolds, 2007) postulates that humans automatically structure the stream of sensory and sensorimotor information into meaningful events. Events are defined as "a segment of time at a given location that is conceived by an observer to have a beginning and an end" (Zacks \& Tversky, 2001, p. 3). This definition is formulated rather broadly, containing long, abstract events (e.g. 'going on a vacation'), more concrete events (e.g. 'taking a taxi to the airport'), and very short events (e.g. 'grasping something'). Zacks and Tversky (2001) suggest that events can be organized in event taxonomies, where abstract events consist of multiple, more concrete events.

In Gumbsch, Kneissler, and Butz (2016) we proposed a system that learns events and event boundaries from the sensorimotor stream an agent experiences while interacting with its environment. Following EST, we defined predictive events (Zacks et al., 2007) as sets of forward models, i.e. internal models that predict the sensorimotor consequence of an agent's actions. Moreover, event boundaries were defined as the determining features of a situation that typically lead to a transition between events, that is, between active forward models (Butz, 2016). Events and event boundaries are encoded in a Bayesian fashion, whereby learning and updating can be closely related to the free energy minimization principle (Friston, 2009). In addition, though, the detection of event
boundaries, and the consequent possible transition to another event model, was biased towards the detection of transient free energy signals. This is closely related to the transient error principle of Zacks et al. (2007), according to which event boundaries are characterized by transient increases in the perceptual prediction error. The result is an algorithm that learns event boundaries from "surprising" perceptions. We have shown that the algorithm learns a compositional conceptual structure of the experienced environment. Algorithmically, the system monitors the current prediction error of the active forward models and registers surprise when the encountered prediction error surpasses an adaptive confidence threshold. As a result, the set of active models is changed, the relevant features that characterize the encountered event boundary are identified, the event model transitions are memorized, and new event models may be learned. We have shown that the developing model can be used to both predict sensorimotor changes and plan in a goal-directed manner.

In this paper, we generalize the established mechanism, making it more noise robust and more generally applicable beyond linear models and recursive least squares updating. Moreover, we show that the surprise signal and the noise level determine the granularity of the event segmentation. As a result, an event hierarchy can emerge naturally during this process. Finally, we explicitly derive the goal-directed planning process from formalizations of active inference (Friston, 2009; Friston et al., 2015), showing that the developing event and event boundary models are very well-suited for the invocation of inverse, hierarchical, goal-directed behavior.

## Architecture

The system architecture $S$ consists of three continuously interacting main components $\mathcal{S}=\{\mathcal{M}, \mathcal{B}, \mathcal{P}\}$. The set of event models $\mathcal{M}$ comprises all so-far learned temporal forward models. At every point in time, a subset of forward models is active, simulating and predicting the spatiotemporal changes in the environment. These spatiotemporal simulations are determined in the predicted perceptual space $P$. Event transitions are detected based on statistical evaluations of the prediction error, detecting free energy transients. They are stored in the event boundary models $\mathcal{B}$, where each model attempts to identify the critical sensory features that allow the probabilistic prediction of an event transition.

Figure 1 and Figure 2 show the three components in interaction with the outside environment and the internal moti-

Figure 1: Illustration of the system during forward modeling. An active event model predicts the perception based on the next action. The predictions are compared with the real observations and the event model is updated based on the deviation. If this deviation exceeds a threshold, a surprise is detected, the event boundary models are updated, and a transition in the event models may be triggered. Rewards experienced during transitions are registered in the motivational system and are associated with the respective event boundary.
vational system during prediction and during planning mode, respectively. While interacting with the environment, the architecture generates temporal forward predictions and learns from the registered errors (Figure 1). Inversely, the architecture can generate active inference-driven probabilistic planning by activating event boundaries as goals and inversely propagating these goals into $\mathcal{P}$ and $\mathcal{M}$, leading to the generation of goal-directed actions based on the believed knowledge about the environment (Figure 2). Due to the developing event-based predictive environmental model, hierarchical, conceptual planning becomes possible.

## Model components and functionality

Event models $m \in \mathcal{M}$ are encoded as sets of $N$ forward models, given an $N$-dimensional observational space. At a certain point in time $t$ one event model $m(t)$ is active, with $m(t)=\left(m_{1}^{v}, m_{2}^{v}, \ldots, m_{N}^{v}\right)$, where $m_{i}^{v}$ references the currently active forward model component with respect to a particular dimension $i$. Each active forward model $m_{i}^{v}$ predicts the changes in one dimension of the sensory observation $\Delta o_{i}^{\prime}(t)$, given a particular action $a(t)$. After executing $a(t)$, the real observation $o(t+1)$ is compared with the predicted observation $o^{\prime}(t+1)=o(t)+\Delta o^{\prime}(t)$. As a result, the active forward models in $m(t)$ are updated based on the error signal to improve the respective forward models. To maintain minimal additional statistics, each forward model $m_{i}^{v}$ stores the moving average (currently fixed over the last 100 steps) of its prediction error $\bar{e}\left(m_{i}^{v}\right)$, and the moving average of the variance of that prediction error $\bar{\sigma}^{2}\left(m_{i}^{v}\right)$, thus estimating the first three moments of the model's predictions.

Event boundaries $b \in \mathcal{B}$ are represented as top-down generative predictive models, which probabilistically predict the
perceptual features of the environment that are relevant for enabling or causing the transition from one particular event $v$ to another one $\mu$, i.e. $P\left(o \mid m_{i}^{v} \rightarrow m_{i}^{\mu}\right)$. Thus, the models currently assume that all relevant information for the occurrence of an event boundary is observable when an event model transition occurs. In our current implementation, we model these event transitions by means of multivariate Gaussians.

As a result, at any point in time $t$ the generative model of the system is in a particular state $s(t)=$ $\left\{m(t), P(\mathcal{B}), \mathbf{o}(\mathbf{t}), \mathbf{o}^{\prime}(\mathbf{t})\right\}$, where $m(t)$ denotes the current vector of active forward models (winners take all), $P(\mathcal{B})$ denotes the probability mass over possible event boundaries, and $\mathbf{o}(\mathbf{t})$ and $\mathbf{o}^{\prime}(\mathbf{t})$ denote observation densities.

## Simulation and inference-based learning

While interacting with the environment, the system develops its predictive models $\mathcal{M}$ and $\mathcal{B}$, which are updated and improved based on the comparisons between predicted and actually encountered observations in $\mathcal{P}$ (illustrated in Figure 1). Event models are updated by standard gradient descent techniques, seeing that we face a self-supervised learning problem. We evaluate recursive least squares as well as delta-rule based gradient descent-based event models.

Event boundaries are detected by a sudden, significant rise of the prediction error above the tolerated uncertainty. The prediction error $e_{i}(t)$ of sensory dimension $i$ at time step $t$ is considered "surprising" when

$$
\begin{equation*}
e_{i}(t)>\bar{e}\left(m_{i}^{v}\right)+\theta \bar{\sigma}\left(m_{i}^{v}\right) \tag{1}
\end{equation*}
$$

with $m_{i}^{\nu}$ denoting the active forward model of dimension $i$ and $\theta$ the confidence-dependent surprise threshold. This threshold essentially determines when an error is considered significant depending on the currently estimated standard deviation, i.e. the inverse confidence or precision, of the respective forward model. It modulates the granularity of the event segmentation performed by our system, which in turn strongly influences how accurately each ongoing event is predicted.

If a surprise-signal is detected, the system is allowed to switch the active forward models $m(t)$. The system enters a searching period during which the next active models are determined. To do so, all existing forward models $m_{i}$ of dimension $i$ are taken into consideration. For a fixed number of time steps (10 time steps in our simulations) each model predicts the change in observation and is updated. After this search period, if the prediction error is still considered "surprising" by all existing forward models (determined by Eq. 1), a new forward model is generated and added to the possible forward models $m_{i}$. On the other hand, if the prediction error is not surprising for at least one existing model, the forward model $m_{i}^{\mu}$ with the smallest mean error is chosen as the new forward model for dimension $i$.

To summarize, our generative model space essentially consists of a set of temporal forward models $\mathscr{M}$ and a set of probabilistic transition models $\mathcal{B}$, that is, event boundary models. To minimize free energy, the validity of each temporal forward model is optimized by gradient descent - maximizing

Figure 2: Illustration of the system during planning. Based on the system's goal, an event boundary is chosen. The required perception to reach this boundary is compared with the currently predicted perception and the necessary perceptual change is computed. If this change can be achieved by the active event model, a suitable motor command is determined. Otherwise, a new model to fulfill this change is chosen and the event boundary to reach this new model is determined, proceeding recursively.
its predictive accuracy in its applicable subspace. Combined with its current minimal statistics (first three moments), the temporal forward models can be viewed as Gaussian densities, which are optimized approximately optimally based on the incoming sensory feedback (Kneissler, Drugowitsch, Friston, \& Butz, 2015). Additionally, the approach has - as a structural prior - the assumption that temporal forward models will be typically applicable during an extended period of time and that transitions between forward models can be characterized by event boundaries (Butz, 2016). As a result, event boundaries are optimized such that free energy can be minimized equally well in all subspaces of the environment.

## Goal-directed behavior

To invoke goal-directed behavior, we add a simple "motivational" system to the architecture, which associates model states with changes in its internal motivational state (Butz, Shirinov, \& Reif, 2010). In the current implementation, we simplify this part by associating particular motivations with particular event boundaries, such as the disappearance of food due to its consumption. Thus, when goal-directed planning is invoked, a desired event boundary is activated and inversely propagated through the system's generative model.

Formally, we can infer the optimal behavioral policy $\pi$ by assigning a value to all imaginable policies given the current beliefs of the model and choosing the best one:

$$
\begin{align*}
& Q_{\tau}\left(\pi, s_{t}\right)=-E_{\pi}\left[H\left(P\left(o_{\tau} \mid s_{\tau}\right)\right)\right]- \\
& D_{K L}\left[P\left(o_{\tau} \mid s_{\tau}\right)| | P\left(o_{\tau} \mid s_{G}\right)\right] \tag{2}
\end{align*}
$$

which is based on (Friston et al., 2015). This formulation essentially states that a policy $\pi$, starting at believed situational
system state $s_{t}$, will result in the minimization of free energy by minimizing (i) predicted uncertainty over the expected unfolding successive states up to a certain temporal horizon $T$ into the future $\tau=\{t, t+1, \ldots, T\}$ measured by the entropy $H\left(P\left(o_{\tau} \mid s_{\tau}\right)\right)$ over expected states $s_{\tau}$ when pursuing policy $\pi$ and (ii) the divergence, formulated as the Kullback-Leibler divergence $D_{K L}$, between expected future observations and desired future observations given a goal state distribution $s_{G}$, i.e. $P\left(o_{\tau} \mid s_{G}\right)$.

When we fully focus behavior on maximizing reward outcomes, ignoring uncertainties in our expected progression through the environment, it is possible to cancel out the term $E_{\pi}\left[H\left(P\left(o_{\tau} \mid s_{\tau}\right)\right)\right]$ in $D_{K L}$, yielding:

$$
\begin{equation*}
Q_{\tau}^{\prime}\left(\pi, s_{t}\right)=P\left(o_{\tau} \mid s_{\tau}\right) \ln P\left(o_{\tau} \mid s_{G}\right) \tag{3}
\end{equation*}
$$

As a result, the goal is to maximize the overlap between these two probability densities.

In our model's case, $P\left(o_{\tau} \mid s_{G}\right)$ will correspond to a particular model transition $m_{g}^{\nu} \rightarrow m_{g}^{\mu}$ and all other model transitions will be set to zero for all future points in time $\tau$. As a consequence, the model essentially "wants" to maximize

$$
\begin{equation*}
P\left(m_{i}^{\vee} \rightarrow m_{i}^{\mu} \mid s_{\tau}\right) \tag{4}
\end{equation*}
$$

i.e. the probability of the model transition $m_{i}^{\nu} \rightarrow m_{i}^{\mu}$. This corresponds to first maximizing $P\left(m_{i}^{\vee} \mid s_{\tau}\right)$, that is, being in model $m_{i}^{v}$ and then maximizing the likelihood of the transition, which, in turn, corresponds to maximizing the probability of the observation that characterizes the transition, that is, $P\left(\mathbf{o}_{\tau} \mid m_{i}^{v} \rightarrow m_{i}^{\mu}\right)$. Thus, given the current state of the model $s(t)$, the inference process may directly yield motor actions that attempt to maximize $P\left(\mathbf{o}_{\tau} \mid m_{i}^{\nu} \rightarrow m_{i}^{\mu}\right)$ if this seems possible given the current event model state. However, when the event model $m_{i}^{v}$ is currently not active, then a recursive process must start that selects another model transition $P\left(m_{i}^{\nu^{\prime}} \rightarrow m_{i}^{v}\right)$ in order to reach the goal transition by first invoking an intermediate transition (illustrated in Figure 2).

As a result, hierarchical, conceptual goal-directed probabilistic inference-based planning is implemented, which invokes event boundaries as subgoals, given the final goal cannot be reached by the currently available control options. For example, the model can infer that if it wants to drink out of a mug but the mug is not in the hands, the mug first needs to be approached and grasped before it can be transported to the mouth. Note that the recursive planning procedure, in principle, can find any sequence of events and event boundaries, which are believed to lead to the goal. However, time and space as well as precision limitations may generally apply when propagating the active inference signals through the system architecture $\mathcal{S}$.

## Evaluation

To investigate the event segmentation and hierarchical planning capabilities of our system, we have chosen a testing scenario, in which a simulated agent, operating in continuous space, can interact with different objects in multiple ways

Figure 3: The evaluation scenario: Objects (here a sticky object) are generated in the white area and vanish when they enter the black, rectangular mouth area. The blue hand is able to grasp or attach objects. They are detached from the hand once they are inside the red "release-area" cube.
(Figure 3). The agent consists of a hand with three shovellike fingers and a stationary "mouth". The hand is able to move freely through a limited 3-dimensional workspace with a "release-area". Three types of differently colored objects appear in our simulation (two types of "sticky objects" and one type of "marble"). Sticky objects are big and spiky. They automatically attach to the hand upon contact. Once attached they are dragged alongside the hand until they enter the release-area, wherein they detach and drop into the mouth. We use two types of sticky objects in our simulation: light objects do not alter the hand movement when attached to it; heavy ones slow down the hand movement by a factor of $\frac{1}{4}$. Marbles are small spheres that need to be grasped to be transported by the hand. To grasp a marble the hand has to be positioned directly over a marble for a grasping reflex to activate. The fingers open again when the marble is inside the release-area. Carrying a marble is usually far more difficult to predict than dragging a sticky object, since marbles sit loosely between the fingers and shake while being transported. If an object is dropped into the mouth, it is consumed and a new object is generated. In our scenario the system is rewarded once an object is consumed. Thus, to receive rewards, the agent has to attach or grasp the present object, transport it to the release-area, and drop it into the mouth.

In every time step $t$, a motoric action $a(t)$ is performed and a sensory observation $o(t)$ is perceived. In particular $o(t)$ consists of the position of the hand $x_{h}, y_{h}, z_{h} \in[-100,100]$, the position of the object $x_{o}, y_{o}, z_{o} \in[-100,100]$, and the position of the object in a hand-centered frame of reference $x_{o, h}, y_{o, h}, z_{o, h} \in[-200,200]$. Additionally $o(t)$ contains the color of the object and boolean information whether the object has spikes or not. The motor command $a(t)$ determines the change in hand position $\Delta x_{h}, \Delta y_{h}, \Delta z_{h} \in[-1,1]$. Furthermore, $a(t)$ contains the velocity of the object to enable computation of the object's next position even while it is falling.

To evaluate the system, we investigate how the learning capabilities depend on the underlying learning rule. Therefore,
we learn the forward models, currently linear prediction models, both by means of delta rule based gradient descent (learning rate $\eta=0.1$, momentum term $\alpha=0.9$, linear activation function) as well as by means of recursive least squares (RLS) (forgetting factor $\lambda=0.99$ ). RLS essentially implements an adaptive filter that minimizes the sum of squared residuals recursively in an optimal online fashion. Furthermore, we show that both the threshold $\theta$ and sensory noise influence the granularity of the determined event segmentations - allowing the formation of event taxonomies. We performed every simulation 10 times with a different random initialization.

## Results

In a first test we analyzed how the underlying learning rule of the forward models influences the event segmentation and learning accuracy of the system, comparing stochastic gradient descent with RLS. During learning, the motoric action $a(t)$ was determined by an external algorithm, which performed a mixture of random movements and behaviors leading to a new event. Every simulation consisted of 10 training and 10 test epochs, during which no forward model updates took place. In every epoch all three objects were generated once and manipulated by the agent until they were consumed.

The system was able to identify all existing events in the simulation (hand moving normally/slowly, object lying, light/heavy sticky object dragged, marble carried, object dropped) for both types of forward models used. The average prediction error of all active forward models for three different events is shown in Figure 4a. For both learning rules the system improves the prediction accuracy over the training epochs, but RLS-based learning quickly reaches a much better prediction. While this result shows that both forward model learning approaches can be applied, further tests were conducted using RLS-based learning to speed-up the process.

In a second test we analyzed how the surprise threshold $\theta$ influences the granularity of the event segmentation. Thus we performed this test with three different surprise thresholds $(\theta \in\{10,50,100\})$. Since we hypothesized that sensory noise also alters the granularity of segmentation, we additionally varied the amount of Gaussian distributed noise $(\sigma \in\{0.001,0.01,0.05,0.1\})$ that was added to each observation $o(t)$. Additionally, a small amount of Gaussian distributed noise $(\sigma=0.01)$ was added to each action $a(t)$.

The average prediction error for different events at the lowest level of noise tested $(\sigma=0.001)$ is shown in Figure $4 b$. The prediction error of the system greatly varies for the different surprise thresholds. After only a few training epochs, the prediction accuracy of the active forward models for the smallest tested surprise threshold is close to the level of sensory noise. In contrast, the mean prediction error of the system for the largest threshold is only slightly below 1 . For $\theta=50$ the prediction error varies among the different events.

To further analyze this difference in prediction accuracy we examined the number of forward models generated for the different surprise thresholds and determined which forward

Figure 4: Mean prediction error of all active forward models for different events for (a) different forward models without sensory noise; (b) different surprise thresholds $\theta$ using RLSbased forward models and Gaussian distributed sensory noise ( $\sigma=0.001$ ). Three events are shown: object lying $(\diamond)$, light object dragging ( $\square$ ), and heavy object dragging (०).
models were most active for which event. In the following, we first refer to the case with the lowest level of sensory noise ( $\sigma=0.001$ ). Later, we analyze how a variation in sensory noise influences the number of event models. All identified event models are shown taxonomically structured in Figure 5.

For $\theta=100$ two forward models developed for predicting object positions. One of these models was active when the object was lying, the other one was active for the rest of the time. Thus the system differentiated between a moving and a still object in terms of object position. For $\theta=50$ three models were predicting $x_{o}$ and $z_{o}$-position. Here the system further differentiated between slowly carrying a heavy object or transporting a light object at normal speed. For the $y_{o}$-position one additional model was generated, which was active when an object was falling. For $\theta=10$ every type of transportation was represented by a different forward model. Hence, for the smallest surprise threshold, the system even differentiated between slow and normal hand movements, while for larger values of $\theta$ this was not the case.

Sensory noise additionally influences the granularity of the performed event segmentation. While for low noise levels ( $\sigma=0.01$ and $\sigma=0.001$ ) the identified events did not differ, an increase in noise results in a coarser event segmentation. For $\sigma=0.05$ and $\theta=10$ the system used one forward model for every sensory dimension describing hand position and three forward models to predict changes in object position: one for a lying object, one for a transported object, and one for a falling object. The segmentation further coarsened for $\sigma=0.1$, where the system only distinguished between lying and moving objects. If both noise level and surprise threshold were too large ( $\sigma \geq 0.05, \theta \geq 50$ ) the system did not detect event transitions at all, such that only one forward model was generated per sensory dimension.

| $\begin{aligned} & \theta \geq 50 \\ & \theta \geq 50 \end{aligned}$ | object exists |  |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: |
| $\begin{gathered} \theta=10 \\ \theta=100 \end{gathered}$ | object is lying | object moves |  |  |  |
| $\theta=10$ |  | object moves alongside hand |  |  | object is <br> falling |
| $\theta=50$ |  | object moves with hand normally |  | object is dragged slowly |  |
| $\theta=10$ |  | object is dragged | object is carried |  |  |
| Real Events |  |  |  | - |  |

Sensory noise levels: $\square \sigma=0.1, \square \sigma=0.05, \square \sigma \leq 0.01$
Figure 5: The event models regarding object position identified by the system for different surprise thresholds and sensory noise levels. The column on the left states the surprise threshold $\theta$. The associated sensory noise $\in[-\sigma, \sigma]$ is illustrated by color, as explained by the color legend below the table. Each row shows the identified event model for this surprise threshold and noise level. The bottom row illustrates the real, underlying interactions found in our scenario.

In a third test we evaluated the planning capabilities of our system, using its representation of events and event boundaries to generate goal-directed behavior. Furthermore we analyzed how the granularity of the underlying event representations influences planning. Thus, we varied granularity by using three values of the surprise threshold $(\theta \in\{10,50,100\})$ under the low noise condition $\sigma=.001$. Every simulation consisted of 30 training and 30 testing epochs. During each training epoch one sticky object and one marble were generated. The goal of the system was to consume the objects. The system was given a fixed time interval ( 500 simulation steps) to interact with each object. If the system failed to remove an object in the given time period, an external algorithm performed the required movements. During testing, we introduced a new object that closely resembled the marble in its visual characteristics (small, similar color, no spikes). Once grasped, however, the new object behaved like a sticky object and attached to the hand. The challenge of successfully interacting with the new object is thus to grasp the object like a marble (by means of the appropriate event boundary models) but to then transport the object like a sticky object (with the help of the appropriate event models).

Already after the first training epoch, the system consumed $50 \%$ of the novel objects correctly when a fine-grained event segmentation was used $(\theta=10)$. From 25 training epochs onward, the system managed to successfully interact with every new object. For $\theta=50$, the system on average only interacted with $70 \%$ of the new objects correctly after all 30 training epochs. For $\theta=100$, the system did not manage
to interact with any test object successfully. The difference in performance can be explained by examining the identified events (see Figure 5). For $\theta=100$ the system does not distinguish between transporting and dropping an object, such that the 'detachment' event boundary was not learned and thus could not be used as a subgoal. Similarly, for $\theta=50$ the system does not distinguish between transporting a marble or a sticky object, such that the 'grasp' and 'attach' event boundaries were mixed - often leading to unsuccessful grasps.

## Conclusion

Based on event segmentation theory (Zacks et al., 2007) and the principle of free energy minimization (Friston, 2009), we have developed a computational model of hierarchical, behavior-grounded event segmentation. Our system uses a strictly statistical measure of "surprise" to segment the sensorimotor stream, which an agent experiences while interacting with its environment, into events encoded by temporal forward models. In a continuous, noisy simulation, our system was able to identify event models characterizing particular object interactions, e.g. 'carrying an object' or 'dropping an object'. Furthermore, the environment was structured into conceptual event and event boundary encodings, which discriminate the critical features that are crucial for the occurrence of an event, e.g., 'hand contact' is required to manipulate an object. Due to the event-based architecture, the system accomplished to plan hierarchical behavior consisting of multiple subroutines to reach desired goal states.

We showed that a change in the confidence-threshold, which determines when a transient free energy signal is considered "surprising", affects the granularity of the event segmentation. Depending on this threshold, the system accomplished to identify events for concrete object interactions, e.g. 'carrying a marble', or abstract representations of interactions, which subsume several more concrete events, e.g. 'moving an object'. Similarly, an increase in sensory noise entailed a coarser segmentation. Thus, based on these simple statistical principles, a hierarchy can emerge, similar to the event taxonomy proposed by Zacks and Tversky (2001), in which abstract events comprise several more concrete events.

The developing hierarchical organization of event models and consequent event-oriented behavior is closely related to hierarchical reinforcement learning (Botvinick \& Weinstein, 2014; Sutton, Precup, \& Singh, 1999). Similar to our event models, options predict changes in the system's state when performing a sequence of behavior without considering lowlevel steps. While the composition of options has been shown to enable the learning of complex behavior when using a predefined set of goals (Kulkarni, Narasimhan, Saeedi, \& Tenenbaum, 2016), our system determines subgoals by itself by the principle of surprise-detection.

In sum the proposed model offers a general algorithm for online, hierarchical event segmentation learning given continuous sensorimotor experiences. Two main learning biases lead to successful segmentations: first, the partition of the de-
veloping generative model into probabilistic models of events and transitions between events; second, the focused learning of event transitions based on transient free energy signals. Besides the emergence of event taxonomies, we also showed that the developing conceptual structures can be learned to invoke hierarchical, goal-directed planning and behavioral control.

Our current research aims at integrating boundedly complex, non-linear forwards models and recurrent context information. Such enhancements will be necessary to handle non-uniform motion patterns and partially only indirectly observable causes of event transitions robustly. As a result, we hope to be able to show the more general and more scalable applicability of the principles we have introduced herein.

# Reverse-engineering the process: Adults' and preschoolers' ability to infer the difficulty of novel tasks 

Hyowon Gweon (hyo@stanford.edu) Mika Asaba (masaba@stanford.edu), Grace Bennett-Pierre (gbp@stanford.edu)<br>Department of Psychology, Stanford University, Stanford, CA 94305

#### Abstract

The ability to reason about the difficulty of novel tasks is critical for many real-world decisions. To decide whether to tackle a task or how to divide labor across people, we must estimate the difficulty of the goal in the absence of prior experience. Here we examine adults' and preschoolers' inferences about the difficulty of simple block-building tasks. Exp. 1 first established that building time is a useful proxy for difficulty. Exp. 2 asked participants to view the initial and final states of various block-building tasks and judge their relative difficulty. While adults were near-ceiling on all trials, children showed varying levels of performance depending on the nature of the dimensions that varied across structures. Exp. 3 replicated the pattern. These results suggest that children can reverse-engineer the process of goal-directed actions to infer the relative difficulty of novel tasks, although their ability to incorporate more nuanced factors may continue to develop.

Keywords: Difficulty; Physical reasoning; Social cognition

## Introduction

We often think about how easy or difficult it is to achieve a goal. From a child trying a new jungle gym to a scientist building a research team, the ability to reason about task difficulty is critical for many real-world decisions; it informs decisions about the self (e.g., deciding whether to tackle a task or seek help), about others (e.g., understanding who needs help), and even about groups (e.g., assigning tasks in a collaborative project). Although these decisions might seem "easy", they involve more than simply remembering and retrieving our past experiences; they often require estimates and predictions about novel tasks. Such sophisticated inferences might be especially challenging for young children, who frequently face tasks they have never attempted or completed.

Indeed, having this ability does not mean that our estimates are always accurate. Even as adults, we often under- or overestimate the difficulty of certain tasks, failing to meet deadlines or suboptimally allocating time and effort. Nevertheless, our estimates are usually accurate enough to get by, suggesting that even these inaccurate estimates might be generated in systematic ways. Indeed, our accuracy and precision in estimating the difficulty of a task might improve with experience and knowledge about the task. However, the ability to predict the difficulty of a novel task (i.e., prior to the actual experience with the task) is crucial for making effective decisions about planning, learning, and even interacting with others. What are the cognitive mechanisms that underlie our ability to predict and estimate difficulty, and how does this ability develop in early childhood?

## An intuitive understanding of difficulty

Judgments about perceived task difficulty, or task-related effort, have been mostly studied in terms of its effect on achievement, motivation, and performance attribution in personality and social psychology (e.g., Atkinson, 1957; Weiner, 1966). Early work has operationalized the notion of difficulty as the subjective probability of success or the introspective assessment of required effort (e,g., Atkinson, 1957; Heider, 1958), allowing the notion of difficulty to be measured in quantifiable terms. However, these definitions could easily be intertwined with other agent-dependent concepts such as competence, ability, or intelligence. Prior developmental work has also focused on children's perception of task difficulty and its relationship to motivation and performance in formal educational contexts (Crandall, Katkovsky, \& Preston, 1962; Nicholls, 1978; Nicholls \& Miller, 1983). These studies suggest that although children around age six consider task difficulty in selecting their own goals (Heckhausen, 1967) they still have trouble differentiating objective task difficulty from agent ability (Nicholls \& Miller, 1983).

Some recent work provides indirect support for the idea that children ages 5 to 6 can differentiate objective difficulty from subjective competence. Given information about agents' decisions to pursue goals that vary in costs (i.e., climbing a high hill vs. a low hill) and subjective rewards, children infer agents' competence (subjective costs) (JaraEttinger, Gweon, Tenenbaum, \& Schulz, 2015). Children also reason about the expected costs for discovering a causal mechanism, and prefer to teach someone a toy that would be harder (i.e., require more trial-and-error) for the person to figure out on her own (Bridgers, Jara-Ettinger, \& Gweon, 2016) even though both toys are equally easy for them. These results suggest that children may be able to use the properties of the physical environment to estimate the costs of achieving a goal even without any prior experience.

Indeed, an intuitive understanding of task difficulty does not guarantee adult-like inferences. Numerous studies report children's failure in planning and problem-solving tasks that require sequential representation of task space (e.g., Tower of Hanoi; Klahr \& Robinson, 1981). While children may successfully detect explicit, perceptual cues (e.g., height of hills, number of buttons on toys), average performance of others (Nicholls, 1978), or actual subjective experiences (e.g., solving standardized test problems such as Raven's matrices; Mueller \& Dweck, 1998), they may still fail to infer the difficulty of novel tasks especially when it requires representing or simulating possible states of the world that are not readily
observable. Despite the importance of effort estimation however, children's intuitive concept of difficulty has been rarely studied in its own right. Thus the mechanisms that underlie our ability to reason about difficulty and how they develop in early childhood still remain as important open questions.
Current approach Here we explore adults' and children's ability to estimate the difficulty of novel tasks. Given the early-emerging understanding of physical events (Baillargeon, 2004; Spelke, Breinlinger, Macomber, \& Jacobson, 1992), and the costs of simple goal-directed actions (Liu \& Spelke, 2016; Csibra, 2003), our approach is to ground the basic source of difficulty in agents' interventions on the physical world. We designed a novel task that asked participants to estimate the difficulty of simple engineering goals: building block structures. We explore the idea that humans, even early in life, can estimate the difficulty of novel tasks by reasoning about (1) what physical transitions are involved in the building process, and (2) how an agent might act on the physical states to cause these transitions.

One challenge with eliciting difficulty estimates is that there is no standard metric for measuring the actual difficulty. To establish an objective "ground truth" for our tasks, we used a variable that is often used to capture the lay notion of difficulty: time needed to complete a task. In Exp. 1 we first establish that people's intuitive sense of difficulty is tightly correlated with their estimates of expected time and the actual time. In Experiments 2 and 3, we systematically vary the physical features of the block structures as well as other factors that influence properties of agents' actions in order to examine adults' and preschoolers' ability to judge relative difficulty of various building tasks.

## Experiment 1

In Exp. 1 we had two basic goals for investigating people's ability to estimate task difficulty. First, we wanted to verify that people's difficulty estimates systematically reflect a real-world property of the task that can be measured in standard metric (i.e., time). We thus recruited separate groups of participants to get (1) difficulty estimates and (2) building time estimates of various block structures, as well as their (3) actual building times, and explored the relationships among these variables. Next, we used these estimates to verify that the pairs of block structures (to be used as stimuli in subsequent experiments) varied in their relative difficulty.

## Methods

Participants Separate groups of adults were recruited for the Difficulty Estimation task ( $\mathrm{N}=57$, Age: 20-56), Time Estimation task ( $\mathrm{N}=60$, Age: 21-68), and Build task ( $\mathrm{N}=14$, Age: 18-31). The Difficulty Estimation and Time Estimation tasks were conducted on Amazon's Mechanical Turk (AMT); we excluded participants who gave identical responses on all trials (Difficulty, $\mathrm{N}=3$ ). The Build task was conducted in lab; one participant was dropped due to technical error.

Materials 28 photos (14 each for initial and final states) of various block structures were used for the task. Each structure had a photo of its initial state (e.g., scattered blocks) and final state (completed structure). Blocks were 1" plain, yellow, green, red, or blue wooden cubes. We designed seven pairs of structures that varied in specific dimensions: (1) Numberl ( 3 blocks forming a triangle vs. 10 blocks forming a circle), (2) Number 2 ( 5 blocks forming a small cross vs. 13 blocks forming a larger cross), (3) Stabilityl (10 blocks in a horizontal line vs. 10 blocks stacked vertically), (4) Stability2 (two piles of blocks divided by color (yellow and green) vs. a castle-like structure with levels of yellow and green blocks), (5) Number\&Stability (2 long green blocks stacked vertically vs. 10 plain blocks stacked vertically, height matched), (6) Probability (5 red blocks taken out of a transparent box that contained approximately $85 \%$ red and $15 \%$ blue, or $15 \%$ red and $85 \%$ blue), and (7) Process ( 2 towers of 5 blocks from an initial state that was either near-complete or very incomplete).
Procedure Participants in all three tasks viewed the same initial and final state photos, but responded to different questions depending on the task. In the Difficulty Estimation task, participants were provided examples of very "easy" and "hard" structures in the beginning to anchor them appropriately on the scale $(0-100)$. In each trial, they viewed the initial and the final state photos of a given block structure on the screen (with an arrow pointing from the initial to the final state photo to indicate the physical transition) and answered the question "How difficult would it be to do this?" with a sliding bar. In the Time Estimation task, participants saw the same example structures (presented as structures that take a short or a long time to make) to anchor them on the scale ( $0-100$ seconds); the question in each trial was "How long would it take to make this?". Two structures within a pair were presented sequentially, but the order of presentation was counterbalanced both within each pair and across all pairs.

In the Build task, the experimenter laid out blocks in front of the subject as in the initial state photo in each trial, and asked to use the blocks to create the structure shown in the final state photo. We recorded how long the subject spent building the block structure from start to finish.

## Results

First, we asked whether expected building time can be a good proxy for estimated task difficulty. Even though separate groups participated in the Difficulty Estimation and Time Estimation Tasks, these estimates were highly correlated (Fig. 2 Right: $r=.923, t=8.296, d f=12, p<.001)$. This suggests that people's intuitive sense of difficulty can be directly mapped onto estimates of time, and that actual building times may be an approximate "ground truth" for difficulty. Given this result, we then asked how well people's estimated building times reflect actual building times. Although people generally overestimated the building times (Fig. 2 Left: intercept $=13.647, t=4.227, p=.001)$, the correlation was fairly high $(r=.780, t=4.3167, d f=12, p=.001)$. Sec-

Figure 1: Stimuli used in Expts. 2-3 (final states, except for Process); Exp. 1 stimuli did not include agents. Each pair (shown as columns) had an easier structure and a harder structure. Ratio of difficulty estimates are shown beneath each trial.
ond, we verified that the difficulty of block structures within a pair was significantly different in all pairs (paired t-tests, $p$ 's $<.002$ ); differences in estimated time and actual building times were also significant (paired t-tests, $p$ 's $<.001$ ). These graded measures of difficulty also allowed us to calculate the degree to which one structure was "harder" than the other. We calculated the ratio of estimated difficulty between the two structures (higher value indicates a larger difference) and report these in Figure 1.

Collectively these results suggest that adults can make reliable difficulty estimates of individual block structures in ways that systematically reflect some objective, quantifiable aspect of these tasks (i.e., how long it takes to build the structures). Furthermore, we were able to verify that within a pair of block structures, one was clearly more difficult than the other. Despite all pairs having a clear "answer", the magnitude of the difference between the structures varied across pairs.

Figure 2: Results from Exp.1. Correlation between Actual Build Time and Estimated Build Time (left); correlation between Estimated Difficulty and Estimated Build Time (right).

## Experiment 2

In Exp. 2, we used the stimuli from Exp. 1 to ask whether adults and children can infer the relative difficulty of blockbuilding tasks. Given the results from Exp. 1, we expected adults to show high accuracy in these binary judgments, choosing the structure that was verified as "easier(harder)" in both estimated difficulty and the actual building times.

Our main goal was to examine how children's performance might differ from that of adults. Although adults' estimates indicated that all 7 pairs had a clearly "harder" structure, they varied in why the structures varied in difficulty. In Number and Stability trials, the final structures differed in their observable perceptual properties (size, height). The Number\&Stability trial was matched on these perceptual cues, making the number of actions needed to complete the task the only determining factor for difficulty. To succeed in the Probability trial, children had to understand that relative difficulty is influenced by the availability of the required blocks (thus the ease of acquiring them) even when the final structures are identical. Success in the Process trial required an understanding that the overall difficulty of a task is easier when one starts from a partially complete state.

In light of prior work reviewed above (e.g., Nicholls, 1978, and Liu \& Spelke, 2016), we could consider two extreme possibilities: preschool-aged children might fail to distinguish relative difficulty across the board, or they might successfully detect relative difficulty on all trials. However, a more plausible possibility is that children may succeed in some cases, but selectively fail on other cases. For instance, although it may be easier to detect the differences when a property of the block structures are clearly different (e.g., number, stability), children might struggle in cases where identical structures were built via different processes. In particular, in Probability and Process trials, one cannot rely on the number of blocks used in the structures or their final shapes; one must reason about the agents' actions involved in building the structures. Thus children might struggle selectively in these trials.

Indeed, it is also possible that children have a simple heuristic that difficulty depends entirely on the structure alone. Thus in Exp. 2 we added another trial: two identical sets of towers were built, but one was built by two agents (one tower each) while the other was built by a single agent. Success on this task might speak against the possibility that children fail simply because identical structures were built.

## Methods

Participants Adults ( $\mathrm{N}=45$, Age: 21-59) were recruited on AMT. An additional 13 adults were excluded because they failed the warm-up task $(\mathrm{N}=8)$ or the attention check questions ( $\mathrm{N}=5$ ). Twenty-five preschoolers (17 female, $\operatorname{Mage}(S D)$ : 4.8(.4), Range: 4.1-5.4) were recruited from a laboratory preschool. Seven additional children were excluded due to failure to respond correctly in the warm-up task $(\mathrm{N}=6)$ or experimenter error $(\mathrm{N}=1)$.

Materials The materials were almost identical to those in Exp. 1, except that the photos now showed an agent looking neutrally at the blocks (initial state) or completed structure (final state). Children viewed these photos on a 15 " Macbook Pro (using MATLAB and Psychtoolbox) and indicated their responses by placing their hands on a response pad. Adults viewed the stimuli on Qualtrics. See Fig. 1 for stimuli.

Procedure All children were tested in a quiet room, seated next to the experimenter. Half of the children were always asked to indicate the "easier" one, and the other half were always asked to indicate the "harder" one. A warm-up task ensured children understood the meaning of the word "easier(harder)"; children were first presented with two identical boxes, which the experimenter had them first push and then lift, and were asked "Which one is easier(harder) to push?" and "Which one is easier(harder) to lift?" In the main task, children saw photos of green and yellow blocks presented side by side on the laptop screen. All children were able to identify the green (yellow) blocks by placing their left (right) hand on the response pad. In subsequent test trials, children were told: "Anne and Sally were playing with blocks today." as two initial state photos were presented on the screen. The two final state photos were then revealed below the initial state photos; the experimenter pointed to each photo and said, "This is what Anne made, and this is what Sally made. One of them was easier(harder) to make. Which one was easier(harder) to make?" Agents differed across trials and unique names were used for each agent. Trial order and the side of correct response (L/R) were counterbalanced across trials.

Adults participated in an almost identical task on AMT. Similarly to children, the initial states were presented first and then the final states were revealed below these photos. The only difference was that adults read the questions on the screen and answered by clicking on the correct answer.

## Results

Adults: As expected, adults performed near-ceiling on all trials ( $p<.001$ ). See Fig.3.

4-5 year-olds: Performance did not differ by question type (easier/harder) so we collapsed the responses throughout $\left(\chi^{2}=.784, d f=1, p=.376\right)$. Children showed above-chance performance in 6 of the 8 trials (Number1 ( $77.3 \%, p=.017$ ), Number2 $(73.9 \%, p=.035)$, Stability1 $(81.0 \%, p=.007)$, Stability2 ( $90.5 \%, p<.001$ ), NumStab ( $80.0 \%, p=.004$ ), Cooperation $(81.0 \%, p=.007)$ ), while they did not show

Exp. 2: Adult and Child Forced Choice Data

Figure 3: Exp. 2 results. Average \% correct for each trial (error bars indicate $95 \%$ confidence intervals; $* * * p<.001$, ** $\left.p<.01,{ }^{*} p<.05\right)$.
above chance performance on the remaining two, Process ( $41.7 \%, p=.541$ ) and Probability ( $57.1 \%, p=.664$ ).

We asked whether children's chance-level performance was lower than other trials with similar properties. Performance on Process trial was lower than the Number trials ( $\chi^{2}$ $=14.894, d f=1, p<.001$ ), suggesting that even though the two structures differed in the overall number of actions, children failed if two identical structures were built from diffrent starting points. Similarly, children performed significantly worse in the Probability trial than the Stability trials $\left(\chi^{2}=\right.$ 20.313, $d f=1, p<.001)$; even though the two structures were made of the same number of blocks, children failed when difficulty judgment relied on the process of sampling.

To examine whether children's performance improved with age, we conducted a logistic mixed-effects model with age and trial as fixed effects and subject as a random effect. Age and the Process trial predicted children's accuracy (age: $\beta=1.523, z=2.463, p=.014$; Process: $\beta=$ $-1.765, z=-2.500, p=.013$ ), suggesting that children's accuracy improved with age but they struggled in the Process trial regardless of age. Finally, among trials where children were reliably above chance, children performed worse than adults in Number2 $\left(\chi^{2}(1)=6.98, \mathrm{df}=1, p=.008\right)$ Process $\left(\chi^{2}(1)=12.57, \mathrm{df}=1, p<.001\right)$ and Probability trials $\left(\chi^{2}(1)=17.36, \mathrm{df}=1, p<.001\right)$, and marginally for Number1 $\left(\chi^{2}(1)=3.51, \mathrm{df}=1, p=.061\right)$ and Stability1 $\left(\chi^{2}(1)=\right.$ $3.64, \mathrm{df}=1, p=.057$ ), but not in other trials).

Overall, adults and children were able to judge the relative difficulty of simple physical tasks from just the initial and the final states, without any information about the intermediate processes. It is unlikely that participants had built identical structures in the past and simply recalled their prior experiences to answer these questions. Furthermore, our results suggest that participants did not rely on simple heuristics (e.g, number of blocks, sizes of the structures); their performance was above-chance even when the number and the shape of the structures were identical (Stability1) or their shape and height were matched (Number\&Stability). These results suggest that adults and children were able to reason about the process of the physical transitions between the initial and the
final states. Children were less accurate than adults on some but not on all trials; importantly, they showed a marked diffculty to detect the differences when identical structures were built and the only determining factor was the quality of the actions involved in the building process.

## Experiment 3

Exp. 3 replicated Exp. 2 with separate groups of children and smaller number of trials per child. In addition to successes, we were interested in replicating the failures in Process and Probability trials that presumably tested a more nuanced understanding of the building process.

Participants Thirty-five preschoolers (18 female, $\operatorname{Mage}(S D)$ : 4.7(.4), Range: 4.0 - 5.4) participated in Number, Stability, and Number\&Stability trials (Group1). Another 35 children (15 female, Mage (SD) : 4.2(.7), Range: 4.0-5.8) participated in the Sampling, Process and Cooperation trials (Group2). Across groups, 17 additional children were dropped due to experimenter error ( $\mathrm{N}=7$ ), sibling interference ( $\mathrm{N}=1$ ), not speaking English ( $\mathrm{N}=2$ ), failing the warm-up task $(\mathrm{N}=6)$ or not finishing the game $(\mathrm{N}=1)$.

Materials \& Procedure The task was almost identical to Exp. 2, except that in the warm-up task children were presented with simple line drawings and indicated which was easier(harder) to make, and the photos for Sampling, Process, Cooperation trials were presented on paper ( $8.5 \times 11$ ").

Results Children's performance was highly similar to the pattern in Exp.2: Again, accuracy was above-chance on the same 6 of 8 trials (Number1 ( $77.1 \%, p=.002$ ), Number2 ( $68.6 \%, p=.041$ ), Stability1 ( $85.7 \%, p=.001$ ), Stability2 ( $74.3 \%, p=.006$ ), Num\&Stab $(85.7 \%, p=.001)$, Cooperation ( $77.1 \%, p=.002$ ); children were at chance on Probability $(62.9 \%, p=.176)$ and Process $(57.1 \%, p=.500)$ trials.

Although age did not predict performance in each group (Group $1: \beta=.583, z=1.271, p=.204$, Group $2: \beta=$ $.404, z=.952, p=.341$ ), collapsing across groups (similar in size to Exp.2), we again saw a trending relationship between age and accuracy $(\beta=.522, z=1.676, p=.094$; collapsing across all data, age was a significant predictor of accuracy ( $\beta=.693, z=2.694, p=.007$ ).

## General Discussion

In order to investigate the development of the intuitive sense of difficulty, we designed a concrete, manual activity that even young children enjoy and easily understand: building block structures. Across three experiments, we showed that (1) adults' intuitive sense of difficulty accurately reflects actual measures of difficulty (i.e., building time) in both graded estimates and binary judgments, (2) preschoolers show above-chance performance when the pair of structures varied in the expected number of required actions (due to number of blocks, stability, or the number of agents), but (3) they fail on trials in which identical trials were built, which presumably require them to reason specifically about the pro-
cess of building and the property of actions involved. Collectively, adults and children made systematic judgments about the difficulty of physical tasks from visually observing their initial and final states, without prior experience with the exact building activity or explicit information about the intermediate processes. However, children are still developing these skills throughout the preschool years and possibly beyond.

We found that although adults had a tendency to overestimate the building time, it was strongly correlated with the actual build time, suggesting that these estimates systematically reflected some "ground truth" difficulty of these tasks. Furthermore, these time estimates were tightly linked to adults' difficulty estimates. Indeed, adults' binary judgments reflected the relative difficulty of pairs of structures, resulting in near-ceiling accuracy. This was in stark contrast to children's performance, which was similar to adults in some trials but at chance on some others.

What develops, and what makes us better? One possibility is that the accumulated experience of interacting with physical objects might support a more robust understanding of the underlying physics, increasing the precision of the simulation that might be necessary for generating these intermediate processes (Battaglia, Hamrick, \& Tenenbaum, 2013). Another possibility is that experience improves children's understanding of the dynamics between the physical states and the actions required to cause appropriate transitions between these states. These are not mutually exclusive, and both might lead to more accurate representations of the intermediate processes and the effort (e.g., physical, mental) associated with these transitions. Having self-experience with objects helps infants understand others' goal-directed actions (Sommerville, Woodward, \& Needham, 2005); it is possible that self-experience continues to help adults and children in making these everyday estimates. Future work may explore whether direct experience with these building tasks increases the precision of time and difficulty estimates.

One important question here is how and when children begin to utilize different dimensions of tasks (e.g., process, probability) when making judgments about difficulty. Despite recent work showing an early-emerging sensitivity to statistical distributions of objects (Xu \& Garcia, 2008) and the process by which these objects are sampled by an agent (Gweon \& Schulz, 2011), our results suggest that preschoolers may still fail to incorporate this understanding in reasoning about the relative difficulty of agents' sampling behaviors. Children's failure on Process trials parallels school-aged children's difficulty understanding the relationship between time, speed, and distance concepts (Siegler \& Richards, 1979); when one train started to travel ahead of another train (but they travelled at equal speeds and stopped at the same place), children fail to answer that this train travelled for a shorter time. These observations are consistent with the possibility that children may struggle to discern the differences in difficulty when the tasks are highly similar in their physical properties. While these results suggest the role of a representa-
tional capacity that allows children to simulate multiple intermediate future states sequentially over time, further research is needed to understand the exact nature of their difficulty.

On the other hand, children's robust performance on most trials points to the possibility that the basic inferential ability to estimate difficulty may emerge early. Prior work has found remarkable sophistication in infants' understanding of physical events (e.g., Spelke et al., 1992; Stahl \& Feigenson, 2015), as well as their understanding of agents' actions and interventions on the physical world, both for others (e.g., Liu \& Spelke, 2016; Newman, Lockhart, \& Keil, 2010) and their own (Upshaw \& Sommerville, 2015). Thus it is possible that even younger children have the necessary inferential and representational prerequisites for an intuitive sense of difficulty that may manifest not only in their immediate motor plans but also in their predictions of future events. Due to the verbal demands (e.g., meaning of the words "easy" and "hard"), the current paradigm is unlikely to be useful for children under age 3. Future work might exploit building time (a proxy for difficulty in our tasks) in a predictive looking paradigm to address this possibility. Indeed, a time-consuming task is not always judged as harder than a less time-consuming task. Although here we looked at simple cases in which estimated difficulty directly maps onto time, it would be interesting to further investigate how objective and subjective aspects of physical effort (e.g., height of tower and an agent's building competence) as well as mental effort (e.g., careful placement of blocks) may dissociate time and difficulty estimates.

Difficulty is a difficult concept to investigate scientifically. The current work is a small step to understanding this intuitive yet incredibly complex concept. By first examining how people reason about simple, concrete tasks we may obtain clearer insights on how these intuitions arise, and how they develop into more abstract notions of difficulty that are embedded in people's lay use of this word.

# Categorization, Information Selection and Stimulus Uncertainty 

David J. Halpern (david.halpern@nyu.edu)<br>Todd M. Gureckis (todd.gureckis@nyu.edu)<br>Department of Psychology, NYU, 6 Washington Place<br>New York, NY 10003 USA

#### Abstract

Although a common assumption in models of perceptual discrimination, most models of categorization do not explicitly account for uncertainty in stimulus measurement. Such uncertainty may arise from inherent perceptual noise or external measurement noise (e.g., a medical test that gives variable results). In this paper we explore how people decide to gather information from various stimulus properties when each sample or measurement is noisy. The participant's goal is to correctly classify the given item. Across two experiments we find support for the idea that people take category structure into account when selecting information for a classification decision. In addition, we find some evidence that people are also sensitive to their own perceptual uncertainty when selecting information.

Keywords: attention, categorization, information sampling
Categorizing objects or situations into meaningful groups is a critical cognitive ability. Many existing theories of categorization share an unrealistic assumption that information about the features of a to-be-categorized object can be directly and precisely observed (Medin \& Schaffer, 1978; Nosofsky, 1986; Smith \& Minda, 1998; Love, Medin, \& Gureckis, 2004). But this is often not the case; for example, doctors do not always have full access to all the information about patient symptoms (i.e., stimulus features) but instead can only rely on a patient's self-report and medical tests which are subject to selective reporting and noise (perceptual or otherwise). If a doctor orders a cholesterol test, they must take into account that the patient's true levels are somewhat different than those reported by the test due to error or noise. There is often uncertainty not only about the category of an object but also about its specific dimension or feature values.

If noise and uncertainty are the affliction, then the antidote is the fact that categorizers can often select how feature or stimulus measurements are made. In many cases, a good strategy for selecting measurements (e.g., repeating the same measurement when it is known to be noisy) can significantly improve categorization performance. Here we ask what strategies people use to select stimulus measurements in the service of categorization. While previous approaches to this question tend to focus on how people select stimulus features to view without noise before making a categorization decision (e.g., Nelson, McKenzie, Cottrell, \& Sejnowski, 2010 or in eye and mouse tracking studies, Rehder \& Hoffman, 2005; Matsuka \& Corter, 2008; Blair, Watson, Walshe, \& Maj, 2009) here we explore the effect of measurement or perceptual noise on information sampling strategies.

## Categorizing in a Noisy World

We begin by presenting an Ideal Actor analysis of categorization under measurement noise which extends the General

Recognition Theory (Ashby \& Townsend, 1986). We then present a series of experiments exploring how people sample information about category features under conditions of stimulus noise.

Categorizing without perceptual noise The standard model of a probabilistic binary categorization task (Medin \& Schaffer, 1978; Nosofsky, 1986; Smith \& Minda, 1998) assumes that on a given trial $t$, a category $C_{t} \in\{A, B\}$ is drawn randomly and a stimulus $\mathbf{s}_{t}$ is generated from the distribution associated with $C_{t}$ (see Figure 1a). Subjects are assumed to either learn the parameters of these distributions through experience or description. Based on the information in $\mathbf{s}_{t}$, subjects guess which category $C_{t} \in\{A, B\}$ it was generated from. For example, in our first experiment, the stimuli have two dimensions, color and orientation, i.e. $\mathbf{s}_{t}=\left[s_{t_{\text {orientation }}}, s_{t_{\text {color }}}\right]$ and the category distributions are bivariate Gaussian distributions $\mathcal{N}\left(\boldsymbol{\mu}_{C_{t}}, \boldsymbol{\Sigma}\right)$ where the mean is dependent on the category and we can decompose the covariance matrix as $\boldsymbol{\Sigma}=$ $\left[\begin{array}{cc}\sigma_{\text {orientation }}^{2} & \rho \sigma_{\text {orientation }} \sigma_{\text {color }} \\ \rho \sigma_{\text {orientation }} \sigma_{\text {color }} & \sigma_{\text {color }}^{2}\end{array}\right]$. The Ideal Observer decision rule, assuming knowledge of the category distributions, is to use the log-likelihood ratio

$$
\begin{equation*}
l\left(\mathbf{s}_{\mathbf{t}}\right)=\frac{\log P\left(\mathbf{s}=\mathbf{s}_{t} \mid C_{t}=A\right)}{\log P\left(\mathbf{s}=\mathbf{s}_{t} \mid C_{t}=B\right)} \tag{1}
\end{equation*}
$$

This rule responds $A$ when $l\left(\mathbf{s}_{\mathbf{t}}\right)>0$ and $B$ otherwise (Ashby \& Gott, 1988).

Categorizing with perceptual noise In the 1980s, Ashby and colleagues developed General Recognition Theory (GRT), a family of models of multidimensional classification that assumed perceptual noise, in contrast to the models above (Ashby \& Townsend, 1986). Here we discuss a special case of GRT that uses the Ideal Observer decision rule and makes two critical assumptions about perceptual noise: that perceptual noise has a normal distribution and that the noise in perceiving each stimulus dimension is independent. In this model, on trial $t$ the subject perceives a percept $\mathbf{p}_{t}=\left[p_{t_{\text {color }}}, p_{t_{\text {orientation }}}\right]$ with probability $\mathcal{N}\left(\mathbf{p}_{t} ; \mathbf{s}_{t}, \boldsymbol{\Sigma}_{p}\right)$ where $\boldsymbol{\Sigma}_{p}=\left[\begin{array}{cc}\sigma_{\text {Porientation }^{2}}^{2} & 0 \\ 0 & \sigma_{p_{\text {color }}}^{2}\end{array}\right] . \boldsymbol{\Sigma}_{p}$ is diagonal due to the independent noise assumption and $\sigma_{p_{\text {orientation }}}^{2}$ and $\sigma_{p_{\text {color }}}^{2}$ are a subject's perceptual noise for orientation and color respectively. When making their categorization decision, subjects only have access to $\mathbf{p}_{t}$ rather than $\mathbf{s}_{t}$ as before (see Figure 1b). Therefore, the Ideal Observer's decision rule is now based on the $\log$ likelihood ratio $l\left(\mathbf{p}_{\mathbf{t}}\right)$ where $\mathbf{p}_{\mathbf{t}}$ is distributed under each category as $\mathcal{N}\left(\mathbf{p}_{t} ; \boldsymbol{\mu}_{C_{t}}, \boldsymbol{\Sigma}+\boldsymbol{\Sigma}_{p}\right)$

Reducing uncertainty by making measurements One strategy for dealing with uncertainty in the percept $\mathbf{p}_{t}$ is to exert control over the amount of information collected about each stimulus dimension. In our task, the categorizer is given a fixed budget of $\kappa$ noisy measurements $\mathbf{m}_{t}$ of a stimulus made up of two dimensions. These measurements can be allocated so that there are $\lambda_{\text {orientation }}$ measurements of the orientation dimension and $\kappa-\lambda_{\text {orientation }}$ measurements of color with $\lambda_{\text {orientation }} \in[0, \kappa]$. Conceptually, this is like a doctor ordering multiple runs of medical tests and collect more or fewer runs of some tests over others. As in our experiment, orientation measurements are each independently distributed with probability $\mathcal{N}\left(s_{t_{\text {orientation }}}, \sigma_{m_{\text {orientation }}}\right)$ and similarly for color. Because these measurements are all normally distributed, the mean measurement $\overline{\mathbf{m}}_{t}$ is distributed as $\mathcal{N}\left(\mathbf{s}_{t}, \boldsymbol{\Sigma}_{m}\right)$, where $\boldsymbol{\Sigma}_{m}=\left[\begin{array}{cc}\frac{\sigma_{m_{\text {orientation }}}^{2}}{\lambda_{\text {orientaion }}} & 0 \\ 0 & \frac{\sigma_{m_{\text {color }}}^{\mathrm{K}-\lambda_{\text {orientation }}}}{}\end{array}\right]$. We now assume that subjects estimate the mean of several colors or oriented lines with a constant variance, largely supported by the literature on ensemble perception (e.g., Maule \& Franklin, 2016; Dakin \& Watt, 1997). We assume the same perceptual distribution as above except $\overline{\mathbf{p}}_{t}$ represents a subjects estimate of the mean measurement and $\boldsymbol{\Sigma} p$ represents their noise in estimating that mean. Let $\boldsymbol{\Sigma}_{m p}=\boldsymbol{\Sigma}+\boldsymbol{\Sigma}_{m}+\boldsymbol{\Sigma}_{p}$. Therefore,

$$
\begin{equation*}
P\left(\overline{\mathbf{p}}=\overline{\mathbf{p}}_{t} \mid C_{t}\right)=\mathcal{N}\left(\overline{\mathbf{p}}_{t} ; \boldsymbol{\mu}_{C_{t}}, \boldsymbol{\Sigma}_{m p}\right) \tag{2}
\end{equation*}
$$

The optimal decision rule depends on the log likelihood ratio $l\left(\overline{\mathbf{p}}_{t}\right)$ as above.
Optimizing stimulus measurement In our most interesting setting (see Figure 1c), we allow subjects to choose $\lambda$ in order to maximize their own categorization performance. This is akin to the doctor trying to optimize the probability of a correct diagnosis while trying to keep the cost of running the medical tests below a budget. To make the dependence on $\boldsymbol{\lambda}$ explicit, we can rewrite $\boldsymbol{\Sigma}_{m p}$ as $\boldsymbol{\Sigma}_{m p}\left(\boldsymbol{\lambda}_{\text {orientation }}\right)=$ $\left[\begin{array}{c}\left(\sigma_{\text {orientation }}^{2}+\frac{\sigma_{\text {morientaion }}^{2}}{\lambda_{\text {Orientation }}^{2}}+\sigma_{P_{\text {orientation }}^{2}}^{2}\right) \\ \rho \sigma_{\text {orientation }} \sigma_{\text {color }}\end{array}\right.$
 expected percent correct of an Ideal Observer with a given $\lambda_{\text {orientation }}$ should be (Anderson, 1958):

$$
\begin{equation*}
\mathrm{EC}\left(\lambda_{\text {orientation }}\right)=\frac{1}{2} \operatorname{erfc}\left(-\frac{\sqrt{\left(\boldsymbol{\mu}_{A}-\boldsymbol{\mu}_{B}\right)^{\prime} \boldsymbol{\Sigma}_{m p}\left(\lambda_{\text {orientation }}\right)^{-1}\left(\boldsymbol{\mu}_{A}-\boldsymbol{\mu}_{B}\right)}}{2 \sqrt{2}}\right) \tag{3}
\end{equation*}
$$

The Ideal Actor should then set $\lambda_{\text {orientation }}$ to $\lambda_{\text {orientation }}^{*}=$ $\arg \max _{\lambda_{\text {orientation }}} \mathrm{EC}\left(\lambda_{\text {orientation }}\right)$.

## Theoretical Predictions

In the following experiment, subjects perform a categorization task with stimuli that vary on color and orientation dimensions. Subjects only receive $\kappa$ noisy signals of what the color and orientation of the stimulus are but choose a number $\lambda_{\text {orientation }}$ of signals to receive of the orientation dimension. By varying the type of category structure (the

Figure 1: (a) Graphical model of the standard categorization model where stimuli $s$ depend on the category $C$. (b) a model analogous to General Recognition Theory where stimuli $s$ depend on the category $C$ but are never directly observable. Instead, the observer has access to $p$ which itself depends on $s$ but is corrupted with noise. (c) An active learning model of categorization under uncertainty. Here $\lambda$ reflects the number of measurements $m$ made of the stimulus $s$. The categorizer has access to $p$ which depends on the category, stimulus, and the information sampling strategy ( $m$ and $\lambda$ ).
two $P(\mathbf{s} \mid C)$ for category A and B) experimentally and using natural variation in perceptual noise, we can test two predictions about how subjects should select signals based on the above Ideal Actor model. We first divide category structures into three groups: 1D-color structures where $P($ orientation $\mid A)=P($ orientation $\mid B), 1 \mathrm{D}-$ orientation structures where $P($ color $\mid A)=P($ color $\mid B)$ and 2D structures otherwise. We predict:

1. The rank ordering of subjects choice of $\lambda_{\text {orientation }}$ should be 1D-color $\leq 2 \mathrm{D} \leq 1$ D-orientation
2. Within 2D categories, subjects choice of $\lambda_{\text {orientation }}$ will be modulated by the subject's measured perceptual noise.

Intuition for the two hypotheses can be seen in the Ideal Actor predictions in Figure 2 which plots expected Ideal Observer percent correct as a function of strategy and category structure in (a) and perceptual noise in (b). In the 1D-color situation accuracy is optimized by collecting zero orientation samples. In the 1D-orientation, accuracy is highest with 10 orientation samples. In the 2-D case, accuracy is optimized with 5 samples (Figure 2a). Furthermore the peak of these functions changes with perceptual noise (Figure 2b).

## Experiment 1

In order to test these predictions, we used a task divided into six phases. In the first two phases, we estimated the free parameters of the Ideal Actor, $\sigma_{p_{\text {orientation }}}^{2}$ and $\sigma_{p_{\text {color }}}^{2}$, the subjects' noise in estimating the mean of a number of colored dots and oriented lines using a 2 AFC task. In the next three phases,

Figure 2: (a) Ideal Observer expected percent correct as a function of condition (described in Table 1) and strategy. The rank order of the max of these curves is 1 D -color $\leq 2 \mathrm{D} \leq 1 \mathrm{D}$-orientation. (b) Ideal Observer expected percent correct if subjects had no perceptual noise (in red). In our experiment, we estimated noise parameters ( $\sigma_{\text {orientation }}$ and $\sigma_{\text {color }}$ ) using a 2AFC task. Shown in blue and purple are Ideal Observers with estimated noise parameters from two different subjects. Perceptual noise has a strong influence on optimal strategy which is indicated by the arrow
subjects underwent extensive training to learn the category and measurement distribution parameters (assumed known by the Ideal Actor). In the final test phase, subjects performed a categorization task where they could decide how allocate a fixed budget of samples to the two stimulus dimensions. All phases were 100 trials except the first category learning phase which was 200.
Participants Sixty one participants were recruited through Amazon Mechanical Turk. Participants received $\$ 8$ for participating in the experiment with a performance based bonus of up to $\$ 10$. Ten trials were selected at random from the entire experiment and participants were awarded a bonus of $\$ 0.25$ for each trial correct. Participants were randomly assigned to the eight conditions described in Table 1.
Stimuli and Procedure All stimuli in the experiment were generated randomly by drawing samples from the generative model. To generate the stimuli, each sample corresponded to either the angle of an oriented line relative to the circle or the color of a dot where the number was the angle on a circle of radius 60 in CIE 1976 (L*, $\mathrm{a}^{*}$, $\mathrm{b}^{*}$ ) color space. The locations of the colored dots on the screen were determined by force layout, an algorithm within the d3 javascript visualization library (Bostock, Ogievetsky, \& Heer, 2011). Examples of these stimuli can be seen in (Figure 3). Throughout the experiment, the "measurement noise" $\sigma_{m}=\sigma_{m_{\text {orientation }}}=$ $\sigma_{m_{\text {color }}}=.6$.
Perceptual Noise Estimation Phases. We adapted a 2AFC task from Jogan and Stocker (2014) designed to estimate subjects' noise in estimating a property of a stimulus. We conducted this task in two phases, one for orientation and one for color (with order counterbalanced across subjects). On each trial of the task, three stimuli $s \in\left\{\right.$ test, reference ${ }_{1}$, reference $\left._{2}\right\}$ were presented. The subject was asked which of the two reference stimuli was closer in terms of the property of interest to the test stimulus and responded by pressing the appropriate computer key. The specific properties of interest here were the average orientation of a set of several lines or the aver-
age color of a set of several dots. The stimuli during these phases looked the same as the stimuli in the later categorization phase (Figure 3b) but with just one feature present. On a given trial $t$, stimuli were generated by drawing $n_{t}$ samples from $\mathcal{N}\left(\mu_{s t}, \sigma_{m}^{2}\right)$ with $n_{t} \in[1,10]$ to keep the range and set sizes of the stimuli the same as in the later categorization experiment. $\mu_{s t}$ was selected on each trial by a Bayesian adaptive procedure (Kontsevich \& Tyler, 1999). Using an Ideal Observer analysis detailed in Jogan and Stocker (2014), we can estimate the perceptual noise parameters for identifying the mean of the stimuli based on subjects' performance in this task.
Category structures/conditions. Throughout the four categorization phases, stimuli were generated from a single pair of categories, chosen from a set of eight categories described in Table 1. For each subject, each dimension was shifted by a random amount chosen from a uniform on $[0,2 \pi]$ to wash out any effect of a specific stimulus range.

| Condition | $\mu_{A}$ | $\mu_{B}$ | $\Sigma$ |
| :---: | :---: | :---: | :---: |
| 1D-orientation | [0, 0] | [1, 0] | $\left[\begin{array}{cc}.2 & 0 \\ 0 & .2\end{array}\right]$ |
| 1D-color | [0, 1] | [0, 0] | $\left[\begin{array}{cc}.2 & 0 \\ 0 & .2\end{array}\right]$ |
| $2 \mathrm{D}_{1}$ | [0, 0] | [.24, 62] | $\left[\begin{array}{cc}.22 & -.2 \\ .2 & .22\end{array}\right]$ |
| $2 \mathrm{D}_{2}$ | [.24, 62] | [0, 0] | $\left[\begin{array}{cc}.22 & -.2 \\ .2 & .22\end{array}\right]$ |

Table 1: Category parameters for Experiment 1. There were eight categories total, with the other 4 being the same but with the entries of $\boldsymbol{\mu}_{A}$ and $\boldsymbol{\mu}_{B}$ swapped. For the main analysis, we collapse the conditions that share the parameters.

Category Learning Phase. In the category learning phase, a category was drawn from a uniform distribution and a bivariate sample was drawn from that category's associated distribution. This sample was converted to the color and orientation stimulus space using the procedure described above (see Figure 3a for an example). Subjects responded by hitting the "Q" key if they thought the stimulus was in category A and the "P" key if the stimulus was in category B. Subjects then received feedback on whether they were correct or incorrect depending on the category structures defined above.
Measurement Noise Learning Phases The measurement noise learning phases were meant to acclimatize the subject to the effects of measurement noise on categorization. The stimuli were created by sampling from the full generative model for the task as described in the theory section and converting samples to the stimulus space as described above. During this phase, subjects did not get to choose the number of measurements of each dimension. Instead, stimuli in the first phase included ten measurements of each dimension ( $\kappa=20$ and $\lambda_{\text {orientation }}=10$ ) and stimuli in the second included a total of ten measurements with a random number of them allocated to orientation $\left(\kappa=10\right.$ and $\left.\lambda_{\text {orientation }} \in[0,10]\right)$ See Figure 3b for an example of the stimuli in this phase. Note that there

Figure 3: Example categorization trials
are multiple lines/dots in this stimulus reflecting the multiple noisy "measurements" made of each dimension. In order to gain an intuitive understanding of the measurement procedure, subjects were told "we showed the color of the stimulus to 10 people and the location of the stimulus to 10 different people. Later each of them had to re-create what they saw from memory. Your task will be to take their recreations and try to guess what category you think the original stimulus belonged to." After every trial, subjects would receive feedback on their categorization judgement as well as feedback about what the true stimulus $\mathbf{s}_{t}$ had been on that trial.
Test Phase During this phase, subjects chose on a slider how many measurements of each dimension they would see on each trial $\left(\lambda_{\text {orientation }}\right)$. Stimuli were then generated in the same manner as in the measurement noise learning phases. Subjects then performed the classification task as in the previous training sections.

## Results

For each subject, we computed the posterior over the $\sigma_{p_{\text {orientation }}}^{2}$ and $\sigma_{p_{\text {color }}}^{2}$ parameters using the analysis described in Jogan and Stocker (2014). In order to check that the Bayesian adaptive procedure converged towards the correct estimate, Jogan and Stocker use a diagnostic called the Boundary Index (BI) a measure of the number of trials that were chosen to be at the boundary of the space. All of our subjects were below the recommended threshold of 0.9.

Using the perceptual noise posterior, we compute a posterior over Ideal Actor strategies for every subject in our experiment. Since each subject only experienced a single set of categories in the test phase, the Ideal Actor only uses a single $\lambda_{\text {orientation }}$ parameter for the entire experiment. However, subjects were able to change their choice of $\lambda_{\text {orientation }}$ parameter on every trial and relatively few subjects used just a single value. In order to compare subjects to the model, we took an average each subjects' setting of $\lambda_{\text {orientation }}$. We chose a priori to average only the second half of test trials to ensure that subjects had stabilized after having experience with using the slider. The results turn out to be unchanged even if we use all of the data from the test phase.

In order to test our first hypothesis we used Kendall's $\tau$, a

Figure 4: (a)Scatter plot of subjects strategies vs. the Ideal Actor (IA) strategy posterior mean. X error bars are + - 1 SD of the IA posterior and Y-error bars are standard error of mean subject strategy. (b)Expected number additional incorrect Ideal Observer (IO) trials relative to the Ideal Actor (IA). We do not include error bars on the actual performance since the sampling distribution is over trial sequences while the sampling distributions on the Ideal Observers are over measurement selections averaged over trial sequences.
common non-parametric rank-correlation method. We found a significant monotonic relationship between category structure and subjects' $\lambda_{\text {orientation }}$ choice with 1D-color $<2 \mathrm{D}<$ 1D-orientation (Kendall $\tau(59)=0.52, \mathrm{p}<1 \mathrm{e}-8$ ).

We also found a significant linear relationship between subjects' $\lambda_{\text {orientation }}$ parameters and the posterior mean Ideal Actor (Pearson $r(59)=0.65, \mathrm{p}<1 \mathrm{e}-8$ ). This result was still significant using just the data from the 2D structure where differences in Ideal Actor strategies are only due to differences in estimated perceptual noise (Pearson $r(30)=0.38, \mathrm{p}=0.03$ ). This provides weak evidence for our second hypothesis.

Given that many subjects did not use just a single $\lambda_{\text {orientation }}$ throughout the whole experiment, what was the cost of their suboptimal choice? Did they know to avoid choices that would lead to significantly worse performance? To answer this, we compare the theoretical performance of the Ideal Actor to what we call the subject Ideal Observer, the theoretical performance of an Ideal Observer who chose $\lambda_{\text {orientation }}$ on every trial as the subject did. The subject Ideal Observer performance is of interest because it isolates the expected decrease in performance solely due to choice of $\lambda_{\text {orientation }}$. In contrast, differences between subjects' actual performance and the Ideal Actor may be for several reasons unrelated to the information selection strategy. In Figure 4b, we compare the Ideal Actor to subject Ideal Observer performance (in blue), subjects' actual performance (in black) and a baseline where the Ideal Observer who chose $\lambda_{\text {orientation }}$ randomly (in purple). Only seven out of sixty-one subjects had subject Ideal Observers that did not perform significantly better than the baseline suggesting that most subjects were sensitive to the costs of choosing $\lambda_{\text {orientation }}$ incorrectly.

## Discussion

We found some preliminary evidence suggesting that people take category structure and perceptual noise into account. While the correlation between the Ideal Actor and subjects strategies was significant, subjects deviated from the Ideal Actor in other significant ways. In particular, subjects of-
ten used multiple $\lambda_{\text {orientation's }}$ throughout the experiment and actual categorization performance did not match the subject Ideal Observer - two substantive suboptimalities. There may be several reasons for this including that subjects might not use the Ideal Observer rule for categorization or subjects did not learn the exact category parameters in the time allotted. It is difficult to assess subject knowledge in this task since the average subject only had $75 \%$ agreement with the Ideal Observer during the last 10 trials of the category learning phase. Also, a MANOVA found that subjects' disagreement with the Ideal Observer and suboptimality was significantly different across category types (Wilk's $\Lambda=.62, \mathrm{~F}(2,58)=7.6, \mathrm{p}=1 \mathrm{e}-4$ ). This suggests that subjects might have significantly different knowledge about the category across conditions. Finally our estimates of $\sigma_{p_{\text {orientation }}}^{2}$ and $\sigma_{p_{\text {color }}}^{2}$ may not be perfect which might bias our Ideal Actor model.

Not learning the category parameters is probably the most serious issue since the Ideal Actor strategy depends heavily on these parameters. In order to address this, we conducted a second study involving only binary-valued stimulus features. With only a finite number of possible stimuli, we can easily check whether subjects have "learned" the category in the sense of having a high agreement with the ideal observer when selecting the category for a given stimulus.

## Experiment 2

Participants Thirty three participants who did not participate in the previous experiment were recruited through Amazon Mechanical Turk. Payment was the same as in Experiment 1.

Categorization Task Subjects in this task were instructed that they needed to help a doctor discover how to categorize patients presenting certain symptoms. Subjects would see the outcome of two medical tests represented as the color of horizontal and vertical lines (blue if positive and red if negative). All four of the possible outcomes can be seen in Figure 5 (a). Based on the stimulus, subjects would have to determine which of two diseases (A or B) the patient had. These diseases (or categories) were defined as bivariate Bernoulli distributions over possible test outcomes. Let 1 denote a positive test and 0 denote a negative test. Then let $P(\mid D)$ be a matrix where each entry with index $[v, h]$ indicates the probability of the vertical test taking on value $v \in(0,1)$ and the horizontal test taking on value $h \in(0,1)$ given that the patient has disease $D \in A, B$. We used category conditions described in Table 2.

In the first phase of the experiment, subjects simply saw the stimuli in Figure 5 with the above probabilities and subjects were told that the tests were performed with no measurement noise. In the later phases, subjects were told that they now would see $\kappa$ tests on every trial with $\lambda_{\text {horizontal }}$ measurements of the horizontal tests. These tests had Bernoulli measurement noise, i.e. the probability of the horizontal test outputting $k$ tests with the true value on each trial was $\left(\begin{array}{c}\lambda_{\text {horizontal }}\end{array}\right) p^{k}(1-p)^{\left(\lambda_{\text {horizontal }}-k\right)}$. In this experiment, we used
$\left.\begin{array}{|c|c|c|}\hline \text { Condition } & P(\mid A) & P(\mid B) \\ \hline \text { 1D-horizontal } & {\left[\begin{array}{cc}.5 & 0 \\ .5 & 0\end{array}\right]} & {\left[\begin{array}{cc}0 & .5 \\ 0 & .5\end{array}\right]} \\ \text { 1D-vertical } & {\left[\begin{array}{cc}.5 & .5 \\ 0 & 0 \\ \hline\end{array}\right]} & {\left[\begin{array}{cc}0 & 0 \\ .5 & .5 \\ 0 & .5 \\ .5 & 0 \\ 0 & .5\end{array}\right]}\end{array}\right]$

Table 2: Category parameters for Experiment 2. There were six conditions total, with the other three being the same but with the category labels swapped. For the main analysis, we collapse the conditions that share the parameters.
a $p$ of .8. Figure 5 shows an example of a noisy stimulus (i.e., multiple measurements of the horizontal or vertical line segment) with it's true value below. The choice of $\kappa$ and $\lambda_{\text {horizontal }}$ in each phase was exactly the same as in Experiment 1 with subjects having a choice of $\lambda_{\text {horizontal }}$ in the last phase as before. The first three phases of this experiment each consisted of 200 trials and the last phase had 100 . While we could not derive a general analytic solution to the Ideal Actor in this case, we can easily compute the strategy by enumerating all of the potential observed measurements. We also assume that in this case the effects of perceptual noise on performance are minimal.

Figure 5: Example experiment 2 stimuli

## Results

According to hypothesis 1 above, the rank order of the subject $\lambda_{\text {horizontal }}$ in each category structure should be [1D-vertical $\leq$ 2D $\leq 1 \mathrm{D}$-horizontal]. We again found a significant monotonic relationship between category structure and subjects' $\lambda_{\text {horizontal }}$ choice in the direction we hypothesized (Kendall $\tau(31)=0.747, \mathrm{p}<1 \mathrm{e}-9)$. In addition, we found a significant linear relationship (Pearson $r(31)=0.855, \mathrm{p}<1 \mathrm{e}-9$ ) meaning that the exact number of samples subjects chose were proportionally similar to the Ideal Actor. One interesting feature of the data was that most of the errors in subjects responses were in the one-dimensional categories, which may be due to a general hesitancy to only sample information about one feature.

We can also perform the same cost analysis as for the previous experiment. Figure 6 b shows that only one subject did not select measurements significantly better than the random

Figure 6: (a)Violin plot of subjects strategies as a function of category structure. (b)Expected number of additional incorrect trials relative to the Ideal Actor
baseline. We can also check whether subjects truly learned the categories: on average subjects had a $96 \%$ agreement with the Ideal Observer in the second half of the category learning phase and only 1 subject was below $90 \%$. In addition, based on a MANOVA, there was no effect of category structure on suboptimal measurement selection or agreement with Ideal Observer (Wilk's $\Lambda=.88, \mathrm{~F}(2,30)=.96, \mathrm{p}=.43$ ) suggesting that none of the conditions were more difficult than the others.

## Conclusion

We developed a new categorization paradigm in order to study people's strategies for information selection. These tasks allowed us to study human information selection in categorization tasks with measurement and perceptual noise, which we argue is the typical situation in everyday categorization. We analytically derived an Ideal Actor model of this task and from that derived two qualitative predictions for human behavior: 1) that subjects would be sensitive to the category structure and 2) their own perceptual noise. In Experiment 1, the predictions for perceptual noise were not fit to the selection task but estimated in a separate psychophysics task. Across two experiments, we demonstrated that most subjects take into account the category structure. The first experiment provided some evidence that subjects take into account perceptual noise as well although the evidence is somewhat weaker.

In order to get a better understanding of people's strategies, future work could address several additional questions including whether people are sensitive to the costs of information collection (see Meder and Nelson (2012) for some evidence that they do not) of different costs for correct or incorrect answers. Another direction might be whether people may be more sensitive to certain features of the categories (such as differences in the mean) than others (like the feature covariance). Finally, information selection has been proposed to be important in several other domains. Feature-based perceptual attention (Scolari, Edward, \& Serences, 2014) can be thought of as a type of information selection and our model has parallels with some existing models in that literature (Palmer, 1990). A future experiment could use our model to investigate how people allocate perceptual resources during categorization. Many economists have recently investigated limited
information as an explanation for many economic phenomena (Caplin, 2015) but have often assumed that people collect information optimally. Using this model and measurement selection task could allow assessment of how people actually select information in choice situations.

# Perceptual contrast and response assimilation in sequential categorization without feedback 

James A. Hampton (hampton@city.ac.uk)<br>Department of Psychology, City, University of London<br>Northampton Square, London EC1V OHB

#### Abstract

Sequential categorization of perceptual stimuli typically shows contrast from one trial to the next. Using familiar categories of animals and faces, contrast effects were dissociated from assimilation effects. Two independent main effects were observed: contrast to the preceding stimulus, and assimilation to the previous response. It is argued that contrast and assimilation may reflect different processes in categorization.

Keywords: categorization, contrast, assimilation

## Introduction

Learning to categorize stimuli along a perceptual dimension (e.g. the pitch of a tone) would appear to require the establishment of a criterion value against which each stimulus can be judged. Above the criterion stimuli fall in one category, and below in the other (Ashby \& Gott, 1988). However Stewart, Brown, and Chater (2002; 2005) argued that people may be unable to keep a consistent criterion in mind through the course of a sequence of such decisions. It is well known from the literature on absolute identification (where each value on the dimension must be identified separately) that learning to make such judgments is very difficult and prone to bias (Garner, 1953; Baird, Green, \& Luce, 1980). In the same way, Stewart et al. (2002) argued, learning and retaining a given boundary on a perceptual dimension such as the pitch of a tone, will also be hard. Instead of making a judgment relative to an absolute value held in memory, people may instead rely on the difference between the current stimulus and the previous one. Since in a categorization task, feedback is normally provided on every trial, people can use the feedback on the previous trial, together with the direction and degree of change between the previous and the current stimulus to arrive at a reasonably accurate judgment. Stewart et al. referred to this way of doing the task as a MAC, or Memory and Contrast, strategy. Such strategies can lead to reasonable accuracy in the task, without recourse to the representation of absolute values in memory.

In this and subsequent research (Stewart \& Brown, 2004, 2005; Stewart, Brown \& Chater, 2005; Stewart \& Morin, 2007), Stewart and colleagues have shown that the use of MAC strategies produces a category contrast effect between one trial and the next. If a sequence of ten tone stimuli is divided into two categories \#1 to \#5 as "low" and \#6 to \#10 as "high", then a given stimulus next to the borderline (e.g. \#5) will be more likely to be correctly called "low" if preceded by a clearly high case (e.g. \#10) than by a clearly low case (e.g. \#1).

Stewart and Brown (2005) proposed that the category contrast effect could be part of a pair of heuristics in which the similarity and dissimilarity of a stimulus to the preceding stimulus is used to inform its categorization. In their Similarity-Dissimilarity (SD-GCM) adaptation of Nosofsky's Generalized Context Model (GCM) (Nosofsky, 1986), they proposed that categorization takes account not only of similarity to the exemplars of a class, as in the GCM, but also dissimilarity. Adopting Nosofsky and Palmeri's (1997) proposal that recently classified exemplars will have greater influence on the decision, the SD-GCM proposes that when a stimulus is very similar to one on the preceding trial or trials, then it should tend to be put in the same category, while when it is very dissimilar, it will tend to be put in the opposite category. The model thus predicts a contrast effect that increases with the dissimilarity between neighbouring stimuli in a sequence, and turns into an assimilation effect as the two become increasingly similar. Jones, Love and Maddox (2006) describe this prediction in terms of a generalization curve from one trial to the next that is positive for similar items (assimilation), but negative for highly dissimilar items (suppressing categorization, and thus generating contrast).

Evidence for the SD-GCM was also found in a series of studies by Hampton, Estes and Simmons (2005). In their paradigm, pairs of ambiguous stimuli were presented simultaneously and participants judged whether both, just one, just the other, or neither were in a category. A strong contrast effect was observed, seen as a bias to judge that just one stimulus was in the category, rather than both or neither.

The aim of the current study is to investigate contrast and assimilation in sequential judgments empirically. To provide a clear picture of the effect of the previous trial however, it is important to be able to separate out the effects of the previous stimulus from the previous feedback (category membership). Jones et al. (2006) pointed out that Stewart et al.'s (2002) procedure of providing correct feedback on every trial means that the two effects are confounded. To remove this confounding, Jones et al. introduced probabilistic category feedback, with the likelihood of a stimulus being categorized in a given category ranging from $90 \%$ to $10 \%$ across the range of stimuli. With this task, it was possible to separate out the effect of the previous stimulus - which they argued would be based on perceptual contrast - from the effect of the previous feedback, which would be a decisional effect. In their study they found that the previous stimulus produced a perceptual contrast effect, while the previous feedback produced assimilation when stimuli were similar, and contrast when they were very different. The heuristics
proposed by the SDGCM were therefore supported by the decisional contrast and assimilation observed, while in addition the effect of one stimulus was shown to lead to contrast with the next. Looking at the parametric properties of these two effects, they suggested that Stewart et al.'s original category contrast effect was probably perceptual in origin, since the decisional contrast only appeared at extreme distances.

The present study aimed to extend the method used by Jones et al. (2006) by differentiating the effects of the stimulus and the prior category in a simpler way. One problem with probabilistic category feedback is that participants may develop higher order models of the task. For example, if the most typical member of Category A is actually categorized by feedback as a B on $10 \%$ of trials, (non-modal feedback) the participant may develop a justified belief that the feedback is erratic and sometimes gives the wrong answer. They may even believe that the stimulus-response mapping has changed (Berg, 1948). Nonmodal feedback is thus likely to cause disturbance to the current response strategy. Indeed, the reported results (Jones et al., 2006, Figure 5) are consistent with this suggestion. When the previous trial gave modal ("correct") feedback, the response curve rose smoothly with position along the physical dimension, asymptoting near 0.95 for the last two or three stimuli. When the previous trial's feedback was non-modal however, the data showed a pattern of similarity based responding, with generalisation of the same category response to similar stimuli, but also a tendency to reverse categorization for distant stimuli, thus leading to the negative generalisation or contrast for large shifts in stimulus values.

Given the possibility of different interpretations of Jones et al.'s results, it is therefore important to find other means of separating the effects of the prior stimulus and feedback to test the generality and reliability of their result. To do this, a categorization task was used in which, because the categories are well known prior to the experiment, no feedback is needed. Hampton, Estes and Simmons (2005) used a categorization task in which 7 images were shown varying along a dimension in which an image of a cat was morphed into that of a dog (see Figure 1). The task was simply to categorize the images as cats or not cats. Since responses to stimuli in the middle of the range will be probabilistic it is possible to break the data down as a function not only of the previous stimulus, but also of the previous response. While this feedback-free procedure has been used in absolute identification (e.g. Mori \& Ward, 1995) it has not been attempted before for categorization.

Based on the results of Jones et al. (2006), assimilation to the previous response/category was predicted, that is, a bias to place a stimulus in the same category as the previous stimulus. Second, this bias should be stronger when the two stimuli are similar, and may even reverse to a contrast effect if they are very dissimilar. Third, it was predicted that there would be a perceptual contrast effect, such that, holding the previous response constant, then a current stimulus would
be more likely to be placed in the opposite category to the previous one.

## Experiment 1

## Method

Participants. Nineteen students from City University London (10 males) took part in the study.

Materials. Seven images (see Figure 1) were taken from Hampton et al. (2005, with thanks to Vladimir Sloutsky). They ranged from a clear picture of a kitten (\#1) through to a clear picture of a puppy (\#7), with equal morphed steps in between. Each image was $200 \times 200$ pixels, measuring 6.6 cm square on the display screen.

Figure 1: Stimuli used in Expt 1
Apparatus. A Dell PC with a 15-inch CRT was programmed in Microsoft Visual Basic.

Design. A repeated measures factor of Preceding Stimulus with 7 levels corresponded to the stimulus (\#1 to \#7) on the preceding trial. For analysis, this was converted to a measure of Relative Distance between the current and preceding stimulus. A post hoc factor of Response differentiated trials on the basis of the response given on the previous trial. The trial sequence provided a balanced pseudo-random sequence maximizing the number of useful trials. There were 6 blocks of 42 trials each. The 3 central images (\#s 3, 4, and 5) where responding would not be at floor or ceiling were taken as "target" stimuli, and evennumbered trials always featured one of these three. Within a block of 42 trials, each target was preceded on oddnumbered trials by each of the 7 images (including itself and the other target stimuli), and the transition from one trial to the next was balanced as in Table 1. Note that there were no transitions between non-target stimuli. Across blocks, the full transition matrix had 6 times as many trials in each cell as in Table 1. Self-terminated breaks occurred after the second and fourth blocks, and filler trials were introduced at the beginning of the experiment and after each break to provide the starting context for the next set of trials.

Procedure. Instructions were displayed below the 7 images ranked from \#1 to \#7. A trial began with the display of an image below which appeared two response boxes labeled CAT and DOG. The image remained on screen until a response was made with the mouse. A centrally located NEXT button then appeared and had to be clicked, to reduce
response perseveration due to mouse position. On each trial the mouse pointer was moved from the same central starting location. To reduce image persistence, and hence the possibility of detecting small changes from trial to trial, the images were displayed alternately to left and right of center.

Table 1: Transition frequency from one trial to the next within each of the 6 blocks of 42 trials. The shaded area shows the critical trials involving a decision about one of the target borderline images.

|  | Stimulus on Current Trial |  |  |  |  |  |  |  |
| :--- | :--- | :--- | :--- | :--- | :--- | :--- | :--- | :--- |
| Trial <br> Before | 1 | 2 | 3 | 4 | 5 | 6 | 7 | Sum |

| 7 |  |  | 1 | 1 | 1 |  |  | 3 |
| Sum | 3 | 3 | 10 | 10 | 10 | 3 | 3 | 42 |

## Results

Preliminary data processing was required to clarify the results. First, one participant chose "cat" on only 6 of the 180 target trials, and was excluded. Next, the rate of responding "cat" to each stimulus was calculated to check for range effects. The cat/dog boundary was not quite at the center of the scale, but lay between \#3 and \#4 on the CAT side of the center. As a result, almost all responses to \#5 were "dog". Since \#5 would therefore show a floor effect, this stimulus was not used as a target, leaving \#3 and \#4 as the target stimuli. The proportion of "cat" responses given to each of these was calculated as a function of the response given on the previous trial, and the relative distance of the previous stimulus from the current target. Two participants lacked data for just one cell each, and missing values were replaced with the relevant mean group.
Figure 2 shows the proportion of "cat" responses to the current target stimulus, averaged over the two target stimuli \#3 and \#4. The top line shows trials where the preceding response was "cat", and the lower shows trials where it was "dog". The horizontal axis shows the relative distance of the current target from the previous stimulus. Thus CAT+2 represents the case where the preceding trial was 2 steps more cat-like than the target and DOG +3 shows the case where the preceding stimulus was 3 steps more dog-like. TARGET represents the case where the preceding stimulus was the same as the current target stimulus. Note that no data are shown for CAT +3 because target \#3 could only have a previous stimulus (\#1) two steps more cat-like. In addition, two other points are missing from the graph because there were too few data points to estimate the mean.

These points corresponded to the prior stimulus three steps more dog-like (DOG +3 ) being called a "cat", and the prior stimulus two steps more cat-like (CAT+2) being called a "dog".
Figure 2 shows two main effects. First, when the previous response was "cat" (the top line), the current target stimulus was more likely to be called "cat" than when the previous response was "dog" (the lower line). Thus there was an assimilation to the previous stimulus showing up as a perseveration of the previous response. Regardless of the distance on the scale between the current target and the previous stimulus, there was a bias to repeat the same response.

Figure 2: Categorization probabilities for Experiment 1
Second, the lines rise from left to right, indicating a contrast from the previous stimulus. As the prior stimulus became more like a dog (moving from left to right along the axis) so the probability of the current target being called "cat" increased in a linear fashion. For example, consider the lower dotted line in the figure where the previous response was "dog"; the same target was called "cat" only $20 \%$ of the time if following the stimulus CAT+1-a stimulus one step more cat-like - but it was called "cat" over $50 \%$ of the time if following stimulus DOG+3 - where the previous stimulus was 3 steps more like a dog.
The data were submitted to ANOVA with factors of Previous Response (Cat, Dog), and Relative Distance of previous stimulus (four levels for which full data were available: CAT +1 , TARGET, DOG +1 , DOG +2 ). Both main effects were highly significant: Previous Response, $\mathrm{F}(1,17)$ $=76.3, \mathrm{p}<.001$, and Relative Distance, $\mathrm{F}(3,51)=5.36, \mathrm{p}<$ .005 , and there was no interaction $(\mathrm{F}(3,51)=1.4, \mathrm{p}>.2)$. Relative Distance had a significant linear trend $(\mathrm{F}(1,17)=$ 14.7, p < .001).

Before discussing the implications of the results, a replication will be described using the same procedure but a different set of stimuli.

## Experiment 2

## Method

Participants. Participants were 23 students (3 male) from City University, London.

Materials. The stimuli used were a set of morphed images created between two celebrity faces, one of Eva Longoria and the other of Victoria Beckham (see Figure 3). Pilot testing established the necessary gradations to achieve a range of ambiguous images.

Apparatus and Procedure. The same apparatus and procedure was employed as in Expt 1. In addition, in a first phase, participants were shown a sheet of images with 18 morphs changing from Eva to Victoria, and were asked to select the image that they felt was the closest to the 50:50 boundary between the two end images. This image was then used as the central target (\#4) in the sequence for that participant with stimuli \#1 to \#7 in equal steps either side. The same sequence of trials was presented as in Experiment 1, with the question "Is this picture more like Eva or Victoria?" and a mouse response. Data were scored as the probability of categorizing the image as Eva.

Figure 3. Morphed Images of Eva Longoria and Victoria Beckham From the Range of 18 Morphs in Experiment 2

## Results

The mean likelihood of responding "Eva" was calculated for the three borderline target faces, as a function of the relative scale position of the previous face, and the response made to the previous trial. As in Experiment 1, there were two clear effects on the probability of choosing the "Eva" response, over and above the effect of the target face itself. First, the previous response had an assimilation effect when the previous response was "Eva" there was an increase from 0.40 to 0.61 in the probability of the current response being "Eva" regardless of the target or the previous stimulus. Second, as in Experiment 1 the effect of the previous stimulus was to produce a contrasting shift in the response.

Because the range of borderline faces was narrower than in Experiment 1, there were insufficient trials in which an ambiguous target followed another ambiguous face. (These trials are critical to applying the method of analysis used in Study 1).

A different method of analysis was therefore used. The effect of the previous response was calculated for the three images in the middle of the scale $3-5$, where there were sufficient responses of each type. A 2 (Previous response) x 3 (Previous Image) x 3 (Target face) repeated measures ANOVA showed a highly significant effect of the Previous Response, $(\mathrm{F}(1,22)=32.3, \mathrm{p}<.001$.)

To assess the contrast effect, for each participant, target face, and previous response, the correlation was calculated between response probability of saying "Eva" and the scale value of the previous stimulus. For example, for face \#4 in Figure 3, the rate of responding "Eva" was calculated based on which of the 7 faces had been presented on the previous trial. A correlation was then calculated to determine whether the rate was increasing or decreasing as the previous stimulus changed. Six correlations were calculated for each participant, based on the 3 target faces $(3,4,5)$ and two previous response possibilities.

Positive correlations indicated a contrast effect. A higher scale value for the preceding stimulus means it is more like Victoria, so that a contrast effect would see a higher probability of saying "Eva" following face \#7, than following face \#1. The correlations were transformed to Fisher Z and t -tests were run across the participants for each of the 3 targets $(3,4,5)$ and 2 previous responses. Eva responses to Target 3 following an Eva response, and to Target 5 following a Victoria response both showed a range effect (the first being towards ceiling and the latter at floor). For the other four conditions, the average correlation ranged from .35 ( $\mathrm{p}<.05$ ) to .49 ( $\mathrm{p}<.002$ ) all showing a strong positive contrast effect of the previous stimulus.

## Discussion

This study set out to separate the effects of the preceding response and stimulus by using a set of images with a vague borderline region that was wide enough to provide trials where a given prior stimulus could be categorized either way.
First, the results clearly demonstrated strong assimilation to the previous response, in line with the findings of Jones et al. (2006). For the central stimuli where sufficient responses of each kind were available, there was a bias of around .20 to .30 in the probability of a given categorization in the direction of the previous response, regardless of the previous stimulus. Unlike Jones et al. however there was no reduction in the response assimilation effect as the stimuli became more different. There are two likely explanations for this effect. First, in paradigms where feedback is provided, people tend to repeat whatever response was reinforced on the previous trial (Jones \& Sieck, 2003), similar to the situation with probability learning (Edwards, 1961, Jarvik, 1951), and consistent with theories of conditioning (Rescorla \& Wagner, 1972). Even though no feedback was provided (the participants in the present study decided for themselves where the boundary lay) they could nonetheless have treated their previous response as an anchor on which to base the next. This is what Mori and

Ward (1995) reported for an absolute identification task when feedback was omitted. A second explanation would be in terms of instability in the classification criterion adopted by participants over the course of the experiment leading to autocorrelation of responses. If the criterion is sometimes set low, then most stimuli will be "cats", and if it then drifts high, they will mostly be "dogs", yielding a greater preponderance of repeated category responses than expected. (Note that this explanation does not work on the basis of participants having different criteria since response rates were calculated separately for each participant before averaging.)

The failure to show a reduction in response assimilation as the stimuli became less similar may be a function of the design. Trials focused on given borderline targets, preceded by different context stimuli. Thus there were no transitions from one extreme of the scale to the other, which is where Jones et al. observed the response-based contrast effect. There was little point in including such trials as almost all responses to the extreme images were at floor or ceiling. As described in the introduction it is uncertain whether the decisional contrast effect reported by Jones et al. (2006) is genuine evidence for negative generalization of the previously reinforced category (as they argue). When nonmodal feedback was provided (i.e. "false" feedback) performance on the next trial was disturbed, and this could have several alternative explanations. Since the argument for negative generalization depends on the use of invalid feedback, it must be treated with caution.

Once the data were analyzed separately depending on both the stimulus and the response on the previous trial, a contrast effect was also seen, confirming Jones et al.'s report of a perceptual contrast effect between neighboring stimuli, independent of the previous response (or in their case feedback). Unlike Stewart et al.'s (2002) contrast effect, the effect here is unlikely to reflect a MAC strategy.

In comparison with previous research using simple tones or rectangles, participants showed little evidence of noticing when a stimulus changed from the previous trial, and if so in what direction. Our procedure of shifting the image left and right between trials may have made it harder to notice when a stimulus had changed from trial to trial and in what direction. For example, if participants had recognized that a stimulus had been repeated, (the point labeled TARGET in Figure 2) then one would naturally expect the previous response to also have been repeated, leading to extreme response rates of 0 if the previous response was Dog and 1 if the previous response was Cat. The data in Figure 1 show no evidence for this strategy. Similarly, if people noticed the direction of change from trial to trial, extreme responding should have been found when the direction of change was further towards the category previously chosen (the Monotonicity Constraint identified by Hampton et al., 2005). If I have just called something a Cat, and this new image is even more cat-like, I would not now call it a dog. In that case, for example, in Figure 1, the rightmost two points on the top filled line should be at 1 , since here the
participant has said that $\mathrm{DOG}+1$ or $\mathrm{DOG}+2$ looks like a cat, and they are now faced with a more cat-like target. This type of behavior was not seen in the data. It is striking that even though participants appeared to make no use of how the stimuli changed from trial to trial, they were still more likely to judge the current borderline image as a cat, when preceded by a more dog-like image, and vice versa, regardless of how they classified that previous image. Perceptual contrast effects such as this can be explained as adaptation level effects (Hampton et al., 2005; Helson, 1964; Treisman \& Williams, 1984). Treisman and Williams proposed a tracking process, whereby category criteria may adjust themselves towards the average of the current stimulus environment, to maintain maximum sensitivity to change, and thus leading to contrast.
The contrast and assimilation effects built in to Stewart and Brown's (2005) SD-GCM may therefore be operating at different levels, something that previous research has not considered. Contrast - the tendency to see one stimulus as more likely to be in the category opposite to the preceding stimulus - comes out as primarily perceptual in the present experimental set up, showing up regardless of how the previous stimulus was categorized. The fact that pairs of trials where a stimulus was repeated showed no increased tendency to repeat the previous response is clear evidence that participants were not using a MAC strategy in this case. Recall that the MAC strategy explains contrast in terms of a participant judging the sign (and possibly magnitude) of the change in the stimulus presented from one trial to the next. A large shift away from the category of the previous stimulus will give rise to contrast.
Assimilation can also have two sources. According to the SD-GCM it is the similarity of two sequential stimuli that leads to perseverance of the response, and hence to assimilation. If you choose to call one stimulus a cat, and the next stimulus is hardly any different, then you call the next stimulus a cat as well. This type of assimilation should then be sensitive to the distance between the two stimuli. Only when a pair of stimuli are highly similar should you get assimilation.
The assimilation observed here was quite different in character. There was no good evidence in the lines in Figure 1 of the slope flattening out or becoming negative as the previous stimulus approached the target. The large assimilation effect was entirely associated with the effect of the previous response. Having called one stimulus a cat or dog, there was an inertia in the response, leading to a constant bias to place the next stimulus in the same category, regardless of the distance between them.

## Acknowledgments

Komal Nanda and Ibhana Islam contributed to Experiments 1 and 2 respectively. The author acknowledges helpful discussions with Paul Egré and Gregory Murphy, and express warm thanks to Zachary Estes for detailed comments on an earlier draft.

# Radical Embodied Cognition, Affordances, and the (Hard) Problem of Consciousness 

Valerie Gray Hardcastle (VALERIE.HARDCASTLE@uc.edu)<br>Departments of Philosophy, Psychology, and Psychiatry \& Behavioral Neuroscience<br>Cincinnati, OH 45221 USA

#### Abstract

Tony Chemero advances the radical thesis that cognition and consciousness is actually the same thing. He draws this conclusion from his understanding of cognition as an extended process. I question this conclusion because this view expands cognition beyond being the sort of natural kind to which one can tie phenomenal experience. Moreover, because cognition has been radically inflated, despite Chemero's claim to the contrary, embodied cognition does not solve any of the hard problems associated with consciousness.

Keywords: radical embodied cognition; consciousness; perception-in-action; the hard problem.

Novel stimuli capture our attention. This well-known fact forms the basis for several contemporary theories of theories of mind and brain, including Tony Chemero's notion of embodied cognition (Chemero 2009). Chemero holds that noticing unexpected events is key to understanding the larger cognitive system of which our brains are one part. He also believes that expecting some event to occur in the world is somehow tied to our conscious experiences.

In his book Radical Embodied Cognition (2009; see also Silberstein and Chemero 2012, 2015) Chemero (along with Michael Silberstein) advance the radical thesis that cognition and consciousness is actually the same thing. He draws this conclusion from his understanding of cognition as a dynamical, non-linear, relational, and extended process. I question this conclusion. Even if, we are the brain-bodyenvironment synergies that Chemero and others claim we are (e.g., Anderson et al. 2012, Silberstein and Chemero 2012, Kello and van Orden 2009, Kelso 2009), we will not be able to conclude that consciousness and cognition are two sides of the same coin because this view expands cognition beyond being the sort of natural kind to which one can tie phenomenal experience. Moreover, contra Chemero's claim that "the problem of qualia does not arise in radical embodied cognitive science" (2009, Loc 2530/3178), embodied cognition does not solve any of the hard problems associated with consciousness. Nonetheless, some of Chemero's views do help us understand some aspects of conscious experience.

## Radical Embodied Cognitive Science

Most date the recent embodied movement in cognitive science to the work of Rodney Brooks (1991a, 1991b) and Francisco Valera, Evan Thompson, and Eleanor Rosch's book The Embodied Mind (1991), though of course J.J. Gibson's ecological theory is its earliest contemporary incarnation (Gibson 1962,1966,1979). This work was intended to be an antidote for computational views of mind, in which perception, memory, and thought all become manipulations of brain-based mental representations.

Proponents of embodied cognition hold agents' bodies, and often their local environments, are not only physically relevant to cognition, but are also causally constitutive. Moreover, cognition is not the rational and abstract process that computationalists assume, but instead is dedicated to helping our bodies move and act upon our environment.
We evolved as a species to take advantage of our environment, and we do so as we solve so-called cognitive problems. In many cases, what at first appears to be a difficult problem to solve using abstract representations and computations divorced from the physical world turns out to be much easier to resolve if we are allowed to consider our bodies and our environment as cognitive resources. It is easy for a human to learn to move about on land because Mother Nature designed our legs for walking on Earthly terrain (Thelen and Smith 1994). In other words, instead of using our brain to solve problems, we manipulate our bodies and our environments to dissolve them. Moreover, in doing this, we can also alter our bodies and our environments such that the problems we need to solve also change. Gathering food presents a different sort of challenge in a cultivated field, compared to an unspoiled savannah rich with bison.

Hence, instead of thinking of the agent and its environment as two separate entities that occasionally touch each other, it is better to see them a single, interacting, system. It follows from this perspective that cognition is extended into the environment. It also follows that any mathematical model of this larger system should describe how it unfolds dynamically over time, which would require non-linear differential equations.

What makes Chemero's views of embodied cognition radical is that he claims that dynamical systems theory, which we need to be able to model cognition, does not presuppose mental representations, or indeed any representations at all. If brains, bodies, and environment form one unified system, then there is no need for one part of the system to represent another part of the system for everything is always and already connected. Perception, action, and thought itself are all non-representational and non-computational. Let us accept this view as true and see how he might explain consciousness using this understanding of human cognition and action.

## Conscious Cognitive Systems

Silberstein and Chemero (2012) hold that conscious experience is "an essential feature of extended brain-body- environment systems" (p. 36) and that phenomenology and cognition are "inseparable and complementary aspects of coupled brain-bodyenvironment systems....Experience is cognition and cognition is experiential" (pp.40-41). They each "codetermine" the other (p. 41). They get there by positing that some version of neutral monism must be true, if the thesis of radical embodied cognition is true (Silberstein and Chemero 2015). They trace this metaphysics back to William James, who held that there was no actual difference between the so-called objective world out there and the subjective experience of the world in each of us. "What represents and what is represented is here numerically the same" (James 1904, p. 484). Both the subjective and the objective are defined in opposition to one another, and both are ways of understanding the world, which is the "more basic neutral 'stuff' of experience" (Silberstein and Chemero, 2015, p. 186). Hence, one cannot have cognition, an objective process, without also having at the same time, consciousness, the subjective experience.

Computational theories of mind artificially create a problem for consciousness, for they give the impression that one can have mental computation without concomitant conscious thought. We get the problem of consciousness because we can imagine nonhuman, apparently unconscious, machines instantiating a computational theory of mind. That is, we can imagine cognition without consciousness, or so we think.

This is the hard problem of consciousness, a challenge that dates back to at least Gottfried Leibniz in $1714:^{1}$ because we can imagine a something that is

[^85]identical to a human's (or a brain's) physical interactions without also imagining that thing's consciousness, it appears that nothing about any physical interaction should give rise to phenomenal experience. And yet, we are conscious, nonetheless. How can this be? (Leiniz's answer, like David Chalmer's $(1995,1996)$ more contemporary one, is to posit that consciousness is a fundamental part of the ontology of the universe.)
But if computational theories of mind are false, then this particular problem of consciousness does not arise. Cognition is a feature of our extended and embodied system, as is consciousness. By "[refusing] to separate meaningful cognition and phenomenology" (2012, p. 41), Silberstein and Chemero believe that they have eliminated the so-called hard problem of consciousness essentially by definitional fiat. They assert that, "neutral monism properly conceived really does deflate the hard problem once and for all" (2015, p. 182).

Can they do this? To answer this question, we need a more complete picture of what they are envisioning an extended phenomenological-cognitive system to be.

Our nervous system has its own spontaneous and internally generated dynamics, which in turn create transient neural assemblies comprising our sensorimotor capabilities. We are coupled to our environment via these sensorimotor structures, which result in changes to both our internal transient neural assemblies via sensory feedback and in the external environment via behavioral responses. Over time, we become attuned to nuances in the extended brain-bodyenvironment system that complements our sensorimotor sensitivities and external features; this is our niche.
What we perceive in our environment via our sensorimotor structures (and probably other related neural assemblies) are nothing less than Gibsonian affordances, relational features of the brain-bodyenvironment system used to guide our actions and behavior. They are what the environment contains and what we can do. Silberstein and Chemero claim that the "set of affordances" we perceive in our world, "just is the environment as [we] experience it" (2012, p. 43, italics theirs). Hence, "cognition and conscious experience can be understood as a single phenomenon"

[^86](p. 35). Consciousness "is inseparable from cognition, which is the ongoing activity of a nervous system, body, and niche non-linearly coupled to one another" (p. 43).

Just as our neural assemblies are not anatomically hardwired - they are "softly" assembled - so too are the borders of the brain-body-environment system. How far and how much we extend into the environment depend a great deal on what we are trying to do and what barriers or assistance the environment provides to us. The entire system itself then is also a soft assembly whose interaction dynamics determine its structure.

Some call such interaction dominant, softly assembled, systems "synergies." A synergy is a set of structural units that temporarily link together to form a single cohesive functional system. It is maintained or changed on the fly as its dynamics and processes ebb and flow over time (Anderson et al. 2012, Kelso 2009).

We know that we have a synergy when we can measure pink noise associated with it. Pink noise, or $1 / f$ noise, refers to a signal in which the power spectrum density (energy per Hz ) is inversely proportional to the frequency. (It is called pink noise because visible light with this power spectrum looks pink.) We can contrast pink noise with white noise, which has equal energy on every frequency. Pink noise is also a hallmark of fractal timing and appears to be ubiquitous in nature, occurring in everything from cosmic background radiation to flooding patterns of the Nile River (see also Strogatz 2004 for a popular way into these phenomena). It is an indication of nested, selfsimilar structures that occur over time. Guy van Orden and his colleagues (2003) argue that pink noise signifies just the sort of interaction-dominant, softly assembled, system we have been discussing as a model for cognition. (See also Miyazaki et al. 2004.) And with this technical idea in hand, scientists are now able to manipulate and measure our dynamic embodiment experimentally.

For example, Chemero and his colleagues devised an experiment that forces change in our extended cognitive synergy (Dotov et al., 2010, 2017). Undergraduates engaged in a simple video game, using a computer monitor and a mouse. At irregular intervals during each trial, the connection between the mouse and the monitor was disrupted. Interestingly, pink noise is present at the hand- mouse interface until the disruption. Once the disruption is over and the connection returns to normal, the pink noise returns. These measures index changes in the boundary of the extended cognitive synergy. During the normal phase of the task, the mouse is part of the system. During disruption, it is not.

Most important for our purposes, the measures of pink noise correlate with our conscious experiences. When we are engaged in the video game, we are
not aware of the hand-mouse interface per se, but once the connection between mouse and monitor is altered, then the mouse grabs our attention and we become aware of it. The point is, we project ourselves into our environment, and in so doing, we experience the edges of our extended system. We have long known that this is the case, but it is only now that psychologists have been able to develop metrics for measuring changes in our projections.

The pink noise of our cognitive synergy indexes our phenomenal experience. I think that this is the best argument for why the picture Chemero paints might in fact be true. We notice and pay attention to, experience, things that do not match our predictions or expectations. And we experience these things in terms of what we could do, or how we could act. Our experiences are about or of the relationship we have with the world, which is continuously changing and evolving.

These mixes of brain, body, and environment are what Gibson called objective-subjective hybrids. And that fact, Chemero believes, solves the problem of consciousness. For this is how subjectivity exists in an objective world-it exists in the on-going relationship between an agent and the context of its actions. (The relationship itself is neither subjective nor objective. This is the neutral substrate that allows us to define subjectivity and objectivity as two different aspects of the same "monism.")

## The Hard Problem is Hard

What is wrong with this story? Essentially, it is that the sort of non-linear coupling that links us with our environment is found at all sorts of levels of organization. Without further analysis, we cannot identify which level corresponds to cognition; hence, tying consciousness to cognition either means consciousness exists at multiple levels of organization, which strikes most people as improbable, or more work needs to be done to delineate consciousness cognition from other synergies. If we need to do more work, then the problem of consciousness remains to be solved.

To take one example, we find synergies within the brain itself. These are softly assembled, interactiondominant, nonlinear dynamical systems whose behavior strongly resembles prototypical cognition, perception, and action. It is questionable whether these systems are also conscious.
Neuroscientists are now capable of recording responses from thousands of neurons simultaneously. It is becoming clear that neural correlates for things like memory and decision-making are at the population level (Abbott 2012). Modeling studies show that while the action potentials of individual neurons might appear disordered and uncoordinated, population level activity is not.

We know that neurons and neural circuits have to respond quickly and flexibly as contexts change. This means that they need to be able to ignore irrelevant information while reacting to whatever is important to the larger task at hand. Neural responses in the frontal eye fields in monkeys were recorded as they performed a visual discrimination task using noisy stimuli. It turns out that individual neurons simultaneously respond to the motion and color of stimuli, the context, as well as the target itself. However, these signals are separable at the population level through linear regression (Mante et al. 2012). Importantly, stimuli analysis at the population level is integrated with motor choices, just as proponents of embodied cognition would have predicted. We see similar dynamics in the olfactory system of the fly (Luo et al. 2010).

One important facet of nonlinear dynamical systems is that they are nested systems, and their components exhibit the same sort of dynamics as the system as a whole. Individual neurons and the ion channels in neurons also appear to have the same dynamical pink noise properties as the activity of populations of neurons (White et al. 1998, Yu et al. 2005). While most are comfortable believing that monkeys are conscious, it is less clear that we want to assert that flies are, and it is even more problematic to assert that parts of monkey brains or fly brains are conscious.

Chemero perhaps could wriggle out of this problem with his definition of cognition. That is, these might be synergistic systems, but they are not cognitive synergies. He defines cognition as "the ongoing, active maintenance of a robust animal-environment system, achieved by closely coordinated perception and action" (2009, loc. 2696/3178). In other words, the sorts of dynamically coupled systems I have been discussing are necessary but not sufficient for cognition. He is restricting consciousness to the brain-bodyenvironment system's level, or perhaps even to the animal brain-body-environment system. If you move inside the head, while there might exist dynamical systems modeled in identical ways to an animal brain-body-world synergy, there would be no actual cognition. And no cognition would mean no consciousness either, according to Chemero's view.

Of course, this move does not solve the hard problem of consciousness, since it does not explain what might be special about the animal brain-bodyenvironment synergy such that it has consciousness but the olfactory system of the fly brain does not. Indeed, this move echoes the challenge before the computationalist: what is it that is special about human (or primate or animal or whatever is conscious) computations that make them conscious? Prima facie, there is nothing about the computations themselves that should give rise to conscious experience, and there
are certainly many computational systems that we believe are not conscious. Similarly, we can ask: what is it that is special about an animal brain-bodyenvironment interaction that is cognitive and therefore consciousness? Prima facie, there is nothing about being an animal synergy that should give rise to conscious experience. In particular, there does not seem to anything special about an animal brain-body-environment interaction that an animal brain piece-body piece-environment interaction would not also share. Put another way: there does not seem any reason to believe that the neutral monads that comprise our world exist at the level of animalenvironment relations as opposed to animal-partenvironment relations.

Of course, another alternative is that Chemero could bite the bullet here and conclude that fly pieces are indeed conscious, in their own sort of fly-ish way. Being an interaction-dominant, softly assembled, pink noise sort of synergy is both necessary and sufficient for cognition and therefore for consciousness as well. The right sort of dynamics is all you need for cognition; the nested components of the nonlinear systems have all the same properties as the mother system, and this would include cogitating and consciousness.
Perhaps, though, he would not want to do this, since, as Silberstein and he point out, one advantage of tying consciousness to cognition is to "[eliminate] fruitless philosophical discussion of qualia and the so-called hard problem of consciousness" (2012, p. 35). They want to get rid of the challenge of envisioning odd machines as being conscious because they are computing over representations by denying that conscious systems compute at all. But here we are, back discussing an odd machine and whether it has experiences. This time, however, we are wondering whether the system is cognitive after all.

The complaint similar to the one Chemero and Silberstein lodge against traditional consciousness studies can also be lodged against them. While we can define cognition as a particular type of synergy, and we can believe that cognition just is an extended, softly assembled animal brain-body-environment synergy, and we can deny that manipulating representations has anything to do with humans thinking, we still do not escape the fundamental problem with explaining consciousness, that is, explaining why anything at all is conscious.

In other words, there is no reason why a neutral substrate should be conscious. It is, according to their view. But just as we can imagine (or so the story goes) things that are functionally identical to humans but are not conscious, so too can we envision complex brain-body-environment synergies comprised of a neutral substrate that is not conscious. The hard problem remains.

Or, perhaps a more accurate way to describe Silberstein and Chemero's move: consciousness just is an inherent aspect of affordances. Like Chalmers, they try to eliminate the hard problem by making consciousness part of the fundamental structure of the world. But just as with dualism, one needs an argument or evidence for why subjectivity appears where it allegedly does.

## Coda: Consciousness, Projection, and Action

However, there is at least one important difference between the brain-body-environment synergies and the human coupling described above that might give us some insight into conditions for conscious awareness: we do not or cannot project ourselves psychologically onto or through the other individuals. Unlike driving a car, in which we can "feel" the tires on the road, when coupled with another person, we do not "feel" the other person's feet hitting the ground. Whatever sort of system or synergy coupled humans are, the psychological reality of having an animate object in the environment is quite different from having an inanimate object. Inanimate object-environment synergies are transparent to us; human couplings are not.

There has to be something fundamentally different between the two. What is it? I argue that the difference lies in how we perceive the respective affordances. And insofar as how we perceive affordances is tied to how we consciously experience the world, then it could be that Chemero is onto something after all.
For example, there are some odd cases of associative agnosia in which patients are unable to recognize or name living things (like lions or opossums), but they can recognize and name inanimate objects (like forks and radios) without a problem (Satori and Job 1988). If we take a traditional neuro-reductionist point of view, then we should conclude that information about living things is stored in a different place in the brain than information about inanimate objects. Damage to the "living thing" place in the brain results in patients with deficits in recognizing living things and damage to the "inanimate object" place results in patients with deficits in recognizing inanimate objects. But interestingly, and perhaps counter-intuitively, there are very few cases in which a patient cannot recognize inanimate objects, but can recognize living things. We don't get the neat double dissociation that neuropsychologists love.
If there are two separate areas for living and inanimate objects, then why would we find brain damage possible in one area but not the other? Antonio Damasio (1990) suggests that this pattern could be due to a difference in how we perceive living and inanimate objects. In particular, we manipulate inanimate objects, but, for the most part, we do not living ones. As a result, we would be activating a
greater number of brain regions when we perceive inanimate objects than when we do living things: in both cases, we activate the areas associated with visual perception, but in the case of seeing a tool in our environment, we also activate kinesthetic and motor movement brain regions. (Imaging studies bear out Damasio's conjecture, cf., Gerlach et al. 2002, Kellenback et al. 2003.) Hence, it might be the case that we do not have different brain areas that respond differentially to living versus non-living objects, but rather that we just have more regions involved with one type of perception over another. With more regions activated in response to inanimate objects, and therefore more regions that would have to be damaged in order to see the related agnosia, it would not be surprising that we have a hard time finding patients with deficits naming inanimate objects but not living ones.
Here then is the hypothesis: we distinguish objects in our environment based on how we (potentially) interact with them. We perceive living things by their visual features and concomitant affective responses, but inanimate objects based on functional properties. This, of course, is just another way to look at affordances: we see and understand the objects around us in terms how we relate to them, and they to us. But now we can go further: not only are differences in psychological projection between animate and inanimate objects tied to perceptual differences, but also to action-decisions and consciousness itself.
I am claiming that we do not project ourselves through what we perceive to be other living things in our environment. We can only project ourselves through objects that we manipulate functionally (I note that there might be good exceptions to this general rule; for example, when we use a living thing as a tool in our environment. A practiced person might project through a trained seeing-eye dog to the environment beyond.) And, we can only extend our conscious experience into whatever psychological space of projection we have available to us. One limit on our conscious experience is not just the edge of the affordance, so to speak, but it is also the type of affordance we perceive. Functional objects become psychologically transparent to us, such that we project our conscious experiences through them. Animate objects do not.
I conclude: Chemero (and Silberstein) cannot escape the hard problem of consciousness by positing neutral monism. Nevertheless, there is something right about his position. Consciousness is connected to or indexed by or co-occurs with or identical to our perception of affordances, which is intimately tied to how we interact with the objects in our environment. We are aware of what we intend to manipulate in our environment in order to achieve our behavioral goals. Hence, consciousness is not identical to all cognition; it is not even identical to all brain-based cognition.

Instead, it is deeply linked to one very important part of our cognitive processes: perceiving affordances just prior to action.

## Acknowledgments

Early versions of the paper were presented to the Society for Philosophy and Psychology, the University of Waterloo, and at the Conscious Persons workshop at Calvin College. Many thanks to all the participants for their helpful and thoughtful comments. Special thanks are also due to Tony Chemero and Mike Silberstein for engaging with me on this topic, and to the referees for the Cognitive Science Society, whose thoughtful comments made this essay better. This research was partially supported by the Templeton Foundation and the University of Cambridge.

# Convention-formation in iterated reference games 

Robert X.D. Hawkins, Michael C. Frank, Noah D. Goodman<br>\{rxdh, mcfrank, ngoodman\}@stanford.edu<br>Department of Psychology, Stanford University

#### Abstract

What cognitive mechanisms support the emergence of linguistic conventions from repeated interaction? We present results from a large-scale, multi-player replication of the classic tangrams task, focusing on three foundational properties of conventions: arbitrariness, stability, and reduction of utterance length over time. These results motivate a theory of convention-formation where agents, though initially uncertain about word meanings in context, assume others are using language with such knowledge. Thus, agents may learn about meanings by reasoning about a knowledgeable, informative partner; if all agents engage in such a process, they successfully coordinate their beliefs, giving rise to a conventional communication system. We formalize this theory in a computational model of language understanding as social inference and demonstrate that it produces all three properties in a simplified domain.

Keywords: conventions; pragmatics; communication

## Introduction

Just as drivers depend on shared behavioral conventions to safely navigate traffic, successful communication depends on a set of shared linguistic conventions. Speakers of different languages around the world refer to the same object in many different ways, yet when ordering a coffee in San Francisco, one can confidently use the English word "coffee" and be understood. How do these conventions - classically characterized by Lewis (1969) as arbitrary but stable solutions to recurring coordination problems - form in the first place?

While global conventions adopted and sustained throughout a large population of speakers may develop over longer time scales, we also effortlessly coordinate on local conventions - or conceptual pacts (Brennan \& Clark, 1996) within the span of a single dialogue. For example, when discussing possible conditions to use in an upcoming experiment, a team of collaborators might begin the meeting using long descriptions to refer to each condition but end the meeting using conventional terms like "condition A" and "condition B." Since global conventions are hypothesized to emerge through diffuse, repeated interactions of this more local kind (Garrod \& Doherty, 1994), the cognitive mechanisms underlying convention-formation in such interactions are of foundational interest.

In a seminal study by Krauss \& Weinheimer (1964), pairs of participants played a cooperative language game where they were presented with arrays of ambiguous shapes in randomized orders. The players were assigned the roles of director and matcher and allowed to talk freely. The matcher's goal was to rearrange their shapes to match the director's board, and the director's goal was to communicate useful descriptions. Over multiple rounds, descriptions were dramatically shortened: an early description like "upside-down martini glass in a wire stand," became simply "martini" by the
end. Later studies (e.g. Clark \& Wilkes-Gibbs, 1986) refined this paradigm, using larger arrays of tangram-like figures and emphasizing the intricate back-and-forth process through which speakers and listeners negotiate over references. The referring expressions generated by participants in these studies revealed a number of rich qualitative phenomena. Here, we focus on three that are both prescribed top-down by theories of convention-formation and also arise bottom-up as major axes of variation in our data: arbitrariness, stability, and the systematic reduction of utterance length over time.

Arbitrariness is a definitional property of conventions (Lewis, 1969): there must be multiple solutions that would be equally successful as long as both players "agree" (e.g. driving on the left vs. right side of the road). By the final round in a language game, for example, one pair might successfully use the expression 'dancer' to refer to a tangram, while another might use 'skater'. The other definitional property we consider is stability: it is in everyone's best interest to keep using a convention once established. Finally, reduction is more specific to the reference game paradigm and refers to the transformation of longer, complex expressions into simpler expressions over the course of interaction, as Krauss \& Weinheimer (1964) observed. While this broad phenomenon has been replicated many times, exactly what is reduced remains an open empirical question.

Theories of convention-formation differ primarily in the extent to which sophisticated social reasoning and common ground is required. At one extreme, agents use simple heuristic updating rules and do not need to represent or reason about other agents at all (Barr, 2004; Centola \& Baronchelli, 2015; Young, 2015). Simulations elegantly show how arbitrary signaling systems can spread and come to stably dominate large populations. However, due to their 'rich get richer' dynamic, it is not clear how simple heuristic updating mechanisms alone could account for reduction in repeated interaction. At the other extreme are theories in which agents recursively track what information is mutual knowledge, often formalized in a game theoretic setting (Lewis, 1969). Wilkes-Gibbs \& Clark (1992) and others have proposed that agents engage in a collaborative process of actively establishing mutual knowledge, though the mechanisms allowing conventions to emerge under such conditions have not been instantiated in a formal model to our knowledge.

In this paper, we argue for a theoretical position on the spectrum between these poles: conventions form when uncertain agents treat their partners' knowledge as ground truth. In other words, agents assume their partner is knowledgeably and rationally using some conventional lexicon mapping labels to meanings but are themselves initially unsure of its

Figure 1: Example trial in experimental interface. Both players could freely use the chat box, and the matcher could click and drag the tangram images.
identity. Through observing their partner's behavior in repeated actions, agents learn and adopt that lexicon, though their partner in fact begins in the same state of ignorance. When both agents independently adopt such a social learning strategy, they align to one another, coordinating on and implicitly creating shared conventions.

To motivate this theory, we first conduct a large-scale replication of the tangrams task on the web, which has traditionally been limited to relatively small sample sizes in the lab. We use distributions of lexical and syntactic features in the text corpus to operationalize arbitrariness, stability, and reduction, which have been difficult to analyze at a fine-grained level due to the sparseness of existing data. Taking these insights into account, we then formalize our theory in a computational model of communication in repeated reference games based on recent successes capturing language understanding as social inference (Goodman \& Frank, 2016; Goodman \& Stuhlmller, 2013). Finally, we show that this model qualitatively produces all three empirical signatures in a simplified domain inspired by the tangrams task.

## Replication of the Tangrams task

To collect a corpus of reference game dialogue that supports more detailed analyses of convention-formation, we ported the tangrams task used in Clark \& Wilkes-Gibbs (1986) to a real-time, multi-player web environment.

## Methods

Participants 200 participants were recruited from Amazon's Mechanical Turk and paired into dyads to play a realtime communication game using the framework in Hawkins (2015). We excluded games that terminated before the completion of 6 rounds and where participants reported a native language different from English, leaving a corpus of 67 complete games with a total of 9967 utterances.

Stimuli On every trial of the game, both participants were shown a $6 \times 2$ grid containing twelve tangram shapes, reproduced from Clark \& Wilkes-Gibbs (1986). Cells were labeled with fixed numbers from one to twelve in order to help par-
ticipants easily refer to locations in the grid (see Fig. 1).
Procedure After passing a short quiz about task instructions, participants were randomly assigned the role of either 'director' or 'matcher' and automatically paired into virtual rooms containing a chat box and grid of stimuli. Both participants could freely use the chat box to communicate at any time. The director's tangrams were fixed in place, but the matcher could click and drag the shapes to reorder them. The director had to send messages about the locations of different tangrams on their fixed board; the matcher had to identify the corresponding tangram shapes and move them to the correct locations. When the players were satisfied that their boards matched, the matcher clicked a 'submit' button that gave players feedback on their score (out of 12) and scrambled the tangrams for the next round. After six rounds, players were redirected to a short exit survey. We collected the raw text of every message sent and every swapping action taken by the matcher ${ }^{1}$

## Results

Arbitrariness and stability We begin by examining signatures of arbitrariness and stability in our data. We operationalize these concepts using the information-theoretic measure of entropy:

$$
H(W)=\sum_{w} P(w) \log P(w)
$$

where $P(w)$ denotes the distribution over frequencies of word tokens used within a game. Broadly speaking, entropy measures the predictability of a distribution. It is maximized when all elements are equally likely and declines as the distribution becomes more structured, i.e. when the probability mass is concentrated on a small subset of elements.

To derive predictions, we consider a permutation-test null model in which utterances on each of the six rounds are scrambled across games, designed to break any existing structure in each game's idiosyncratic word distributions. The mean empirical entropy should only differ from the null distribution of entropies generated from this scrambling process if both arbitrariness and stability hold.

First, note that if stability did not hold, scrambling would have no effect on the entropy within individual games: a given speaker would already use different words each round, and swapping out the identity of those words would not affect the entropy of the word distribution. There would be no structure to break.

If stability holds but arbitrariness does not, all players would adopt the single optimal (non-arbitrary) way to refer to each tangram. Therefore, the entropy of their word distributions also should not be affected by scrambling: a speaker's real words would be swapped out for the same tokens generated by another speaker. Scrambling wouldn't break the

structure of the distribution, because the structure would be the same for all participants.

Finally, if both arbitrariness and stability hold, then different speakers would adopt different referring expressions that persist from round to round. Hence, scrambling should increase the average game's entropy from a relatively low level: each game's idiosyncratic, concentrated distribution of words would be mixed together to form more heterogeneous and therefore high-entropy distributions.

To test this prediction, we computed the average withingame entropy for 1000 different permutations of speaker utterances. Since this permutation scheme keeps the number of messages per participant constant and simply swaps out the content of those messages within each round, it controls for the fact that some speakers sent more messages than others and also that speakers in earlier rounds use more words (see next section). We found that our null distribution lay within the interval [4.88, 4.91], which is significantly higher than the true entropy (averaged across games) of 4.36, $p<0.001$. This pattern is consistent only with signatures of both arbitrariness and stability.
Reduction Next, we turn to a set of analyses examining reduction in utterance length over the course of the experiment. At the coarsest level, we find that the mean number of
words used by speakers decreases over time (see Fig. 2). This decrease replicates a highly reliable reduction effect found throughout the literature on iterated reference games (Brennan \& Clark, 1996; Krauss \& Weinheimer, 1964). Likely due to our purely textual (vs. spoken) interface, participants in our task used significantly fewer words overall than previously reported (e.g. an average of 20 words on the 1 st round, compared to 40 in Clark \& Wilkes-Gibbs (1986)) The following analyses break down this broad reduction into a finer-grained set of phenomena.

The next level of granularity motivating our model approach concerns which kinds of words are most likely to be dropped. Is the speaker adopting a shorthand where they drop uninformative function words, or are they simplifying or narrowing their descriptions by omitting meaningful details (Clark \& Wilkes-Gibbs, 1986)? We used the Stanford CoreNLP part-of-speech tagger (Toutanova, Klein, Manning, \& Singer, 2003) to count the number of words belonging to each part of speech in each message. Fig. 3 shows the percent reduction of different parts of speech from the first round to the sixth round. We find that determiners ('the', ' $a$ ', 'an') are the most likely class of words to be dropped with an $86 \%$ reduction rate, on average. Nouns ('dancer', 'rabbit') are the least likely class to be dropped with only an $62 \%$ rate. Closed-class parts of speech are strictly more likely to be dropped than open-class parts of speech.

While this finding is consistent with the possibility that speakers adopt a shorthand using more fragments as the game proceeds, we find a more complex dynamic by examining the table of unigrams and bigrams most likely to be dropped (see Table 11. Note that alongside dropped articles ('a', 'the'), there are a number of words that form conjunctions ('and') and modifiers ('of', 'with', 'the right'). In other words, it may be more likely that when function words are dropped, it is primarily as part of larger grammatical units that provide additional information in identifying the target.

We explicitly examined this hypothesis by running the Stanford constituency parser (Schuster \& Manning, 2016),
tagging the occurrence of subordinate/adverbial clauses ('sitting facing left') and adjectival clauses ('angel that is praying') $\rrbracket^{2}$ We found that both were reduced over the course of the game (see Fig. 2), lending additional support for the hypothesis that whole meaningful clauses are increasingly omitted. This result prompts a characterization of reduction where, due to uncertainty at the outset about the usefulness of any particular lexical unit, initial phrases pile on multiple partially redundant modifiers and descriptors. As the game progresses and ambiguity of reference decreases, these additional meaningful units become less useful and can be dropped. We return to this characterization more formally within the scope of our model below.

## Model

Here, we present a probabilistic model of language production under uncertainty, which captures several of the signature properties of conventions shown above. This model belongs to the family of Rational Speech Act (RSA) models, which have been successful in explaining a wide range of linguistic phenomena - including scalar implicature, adjectival vagueness, overinformativeness, indirect questions, and nonliteral language use - as arising from a process of recursive social reasoning. Most previous applications of RSA have focused on the listener's problem of language comprehension, but the puzzle of conventionalization is primarily a question of speaker production. An $n$th order pragmatic speaker trying to convey a particular state of affairs $s \in S$ assuming lexicon $\mathcal{L}$ is assumed to select an utterance $u \in \mathcal{U}$ by trading off its expected informativity (with respect to a rational listener agent) against its cost, usually based on length (Goodman \& Frank, 2016):

$$
S_{n}(u \mid s, \mathcal{L}) \propto \exp \left(\alpha \log L_{n-1}(s \mid u, \mathcal{L})-\operatorname{cost}(u)\right)
$$

where $\alpha$ is a soft-max optimality parameter controlling the extent to which the speaker maximizes over listener informativity. The listener, in turn, inverts the speaker model to reason about what underlying state $s$ the speaker is trying to convey, given their utterance $u$ :

$$
L_{n}(s \mid u, \mathcal{L}) \propto P(s) S_{n}(u \mid s, \mathcal{L})
$$

This recursion bottoms out in a literal listener who directly looks up the meaning of the utterance in the lexicon:

$$
L_{0}(s \mid u, \mathcal{L}) \propto \mathcal{L}(u, s) \cdot P(s)
$$

As in several other recent applications of RSA (Graf, Degen, Hawkins, \& Goodman, 2016), we use a graded semantics, where utterances are better or worse descriptions of particular referents. For instance, the utterance "dancer" may initially be expected to apply to a photorealistic image of a ballerina $(\mathcal{L}($ 'dancer', ballerina $)=0.99)$ more than an abstract

[^88]image of one ( $\mathcal{L}($ 'dancer', abstract ballerina $)=0.6)$, but apply to both better than a non-category member like an image of a $\operatorname{dog}(\mathcal{L}($ 'dancer', dog $)=0.05)$.

Our approach to convention-formation begins with the additional assumption of lexical uncertainty (Bergen, Levy, \& Goodman, 2016; Smith, Goodman, \& Frank, 2013). In other words, we assume that instead of having perfect knowledge of $\mathcal{L}$, the listener has uncertainty over the exact meanings of lexical items in the current context (i.e. it is initially unclear which of the ambiguous tangram shapes "the dancer" might refer to). They begin with some prior $P(\mathcal{L})$ about the identity their partner's true lexicon, which may be initially biased toward certain meanings. By conditioning on repeated observations of their partner's behavior, they use Bayes rule to infer this true lexicon:

$$
P_{L_{n}}(\mathcal{L} \mid d) \propto P(\mathcal{L}) \prod_{i} S_{n}\left(s_{i} \mid u_{i}, \mathcal{L}\right)
$$

where $d=\left\{s_{i}, u_{i}\right\}$ is a set of observations of $s_{i}$ and $u_{i}$ coming from previous exchanges $3^{3}$ The listener marginalizes over this posterior when interpreting the speaker's utterance:

$$
L_{n}(s \mid u, d) \propto \sum_{\mathcal{L}} P_{L_{n}}(\mathcal{L} \mid d) L_{n}(s \mid u, \mathcal{L})
$$

The speaker, in turn, considers what utterances would be most informative for such a listener:
$S_{n}(u \mid s, d) \propto \exp \left(\alpha \log \left(\sum_{\mathcal{L}} P_{S_{n}}(\mathcal{L} \mid d) L_{n-1}(s \mid u, \mathcal{L})\right)-\operatorname{cost}(u)\right)$
where the posterior over lexica $P_{S_{n}}(\mathcal{L} \mid d)$, uses the listener likelihood $L_{n-1}$. For the purposes of this paper, we fix the depth of recursion at $n=2$. This model is implemented in the probabilistic programming language WebPPL (Goodman \& Stuhlmller, electronic) ${ }^{4}$ Following Smith et al. (2013), we begin by showing how a random initial choice is taken to be evidence for a particular lexicon and becomes the base for successful communication even though neither party knows its meaning at the outset.

## Results

Arbitrariness and stability Consider an environment with two abstract shapes ( $\left\{s_{1}, s_{2}\right\}$ ), where the speaker must choose between two utterances ( $\left\{u_{1}, u_{2}\right\}$ ) incurring equal cost. Their prior $P(\mathcal{L})$ over the meaning of each utterance is given by a Beta distribution ${ }^{5}$, so on the first round both utterances are

[^89]

Figure 4: (A) Probability of speaker using $u_{1}$ to refer to $s_{1}$, broken out by initial observation: while players are initially ambivalent between the two labels (arbitrariness), the initial mapping is likely to persist (stability). (B) Accuracy rises as speaker and listener align. (C) When conjunctions are introduced into the grammar, utterances get shorter over time (reduction).
equally likely to apply to either shape. If the speaker was trying to get their partner to pick $s_{1}$, then, since each utterance is equally (un)informative, they would randomly sample one (say, $u_{1}$ ), and observe the listener's selection of a shape (say, $s_{1}$ ). On the next round, the speaker uses the observed pair $\left\{u_{1}, s_{1}\right\}$ to update their beliefs about their partner's true lexicon, uses these beliefs to generate a new utterance, and so on. To examine expected dynamics over multiple rounds, we forward sample many possible trajectories.

We observe several important qualitative effects in our simulations. First, the fact that a knowledgeable listener responds to utterance $u$ with $s$ provides evidence for lexicons in which $u$ is a good fit for $s$, hence the likelihood of the speaker using $u$ to refer to $s$ increases on subsequent rounds (see Fig 4 A ). In other words, the initial symmetry between the meanings can be broken by initial random choices, leading to completely arbitrary but stable mappings in future rounds. Second, because the listener is also learning the lexicon from these observations under the same set of assumptions, they converge on a shared set of meanings; hence, expected accuracy rises on future rounds (see Fig. 4B). Third, because one's partner is assumed to be pragmatic, agents can also learn about unheard utterances. Observing $d=\left\{u_{1}, s_{1}\right\}$ also provides evidence that $u_{2}$ is not a good fit for $s_{1}$ by Gricean maxims: if $u_{2}$ were a better fit for $s_{1}$, the speaker would have used it instead (Grice, 1975). Finally, failed references lead to conventions just as effectively as successful references: if the speaker intends $s_{1}$ and says $u_{1}$, but then the listener incorrectly picks $s_{2}$, the speaker will take this as evidence that $u_{1}$ actually means $s_{2}$ in their partner's lexicon and become increasingly likely to use it that way on subsequent rounds.

Reduction in utterance length Finally, we show how our model explains reduction of utterance length over multiple interactions. For utterances to be reduced, of course, they must vary in length. Motivated by our empirical observation that meaningful clauses are the primary unit of reduction, we extend our grammar to include conjunctions. This is one of the simplest ways to constructing longer utterances composition-
ally from lexical primitives, using the product rule:

$$
\mathcal{L}\left(u_{i} \text { and } u_{j}, o\right)=\mathcal{L}\left(u_{i}, o\right) \times \mathcal{L}\left(u_{j}, o\right)
$$

Analogous to our tangram stimuli, which have many ambiguous features and figurative perspectives that may be evoked in speaker descriptions, we consider a simplified scenario where speakers can refer to two different features of the two objects $\left\{o_{1}, o_{2}\right\}$. The speaker has four primitive words at their disposal - two words for shape $\left(\left\{u_{s 1}, u_{s 2}\right\}\right)$ and two for color $\left\{u_{c 1}, u_{c 2}\right\}$ - and has uncertainty over the initial meanings of all four.

While we established in the previous section that conventions can emerge over a reference game in the complete absence of initial preferences, players often bring such preferences to the table. A player who hears 'ice skater' on the first round of our tangrams task is more likely to select some objects more than others, even though they still have some uncertainty over its meaning in the context. To show that our model can accommodate this fact, we allow the speaker's initial prior meanings to be slightly biased. $u_{s 1}$ and $u_{c 1}$ are more likely to mean $o_{1} ; u_{s 2}$ and $u_{c 2}$ are more likely to mean $o_{2}$.

We ran 1000 forward samples of 6 rounds of speakerlistener interaction, and averaged over the utterance length at each round ${ }^{6}$ Our results are shown in Figure 4 C : the expected utterance length decreases systematically over each round. To illustrate in more detail how this dynamic is driven by an initial rational preference for redundancy relaxing as reference becomes more reliable, we walk step-by-step through a single trajectory.

Consider a speaker who wants to refer to object $o_{1}$. They believe their knowledgeable partner is slightly more likely to interpret their language using a lexicon in which $u_{s 1}$ and $u_{c 1}$ apply to this object, due to their initial bias. However, there is still a reasonable chance that one or the other alone actually refers strongly to $o_{2}$ in the true lexicon. Thus, it is useful to produce the conjunction " $u_{s 1}$ and $u_{c 1}$ " to hedge against this possibility, despite its higher cost. Upon observing the

[^90]listener's response (say, $o_{1}$ ), the evidence is indeterminate about the separate meanings of $u_{s 1}$ and $u_{c 1}$ but both become increasingly likely to refer to $o_{1}$. In the trade-off between informativity and cost, the shorter utterances remain probable options. Once the speaker chooses one of them, the symmetry collapses and that utterance remains most probable in future rounds. In this way, meaningful sub-phrases are omitted over time as the speaker becomes more confident about the true lexicon.

## General Discussion

In this paper, we revisited the classic phenomenon of convention-formation in a large-scale, text-based replication of the tangrams task. We argued that several key qualitative patterns in the data - arbitrariness, stability, and the reduction of utterance length over repeated interactions - can be explained by our model of informative communication under lexical uncertainty. This model formalizes a theory where conventions emerge via uncertain agents who assume their partner is knowledgably and informatively using some conventional lexicon. Through repeated observations of their partner's actions, agents learn this lexicon, thereby coordinating and aligning to one another.

Theories of convention-formation vary in the extent to which social reasoning about common ground is required. Our agents lie on a spectrum between the heuristic updating agents of Barr (2004) and the sophisticated agents of Clark \& Wilkes-Gibbs (1986), who collaboratively build up explicit representations of mutual knowledge. Speakers and listeners in our model implicitly coordinate their beliefs through a shared history of observations, which serves as "common ground" in an informal sense. They make critical use of pragmatic, social reasoning in order to learn meanings, but do not explicitly consider the fact that this history is shared, or represent their partner's own uncertainty.

By capturing reduction, which purely heuristic theories have not yet demonstrated, we showed that minimal assumptions of social reasoning go a long way in accounting for key phenomena. Still, our model falls short in some ways. For instance, because we do not provide a mechanisms for the listener agent to respond with confirmation, repair, or followup questions, we cannot make explicit predictions about the reduction in listener messages (as shown in Fig. 23) or the effect of listener input on the conventionalization process. These phenomena require our model to deal with planning over extended dialogues, and more sophisticated speech acts. Similarly, while our model was explicitly designed with linguistic conventions in mind, it remains to be seen whether the same formulation generalizes to broader behavioral conventions. For example, the real-time coordination games used in Hawkins \& Goldstone (2016) may not require players to reason about a structured lexicon with noise, but an action policy representation may play a similar role. While there remain many complex aspects of convention-formation in communication games left for future research, our approach nonethe-
less serves as a lower bound on the degree of social reasoning needed to capture lexical conventions in these games.

# Sampling frames, Bayesian inference and inductive reasoning 

Brett K. Hayes (b.hayes@unsw.edu.au)<br>Stephanie Banner (steph22banner@gmail.com)<br>Daniel J. Navarro (d.navarro@unsw.edu.au)<br>School of Psychology, University of New South Wales<br>Sydney, 2052, Australia

#### Abstract

We outline and test a Bayesian model of the effects of evidence sampling on property induction. Our model assumes that people are sensitive to the effects of different sampling frames applied to sampled evidence. Two studies tested the model by comparing property generalization following exposure to samples selected because they belong to the same taxonomic category or because they share a salient property. Both studies found that category-based sampling led to broader generalization than property-based sampling. In line with model predictions, these differences were attenuated when a mixture of positive and negative evidence was presented (Experiment 1) and when category-property relations were probabilistic rather than deterministic (Experiment 2).

Keywords: Inductive reasoning; Sampling; Hypothesis testing; Bayesian models; Categorization

## Introduction

Inductive reasoning - the ability to make plausible guesses given inconclusive evidence - is one of the central topics in cognitive science. Much of the traditional work on the topic has emphasized the importance of similarity between premise and conclusion categories (see Hayes \& Heit, 2013, for a review). While undoubtedly useful, the similarity-based approach overlooks a crucial component of induction: people's inductive inferences are strongly influenced by their beliefs about how the evidence was sampled (e.g., Xu \& Tenenbaum, 2007). This phenomenon is referred to as sensitivity to sampling, and there is considerable evidence that human reasoners show exactly this sensitivity

One form of sampling sensitivity occurs when an argument assembled by a knowledgeable and helpful teacher is evaluated quite differently than a set of random facts, even if - by chance - the random process happens to have sampled the same set of facts. In the reasoning literature, this was first discussed by Medin, Coley, Storms and Hayes (2003) in their relevance theory of induction. They suggested that reasoners often make the pragmatic assumption that premise categories are selected to highlight a salient relation, which is then used to guide inference. For example, on learning that zebras and skunks share a novel property, people may infer that the property involves "having stripes" and generalize accordingly. More recently, the formal foundations for pragmatic inference have been established using Bayesian pedagogical sampling models, that model human inductive reasoning by assuming that helpful teachers select informative evidence (Voorspoels, Navarro, Perfors, Ransom, \& Storms, 2015; Ransom, Perfors \& Navarro, 2016;

Shafto \& Bonawitz, 2015). This account is supported by empirical work showing that many inductive phenomena (e.g., premise non-monotonicity, integration of positive and negative evidence) depend on the assumption of a helpful teacher (Ransom et al., 2016; Voorspoels, Navarro, Perfors, Ransom, \& Storms, 2015).

A second kind of sensitivity arises from the so-called "strong versus weak" sampling distinction. Under strong sampling, the learner observes a set of exemplars (e.g., premise categories) that are constrained to possess property p. Under weak sampling, no such constraint exists. Early work highlighted the fact that even this simple constraint can produce substantial changes to how a Bayesian reasoner make inferences (Tenenbaum \& Griffiths, 2001), but many applications of the strong/weak distinction have tended to conflate it with helpful/random sampling (e.g., Xu \& Tenenbaum, 2007), and those that do not have found mixed evidence (e.g., Navarro, Dry \& Lee, 2012). Although there are good reasons to expect helpfully sampled evidence to be similar to strongly-sampled evidence (e.g., Ransom et al., 2016), it is not obvious whether (or when) people are sensitive to sampling assumptions if no helpful teacher is available. Perhaps people are capable of taking a hint from a helpful teacher, but otherwise are largely insensitive to sampling assumptions. Given other evidence that people struggle with conditional probability (e.g, Fiedler, 2012) this is not an implausible idea.

## How sampling frames shape induction

In this paper, we approach the problem from a different perspective, and consider other ways in which data can be sampled in a constrained way. The statistics literature, for instance, emphasizes the importance of a sampling frame (Jessen, 1978): when designing a survey, the researcher may not be able to sample uniformly at random from the entire population of interest, but is instead forced to sample from a restricted subset. When interpreting such data, those properties of the observed data that are attributable to the sampling frame do not require theoretical explanation, as they are deemed an artifact of the sampling process.
The effect of a sampling frame can be substantial. Imagine that you want to learn what plants make you sneeze. The potential search space is large so we apply a sampling frame - we first test a particular category of plant (e.g., sunflowers) - and find that most sunflowers cause us to sneeze. In this situation, the fact that we have never sneezed at a daisy is

Implausible: SP+ not allowed by hypothesis

Figure 1. Schematic of the hypothesis space about the distribution of property $P+$ and its absence ( $P-$ ). Dark quadrants show the hypothesized extension of $P$ across the target category $(S)$ and non-targets ( $L$ ). Dots represent observation of a sample of small birds that has the property $S P+$. For a hypothesis to be plausible it must allow the $S P+$ case to exist.
irrelevant: it can be attributed to the sampling frame. In this context, absence of evidence is not evidence of absence.

Now consider the effect of shifting the sampling frame. Suppose instances are selected because they share the property of interest (e.g., they give positive result on an allergy test). If most of this sample was sunflowers then the absence of daisies might be seen as inductively informative: it suggests that the allergic reaction is limited to the observed category. Despite the fact that neither scenario involves a helpful teacher, the mere presence of a sampling frame allows
the same data to lead to different generalizations (cf. Hsu, Horng, Griffiths, \& Chater, 2016).

There is evidence that people are sensitive to the sampling frame. Lawson and Kalish (2009) presented participants with samples of animals (small birds) that shared a novel property ("has plaxium blood") and manipulated the way exemplars were sampled. In the "category sampling" condition they were told that items were sampled from a taxonomic category (i.e., the frame selects small birds). In the "property sampling" condition people were told that exemplars with plaxium blood were selected. People in the property sampling condition were less likely to generalize the property to other animals. Lawson and Kalish (2009) noted that this result was inconsistent with similarity-based accounts of induction, but they did not explain why the differences occurred.

As it happens, this pattern of results is exactly what one would expect from a probabilistic reasoner who is sensitive to the sampling frame. Later we present a formal model, but the qualitative intuition is simple. Suppose the learner has observed small birds ( $S$ ) with plaxium blood $(P+$ ), and is trying to determine whether large birds $(L)$ also possess plaxium blood. Subject to the constraint that large and small birds both exist, there are six hypotheses consistent with the observations, as shown in Figure 1, and three that are not.

Now consider the plausibility of these six hypotheses under different sampling frames, illustrated by the red rectangles in Figures 2. In category sampling, it is plausible to assume that if any small birds did not have plaxium blood, the $S P$ - case would have been observed. The lack of such observations strengthens three hypotheses and weakens three others. Notably, two remaining hypotheses allow large birds to have plaxium blood $(L P+)$. By contrast, in property sampling it is reasonable to assume that if any large birds had plaxium blood we should have seen the $L P+$ case. The fact that they were not leaves only two viable hypotheses, both of which restrict property $P$ to the target category. Accordingly, generalization is more restricted under property sampling.

Category sampling: frame selects S

Property sampling: frame selects $\mathrm{P}+$

Figure 2. The effect of sampling frame. When the data consist solely of small birds with plaxium (SP+), plausible hypotheses are those for which only $S P+$ is allowed by the sampling frame and the hypothesis. Consequently, $L P+$ is less plausible under property sampling and the learner does not generalize beyond the observed $S P+$ case.

## Experiment 1

Our experimental work replicates the findings of Lawson and Kalish (2009), and extends them in a way that tests our "sampling frames" explanation. In the first experiment, we considered the impact of explicit negative evidence. If a learner encounters non-target category members that lack property $P$, the differences between the two sampling conditions should attenuate. Explicit negative evidence should have a large effect in the category sampling condition, but only a modest effect under property sampling. We expect this difference because property sampling already provides implicit negative evidence, so the added value of the explicit negative evidence is diminished.

Experiment 1 tested these predictions by presenting participants with identical evidence samples obtained via category or property sampling. Half the participants received positive evidence about members of a target category, as per Lawson and Kalish (2009), and half received additional negative evidence about non-target category members. All participants were then asked to judge whether the novel property generalized to other categories.

## Method

Participants. 92 UNSW students (63 female), participated for course credit or payment. The mean age was 20.9 years.
Design and Procedure. The experiment used a $2 \times 2$ between subjects design with equal numbers in each condition.

The procedure for the positive evidence only groups was patterned after Lawson and Kalish (2009). Participants were told they were investigating the properties of animals on a novel island. In the category sampling condition, participants were told that only small birds were sampled from the island. In the property sampling conditions, they were told that only animals with plaxium blood were sampled from the island. Exemplars were revealed as follows: on each of 20 trials, participants could click on one of a large number of on-screen boxes to see an exemplar (each depicted by a unique picture of a small bird), and to learn if the animal had plaxium blood. In the positive evidence condition, all 20 exemplars sampled had plaxium blood.

For the positive+negative evidence groups the procedure was identical, except that there were five trials at the end in which "new" samples from the island were presented. Each of these revealed a single instance from other animal categories (crow, seagull, eagle, squirrel, frog) that did not have plaxium blood. These five trials were always presented, in random order, at the end of sampling phase.

After the learning phase, all participants proceeded to a generalization test. On each of six trials, participants were shown a picture of an animal and asked to estimate the number of such animals from a sample of ten that would have plaxium blood ( $0-10$ ). The test categories included a member of the same target category that was presented during sampling (a novel picture of a sparrow) and five categories that varied in similarity to the target (pigeon, owl, ostrich, mouse, lizard). Test item order was randomized.

Figure 3: Experiment 1. Test phase generalization in each experimental condition.

## Results and Discussion

Generalization scores (out of 10) for all conditions are shown in Figure 3. Visual inspection suggests that the positive-only condition people generalized more narrowly under property sampling (black squares) than under category sampling (black circles). Moreover, this difference is less pronounced when explicit negative evidence is provided (in grey).

More formally, a mixed effects ANOVA revealed that people were less willing to generalize as similarity decreased (left to right in Figure 3; linear trend contrast: $F(1,84)=$ $420.07, p<.001$ ). Generalization to non-target categories was greater following category than property sampling, $F(1,84)=$ $12.36, p=.001$, and when only positive evidence was encountered during sampling, $F(1,84)=39.54, p<.001$. The critical finding, however is the interaction: the difference in generalization between category and property sampling was larger in the positive evidence only condition than in the positive + negative condition, $F(1,84)=5.81, p=.02$.

These results are exactly what we expected: despite the fact that participants in the category and property sampling groups saw exactly the same information, generalization of the novel property was narrower following property sampling. This replicates the main finding of Lawson and Kalish (2009), showing that people's inductive inferences are sensitive to the sampling frame. Moreover, the data supported a novel prediction of our sampling explanation: presentation of negative evidence had greater impact on generalization following category sampling than property sampling.

## Experiment 2

In the next experiment we consider a second manipulation that should - according to the sampling account - attenuate the difference between category and property sampling: ambiguous evidence. In Experiment 1, every member of the target category had the novel property. In Experiment 2, we considered cases where some of the evidence is ambiguous, by including some observations where the plaxium status of the entity was unknown. The qualitative intuition here is that this should introduce uncertainty about the distribution of the property within the target category. Accordingly, the evidentiary value of the data should decrease, leading to a less pronounced difference between the two sampling conditions.

## Method

Participants. 80 UNSW students ( 76 female), participated for course credit or payment. The mean age was 19.4 years.
Design \& procedure. The experiment used a $2 \times 2$ between subjects design, with equal numbers in each condition. The procedure for the deterministic evidence conditions was identical to the positive evidence only conditions in Experiment 1. The procedure for the probabilistic evidence conditions was similar, except that during the sampling phase participants saw an additional five category or property sampling trials. On these trials, additional small birds were presented whose blood type was unknown due to a "machine error". These trials were randomly interspersed with the other trials. The generalization test was the same as Experiment 1.

## Results and Discussion

Generalization scores are shown in Figure 4. As in Experiment 1, generalization of the novel property decreased as similarity to the target category decreased (linear trend contrast: $F(1,76)=117.94, p<.001$. Overall, generalization to non-target categories was greater following category than property sampling, $F(1,76)=8.88, p=.004$. Notably, there was a significant interaction between sampling condition and evidence certainty, $F(1,76)=5.25, p=.03$. Figure 4 shows that the differences in generalization between category and property sampling were relatively large when the evidence was deterministic, but decreased when the observed evidence was probabilistic.

The results for the deterministic evidence condition replicate the earlier finding that property sampling leads to narrower generalization than category sampling. Consistent with the predictions of our model, the difference between sampling conditions was reduced when the relationship between the target property and category was probabilistic.

## Bayesian reasoning with sampling frames

The sampling explanation outlined at the start of the paper provides an intuitive explanation of our results: in this section we provide a more formal account, introducing an inductive reasoning model that accommodates the effect of the sampling frame within the Bayesian framework introduced by Tenenbaum and Griffiths (2001).

Test phase categories

Category Sampling, Deterministic Evidence
Property Sampling, Deterministic Evidence

- Category Sampling, Probabilistic Evidence
Property Sampling, Probabilistic Evidence
Figure 4: Experiment 2. Test phase generalization in each experimental condition.

A Bayesian analysis of the inductive problem proceeds as follows. The test categories consist of items that belong to different taxonomic classes (birds, mammals, reptiles) and vary in size (small, medium, large, and huge). Given this, we define a hypothesis space $H$ by combining these two characteristics. A hypothesis $h$ is admissible if it includes only a single taxonomic class (e.g., birds only) or allows all animals to possess plaxium. Similarly, it is admissible if it specifies a "connected" region on the size dimension (e.g., small-or-medium is allowed, but small-or-huge is not). For simplicity, the Bayesian model assigns equal prior probability $P(h)$ to all hypotheses, with one exception: to account for the fact that people are less willing to generalize across taxonomic classes than across animal sizes, hypotheses that allows all animals to have plaxium blood are only $1 / 5$ as plausible as hypotheses restricted to a single class.
When presented with a set of observations $x$, the learner updates the prior distribution to a posterior via Bayes' rule:

$$
P(h \mid x, f)=\frac{P(x \mid h, f) P(h)}{\sum_{h^{\prime} \in \mathcal{H}} P\left(x \mid h^{\prime}, f\right) P\left(h^{\prime}\right)}
$$

In this expression, the likelihood term $P(x \mid h, f)$ describes the probability of observing the data $x$ if hypothesis $h$ is true and the sampling frame $f$ applies. When determining the probability that a test item $y$ possesses plaxium blood, a Bayesian learner aggregates the posterior probability assigned to those hypotheses $h$ that assign the test item y to the consequential set:

Figure 5. Inductive inferences made by the Bayesian model plotted as a function of test category, sampling condition and evidence type. See main text for details.

$$
P(y \in c \mid x, f)=\sum_{h \mid y \in h} P(h \mid x, f)
$$

The critical feature of this model is the fact that the likelihood term $P(x \mid h, f)$ is sensitive to the sampling frame. Under category sampling, the fact that all observations happen to be small birds is of no evidentiary value: the sampling frame $f$ only admits small birds, and no explanation for this is required. In this sampling regime, a good hypothesis is required to explain the fact that all observations are plaxium positive. If we assume a noisy relationship, where $\theta>.5$ denotes the probability that an animal that falls within the relevant category possesses plaxium blood, then the likelihood becomes:

$$
P(x \mid h, f)=\left\{\begin{array}{cl}
\theta & \text { if } x \in h \\
1-\theta & \text { otherwise }
\end{array}\right.
$$

Under property sampling, this pattern is reversed: the sampling frame admits only plaxium positive observations, and no explanation for this is required. Instead, the data $x$ that the learner must explain is the fact that all the animals are small birds. Again assuming a noisy relationship,

$$
P(x \mid h, f)=\left\{\begin{array}{cl}
\theta /|h| & \text { if } x \in h \\
(1-\theta) /|h| & \text { otherwise }
\end{array}\right.
$$

In this expression, the normalizing term $|\mathrm{h}|$ denotes the "size" of the hypothesis. For a hypothesis that predicts $m$ species to be plaxium positive and $n$ species to be plaxium negative,

$$
|h|=\theta m+(1-\theta) n
$$

Formal details notwithstanding, the main point of these equations is to highlight the fact that the different sampling frames involved ensures that property sampling imposes a size principle (Tenenbaum \& Griffiths 2001) and category sampling does not. When a size principle applies, Bayesian learners will tend to assign more belief to smaller hypotheses, and as a consequence will generalize narrowly. This is illustrated in the top panel of Figure 5 which plots the generalizations made by the Bayesian model when presented
with 20 plaxium positive small birds, setting $\theta=0.6$. As one might expect, the Bayesian model generalizes more narrowly under property sampling.

In Experiment 1, we found that the difference between the two sampling schemes attenuated when participants were presented with plaxium negative observations from nontarget categories, and generalizations narrowed in general. As shown in the middle panel of Figure 5, this is exactly what the Bayesian model does. Regardless of sampling scheme, the negative evidence serves to decrease the plausibility of larger hypotheses (as they are now somewhat inconsistent with the new data), but this has a much smaller effect in the property sampling condition simply by virtue of the fact that these hypotheses were already judged to be somewhat implausible. Accordingly, the Bayesian model produces narrower generalizations and the difference between the two conditions becomes smaller.

In Experiment 2, participants were presented with additional "ambiguous" observations (small birds that may or may not have been plaxium positive). This manipulation is expected to cause people to suspect a noisier relationship between the category and the observed plaxium status, which we operationalize by setting a lower value for $\theta$. When we set $\theta=.55$, we obtain the generalization gradients shown in the right panel of Figure 5. As expected, the Bayesian model produces an attenuated effect of sampling.

## General Discussion

Traditionally, models of property induction (e.g., Osherson et al., 1990) have focused on the similarity between the categories known to possess a property and other categories to which the property might be generalized. Although category similarity is undoubtedly an important component of induction, the current work highlights the additional impact of beliefs about how observed data is sampled. In both experiments, identical sets of observations led to very different patterns of generalization depending on beliefs about how the observations were selected. In the positive evidence condition in Experiment 1 and the corresponding
deterministic condition in Experiment 2, evidence sampling based on shared category membership led to broader generalization of the target property than evidence sampling based on a shared property.

This result shows that people are sensitive to the effects of particular constraints or sampling frames that are imposed on the observations. In category-based sampling, the absence of observations of members of other categories that share a target property is not necessarily seen as evidence of absence. In property-based sampling, the absence of such observations can be seen as evidence that the property does not project beyond the target category. This phenomenon is naturally accommodated by a Bayesian inductive reasoning model. Moreover, this theoretical perspective allowed us to generate two novel predictions. The effect of sampling frame attenuates when explicit negative evidence is added or when ambiguity is introduced to the sample. Both of these effects are captured by the Bayesian model.

Our Bayesian approach suggests additional factors that should moderate the impact of sampling frames. For example, differences in generalization patterns between types of sampling is likely to depend on beliefs about category base rates. In property sampling for example, if members of both the target category (e.g., small birds) and non-target categories (e.g., various types of large birds) are believed to be relatively common, then the fact that the sample of animals with plaxium blood contains no large birds is highly informative. In contrast, if large birds were uncommon, then the absence of large birds with plaxium blood does not license strong conclusions about property generalization.

Previous work (Ransom et al., 2015; Shafto \& Bonawitz, 2015) has shown that inductive inferences are sensitive to intentional factors associated with sample selection (e.g., whether the observations were chosen by a helpful agent to illustrate the breadth of a hypothesis). The current work, together with that of Lawson and Kalish (2009), highlights the importance of a novel factor in induction, namely sensitivity to different types of conditionalization or filtering of the evidence samples on which inferences are based. While this is a new finding in the domain of induction, it bears some resemblance to results observed in probability judgment tasks (see Fielder, 2012 for a review). Fiedler, Brinkman, Betsch and Wild (2000) for example, presented different groups with different types of conditionalized samples. One group saw instances of women who had received a positive breast scan result, and learned whether each woman had breast cancer. Another group saw instances of women with breast cancer and learned whether they had received a positive breast scan. As in the current work, people were sensitive to these different types of sample conditionalization, with the two groups generating very different estimates of the probability that a woman with a positive scan had cancer. In the Fiedler, et al. (2000) study however, the different types of conditionalization led to differences in the characteristics of the instances observed in each sample. The current work goes further, by showing that very different patterns of inference
emerge when identical evidence samples are selected via different types of sampling frames.

# The adaptive evolution of early human symbolic behavior 

Katrin Heimann<br>Aarhus University<br>Riccardo Fusaroli<br>Aarhus University<br>Sergio Gonzalez de La Higuera Rojo<br>Aarhus University<br>Niels Nørkjær Johannsen<br>Aarhus University<br>Felix Riede<br>Aarhus University<br>Nicolas Fay<br>University of Western Australia<br>Marlize Lombard<br>University of Johannesburg<br>\section*{Kristian Tylén}<br>Aarhus University

#### Abstract

Dating back as far as 100 ka , the Blombos ochre and the Diepkloof ostrich egg engravings are considered among the earliest fossilized evidence of human symbolic behavior. Of special interest to this study is the temporal trajectory spanning more than 30 thousand years from earlier simpler parallel line patterns to later complex cross-hatchings suggesting adaptive compositional development. Through a series of three psychophysical experiments we test the hypotheses that the line engravings at each site evolved to become 1) more salient to the human perceptual system, 2) more discriminable from each other, and 3 ) increasingly associated with symbolic intent. Our findings suggest that just as instrumental tools have been found to undergo cumulative refinements in adaptation to their function, the ochre and egg shell engravings evolved adaptively to become more fit for their cognitive function as signs.

# Children's social referencing reflects sensitivity to graded uncertainty 

Emily Hembacher<br>ehembach@stanford.edu<br>Department of Psychology<br>Stanford University

Benjamin deMayo<br>bdemayo@stanford.edu<br>Department of Psychology<br>Stanford University

Michael C. Frank<br>mcfrank@stanford.edu<br>Department of Psychology<br>Stanford University

#### Abstract

The ability to monitor epistemic uncertainty is critical for selfdirected learning. However, we still know little about young children's ability to detect uncertainty in their mental representations. Here we asked whether a spontaneous information gathering behavior - social referencing - is driven by uncertainty during early childhood. Children ages 2-5 completed a word-learning task in which they were presented with one or two objects, heard a label, and were asked to put the labeled object in a bucket. Referential ambiguity was manipulated through the number of objects present and their familiarity. In Experiment 1, when there were two novel objects and a novel label, the referent was ambiguous; when there were two familiar objects, or only one novel or familiar object, the referent was known or could be inferred. In Experiment 2, there were either two novel objects, two familiar objects, or one familiar and one novel object; in the latter case the referent could be inferred by excluding the familiar object. To further manipulate the availability of referential cues, the experimenter gazed at either the target or the center of the table while labeling the object. In both experiments, children looked at the experimenter more often while making their response when the referent was ambiguous. In Experiment 2, children also looked at the experimenter more when there was one familiar and one novel object, but only when the experimenter's gaze during labeling was uninformative. These results suggest that children's social referencing is a sensitive index of graded epistemic uncertainty.

Keywords: social referencing; help seeking; word learning; uncertainty.

Preschoolers quickly learn new concepts, rules, and language. They also actively explore and ask questions in ways that seem targeted to maximize learning (Chouinard, Harris, \& Maratsos, 2007; Schulz \& Bonawitz, 2007). However, we still have an incomplete understanding of young children's ability to monitor their own mental states, in particular, their epistemic uncertainty (Sodian, Thoermer, Kristen, \& Perst, 2012). Do preschool-aged children monitor uncertainty and actively guide their learning behaviors on the basis of this monitoring, or is early learning better characterized as a process of integrating information that is largely generated externally, for example, by social partners who act as teachers (Csibra \& Gergely, 2006)?

A hallmark of successful uncertainty monitoring is being less confident when the probability of accuracy is lower (Robinson, Johnson, \& Herndon, 1997). This ability includes awareness of complete ignorance, but also of graded evidence in mental representations, which is considered important for predicting outcomes and regulating behavior (Lyons \& Zelazo, 2011). During adulthood, accurately representing one's own learning progress allows for efficient self-directed study and predicts learning outcomes (Dunlosky \& Rawson, 2012). There is mixed evidence about whether young children can
accomplish this type of self-monitoring. For example, 3-year-olds report being equally confident about correct and incorrect responses in memory tasks (Hembacher \& Ghetti, 2014). Preschoolers report being less confident when they are wrong in other tasks, but they are typically overconfident overall (Coughlin, Hembacher, Lyons, \& Ghetti, 2015; Lipowski, Merriman, \& Dunlosky, 2013). However, these studies may underestimate young children's uncertainty monitoring, as they typically rely on explicit metacognitive reports. Children may learn to respond appropriately to uncertainty in everyday learning situations before they can bring it fully into consciousness and report on it.

Several studies have provided evidence that children's spontaneous information-seeking behaviors might track uncertainty. Call and Carpenter (2001) had 2-year-olds choose between several tubes to find a hidden sticker. They found that the toddlers were more likely to peek inside a tube before choosing when they had not seen the baiting of the tubes compared to when they had, suggesting they were aware of their ignorance and managed to delay their response until they were sufficiently confident. In another study, Goupil, Romand-Monnier, and Kouider (2016) found that 20-montholds were more likely to seek help by looking at their parents when they were unable to respond accurately in a memory task. These spontaneous information-gathering behaviors may provide a window into early uncertainty monitoring, and allow us to ask questions about its development.

Here, we focus on the role of uncertainty in guiding social referencing - one form of information gathering - during word learning. Referencing a social partner can provide several types of disambiguating information. For example, children can follow a speaker's gaze direction to infer the referent of a new word, as people tend to look at objects they are referring to. By the second year of life infants follow a speaker's gaze and map labels to objects on the basis of gaze direction (Baldwin, 1991). There is also evidence that infants' propensity for gaze-following predicts later language development (Carpenter, Nagel, Tomasello, Butterworth, \& Moore, 1998), highlighting the importance of this behavior for learning. In addition to monitoring gaze direction, children may reference a social partner's emotional reaction to a stimulus or event, which can help disambiguate the appropriateness of a response (Walden \& Ogan, 1988). Finally, looking at a social partner can be taken as a bid for help (Vredenburgh \& Kushnir, 2015), and may result in explicit instruction.

Social referencing can be an efficient source of disambiguating information, but is it driven by uncertainty during
early childhood? It could be that social referencing is not costly enough to require selectivity, or that uncertainty signals are too weak to drive information-seeking behaviors in young children. Similarly, other learning mechanisms such as the privileging of social information (Ho, MacGlashan, Littman, \& Cushman, 2017) or tracking of regularities in the environment (Yurovsky \& Frank, 2015) may be sufficiently powerful to obviate the need for uncertainty monitoring in preschoolaged children.

The present work asks whether preschoolers reference a speaker more frequently when the referent of the speech is ambiguous. This work adapts a paradigm used by Vaish, Demir and Baldwin (2011) in which 13- to 18-month-olds sat across from an experimenter who produced a label (e.g., "a modi!") in the presence of one or two novel objects. Infants looked towards the experimenter more often when there were two objects present, suggesting that infants' social referencing is driven by referential ambiguity. Here we adapt this procedure for use with preschoolers, who have a richer behavioral repertoire compared to infants, and may not reference social information based on uncertainty for the reasons discussed previously. We ask whether preschoolers look more at a social partner when they are uncertain about the identity of a referent (Experiment 1) and whether they are sensitive to graded uncertainty based on the amount of disambiguating evidence available (Experiment 2).

Figure 1: Study design for Experiments 1 and 2.

## Experiment 1

In Experiment 1, we examined whether children would visually reference a speaker more often when the speaker produced a referentially ambiguous label compared to an unambiguous label. Children sat across from an experimenter who labeled an object on the table between them (Figure 1). The experimenter then asked the child to place the named object in a bucket. Across trials, there were either one or two objects on the table, which were either familiar or novel to the child. This design allowed us to test whether merely having more than one object present is sufficient to increase social referencing (which could not be ruled out by Vaish et al.), or if referential ambiguity (and thus epistemic uncertainty) is the underlying factor. If the latter is true, we expected children to increase their looking to the experimenter only on trials with
two unfamiliar objects, when the object-label mapping was not known and could not be inferred.

We were interested in the amount of social referencing children exhibited across the trial. We considered four different phases of each trial based on the notion that children might expect different social information at different stages of the task. Specifically, we predicted that children might expect the speaker's gaze direction to be informative during the labeling itself, as speakers tend to look at objects they refer to. We predicted that later in the trial, as children reached for an object and placed it in the bucket, they might expect evaluative feedback about their choice (e.g., facial expressions of encouragement or discouragement).

## Methods

Participants We recruited a planned sample of 80 children ages 2-5 years from the Children's Discovery Museum in San Jose, California ${ }^{1}$ The sample included 20 2-year-olds (mean age 31.97 months), 203 -year-olds (mean age 42.65 months), 204 -year-olds (mean age 55.85 months), and 205 -year-olds (mean age 65.21 months). An additional 20 children participated but were removed from analyses because they heard English less than $75 \%$ of the time at home $(n=10)$, because they were unable to complete at least half of the trials in the task $(n=4)$, because of parental interference $(n=1)$, or due to experimenter or technical errors $(n=5)$.
Stimuli and Design Children were presented with one or two objects, heard a label, and were asked to put the labeled object in a bucket. Half of the objects were selected to be familiar to children (e.g., a cow) and half were selected to be novel (e.g., a nozzle). There were four trial types: onefamiliar, one-novel, two-familiar, and two-novel. There were three trials of each type, for a total of twelve trials. Trial types were presented sequentially in an order that was counterbalanced across participants. The assignment of individual objects to trial types was counterbalanced. On familiar trials, the familiar label for the target object was used (e.g., "cow"). On novel trials, a novel label was used (e.g., "dawnoo").

The critical manipulation was of referential ambiguity; on one-familiar and two-familiar trials, there was no referential ambiguity, as children were expected to be certain about the objects and their labels. Similarly, on one-novel trials, children were expected to be certain about the label referent as there was only one option. However, on two-novel trials, the referent was ambiguous, as the novel label could apply to either novel object.

Throughout the task, the experimenter never gazed at the object they were labeling, or responded to children's verbal or non-verbal bids for help by indicating the correct object. Thus, children were expected to remain uncertain about the referent throughout the trial when two novel objects were present.

[^91]Procedure Throughout the study, the child sat at one end of a large circular table, and the experimenter stood at the opposite end. Each trial of the task proceeded as follows: the experimenter placed one or two objects on the sides of the table, out of reach of the child so that the child could not interact with the toys during the labeling event. For oneobject trials, the location of the object (left or right) alternated between trials.

After placing the objects, the experimenter said "Hey look, there's a (target) here." The experimenter gazed at the center of the table rather than the object they labeled (see rationale in Stimuli and Design). The experimenter waited approximately two seconds (based on a visual metronome placed within view) before saying, "Can you put the (target) in the bucket?" They then pushed the object(s) forward within reach of the child, and placed a plastic bucket in the center of the table, also within reach of the child. Prior to the twelve experimental trials, there were two training trials: a one-familiar trial and a two-familiar trial, to acquaint the child with the procedure. A camera placed to the side of the experimenter captured the participant's face, so that looking behavior could be coded from video.

Coding procedure Videos were coded using DataVyu software (http://datavyu.org). For each participant, we coded the number of times they referenced the experimenter across the trial. Because we were interested in the circumstances that elicit social referencing in children, we coded the number of looks that occurred during four phases of the trial: a label phase, which began at the utterance of the label and ended when the experimenter began to slide the objects, a slide phase, in which the experimenter slid the object(s) into the child's reach, a planning phase, which began at the end of the slide and ended when the child touched an object, and a response phase, which began when the child touched an object and ended when the child released the object into the bucket. A second coder independently scored the number of looks for one third of the trials for each participant to establish reliability.

## Results and Discussion

Results of Experiment 1 are presented in Figure 2 Inter-rater reliability for the number of looks in each phase was high, intraclass correlation $r=.97, p<.001$. To test our prediction that referential ambiguity (i.e., having two novel objects) would produce more social referencing, we fit mixed-effects linear regression models separately for each phase with the following structure: number of looks ~ number of objects * familiarity * age in months + (number of objects + familiarity | Subject ID). A single model with phase as a factor did not converge.

We did not find any main or interaction effects of number of objects, familiarity, or age on number of looks during the label or slide phases. Thus, mere novelty or the presence of multiple objects was not enough to increase social referencing. However, we found an interaction effect of number of
objects and familiarity during the planning ( $\beta=0.21, p<$ .001 ) and response phases ( $\beta=0.6, p<.001$ ), such that 2 novel trials were associated with more looking. There was no interaction with age in either phase ${ }^{2}$ In summary, children looked to the experimenter more often when planning and executing a response under uncertainty. These results suggest that children were aware that they did not have sufficient knowledge to answer independently, and referenced the speaker to resolve this uncertainty.

We did not find the expected effect of referential ambiguity in the label phase. It is possible that children failed to predict that they would need more information until later in the trial, when they were actually faced with making a decision. Another possibility is that children's looking was at ceiling during the labeling phase, perhaps because children look at someone who is speaking regardless of the need for referential disambiguation. A third possibility is that this is an artifact of our design, in which the experimenter gazed at the center of the table rather than the referent of the label. Children may have realized that the experimenter's gaze direction during labeling was not informative. Similarly, children may have found it strange to interact with an experimenter who did not gaze at the object they were labeling, which may have produced unnatural patterns of social referencing. Experiment 2 tests these possibilities and examines whether children's social referencing is sensitive to graded uncertainty.

## Experiment 2

Experiment 2 was designed to replicate Experiment 1 and investigate whether children's social referencing is sensitive to uncertainty based on graded evidence about a label's referent. Since we did not observe any difference between one-familiar and one-novel trials, we eliminated single-object trials, leaving the 2 -familiar and 2-novel trials. In addition, we added 1-novel-1-familiar trials. For these trials, we expected that children would be able to infer the referent by excluding the familiar object as a possibility. For example, when a toy lion and a novel item were present, they could exclude that the speaker was referring to the lion as a "blicket" (Markman \& Wachtel, 1988). We predicted that children might be less certain about their choice on these trials compared to when the label and referent were familiar to them (2-familiar trials), but more confident than when there are no cues to reference (2-novel trials).

In addition, we manipulated between participants whether or not the experimenter's gaze during labeling was informative (they gazed at either the referent of their label or the center of the table), allowing us to determine whether children selectively reference gaze during labeling when gaze is expected to be informative. The manipulation of informativity of gaze during labeling also meant that participants in the referential gaze condition had an additional referential cue, which might decrease uncertainty for the remainder of the trial. In Experiment 1, we did not observe an effect of age, so

[^92]

Figure 2: Results of Experiment 1. Number of looks to the experimenter across phases and conditions. Error bars are 95 percent confidence intervals.
we restricted the current sample to 3 - and 4-year-olds.

## Methods

Participants We recruited a planned sample of 80 children ages 3-4 years from the Children's Discovery Museum in San Jose, California ${ }^{3}$ The sample included 40 3-year-olds (mean age 42.89 months) and 404 -year-olds (mean age 53.47 months). An additional 20 children participated but were removed from analyses because they heard English less than $75 \%$ of the time at home $(n=9)$, because they were unable to complete at least half of the trials in the task $(n=7)$, or due to experimenter or technical errors $(n=4)$.
Stimuli and Design The stimuli and design were similar to Experiment 1, except that we eliminated 1-object trials. Instead, we included three trial types: 2-familiar, 2-novel, and 1-novel-1-familiar. There were four of each trial type, totaling twelve trials. In addition, we manipulated the experimenter's gaze behavior between participants. For half of the participants, the experimenter looked at the center of the table while labeling objects; for the remaining half, they looked directly at the objects they labeled.

[^93]Procedure The procedure was identical to Experiment 1, except that there were three practice trials (two familiar trials and one novel trial). We included two familiar trials during the practice so that children would remain motivated to complete the task.

## Results and Discussion

Results of Experiment 2 are presented in Figure 3 Inter-rater reliability for the number of looks in each phase was again high, intraclass correlation $r=.97, p<.001$. To quantify the main and interactive effects of familiarity, gaze informativity, phase, and age on social referencing, we fit a mixed-effects linear regression model with the following structure: number of looks ~ familiarity * age in months * gaze * phase + (familiarity | Subject ID). In contrast to Experiment 1, a model with phase as a predictor converged.

First, do children reference a speaker more often when the objects and label are novel? Phase interacted with familiarity such that the response phase of novel trials was associated with significantly more looks ( $\beta=0.51, p<.001$ ). This result is consistent with our finding from the analysis of the response phase in Experiment 1. However, in contrast to Experiment 1, we did not observe that looking was significantly greater for novel trials in the planning phase.

We were also interested in whether mutual exclusivity tri-

Figure 3: Results of Experiment 2. Number of looks to the experimenter across phases and trial types. Error bars are 95 percent confidence intervals.
als would elicit an intermediate amount of uncertainty. We observed a three-way interaction of familiarity, gaze, and phase, such that the response phase of mutual exclusivity trials in the no-referential-gaze condition was associated with significantly more looks ( $\beta=0.39, p<.01$ ). Thus, mutual exclusivity trials were associated with greater looking only when the experimenter did not provide informative gaze. This finding is intriguing given that children should be able to solve mutual exclusivity trials without gaze information. Instead, they appear to remain relatively uncertain while making a decision if excluding the familiar object is their only cue to reference, but this uncertainty is resolved if the speaker's gaze is informative. On the other hand, informative gaze during labeling did not lessen social referencing for novel trials, suggesting that gaze information alone was not sufficient to reduce uncertainty. Instead, both gaze information and mutual exclusivity provided evidence about a label-object pairing, and children required both types of evidence to feel certain about their response.

Finally, we observed a four-way interaction such that the response phase of novel trials in the gaze condition was associated with more looking with increasing age ( $\beta=0.06, p$ $<.01$ ), suggesting that children may become more selective in their social referencing as they get older. It may be that children improve in their ability to monitor the need for disambiguating information, or they may become more likely to recognize that social information can be a source of disambiguation.

We did not observe social referencing during the label phase, even when referential gaze was available. This result
rules out the possibility that children were less selective during labeling because they learned that gaze direction was not informative.

## General Discussion

During the preschool years, children are increasingly able to actively gather information through help-seeking and exploration (Chouinard et al., 2007; Schulz \& Bonawitz, 2007). Do children monitor their own uncertainty to guide these behaviors, or are they indiscriminate with regard to underlying knowledge states? Here, we examined whether young children's social referencing during a word-learning task was driven by uncertainty about a label's referent.

We found that referential ambiguity strongly predicted children's social referencing. Specifically, we observed this selectivity when children were forced to decide which object the speaker was referring to. We speculate that children referenced the speaker during the decision process because they expected evaluative feedback about their choice, either implicitly through the adult's facial expressions, or through an explicit response. This idea is consistent with other recent research that has found that preschoolers seek help selectively when a problem is difficult or they are less skilled (Vredenburgh \& Kushnir, 2015).

Most intriguingly, we found that children's looking was driven by graded referential evidence. In the case of mutual exclusivity trials, children could solve the problem of reference by excluding the familiar item (Markman \& Wachtel, 1988). Thus, unlike novel trials, they likely had some signal about the correct object-label mapping. If children sim-
ply monitored the presence or absence of such signals, they would have consistently treated mutual exclusivity trials as familiar trials. Instead, their social referencing depended on a combination of cues from mutual exclusivity and gaze informativity, suggesting that they are sensitive to graded evidence and seek disambiguating information only when uncertainty is relatively high. Children's greater social referencing on trials with only one cue to reference (i.e., mutual exclusivity trials with no referential gaze and novel trials with referential gaze) additionally suggests that children may remain uncertain about a new label-object mapping if they have not received confirmation of its accuracy, for example, through explicit feedback or gaze direction.

On the other hand, we found no evidence for selective social referencing as the object was being labeled. One possibility is that young children do not recognize the need for disambiguating information until they need to make a decision. Another possibility is that preschool-aged children spontaneously look at a speaker regardless of ambiguity, and additional looking was not needed or possible. Notably, Vaish et al. observed selective referencing during labeling among infants. Since infants in that study were holding one of the objects during labeling, referencing the speaker would have required them to disengage from that object, and may therefore have been more costly, promoting selectivity. Future research with preschoolers that includes a greater reward trade off between attentional options would help to distinguish among these possibilities. Overall, these results provide evidence that preschool-aged children monitor graded uncertainty in their mental representations and act on that uncertainty through spontaneous information-seeking.

#### Abstract

We explore how adults learn counterintuitive causal relationships, and whether they discover hypotheses by revising their beliefs incrementally. We examined how adults learned a novel and unusual causal rule when presented with data that initially appeared to conform to a simpler, more salient rule. Adults watched a video of several blocks placed sequentially on a blicket detector, and were then asked to determine the underlying causal structure. In the near condition the true rule was complex, but could be found by making incremental improvements to the simple and salient initial hypothesis. The distant condition was governed by a simpler rule, but to adopt that rule participants had to set aside their initial beliefs, rather than revising them incrementally. Adults performed better in the near condition, despite this rule being more complex, providing some of the first evidence for an explore-exploit trade-off in inference, analogous to the trade-off in active learning.

Keywords: causality, Bayesian inference, hypothesis search, process model

## Background

Any time we make plans, predict the future, or attempt to understand why events occurred in the past, we are relying on causal knowledge. In acquiring this knowledge, we must draw conclusions from sparse, noisy, and ambiguous evidence. We gain the ability to make sense of this limited information at an early age, with causal thinking showing signs of emergence even in infancy (Sobel \& Kirkham, 2006; 2007; Walker \& Gopnik, 2014). By adulthood, our frameworks for interpreting causal phenomena become much more complex and able to accommodate diverse areas of knowledge (Kemp, Goodman, \& Tenenbaum, 2007).

Despite its usefulness, sometimes our ability to generalize from past causal inferences can lead us astray, as in the case where we encounter a new causal relationship that is rare or strange by the standards of our past experience. For instance, we might expect that either of two switches will turn on a lamp, when in fact the lamp turns on when the switches are in matched positions. While our causal learning process is generally accurate and adaptive (e.g., Griffiths \& Tenenbaum, 2005), in the current paper we claim - in the spirit of previous "rational process" models (e.g. Sanborn, Griffiths, \& Navarro, 2010) - that human causal beliefs are updated in a limited or local fashion that is efficient but subject to systematic failures under certain conditions. This is especially true when the initial hypothesis is at a local optimum - the best hypothesis within reach, but not the best overall - and when the true causal structure is distant from our initial hypothesis
in some hypothesis space. Suppose you break out in a rash every time you buy your favourite candy bar from a vending machine. After searching for the proper cause, you would probably conclude that you are allergic to the candy as soon as it comes to mind. You may be unlikely to consider that you are actually reacting to the coins used to purchase the candy bar, even if this is indeed the case. In this case, discovering the real cause requires abandoning your working hypothesis, rather than just incrementally refining it.

## Bayesian Models of Causal Inference

Several researchers have attempted to explain learning of novel causal relationships using hierarchical Bayesian models of inference (e.g. Griffiths, Sobel, Tenenbaum, \& Gopnik, 2011; Griffiths, Kemp, \& Tenenbaum, 2008). Recent evidence demonstrates that adults and children can successfully modify their causal beliefs in light of new and surprising evidence in a manner that suggests Bayesian inference strategies (e.g., Griffiths, Sobel, Tenenbaum, \& Gopnik, 2011; Lucas, Bridgers, Griffiths, \& Gopnik, 2014). Through this process, learners also create and update higher-level models of how causal relationships operate in general. Regardless of whether human cognition functions exactly this way, hierarchical Bayesian models have accurately predicted human causal learning (Kemp, Goodman, \& Tenenbaum, 2007; Lu, Yuille, Lijeholm, Cheng, \& Holyoak, 2006; Lucas \& Griffiths, 2010; Ullman, Goodman, \& Tenenbaum, 2012).

Although Bayesian models accurately capture many aspects of human causal reasoning, they may not fully account for adults' relative difficulties in learning more unusual types of causal relationships. Specifically, Lucas and colleagues (2014) found that young children were more likely than adults to discover an unusual conjunctive causal relationship. Children and adults were tasked with inferring a causal principle after viewing a machine that activated when certain blocks or block combinations were placed on top of it. Even after viewing evidence that blocks only activated the machine in specific pairs (and not individually), adults had more difficulty than children with generalizing this principle to new blocks. One possibility for this finding is that adults are more biased by prior experiences-as they have observed that conjunctive relationships are relatively rarewhich leads them to demand strong evidence before they infer a conjunctive relationship is present. Indeed, if cogni-
tion operates via Bayesian principles, there are conceivably instances in which rigid commitment to a prior may preclude learners from uncovering the true nature of a causal relationship. However, this may not apply in novel causal situations with which adults have limited experience. Moreover, adults are cognitively different than children beyond simply having more experience, so differences in causal reasoning may in fact be the by-product of some developmental change.

As an alternative to simply having different priors, adults' relative difficulty with conjunctive causal relationships may be explained in terms of the process by which they explore and weigh new hypotheses in light of their current beliefs. It is typically impossible to evaluate all potential hypotheses (of which there may be an infinite number). Bayesian inference is often intractable in practice for complex problems, so human inferences must sometimes depart from the Bayesian ideal. Nonetheless, there is evidence that people may be resource rational observers, making approximately Bayesian inferences in ways that make efficient use of limited time and memory (Bonawitz, Denison, Gopnik, \& Griffiths, 2014; Sanborn, Griffiths, \& Navarro, 2010). As for possible processes underlying these approximations, some empirical phenomena, such as order effects, offer clues. If learners make inferences from a complete set of data, as traditional Bayesian models assume, then they should not be influenced by the order in which stimuli are presented. Nevertheless, humans are sensitive to presentation order (Danks \& Schwartz, 2006; Sanborn, Griffiths, \& Navarro, 2010). One explanation for these order effects is that people arrive at solutions by considering a small number of hypotheses at any single moment in time, and updating or replacing them sequentially with more data - sometimes losing information and leading to small but systematic errors. More recently, Bayesian process models have been proposed to explain these patterns of errors by drawing analogies to Monte Carlo sampling methods that permit tractable and efficient inference in applied statistics and machine learning (Abbott, Hamrick, \& Griffiths, 2013; Shi, Griffiths, Feldman, \& Sanborn, 2010).

Inference techniques are often modelled using Monte Carlo methods that update sequentially and incrementally. These methods allow hypotheses to be revised by sampling from the posterior, without computing the posterior distribution in its entirety. Markov chain Monte Carlo sampling is a popular and efficient subclass of Monte Carlo methods, and it is marked by a degree of stickiness or inertia, in which people hew more closely to their initial hypotheses than a truly optimal Bayesian learner would. This family of models predicts that individuals will tend toward inferences that are similar to their prior beliefs. For example, one study showed that when people made inferences about a causal system, they tended toward solutions that required the fewest single edits to their initial hypothesis, where a single edit is an addition, subtraction, or reversal of a causal link (Bramley, Dayan, Griffiths, \& Lagnado, 2017). Therefore, causal process models can account for multiple limitations on causal learning, and have re-
cently been shown to explain phenomena such as classical anchoring (Lieder, Griffiths, Huys, \& Goodman, 2017). Learners can be constrained not only by priors, but also the similarity of candidate hypotheses to their current beliefs, perhaps precluding them from finding too-distant hypotheses.

## The Explore-Exploit Trade-off in Inference

These findings could reflect a cognitive tradeoff in development that affects how learners search through hypotheses. When presented with a wide range of possibilities, individuals must often decide whether to employ a general, shallow search or a narrow, deep one. This decision is analogous to the explore-exploit tradeoff, whereby decision-makers must allocate cognitive resources to either exploit previous knowledge or explore alternatives (Sutton \& Barto, 1998). Adults may be more inclined to exploit, by searching nearby solutions extensively—and less likely to explore hypotheses that require unusual, low-probability edits to the current hypothesis. With limitations on the number of hypotheses a learner can consider, exploitation-biased adult learners could plausibly benefit from focusing cognitive resources on hypotheses that are refinements of an initial proposal that is plausible and informed by long experience. This will increase efficiency of finding adequate solutions but potentially limit access to distant alternatives. Conversely, exploration-focused learners (young children, perhaps) may spread out their search over a more diverse range of possibilities. Although this approach sacrifices the ability to efficiently refine already-reasonable hypotheses, it may grant access to unusual solutions that would be unreachable with a more conservative search.

Thus, the inferential explore-exploit trade-off may have interesting implications for the process of selecting between competing hypotheses. This selection process has been modelled using Bayesian algorithms for both children and adults (Bonawitz, Denison, Gopnik, \& Griffiths, 2014; Denison, Bonawitz, Gopnik, \& Griffiths, 2013; Lieder, Griffiths, \& Goodman, 2012; Sanborn, Griffiths, \& Navarro, 2010), but relatively little previous work has examined adults' potential tendencies toward exploitation. As one possible example of how hypothesis search may reflect an exploitation bias, Gopnik and colleagues have likened human belief updating to simulated annealing; just as the heating and gradual cooling of metal can increase its malleability, so can a gradual "cooling" of an inference method corresponding to an increasingly conservative search policy lead to better inferences (Gopnik, Griffiths, \& Lucas, 2015; Lucas, Bridgers, Griffiths, \& Gopnik, 2014). For instance, while young children may use hightemperature searches, considering a wide range of hypotheses with relatively equal probability, adults' searches are "cooler" and more narrow in scope. Although commitment to priors may still matter, simulated annealing allows us to examine which types of hypotheses are considered. High-temperature searches are more likely to discard adequate hypotheses, but may allow individuals to escape local optima and discover unlikely solutions that are potentially better. In contrast, lowtemperature searches can quickly converge to good solutions
if fewer low-probability edits are required to get there, but may otherwise get trapped in local optima. With this in mind, adults may have more difficulty discovering unusual causal relationships because their search is too focused and too close to their initial guesses to accommodate distant ideas.

The purpose of our current studies is to test the hypothesis that belief updating in adults is exploitation-biased. To accomplish this, we designed a task encouraging participants to generate a particular initial hypothesis about a novel causal relationship. Evidence that contradicted this hypothesis was then presented, causing participants to modify their beliefs. The true causal structure took one of two forms corresponding to two experimental conditions. In the near condition, the correct causal structure was closer to the initial hypothesis but designed to be relatively complex. In the distant condition, the correct causal structure was simpler but possibly harder to reach when making incremental changes from the initial hypothesis, which is a local optimum. Thus, we hoped to determine the breadth of hypotheses that participants were willing to entertain. If adults' search process is more exploitationbiased, we should expect the near-hypothesis solution would be more easily found than the distant one, even if both rules are a priori equally unlikely. However, if adults' failure to infer unlikely causal relationships is simply due to the low prior probability that they place on these relationships, then they should be equally unlikely to consider either solution.

## Experiment 1: Investigating the Explore-Exploit Tradeoff in Inference

Participants Participants were 90 adult US residents, recruited through Amazon Mechanical Turk and paid a base rate of $\$ 1$ for their time. An additional $\$ 1$ bonus was given to the top $10 \%$ performers as an additional incentive. Participants were divided randomly among near $(\mathrm{n}=45)$ and distant ( $\mathrm{n}=45$ ) conditions. Six participants from the near condition and seven from the distant condition were excluded due to failure to correctly answer attention manipulation tasks.

Materials and Procedure The methods used in this study are similar to those used in previous blicket tasks (e.g. Gopnik \& Sobel, 2000), except that animated video stimuli were presented online using Qualtrics survey software (similar to Buchsbaum et al., 2012). Participants were asked to examine several blocks and determine which blocks are blickets. They were informed that blickets are blocks that activate the blicket detector, and were shown a video of an animated blicket detector activating and not activating. Participants then watched a five-minute animation depicting 20 blocks being consecutively placed onto the blicket detector. If the block was a blicket, the detector lit up and a sound played. The blocks were sorted into blicket/non-blicket categories and left on screen for participants to study.

Whether a block was a blicket depended on specific aspects of the block pattern. Each block had a coloured background (red or blue) and several small red or blue triangles in a fixed pattern (see Figures 1 and 2). The block pattern was such

Figure 1: Examples of blickets in the near condition (left) and the distant condition (right).
that the background colour was the most obvious and visually striking feature. For the first 15 blocks (the initial ruleconsistent blocks), the background colour appeared to determine whether the blocks activated the machine-i.e. blocks with one background colour consistently activated the machine, while the others did not. Inspired by an experimental manipulation in Williams and Lombrozo (2010; 2013), this was designed to lead participants to an initial causal hypothesis based on the objects' most salient feature. The final five blocks (the initial rule-violating blocks), however, violated this initial hypothesis; the blocks that did and did not activate the machine had the opposite background colour as before. Thus participants needed to modify their initial hypothesis to capture the optimal solution.

The true rule separating blickets from non-blickets varied based on condition. This true rule determined whether a block was a blicket $100 \%$ of the time. In the near condition, the background colour was related to whether a block was a blicket, whereas in the distant condition the background colour was unrelated. Each block had five binary features (Figure 1), which could vary by colour on each block (background, corners, centre-left triangle, centre-right triangle, and border), giving a total of 32 different colour combinations. In the near condition, blocks were blickets based on a combination of the background colour and the colour of two secondary features. In the distant condition, only the colour of these two secondary features determined whether a block was a blicket, while the background colour was irrelevant.

Thus, the five features could be labeled as follows: one primary feature (A), two relevant secondary features (B and C), and two irrelevant secondary features (D and E). In the distant condition, the optimal rule for determining whether a block is a blicket-that is, the simplest rule that perfectly explains the data-can be written as $R=(B==C)$, whereas the optimal rule in the near condition can be written as $R=$ $(A \cap \neg B) \cup(\neg A \cap \neg C)$. These rules were designed to seem arbitrary to naïve participants and minimize the role of the participants' prior knowledge. In the near condition, there is a consistently-improving path of single edits to transition from the initial hypothesis, $R=A$, to the correct rule, where a single edit consists of adding or subtracting a variable or chang-
ing an operator (e.g. changing $R=A$ to $R=A \cap \neg B$; Goodman \& Tenenbaum, 2008 use a similar approach for searching a hypothesis space). In the distant condition, the single-edit path to the correct rule requires edits that initially worsen the hypothesis (e.g. removing $A$ as a relevant variable). Participants must therefore ignore the ineffectiveness of these local edits and keep exploring to find the correct solution. Thus, if adults use a Bayesian single-edit search process with an exploit bias, participants should be less likely to abandon $R=A$, and thus should perform more poorly in the distant condition, where $R=A$ is the local optimum.

The lists of blocks seen by participants in the near and distant conditions were generated randomly with the following constraints: a) there were ample block feature combinations that participants did not see, so that they could be tested on these blocks later, and b) the rules and edit paths conformed to the specifications in the previous paragraph. Thus, the final sets of blocks were as follows: near condition participants saw 11 blickets ( 3 initial rule-violating) and 9 non-blickets ( 2 initial rule-violating), whereas distant condition participants saw 10 blickets ( 2 initial rule-violating) and 10 non-blickets (3 initial rule-violating). The differences in block numbers were necessary due to the constraints of the conditions.

Following the presentation of all of the blickets, participants saw a blicket rating task, in which they were asked to judge whether a randomized series of eight blocks were blickets. For each block, participants rated how certain they were that it was, or was not, a blicket, on a seven-point Likert scale ranging from "definitely a blicket" to "definitely not a blicket". Blocks were balanced by background colour, blicket/non-blicket status, and whether they had already been presented in the observation stage. Participants received a score between -3 and 3 for each block based on accuracy and certainty, and the sum of these scores determined their final score for this task. Next, participants completed a forcedchoice task, where they chose which of two blocks was more likely to activate the blicket detector, for a series of four pairs. Blocks were selected randomly such that there were an equal number of initial rule-consistent and initial ruleviolating blocks, and blocks in each pair differed from each other in background colour and whether they were a blicket. Participants received a point for each correct block judgment.

Afterwards, the participants were asked to describe the causal rule they had inferred. They were then told to imagine that a new rule was suggested by a friend, and asked if they preferred this rule over their own. This rule always represented the correct causal structure. The purpose of this question was to ensure that any differences between the two conditions were not due to participants finding the near rule inherently more plausible or likely than the distant one. The participants' rule preference was measured using a seven-point scale. Finally, each participant received questions to test their task comprehension and an instructional manipulation task to control for inattention, similar to the one used by Oppenheimer, Meyvis, and Davidenko (2009).

Results and Discussion If adults' hypothesis search strategy is exploitation-biased, participants in the near condition will perform better on both tasks than those in the distant condition. The results supported our predictions. For the forced-choice task, a $2 \times 2$ ANOVA was run with condition (distant/near) and rule consistency (initial ruleconsistent/violating) as factors (see Table 1 for a score summary). Near condition participants outscored those in the distant condition, $F(1,84)=6.46, p=.01, M S E=0.26$. Participants also scored higher for initial rule-consistent blocks, than for rule-violating blocks, $F(1,84)=226, p<.001, M S E$ $=0.34$. There was no significant interaction effect, $F(1,84)=$ $0.154, p>.69, M S E=0.34$.

For the blicket rating task, a $2 \times 2$ mixed ANOVA (condition x rule consistency) was run (see Table 2 for a score summary). The analysis found that participants were much more likely to confidently identify initial rule-consistent blocks than initial rule-violating blocks $F(1,84)=131, p<.001, M S E=15.32$, suggesting that the salience manipulation was effective and participants were influenced by the background colour. Supporting our forced-choice results, there was a marginally significant effect of condition, $F(1,84)=3.77, p=.06, M S E=$ 11.87, with a mean score of 7.51 for the near condition and 4.63 for the distant condition (scores ranged from - 24 to 24 ).

Intriguingly, and unlike in the forced-choice task, there was also a significant interaction effect, $F(1,84)=3.34, p=.04$, $M S E=15.32$. This is a result of participants in the near condition performing better than those in the distant condition on initial rule-consistent blocks, but equally poorly on initial rule-violating blocks. To assess whether this interaction was due to differences in confidence for some blocks, an additional $2 \times 2$ mixed ANOVA (condition $x$ rule consistency) was run to investigate participants' certainty ratings when evaluating blocks. The analysis showed no main effect of condition, $F(1,84)=2.30, p>.13, M S E=0.69$. Mean confidence ratings were relatively near ceiling in both conditions (greater than 2 out of 3 ), which may partially explain the lack of a main effect. However, participants were more certain of their answers when rating initial rule-consistent blocks than when rating rule-violating blocks, $F(1,84)=22.0, p<.001, M S E$ $=0.32$. There was also a highly significant interaction effect between condition and rule-consistency, $F(1,84)=13.1, p$ $<.001, M S E=0.32$, driven by participants in the near condition having more certainty for initial rule-consistent blocks than for rule-inconsistent blocks, suggesting that while participants in the near condition were better able to correctly categorize both initial rule-violating and initial rule-consistent blocks, they were most confident about the latter.

Additional one-sample t-tests examined whether participants scored better than would be expected by chance. For the forced-choice task, participants correctly classified blocks as blickets and non-blickets significantly better than chance in the near condition, $t(42)=5.82, p<.001$, but not in the distant condition, $t(42)=1.31, p=0.20$. In the blicket rating task, however, participants classified blocks better than

Table 1: Mean scores and SE for forced-choice task. Total scores range from 0 to 4 , and scores for initial rule-consistent and initial rule-violating blocks range from 0 to 2 .

| Condition | Near | Distant |
| :--- | :---: | :---: |
| Total score | $2.53( \pm 0.10)$ | $2.24( \pm 0.12)$ |
| Rule-consistent | $1.90( \pm 0.08)$ | $1.82( \pm 0.07)$ |
| Rule-violating | $0.77( \pm 0.13)$ | $0.42( \pm 0.07)$ |

Table 2: Mean scores and SE for blicket rating task. Total scores range from -24 to 24 , and scores in each sub-category range from -12 to 12 .

| Condition | Near | Distant |
| :--- | :---: | :---: |
| Total score | $8.00( \pm 1.04)$ | $4.87( \pm 1.26)$ |
| Rule-consistent | $9.59( \pm 0.51)$ | $6.39( \pm 0.72)$ |
| Rule-violating | $-1.59( \pm 1.01)$ | $-1.53( \pm 1.06)$ |

chance in both the near condition, $t(42)=7.69, p<.001$, and the distant condition $t(42)=4.13, p<.001$. The at-chance performance of distant condition participants in the forcedchoice task may simply reflect the low number of trials compared to the blicket rating task.

Finally, we looked at participants' preference for the correct rule over their own. Participants in the distant condition significantly preferred the correct friend's rule over their own rule, $\mathrm{t}(42)=4.78, \mathrm{p}<.001$, while participants in the near condition did not, $\mathrm{t}(42)=1.55, \mathrm{p}=.13$. Participants in the distant condition also preferred the friend's rule significantly more than those in the near condition, $t(75)=2.09, p=.04$. This supports our hypothesis that participants in the distant condition had not previously considered the distant rule, rather than that they considered it, but dismissed it as unlikely.

## Experiment 2: A priori rule preference

Although the main study compared the extent to which participants preferred the correct rule over their own, it did not examine the rules in both conditions side-by-side. This study investigated adults' a priori preference for either the near or the distant rule without differentiating data. This was to confirm that differences in causal learning and rule preference between conditions in Experiment 1 were not due to an intuitive preference for the near rule before seeing any data.

Participants Participants were 51 adult US residents, recruited through Amazon Mechanical Turk (MTurk) and paid a base rate of $\$ 0.50$ for their time.
Materials and Procedure As in the previous study, participants were told that blickets were blocks that activated the blicket detector, and saw an animated blicket detector activating and not activating. Unlike the previous study, however, participants only saw one block placed on the machine, causing it to activate. They were then told the two possible
rules, and that both rules accurately described this block, but that only one rule was the correct rule for identifying blocks that activate the machine. Participants were asked to choose which rule they thought was more likely to be correct. These rules were identical to the near rule and the distant rule from the previous study, and the blicket that participants saw was chosen from a set of blocks that conformed to both rules. Finally, after selecting a rule, participants explained why they chose that rule and rated their confidence in their decision, ranging from 1 (just guessing) to 7 (completely certain). This confidence rating was turned into a score ranging from -7 (completely certain the near rule is correct) to 7 (completely certain the distant rule is correct) for statistical analysis.
Results and Discussion Of the 51 participants, 22 preferred the near rule and 29 preferred the distant rule, $\mathrm{p}=.41$, exact binomial test. A one-sample t-test demonstrated that the rule preference scores, $M=0.25, S E=0.50$, did not significantly differ from chance, $t(49)=0.71, p=0.48$. Thus, participants did not prefer one rule over the other, suggesting that it was not an a priori preference for the near rule driving the results of Experiment 1.

## General Discussion

The findings obtained by these studies lend support to the exploitation-biased search hypothesis. We expect that exploitation-biased searches of the hypothesis space will be more likely to discover rules close to the initial hypothesis, and less likely to discover more distant rules, even if they are less complex. As predicted, participants were more accurate at classifying blocks in the near condition than the distant condition. This is especially notable given that participants in Experiment 2 found both rules equally a priori plausible, which supports that the near rule is at least as complex as the distant rule. This in turn makes it less likely that the differences between conditions can be explained by differentlyweighted prior probabilities. Participants performed better in the near condition, where the true rule was arguably more complex, but was comparatively easier to discover from the salient starting point due to the consistently-improving edit path, than in the distant condition, where the true rule was simpler, but where the salient rule was a local optimum. This suggests that adults are searching through their hypothesis space in an exploitation-biased manner.

Nevertheless, participants were better able to identify initial rule-consistent blocks than initial rule-violating ones in both tasks. This suggests that the strength of one's priors may still play a role in conjunction with the exploitation bias. However, this difference in performance suggests intriguing future research avenues-in particular, the finding in the blicket rating task that participants in the near condition scored higher than those in the distant condition on initial rule-consistent but not initial rule-violating blocks. This seems to be driven largely by participants' relative certainty toward initial rule-consistent blocks in the near condition, rather than their accuracy at categorizing the blocks (as mea-
sured by the forced choice task). Future studies might assess how nearness to an initial hypothesis affects the certainty of judgments of causal relationships.

It is still unclear, however, if these difficulties in discovering certain causal relationships are the result of a developmental process. Consequently, we plan to expand this study to directly compare adults with children, to examine whether children possess these same search-related difficulties. If these findings are the result of a developmental shift toward exploitation-based search strategies, then explorationoriented children could perform just as well-if not betterthan adults in tasks such as those in this study. Children should also perform equally well in both experimental conditions, or perhaps even better in the distant condition than in the near one. Particularly, this may be the case if children see the near rule as a priori less likely. When comparing children's and adults' performance, it may also be useful to note differences in time spent on each task, as it might generate additional insights about their hypothesis search process. Although participants in the current studies had unlimited time to complete each task, timing data were not recorded.

In the future, it may be useful to develop a more explicit process model to measure hypothesis distance. Although the near-hypothesis rule is closer to the salient hypothesis, in that adding and subtracting particular predicates improves the hypothesis toward the correct rule, this may not accurately represent how individuals process locality. In other words, we lack a precise model for how people move between rules, and thus exactly how far $R=(B==C)$ is from $R=A$, and how much harder it is to find $R=(A \cap \neg B) \cup(\neg A \cap \neg C)$. In future experiments, this process model will need to be clarified.

Overall, our results demonstrating that adults are able to discover a true causal structure nearer to an initial hypothesis more readily than a distant causal structure of equal or greater complexity provides compelling initial evidence for an explore-exploit trade-off in causal inferences. This may help inform future research on how individuals generate new hypotheses about everyday causal interactions.

# Modeling transfer of high-order uncertain information 

Michele Herbstritt (michele.herbstritt@gmail.com) Michael Franke (mchfranke@gmail.com)<br>Department of Linguistics, University of Tübingen<br>Wilhelmstraße 19, 72070 Tübingen, Germany

#### Abstract

Complex uncertainty expressions such as probably likely and certainly possible naturally occur in everyday conversations. However, they received much less attention in the literature than simple ones. We propose a probabilistic model of the use and interpretation of complex uncertainty expressions based on the assumption that their predominant function is to communicate factual information about the world, and that further layers of uncertainty are pragmatically inferred. We collected empirical data on the use and interpretation of these expressions and use it for detailed model criticism.

Keywords: uncertainty; probability; experimental pragmatics; computational modeling

## Introduction

One of the main goals of human linguistic interactions is the exchange of information. However, the information that we want to exchange can be uncertain: we often talk about things that we do not know for sure. As a consequence, it should not surprise us that human languages are equipped with so called "uncertainty expressions" such as epistemic modals (possible, might) and probability expressions (probably, likely).

Simple uncertainty expressions have been extensively investigated in psychology (Beyth-Marom, 1982; Teigen, 1988; Windschitl \& Wells, 1996, 1998) and formal linguistics (Kratzer, 1991; Yalcin, 2010; Egan \& Weatherson, 2011; Lassiter, 2011), where some consensus has recently emerged about the advantage of adopting a formal semantics that uses probability measures (contra the purely qualitative semantics à la Kratzer). Herbstritt and Franke (2016) empirically investigated the production of simple uncertainty expressions (probably, possibly) and propose a pragmatic model of their production. This paper substantially extends the scope of that work: here we investigate complex (or nested) expressions such as probably likely and certainly possible and we model both their production and interpretation in a conversation.

Complex uncertainty expressions have received much less attention in the literature. ${ }^{1}$ Indeed, many foundational issues arise in the attempt to formalize a model of their use and interpretation. Most pressingly are two interrelated concerns: (i) what is the semantic meaning of a complex uncertainty expression? and (ii) what is the communicative goal of a complex uncertainty expression, i.e. what is the pragmatic purpose of communication? In this paper we present a first model that commits itself to what are arguably the most natural answers to (i) and (ii) from the point of view of formal semantics (Swanson, 2006; Moss, 2015) and a rational analysis of communicative practices as efficient transfer of information about the world (Anderson, 1990, 1991).

[^94]This approach enables a straightforward regular and compositional treatment of the meaning of uncertainty expressions: simple and complex uncertainty expressions denote sets of probability distributions over the state space that represents the possible ways in which the world can be. The meanings of simple expressions are always singleton sets. The meanings of complex expressions are derived compositionally in terms of the simple ones and in general they contain more than one distribution (see details below). If we model agents' uncertain beliefs about the world as (sets of) probability distributions over the same state space, then the meaning of a simple or complex uncertainty expression can be seen as a collection of ways to update the agents' beliefs. Figure 1 displays an intuitive representation of this idea.

We incorporate this idea in a probabilistic pragmatic model of language production and interpretation based on the Rational Speech Acts (RSA) model (Frank \& Goodman, 2012). In particular our model can be seen as a conservative generalization of the RSA model proposed by Goodman and Stuhlmüller (2013). The key innovation of our model is to treat uncertain beliefs of agents (and thus the communicative effect of messages) as sets of probability distributions, hence more fine grained than in the usual approach.

Figure 1: Listener's beliefs as complex uncertainty state. Each probability distribution in the listener's beliefs is compatible with the literal meaning of the received message.

The details of the model are spelled out in the next section. In the following section we report on two experiments designed to collect human data about production and interpretation of complex uncertainty expressions. Finally, the predictions of the model are evaluated against experimental data with Bayesian inference and model criticism.

## Pragmatic model

Setup We want to model communication in situations of what we call high-order uncertainty. To illustrate, imagine an urn containing 10 balls of two different colors (e.g., red
and blue). The universe of the discourse, the set of possible states of affairs, can be modeled as the set of natural numbers $S=\{0, \ldots, 10\}$ where each $s \in S$ is a possible quantity of red balls in the urn. The ratio $s / 10$ expresses the objective chance that a randomly drawn ball will be red, and represents first-order uncertainty: even if we know the objective chance, we are uncertain about the color of a randomly drawn ball. The second, high-order level of uncertainty comes into play when we are uncertain about the objective chance too. We model agents that do not have direct access to the objective chance. Instead, one agent (the speaker) can draw a certain number of balls from the urn (referred to as the "access" and denoted with $a$ ) and look at them. The set of possible access values is $A=\{1, \ldots, 10\}$. The number of red balls among the accessed ones is referred to as the "observation" and denoted $o, 0 \leq o \leq a$. We assume that the communication is about the content of the urn: after her observation, the speaker puts all balls back in the urn and makes a prediction about the color of a randomly drawn ball (see Figure 2). This prediction is what the speaker will try to communicate.

Figure 2: Partial observation of the content of the urn.
The probability of observing $o$ red balls when the speaker draws $a$ balls and there are $s$ red balls in the urn is given by the hypergeometric distribution. Assuming that the agent has a prior belief distribution over the state space $S$, we can say that each pair $\langle o, a\rangle$ induces a posterior rational belief distribution over $S$, computed as the Bayes-inverted hypergeometric distribution: ${ }^{2}$

$$
\begin{equation*}
\operatorname{rat} . \operatorname{bel}(s \mid o, a) \propto \operatorname{hypergeom}(o ; a, s, 10) * \operatorname{prior}(s) \tag{1}
\end{equation*}
$$

On the basis of the rational belief resulting from her observation, together with the lexical meaning of the available messages, the speaker chooses the best message to send given her communicative goal.

Messages and semantics The speaker sends messages of the form It is [...] that a randomly drawn ball will be red, choosing from the following 12 expressions to fill the gap:

| likely | possible | unlikely |
| :--- | :--- | :--- |
| certainly likely | certainly possible | certainly unlikely |
| probably likely | probably possible | probably unlikely |
| might be likely | might be possible | might be unlikely |

[^95]Simple messages (likely, possible, unlikely) have a simple threshold semantics:

$$
\begin{aligned}
& \llbracket \operatorname{likely}(p) \rrbracket=\left\{s \in S \mid s / 10>\theta_{\text {likely }}\right\} \\
& \llbracket \operatorname{possible}(p) \rrbracket=\left\{s \in S \mid s / 10>\theta_{\text {possible }}\right\} \\
& \llbracket \operatorname{unlikely}(p) \rrbracket=\left\{s \in S \mid s / 10<1-\theta_{\text {likely }}\right\}
\end{aligned}
$$

The thresholds $\theta_{\text {likely }}$ and $\theta_{\text {possible }}$ are free parameters in the model (more about this below). The variable $p$ can be instantiated with a sentence such as A randomly drawn ball will be red. For example, this semantics states that the meaning of It's possible that a randomly drawn ball will be red is the set of states where the objective probability of the ball being red is bigger than a certain threshold $\theta_{\text {possible }}$.

The semantics of complex messages is stated in a general form as follows:

$$
\llbracket \operatorname{modifier}[\operatorname{simple}](p) \rrbracket=\left\{\langle o, a\rangle \mid \sum_{s \in \llbracket \operatorname{simple}(p) \rrbracket} \operatorname{rat.bel}(s \mid o, a)>\theta_{m}\right\}
$$

where $\theta_{m}$ is the semantic threshold associated with the modifier. ${ }^{3}$ Each state in the meaning of the simple message $\llbracket \operatorname{simple}(p) \rrbracket$ is associated with a certain probability mass according to the rational belief induced in the speaker by each pair $\langle o, a\rangle$; the meaning of the complex message is computed collecting the pairs $\langle o, a\rangle$ where the probability mass of the states in $\llbracket \operatorname{simple}(p) \rrbracket$ is greater than the semantic threshold of the modifier. The semantics of complex messages is rooted in the literal semantics of the simple ones. The difference between the two is that while the meanings of simple messages contain states of affairs, the meanings of complex expressions contains pairs denoting partial observations, i.e. distributions over states. Still, both simple and complex expressions can be linked to sets of probability distributions over world states. Making use of this allows for a uniform grounding of semantic meaning in a model of rational communication.

Beliefs and expected utility On the basis of the literal meaning of each message, we compute their effect on the socalled "literal listener", a theoretical construct modeling the interpretation process of a non-pragmatic agent. Each simple message induces exactly one belief distribution in the literal listener, whereas each complex message induces a set of distributions (one for each pair $\langle o, a\rangle$ in the meaning of the expression). This idea is captured in Equation 2, where the set of distributions lit.bel is defined by cases as a function of messages. ${ }^{4}$

[^96]\[

$$
\begin{align*}
& \text { lit.bel }(m)= \\
& =\left\{\begin{array}{l}
\left\{P \in \Delta(S) \mid \forall s \in S: P(s) \propto \delta_{s \in \llbracket m \rrbracket} * \operatorname{prior}(s)\right\} \quad m \text { simple } \\
\{P \in \Delta(S) \mid \exists\langle o, a\rangle \in \llbracket m \rrbracket: P=\operatorname{rat} . \operatorname{bel}(. \mid o, a)\} m \text { complex }
\end{array}\right. \tag{2}
\end{align*}
$$
\]

We assume that the communicative goal of the speaker is to maximize the information transferred to the listener. Here we formalize this concept as choosing the message which brings the listener's factual beliefs as close as possible to the speaker's, i.e. which minimizes the distance between the probability distributions expressing these beliefs. In general each message is associated with a set of probability distributions over states, according to Equation 2. Idealizing, we assume that the literal listener would uniformly sample from this set of uncertain beliefs upon hearing each message. For this reason the expected utility (EU) of a message $m$ given an observation $\langle o, a\rangle$ is defined as the negative average Hellinger distance between the speaker's belief distribution given an observation and the set of the listener's distributions given a message (Equation 3).

$$
\begin{equation*}
\mathrm{EU}(m ; o, a)=-\operatorname{avg}[H D(\{\operatorname{rat} . \operatorname{bel}(. \mid o, a)\}, \text { lit.bel }(m))] \tag{3}
\end{equation*}
$$

where $H D$ denotes a function computing pairwise Hellinger distances between two sets of discrete distributions. ${ }^{5}$

Production and interpretation Adopting the terminology of rational choice theory, the speaker's behavior is to softmaximize the EU of each message given her observation:

$$
\begin{equation*}
\operatorname{speaker} . \operatorname{prob}(m \mid o, a) \propto \exp (\lambda * \mathrm{EU}(m ; o, a)) \tag{4}
\end{equation*}
$$

EU is multiplied by a rationality parameter $\lambda$ (free in the model) that modulates "how rational" the choice is. ${ }^{6}$ The distribution over messages defined in Equation 4 gives rise to the first half of the set of predictions made by our model, whose fit to the experimental data is discussed below.

A pragmatic listeners reasons about the received message and her model of speaker's behavior in order to infer the most likely interpretation. The pragmatic listener's behavior is modeled as the joint Bayesian inference over the variables of interest:

$$
\begin{equation*}
\text { listener.prob }(s, o, a \mid m) \propto \text { speaker. } \operatorname{prob}(m \mid o, a) * \text { priors } \tag{5}
\end{equation*}
$$

We are interested in the interpretation of uncertainty expressions alongside two axes of their communicative effect. One

[^97]is the objective state of affairs communicated (i.e., the inference of $s$ ). The other is the subjective, high-order, state of uncertainty of the speaker (i.e., the inference of $\langle o, a\rangle$ ). The joint distribution defined in Equation 5 gives rise to the second half of the set of predictions made by our model, whose fit to the experimental data is discussed below.

## Experiments

We conducted two experimental studies, a production task and an interpretation task. The goal of the production task was to collect human data on the use of simple and complex uncertainty expressions under different high-order uncertainty conditions. The goal of the interpretation task was to collect human data on the interpretation of the expressions in terms of inference of $s, o, a$.

Participants 252 self reported English native speakers with USA IP-addresses were recruited via Amazon's Mechanical Turk. 102 participants completed the production task, 150 participants completed the interpretation task.

Material Participants in the production task were exposed to visual stimuli depicting partial observations of the urn. We asked participants to imagine drawing a number of balls (access) and counting the red balls among them (observation). Then they would put the balls back in the urn, and make a prediction about the color of another randomly drawn ball (Figure 2).

The experimental conditions are the different observation/access configurations displayed to the participants. We selected 15 such configuration:

| high | $0 / 2$ | $1 / 4$ | $2 / 4$ | $3 / 4$ | $2 / 2$ |
| :---: | :---: | :---: | :---: | :---: | :---: |
| low | $0 / 8$ | $2 / 8$ | $4 / 8$ | $6 / 8$ | $8 / 8$ |
| none | $2 / 10$ | $3 / 10$ | $5 / 10$ | $7 / 10$ | $8 / 10$ |

Each fraction in the table corresponds to a possible partial observation, e.g. $3 / 4$ means accessing 4 balls and observing that 3 of them are red. The fractions are grouped according to their level of high-order uncertainty. Access values smaller than 5 balls are labeled "high" high-order uncertainty, whereas values greater than 5 correspond to "low" high-order uncertainty, and values equal to 10 represent no high-order uncertainty whatsoever.

The set of stimuli for the interpretation task was derived from the 12 expressions assumed in the model.

Procedure Before the experimental phase, participants completed a training phase which contained a cover story introducing an interactive game between two players, a sender and a receiver. Participants in the production task were told that they would play as senders, and that other players would receive their messages and try to guess the content of the urn. Participants in the interpretation task were told that they would play as receivers. The motivation for this setup was to
clarify the purpose of the conversation when producing uncertainty expressions and to prompt participants to reason about the effect of their choices on other agents.

Each participant in the production task completed 12 trials, one for each of 12 conditions randomly picked from the 15 total conditions. In each trial the participant made the partial observation of the urn corresponding to the selected condition and was asked to send a message containing a prediction about the color of a randomly drawn ball. Crucially, this prediction must be expressed by completing a sentence of the form It $[\ldots][\ldots]$ that the next ball will be red, selecting the most appropriate combination of auxiliary/modifier and uncertainty expression from two drop-down menus (Figure 3). ${ }^{7}$

Figure 3: Input menus in the production task.
Each participant in the interpretation task completed 24 trials, 2 for each of the 12 expressions. That is, for each expression there were 2 kinds of trials, perfectly balanced, in random order. Half of the trials ("state" trials) recorded participants' interpretation of the message alongside the objective axis, i.e. their answer to the question "How many red balls do you think there are in the urn?", expressed with a natural number selected with a slider ranging from 0 to 10 . Half of the trials ("observation" trials) recorded participants' interpretation of the message alongside the subjective uncertainty axis, i.e. their answers to the questions "How many balls do you think the sender has drawn? And how many of them do you think were red?", expressed with two natural numbers selected on sliders ranging from 0 to 10 (Figure 4).

Figure 4: Input sliders in observation trials. The picture on the right dynamically visualized the current slider selection in order to provide immediate visual feedback for a selection.

Results Results are visualized in Figures 5 and 6 and will be discussed in the light of the model's predictions below.

[^98]
## Model evaluation and criticism

Model fit The data collected in the production task and the interpretation task are respectively counts of expression choices in each observation condition, and counts of state, access and observation choices for each expression. We used the data to compute credible values for the free parameters of the model, i.e. the semantic thresholds $\theta_{\text {likely }}, \theta_{\text {possible }}$, $\theta_{\text {certainly }}$, the shape parameter of the prior belief distribution $\alpha$, the rationality parameter $\lambda$. We implemented the computational model in JAGS (Plummer, 2003) and approximated the posterior distribution of parameters given the experimental data. We assumed flat prior distributions over the parameters with support $[0 ; 1]$ for the semantic thresholds and $[0 ; 20]$ for $\alpha$ and $\lambda$. We gathered two chains of 2500 samples after an initial burn-in of 2500 . We checked convergence via $\hat{R}$ (Gelman \& Rubin, 1992). Each sample consists of a vector of inferred values for each parameter. The following table summarizes the mean values for the threshold parameters together with their $95 \%$ highest density intervals (HDIs): ${ }^{8}$

|  | $\theta_{\text {likely }}$ | $\theta_{\text {possible }}$ | $\theta_{\text {certainly }}$ |
| :---: | :---: | :---: | :---: |
| mean | 0.531 | 0.214 | 0.979 |
| HDI | $0.511-0.551$ | $0.200-0.236$ | $0.965-0.996$ |

Notice that the model recovers plausible values for thresholds given the data without assuming them from the start.

For each sample vector of parameter values our model generates a set of predictions about speaker's and listener's behavior. In order to evaluate our model we correlated each set of predictions with the set of corresponding experimental count data. The results are collected in vectors of Pearson's correlation scores, whose means and HDIs give us an indication of the overall performance of the fitted model, as summarized in the following table:

|  | expression | state | access | observation |
| :---: | :---: | :---: | :---: | :---: |
| mean | 0.649 | 0.862 | 0.883 | 0.941 |
| HDI | $0.647-0.651$ | $0.857-0.867$ | $0.880-0.886$ | $0.938-0.943$ |

Discussion Correlation scores do not provide detailed information about what aspects of the data the model can and cannot explain. To get a better sense of the performance of the model we compare data and predictions in more detail with posterior predictive checks (PPCs) (Kruschke, 2014).

We begin with the production task (Figure 5). Visual inspection of the plot suggests interesting features of the data. First, the number of observed red balls seems to have an influence on the choice of expressions. For example, with the same access of 8 (middle row of Figure 5), different observation values ( $0,2,4,6$ and 8 ) resulted in different distributions of expressions. This is an intuitive result, and the model correctly predicts the general pattern. Second, the same proportions of red balls but with different access levels seem to result in different expression choices. For example, compare the distributions of expressions observed (and predicted) with

[^99]a proportion of 0 observed red balls and access values equal to 2 and 8 , and similarly with a proportion of 1 and access values equal to 2 and 8 . The distributions are different, and the model seems to predict the patterns.

However, there are also several discrepancies between observed data and the models PPCs. Discrepancies show in Figures 5 and 6 whenever the HDIs of the PPCs do not include the observed frequencies: in these cases the model, being trained on the data, would still be surprised, so to speak, by seeing the data points where observations do not fall in to the HDIs of our PPCs. For example, the model underpredicts choice frequencies of might be possible in favor of possible in the high uncertainty conditions and underpredicts unlikely and likely in the no uncertainty conditions. More in general, the model almost always overpredicts choice of, e.g., certainly possible and might be unlikely. At the same time, whenever PPCs are off for simple expressions, the model underpredicts their choice frequency. This suggests that a crucial ingredient might be missing from the model, namely a baseline preference of some expressions over others.

Turning now to the interpretation task (Figure 6), we observe that in general the patterns displayed in the data seem to be captured relatively well by the model. However, PPCs highlight a number of discrepancies. One clear example concerns the state interpretation for unlikely and its nested versions (left panel, right column): the predictions are visibly shifted to the right compared to the data. Another feature that the model fails to predict is the relatively low counts of access choices of 5 (compared to 4 and 6) for several expressions (middle panel), although this seems to be a puzzling feature of the data rather than an obvious shortcoming of the model.

## Conclusion

Communication under high-order uncertainty raises a number of issues for formal semantics and pragmatics. Our work here is intended as a first but transparent explication of a number of assumptions that allow the formulation of a computational model of the use and interpretation of complex uncertainty expressions. The resulting model captures basic patterns in the data well enough, suggesting that our basic assumptions are not entirely off. Still, detailed model criticism also reveals a number of shortcomings. These point the way to further exploration; we see our main contribution exactly in this pointing. Most importantly, a measure of a differential inclination to produce messages (e.g., in terms of frequency, length, salience) should be included. Also, the artificial restriction on the set of message choices should ideally be relaxed as much as possible. Moreover, it will be telling to see how participants react to contextual manipulations such as of the relative relevance of information about the world state vs. information about the speaker's epistemic state.

# A Priming Model of Category-based Feature Inference 

Laura M. Hiatt (laura.hiatt@nrl.navy.mil)<br>US Naval Research Laboratory<br>Washington, DC 20375 USA

#### Abstract

Categorization has a large impact on how people perceive the world, especially when used to make inferences about uncertain features of new objects. While making these inferences, people tend to draw information from only one possible categorization of a new object; in addition, people are sensitive to pre-existing correlations between features. Here, we explain these trends of feature inference using a priming-based cognitive process model, and show that our model is distinguished in that it can explain not only these two main trends, but also cases where people seem to reverse the first trend and base inferences on information from multiple categories.

Keywords: categorization; priming; spreading activation; inductive inference; cognitive models

## Introduction

Categorization is a fundamental tool in human cognition. One of its main functions is to allow people to more easily understand the world by making inferences about new objects based on existing knowledge that they already have. If one sees a furry animal coming towards it and categorizes it a loose dog, then it would be natural to further infer that the animal is probably friendly.

Systematic research into how these inferences are made has shown two major trends in performance (Nosofsky, 2015; Murphy \& Ross, 1994, 2007; Griffiths, Hayes, \& Newell, 2012). First, people seem to base inferences on a single identified category for an object, even if the object's categorization is uncertain (called the single-category view). So, for example, people would typically infer that the dog is friendly without considering that it might be a fox, which should be avoided. Second, people are sensitive to correlations between features, and are more likely to infer features that are strongly associated with the observed features of the new object. For example, people would be further biased towards inferring the dog is friendly if it were wagging its tail.

While there is a large body of research that supports these two trends, here we consider a series of experiments performed by Murphy and Ross (1994) that comprehensively considered several variants and extensions of the basic inference paradigm. The authors, however, admit that their overall results challenge many of the formal models of categorization and inference (Murphy \& Ross, 1994, 2007), with none fully explaining the results. Recently, Nosofsky (2015) developed a exemplar model of feature inference that does qualitatively capture their results. Notably, however, Nosofsky's (2015) analysis does not discuss an important caveat of the first trend: that responses seem to shift towards a multicategory view, where more than one possible category is considered when making the inference, if participants do not explicitly identify the category before making the feature inference (Murphy \& Ross, 1994; Griffiths et al., 2012).

We present here a priming-based process model of inductive feature inference that explains these two main results, including this caveat. Situated in the cognitive architecture ACT-R/E (Trafton et al., 2013), a critical aspect of our model is that its inferences are based not only on what stimuli have been seen, but also on what the model is currently thinking about (i.e., what is in its working memory). We show our model's ability to account for feature inferences in four main experiments that are particularly indicative of the trends of feature inference: Experiments 1, 5, 6, and 8 from Murphy and Ross (1994).

## Experiments

In the four experiments we consider from Murphy and Ross (1994), participants were shown category structures with differently shaded geometric objects, grouped together and labeled with the category they represent (e.g., Figure 1). Participants were told that the categories represented different children who drew the objects, and that the objects were illustrative of a larger set of drawings by each child. Then, the experimenter told participants about a new drawing, but only shared one feature of it, such as a triangle; this feature, the query feature, was typically chosen to be ambiguous in which child drew it. Participants were then asked what they thought the other feature of the new drawing was (such as the triangle's color). Additionally, in some experiments, participants were asked to categorize the drawing (i.e., say which child drew it) before they inferred the second feature. The most likely category for each query is called the target category.

Experiment 1 focused on whether inferences are made using information from single, or multiple, categories. The categories are shown in Figure $1^{1}$. This experiment had two conditions. In the increasing condition, the query feature was a triangle. The target category for a triangle is Bob, since Bob has the most triangles. The target-category feature, or the feature that would be selected by primarily considering the target category using a single-category view, is black. This condition is called increasing because there is additional evidence outside the target category that the triangle would be black, since Sam and John also sometimes draw triangles, and they also sometimes draw black objects.

Now, consider a new drawing that is a square. Here, the target category is John, and the target-category feature is white. In this condition, the neutral condition, there is no evidence outside of the target category that the square would be white;

[^100]

Figure 1: Category structure for Experiment 1. In the increasing condition, the query feature is a triangle, the target category is Bob, and the target-category feature is black. For the neutral condition, the query feature is a square, the target category is John and the target-category feature is white. Adapted from Figure 1 of (Murphy \& Ross, 1994).
no other child draws both squares and white objects.
Almost all of the 29 participants selected the target category and target-category feature for both the increasing and neutral conditions, and so ceiling effects prevented them from being statistically compared. Participants also, however, provided a probability estimate of their certainty in their response. These probability judgments did not have a ceiling effect, yet provide no evidence of a difference between the two conditions: the average certainty for each condition was $53 \%$. This parity supports the single-category view of feature inference by suggesting that, despite the additional evidence for the target-category feature present in the increasing condition, participants only took the target category into account when making their inference.

Experiments 5 and 6 used a category structure in which the single-category view and multiple-category view suggest different patterns of feature inferences (Figure 2). Further, they considered how the initial step of identifying the target category may affect participants' use of single vs. multiple categories in their inference. Here, the query feature is a triangle, and the target category is Bob, since he drew more triangles than the other children. The single-category view suggests black as the inferred feature; black is thus considered the target-category feature. A multiple-category view, however, suggests that black and white are equally likely.

The results of the experiments support both these views, depending on whether participants were asked to make the initial categorization step. In Experiment 5, where participants did not initially categorize the drawings, $58 \%$ of the 32 participants chose the target-category feature, black, with the majority of remaining responses as white. This difference was not significant, supporting the multiple-category view. In Experiment 6, however, where participants did categorize the drawings before predicting the other feature, $82 \%$

Figure 2: Category structure for Experiments 5 and 6. Here, the query feature is a triangle, the target category is Bob, and the target-category feature is black. Adapted from Figure 3 of (Murphy \& Ross, 1994).
of the 36 participants responded with the target-category feature. Additionally, $88 \%$ of the participants that categorized the drawing into the target category responded with the targetcategory feature. This supports the single-category view and suggests that participants were biased by the target category when they identified it before making their inference.

Experiment 8 focused on exploring how feature correlations may affect predictions. Here, the query features in two conditions were explicitly controlled to have different degrees of correlation with the target-category features. All participants were asked to assign the drawing to a category before responding to the feature queries. Figure 3 shows an example category structure. In the correlated condition, the query and target-category features were perfectly correlated: the query feature was a circle, the target category was " $D$ " and the target-category feature was "vertically striped." In the uncorrelated condition, the features are only weakly correlated, with a query feature of triangle, a target category of "C" and a target-category feature of white.

The results show that $95 \%$ of the 26 participants selected the target category across both conditions. More importantly, more participants selected the target-category feature for the correlated condition ( $94 \%$ ) than for the uncorrelated condition ( $90 \%$ ). This suggests that people are biased towards correlated features when they make inferences.

## Model

We developed a priming-based process model of feature inference given uncertain categorizations, situated within a computational cognitive architecture, ACT-R/E, that allows us to model the processes people undergo as they perform tasks. In this architecture, concepts that are thought about at the same time become associated in memory, and then can prime one another; by using ACT-R/E, we are able to develop a priming-based account of feature inference that is supported by the underlying principles of this existing, well-studied theory of cognition. Here, we first describe the general principles

Figure 3: Category structure for Experiment 8. For the correlated condition, the query feature is a circle, the target category is D and the target-category feature is vertically-striped. For the uncorrelated condition, the query feature is a triangle, the target category is C and the target-category feature is white. Adapted from Figure 5 of (Murphy \& Ross, 1994).
of our model. Then, we give further details of ACT-R/E, and discuss how our model's principles interact with the architecture to make specific predictions about feature inference.

The process model has two phases corresponding to the two phases of the experiment: an initial phase where the model looks at, encodes, and stores the categories and objects in memory; and an inference phase where the model makes the category and feature predictions. During the initial phase, each of the objects becomes associated with its underlying features; both the features and objects, in turn, also become associated with their corresponding category. These associations mean that the concepts prime one another when the model is thinking of them.

Then, during the inference phase, to predict the category of a new object, the model selects the category with the most priming, including priming from the query feature. Consequently, the model's category response is heavily influenced by the presence of the query feature in the category. To perform the feature prediction, the model selects the object in memory that has the most priming, including priming from the query feature and, when applicable, the selected category. The second feature of that object is then considered to be the inferred feature. This means that the predicted feature is heavily influenced by both the correlation between the two features, and the prevalence of that feature within the identified category (when the category is identified).

## Model Architecture

The model was developed within the cognitive architecture ACT-R/E (Trafton et al., 2013), an embodied version of the ACT-R cognitive architecture (Anderson, 2007). At a high level, ACT-R/E is an integrated, production-based system, and models in ACT-R/E capture the core cognitive processes that people go through as they undergo tasks. At its core are the contents of its working memory; working memory indi-
cates, for example, what the model is looking at, what it is thinking, and its current goal. At any given time, there is a set of productions (if-then rules) that may fire because their preconditions are satisfied by the current contents of working memory. From this set, the production with the highest predicted usefulness is selected to fire. The fired production can either change the model's internal state (e.g., by adding something to working memory) or its physical one (e.g., by pressing a key on a keyboard). In our discussion, we abstract over these productions and instead describe processes at a higher level (i.e., we say that we look at an object, instead of discussing the 3-4 productions that must fire to achieve that).

Working memory is represented as a set of limited-capacity buffers that can contain thoughts or memories. In addition to the symbolic information (i.e., factual information) represented as part of these memories, memories have activation values that represent their relevance to the current situation, and guide what memories are retrieved from longterm memory and added to working memory at any given time. Activation has three components, activation strengthening, spreading activation, and activation noise, that together have shown to be an excellent predictor of human declarative memory (Anderson, Bothell, Lebiere, \& Matessa, 1998; Anderson, 1983; Schneider \& Anderson, 2011; Thomson, Harrison, Trafton, \& Hiatt, 2017). Noise is a random component that models the noise of the human brain; since its presence would not affect our results, we ignore noise in the rest of this paper. Activation strengthening is learned over time and is a function of the frequency and recency with which the memory has been in working memory in the past. The predominant role of activation strengthening in this experiment relates to ordering effects, which the experimental stimuli's counterbalancing averages out. Therefore, we primarily focus the rest of our discussion of activation on its third component: spreading activation, or priming.

Priming is a short-term activation that sources from working memory, distributing activation along associations between the contents of working memory and other memories. Memories become associated when they are in working memory at the same time. Once established, an association from memory $j$ to memory $i$ has a strength value that affects the degree to which $j$ primes $i$, and intuitively reflects the probability that memory $i$ is relevant while thinking of memory $j$. This allows spreading activation to capture correspondences between memories that typically co-occur, as well as memories that are semantically related (such as an object and its color and shape). Association strengths are calculated in a Bayesian-like way, and are a non-standard adaptation of ACT-R's Bayesian-based priming mechanisms. We use this adaptation to account for the large numbers of associations and objects needed by the experiments we consider here, which ACT-R's original formulation is unable to do, as well as to capitalize upon its theory that priming stems from working memory; see Hiatt and Trafton (2016) for more information on our priming mechanisms.

Figure 4: Priming for Experiment 1, increasing condition, for the query feature's categorization (left) and the inferred feature (right). Thicker arrows indicate more priming; thinner indicate less. The cumulative priming means that Bob will be selected as the category and black will be the inferred feature.

ACT-R/E models interact with the world using ACT-R/E's built-in functionality. Models can view visual items on a simulated monitor, and can act on the world by pushing keys on a simulated keyboard and clicking a simulated mouse. ACTR/E models are also inherently tied to physical embodiment (i.e., executing models on a robot), but we do not use that functionality in this paper.

## Model Details

Our model for feature inference starts out with only the task knowledge and productions necessary to complete the tasks. It also assumes prior exposure to the category names, since they are names participants would have encountered frequently in their daily lives (i.e., "A", "John", etc.). There are no initial associations; are all learned during the experiment. The model "looks at" the stimuli as the participants did via its simulated monitor.

During the initial experiment phase when the model is looking at the categories and objects, it first finds a category to look at, encodes it and adds it to working memory. While continuing to think of the category, the model then looks at, encodes and adds to working memory each of the objects in that category, while making note of their color and shape. Consequently, as it looks at each object: the object (i.e., "black-triangle") becomes associated with the category (i.e., "Bob"); the object's features (i.e., "black" and "triangle") become associated with both the object and the category; and the features of the object become associated with each other. When it has finished looking at all objects of a category, it repeats this process with the other categories until it has looked at all of the categories and objects on the screen.

During the inference phase, the model first adds the query feature to working memory as part of the process of interpreting the query. When asked to infer the category of an object, the model retrieves the category from memory with the highest activation, including both activation strengthening and spreading activation (i.e., priming), responds with the retrieved category, and leaves the category in working memory. For example, Figure 4, left side, shows the priming when selecting the category for Experiment 1's increasing condition. Then, when asked to infer the object's missing feature,
the model retrieves an object while both the retrieved category (when applicable) and the query feature are in working memory. Again, the object with the highest activation, both activation strengthening and priming, is retrieved; Figure 4, right side, shows this for Experiment 1's increasing condition. The second feature of the retrieved object is given as the response to the query.

## Model Results

In the original experiments, several versions of the basic category structure were created to counterbalance features and category locations. We varied our category structures accordingly, then used our model to simulate data from 500 participants per experiment to allow our results to better converge on the model's true predictions; our reported results are the proportion of the 500 model runs that responded with the target category, target-category feature, etc., for each query.

The model had the same parameters for each experiment. The activation strengthening decay parameter was 0.45 instead of its default of 0.5 . The associative learning rate was 4.8 , representing a moderate rate of learning. There is no real default value for this parameter. All other parameters were set to their default values.

The main experiment and model results are shown in Table 1. For Experiment 1, the model exhibited perfect performance, always selecting the target category, and always selecting the target-category feature for both the increasing and neutral conditions. This is comparable to the experimental results, where almost all participants also selected the target category and target-category features.

In this experiment, however, despite almost all participants selecting the target-category feature, participants' probability judgments of their responses were not as certain, with an average judgment for each condition of $53 \%$ for both the increasing and neutral conditions. While we have no a priori way of extracting probability judgments from the modeling framework we utilize, our model does informally support these results. This is because, from our model's point of view, these conditions' structures are the same. Both include two objects with the query feature and target-category feature in the target category; one object with just the query feature in the target category; and two objects with just the query feature outside of the target category. Thus, in both conditions, while the black-triangle object (or white-square object) is the highest activated object, it only receives about half of the total priming, suggesting a probability judgment of $50 \%$.

For Experiment 5, the model selected the target-category feature $50 \%$ of the time, which moderately reflects the experiment's results. In Experiment 6, the model very strongly matched the experimental data, selecting the target-category feature $80 \%$ of the time, as compared to the experiment's $82 \%$. Additionally, $89 \%$ of the model runs that categorized the drawing into the target category responded with the targetcategory feature, compared to the experiment's $88 \%$.

For Experiment 8, $95 \%$ of model runs selected the target

Table 1: Model Results

| Experiment | Condition/Participant Group | Measurement | Exp. Data | Model |
| :---: | :---: | :---: | :---: | :---: |
| Exp. 1 | increasing | probability judgments | $53 \%$ | $50 \%$ |
|  | neutral | probability judgments | $53 \%$ | $50 \%$ |
| Exp. 5 | all participants | target-cat. feature | $58 \%$ | $50 \%$ |
| Exp. 6 | all participants | target-cat. feature | $82 \%$ | $80 \%$ |
|  | target cat. correct only | target-cat. feature | $88 \%$ | $89 \%$ |
| Exp. 8 | all participants | target category | $95 \%$ | $95 \%$ |
|  | correlated | target-cat. feature | $94 \%$ | $100 \%$ |
|  | uncorrelated | target-cat. feature | $90 \%$ | $91 \%$ |

category, the same as in the experiment. All of the model runs selected the target-category feature for the correlated condition, and $91 \%$ selected the target-category feature for the uncorrelated condition. Again, this strongly corresponds to the experimental results, where there was a significant difference between the two conditions, with $90 \%$ of participants selecting the target-category feature in the uncorrelated condition vs. $94 \%$ for the correlated condition.

## Model Discussion

Recall the two main trends in research on feature inference for uncertain categorizations that are illustrated by the four experiments we consider here. First, people are biased towards the single-category view when making feature inferences; the bias seems to be modulated, however, when they do not categorize the object first. And second, people's inferences are also sensitive to correlations between features, selecting correlated features more often than non-correlated.

The model explains both of these trends via priming between the features, objects and categories. It explains the first trend, and its caveat, because its predictions are based on the sources of priming in working memory, and as such are not inherently based on the consideration of single- or multiplecategories. When making a feature prediction, the model always has the query feature in memory, which primes objects that are associated with it. This serves to provide suggestions compatible with the multiple-category view of what the predicted feature should be. For example, in Experiment 5, where triangle is the query feature and there is no categorization step, triangle equally primes black-triangle and whitetriangle, because there are equal numbers of them. This leads to a roughly an equal likelihood ( $50 \%$ ) of the predicted feature being black or white. While this underestimates the $58 \%$ response rate of the experimental data, given the lack of statistical significance in this experiment, we are comfortable concluding that our model explains this trend.

In conditions where participants categorize the feature before making their prediction, priming stems not only from the query feature but also from the category, which provides suggestions compatible with the single-category view of what the inferred feature should be. In Experiment 6, identical to Experiment 5 but with an added categorization step, when
shown a triangle, the model generally selects Bob as the category (i.e., Figure 4). Bob then strongly primes black-triangle, since it has three of them, and weakly primes white-triangle, since it has only one of them. Combining this category priming with the priming from the query feature, black-triangle overall receives more. Again, this matches the data, where $82 \%$ of participants overall selected black as the inferred feature, and $88 \%$ of participants who identified Bob as the target category selected black as the inferred feature. Overall, then, the model's use of priming in memory allows the model to capture conditions both where participants seem to be biased towards the single-category view, and where they do not - a major contribution of the model.

The model also explains the second main trend of feature prediction, where participants are sensitive to correlations between features. There are two reasons for this. The first is that correlated objects, on average, have slightly higher activation strengthening, since they will be more familiar to participants than objects with less common feature pairings. The second reason is that correlated objects will receive much higher levels of priming from their underlying features because that priming is, in a sense, undiluted by other options. For example, in Experiment 8, where the correlated query feature is circle, the only object primed by circle is vertically-stripedcircle. The target category, D , also spreads a high amount of activation to vertically-striped-circle, since there are three of them in that category, further underscoring the correlated feature as the answer. In contrast, for the uncorrelated query, both sources of priming (the query feature triangle, and the target category C) prime white-triangle in addition to strongly priming the target black-triangle. Thus, the model suggests that for the correlated condition, the target-category feature should almost exclusively be selected, whereas in the uncorrelated condition, the target-category feature should just mostly be selected. These explanations match the data, where the target-category feature was selected for $94 \%$ of correlated, but only $90 \%$ of uncorrelated, structures.

## General Discussion

The authors of the experiments that we model here were ultimately interested in characterizing people's inference behaviors across different manipulations of categories and fea-
tures (Murphy \& Ross, 1994). Recently, as we mentioned, Nosofsky (2015) proposed an exemplar model that qualitatively accounts for the majority of the results. The model is based on an equation that calculates the similarity between feature/category pairs using two parameters: the salience of the feature, and the salience of the category. The probability of inferring the target-category feature is then found by summing the similarity of the query feature/category pair to all displayed feature/category pairs with the target-category feature, and dividing by the summed similarity of the query feature/category pair to all displayed feature/category pairs (irrespective of the target-category feature).

Our view of this promising work, however, is that it does not consider an important result of the experiments: that of the difference in results between experiments where participants explicitly identified the target category, and where they did not (e.g., Experiment 5 vs. Experiment 6). Recall that when participants were asked to identify the target category before making their inference, a large and significant majority responded according to the single-category view; when participants were not asked to identify a target category before making their inference, however, participants' responses greatly shifted towards the multiple-category view. Nosofsky (2015) do not discuss this difference, and considers the results of Experiment 5, instead, as weakly supportive of the singlecategory view that is more strongly suggested by Experiment 6. Although dynamically adjusting the parameter settings depending on the specific queries of the experiment may lead to this difference in predictions, there is no intuition for how this parameter setting change may occur.

Our priming-based process model of feature inference, however, naturally answers that question as part of its core theory. Our model indicates that the difference in results is due to an underlying difference in the way that the experiments are processed by the human mind. It accounts for this difference because it includes the sources of priming in working memory to be a key part of its predictions. It suggests that when a person has explicitly thought about a category, the category is included as part of the inference process, biasing the model towards the single-category view; when a person has not, the model relies only on priming from the query feature, biasing the model towards the multiple-category view. Our model thus explains the same qualitative trends as Nosofsky (2015) while also accounting for this additional aspect of feature inference, and quantitatively matching the data.

Another model that has been proposed for explaining feature inference is the rational model and its associated variants (Anderson, 1991; Sanborn, Griffiths, \& Navarro, 2010). This model, while also rooted in Bayesian-based reasoning, has been shown to have trouble accounting for the breadth of the results we model here (Nosofsky, 2015). A recent promising version of this model was developed by Konovalova and Le Mens (2016), whose rational model is sensitive to uncertainty in categorization; our belief, however, is that it also would have trouble accounting for differences stemming from
the presence or lack of an initial categorization step.

#### Abstract

Past theoretical studies on word learning have offered simple sampling models as a means of explaining real word learning, with a particular goal of addressing the speed of word learning: people learn tens of thousands of words within their first 18 years. The present study revisits past theoretical claims by considering a more realistic word frequency distribution in which a large number of words are sampled with extremely small probabilities (e.g., according to Zipf's law). Our new mathematical analysis of a recently-proposed simple learning model suggests that the model is unable to account for word learning in feasible time when the distribution of word frequency is Zipfian (i.e., power-law distributed). To ameliorate the difficulty of learning real-world word frequency distributions, we consider a type of active, selfdirected learning in which the learner can influence the construction of contexts from which they learn words. We show that active learners who choose optimal learning situations can learn words hundreds of times faster than passive learners faced with randomly-sampled situations. Thus, in agreement with past empirical studies, we find theoretical support for the idea that statistical structure in real-world situations-potentially structured for learning by both a self-directed learner, and by a beneficent teacher-is a potential remedy for the pathological case of learning words with Zipf-distributed frequency.

Keywords: cognitive models of language acquisition; cross-situational word learning; statistical learning

## Child word learning

One of the most prominent differences between human and nonhuman cognition is our language ability. Much research has been dedicated to understanding the human capability for language, with a great deal of discussion focused on the process of language acquisition. A central debate in this conversation considers whether acquisition is based on innate and language-specific mechanisms (Chomsky, 1965; Gleitman, 1990), or bootstrapped from domain-general mechanisms (Smith, 2000; Kachergis, 2012). From the former perspective, humans become competent language users-mastering a complex system of syntax to produce endless semantics-very rapidly, and with relatively little training.

Word learning has been treated as an indicator of language development, and has been compared with a number of other indicators of cognitive abilities, such as memory (Vlach \& Johnson, 2013; Vlach \& Sandhofer, 2012). Although there are multiple empirical estimates of the number of words that children acquire, many studies agree that child's word learning is quite fast. Early
word production starts when the child is 12 months old on average, and by 18 months children can produce 50 words and comprehend 100-150 (Hulit \& Howard, 2002). By 18 years of age, it is estimated we know over 60,000 words (Bloom, 2000). Under the assumption that each child has 8 hours of word learning opportunity everyday, these estimates mean the child learns a new word every learning hour for 18 years of the life.

Given these empirical estimates of word learning, theoretical studies have attempted to account for the quantitative characteristics of word learning. The first question is: What combination of learning mechanisms and structure in the language environment allows children to learn at this rate? This question poses a good necessary condition for any account of child word learning, as it needs to address this quantitative aspect of word learning.

As a first-order approximation, child learning may be modeled as an independent sampling process in which each word is learned independently. To estimate the fastest possible learning rate, (Blythe, Smith, \& Smith, $2010,2016)$ proposed an idealized learning model to address acquiring a full lexicon in the long term: 60,000 words over 18 years. In their model, each word is learned with its first sample - known as fast mapping in the developmental literature. Under the simplifying assumption that each word is independently learned via fast-mapping, and its word frequency is distributed uniformly, their mathematical analysis of the model showed that a cross-situational learner is sufficiently fast to learn all 60,000 words after experiencing a reasonably small number of spoken words.

## Theoretical approach

Blythe et al.'s theoretical estimate has been treated as a theoretical implication that shows learning via independent fast-mapping of words is efficient enough to be a model of child word learning. In this study, we reinspect this theoretical implication by introducing a more realistic word frequency distribution. Our mathematical analysis implies that the learning rate of the independent fast mapping is quite sensitive to the word frequency distribution. More importantly, even fast mapping-the most efficient learning, requiring only a single sample, can be too slow to learn 60,000 words in 18 years, if
word frequency follows Zipf's law (Zipf, 1949) or a fattailed distribution which is often found in natural corpora. Thus, our analysis implies that the independent fast-mapping model cannot be an account for child word learning, if there are many words sampled less frequently. This mathematical implication leads to an empirical test of whether the word distribution in the child-directed speech is uniform or non-uniform such as a Zipf distribution. Thus, in the second study, we analyzed the CHILDES corpora for word distribution in child-directed speech.

Given this result of the mathematical analysis, we explore an extension of the word learning mechanism by additionally assuming that the word learning is more $a c$ tive than that is supposed to be traditionally. Typically, as analyzed in the past studies above (Blythe et al., 2010, 2016), the learning is supposed passive - the learner has no choice but observing samples words and objects from a given probability distribution. This is certainly oversimplified, as actual child word-learners choose when, where and from whom they would like to learn words. Thus, our second analysis estimates the impact of a form of active choice of situations in word learning. Our analysis shows that active learning is likely to have a sufficiently beneficial impact to make word learning fast enough to happen on a realistic timescale.

## Independent fast-mapping learning

## Uniformly distributed word frequency

Blythe, Smith, \& Smith (2010) proposed a mathematical model of word learning, which has a closed-form expression under a certain simplification. In their recent study, Blythe, Smith, \& Smith (2016) analyzed essentially the same model, although slightly modified for analytic convenience. Here we briefly introduce the most recent form (2016) of their model.

Blythe et al. originally consider cross-situational word learning. Suppose there are $W$ words and $O$ objects in the hypothetical world. Further the numbers of words and objects are equal, $W=O$, in their cross-situational learning scheme, and every object has its name and no objects have two names. Namely, there are $W$ correct pairs of words and objects. Without loss of generality, denote the $W$ pairs by $1,2, \ldots, W$, and suppose $k^{\text {th }}$ object is paired with the $k^{\text {th }}$ word.

Given these pairs being unknown, a word learner is to infer correct pairs by going through episodes. In each episode, the learner is exposed to $M \leq W$ words and $M$ objects, without any explicit information on which word is paired with which object. With one episode with $M \geq 2$ objects and words, the learner cannot tell which of $M$ words should be associated to which of $M$ objects.

The most simple model among a series of extended ones is called fast-mapping learning model. In the literature of language development, it is well-known that chil-
dren as young as three years old can quickly generalize a novel name to objects when they hear the novel name given to its fast instance. Due to this one-shot nature of their word learning, it is called fast mapping. Capturing this empirical finding, the fast-mapping learner in the model is supposed to learn a new pair of word and object only with the first experience of it. The fastmapping learner is equivalent to the cross-situational learner, if there is one correct pair of object and word in each episode $(M=1)$.

As fast-mapping learning is the most efficient scheme (at least for independent word learning), it gives a good baseline estimate of the number of samples to learn all the words in a given list. Blythe et al. (2010) model a fast-mapping learner acquiring words independently drawn from a uniform distribution of $W$ words given in each episode. As every episode has one word with probability $1 / W$, this is equivalent to the so-called Coupon Collector's Problem (Blom, Holst, \& Sandell, 1994). In this problem, the expected time $T$ to finish sampling all the words is

$$
E[T]=\sum_{i=1}^{W} E\left[t_{i}\right]
$$

where $t_{i}$ is the time to sample a $i^{\text {th }}$ new word given $(i-1)$ words being learned. Thus,

$$
\begin{equation*}
E[T]=W \sum_{i=1}^{W} 1 / i \approx W \log W \tag{1}
\end{equation*}
$$

Setting the number of words $W=60,000$, which is an empirical estimate of the number of words 18 years old knows on average, $T=660,126$. This estimate is comparable with the "reasonable" number of samples justified by Blythe et al. (2010) which individual children can be exposed to for their 18 years of lives.

## Non-uniformly distributed word frequency

Here we extend this analysis on the fast-mapping learner to the case with word frequency distributed nonuniformly. Our extended analysis will reveal that the estimate based on Equation (1) by Blythe et al. is quite "optimistic", as an estimate with non-uniform word distribution is larger than that in general.

Here let us derive the number of episodes $T$ that, for $0 \leq \epsilon \leq 1$, the $(1-\epsilon)$ of children learned all the $W$ words listed. Suppose a set of $W$ words in which each word $1, \ldots, W$ is drawn from the distribution $p=\left(p_{1}, \ldots, p_{W}\right)$. The proportion of children who finished learning all the words is $(1-\epsilon)$ for $0<\epsilon<1$ requires the number of episodes $T$, which is the root of

$$
\begin{equation*}
\prod_{i=1}^{W}\left(1-\left(1-p_{i}\right)^{T}\right)=1-\epsilon \tag{2}
\end{equation*}
$$

The left hand side of (2) is the probability that every word is present at least once in the $T$ episodes.

Write

$$
f_{W, \epsilon}(x):=\frac{\log \left(1-(1-\epsilon)^{1 / W}\right)}{\log (1-x)}
$$

For the uniform distribution, $p_{i}=1 / W$ for every $i=$ $1, \ldots, W$, the root of (2) is given by

$$
\begin{equation*}
T=f_{W, \epsilon}(1 / W) \tag{3}
\end{equation*}
$$

This $T$ is the number of episodes with which the proportion of children finished learning all the words is $(1-\epsilon)$. Setting $\epsilon=1 / 2$ in (3), we obtain the median of $T$, $f_{W, 1 / 2}(1 / W)$, that is comparable with the mean of $T$ in (1).

Unlike (3) for the uniform distribution, the root $T$ of Equation (2) in general is not closed-form. Thus, let us consider the upper and lower bound for the root instead of the rigorous form of it. For the general word distribution $p=\left(p_{1}, \ldots, p_{W}\right)$, the intermediate value theorem states that there exists a unique constant $c$ holding $\min p \leq c \leq \max p$, with which the root of (2) is expressed as

$$
T=f_{W, \epsilon}(c)
$$

Equivalently, we have inequality

$$
f_{W, \epsilon}(\max p) \leq T \leq f_{W, \epsilon}(\min p)
$$

As we are interested in the worst possible estimate of $T$, this inequality states that the upper bound $T_{+}:=$ $f_{W, \epsilon}(\min p)$ of $T$ is characterized with the probability to sample the least frequent word $\min p$.

This extended mathematical analysis implies that the uniform distribution $q=(1 / W, \ldots, 1 / W)$ of words gives the minimal possible upper bound $T_{+}$among any frequency distribution of $W$ words, as any distribution $\min p$ of $W$ words holds $\min p \leq \min q$. Therefore, the expectation of $T$ in the form of (1) with the uniform distributed words is the most optimistic, which may underestimate the number of episodes required for learning with a realistic word distribution.

For example, let us consider an alternative case that the $W$ word follows the Zipf distribution $p=$ $\left(1^{-1} / H_{W}, 2^{-1} / H_{W}, \ldots, W^{-1} / H_{W}\right)$, where $H_{W}$ is the harmonic number $H_{W}=\sum_{i=1}^{W} i^{-1}$. In this case, the minimal probability is $\min p \approx 1.44 \times 10^{-6}$, and the upper bound $T_{+}$is $1.08 \times 10^{7}$ for $\epsilon=0.01$. This estimate means that learning of Zipf-distributed words requires 16.4 times as many samples as learning of uniformlydistributed words. That means that 206 independent episodes exposed to a word learner every hour (or three episodes every minute), assuming 8 hours of learning everyday of 18 years of life. This estimate cannot possibly be considered "reasonable" with respect to ordinary life of children in any culture.

## Sensitivity to non-uniformity of word frequency distribution

To analyze the sensitivity to the non-uniformity, here we analyze the Zipf distribution with different exponent parameters. Denote the Zipf distribution with the exponent parameter $a \geq 0$ by $p=$ $\left(1^{-a} / H_{W, a}, 2^{-a} / H_{W, a}, \ldots, W^{-a} / H_{W, a}\right)$ where $H_{W, a}$ is the generalized harmonic number $H_{W, a}=\sum_{i=1}^{W} i^{-a}$. It is reduced to the uniform distribution by $a=0$. The larger the exponent $a$ is, the minimal probability $\min p$ is smaller. Thus, here we analyze the upper bound $T_{+}$ as a function of the exponent parameter $a$.

Write $T_{+}=f_{N, \epsilon}(\min p)$, which gives a reasonable estimate of the upper bound of the root $T$ of (2). As a function of the exponent $a$, we have

$$
\frac{\partial \log T_{+}}{\partial a}=\frac{p_{\min }\left(\frac{\partial H_{N, a}}{\partial a} / H_{N, a}+\log W\right)}{\left(1-p_{\min }\right) \log \left(1-p_{\min }\right)}
$$

and further we have

$$
\frac{\partial^{2} \log T_{+}}{\partial a^{2}} \geq 0
$$

This implies the $T_{+}$is a super-exponential monotone function of the exponent $a$. It is also numerically confirmed in Figure 1, in which the numbers of episodes are shown as functions of the exponent for $W=$ 10000,60000 . In this plot, $a=0$ shows an estimate for the uniform distribution, and $a=1$ shows that of the standard Zipfian distribution. It is striking that even the fastest learning such as fast mapping can be quite slow (exponentially as a function of $a$ ) for with distributions with some item with a very small probability.

## Empirical dataset

Given theoretical implication in the previous study, let us analyze an empirical word distribution, which children typically are exposed to. It is difficult to exactly count "episodes" or "pairs of word and object" in a real dataset, due to its ambiguity of definition and it is also up to children's subjective perspective. Here, as a proxy of them, we counted the word frequency based on child-directed speech in the CHILDES corpus (MacWhinney \& Snow, 1990). Figure 2 shows a representative word distribution of 51,446 words aggregated over 4,163 transcripts of all the corpora in CHILDES retrieved in December 2007. The minimal word probability was $1.089 \times 10^{-7}$, which gives the upper bound $T_{+}=$ $f_{51446,0.01}\left(1.089 \times 10^{-7}\right)=1.420 \times 10^{8}$ or the median estimate $T_{+}=f_{51446,0.5}\left(1.089 \times 10^{-7}\right)=1.030 \times 10^{8}$. These estimates of required samples, an order of magnitude larger than the optimistic theoretical estimate, suggest that it is difficult to learn these empirical words with this Zipfian-like frequency distribution.

Figure 1: For $\epsilon=0.01,0.5,0.99$ (broken and solid lines), $N=10000,60000$ and the exponent $a=0,0.25, \ldots, 1.5$, the required number of samples $M$ for a generalized Zipf distribution $p_{k}=k^{-a} / \sum_{k=1}^{N} k^{-a}$ is numerically calculated by the root of Equation (2).

## Active choice of situations

## Formulation

The implication of the mathematical analysis above, which suggested that even fast-mapping may not be efficient enough for non-uniformly distributed words, raises a controversy between past theoretical analyses and empirical findings of quantitative aspects of word learning.

Here, we explore a possibility to reconcile the discrepancy between theory and empirical findings, by considering a further relaxation of past theoretical assumptions about children's word learning. In the conventional theoretical framework, the learner is assumed to be passive, having no choice but to observe and learn from a given context: a randomly-sampled set of of objects, of which a (random) subset are labeled with words. This assumption of a passive learner simplifies the theory, but surely underestimates real learners, who have some choice about which contexts they experience. Here, we consider a type of active learner who is able to choose from which situation/context he or she learns words.

Suppose that there are $N$ word-object pairs and $M$ situations, and that the conditional probability to observe the $i^{\text {th }}$ word-object pair is $p_{i j}$ given the $j^{\text {th }}$ situation. Thus, the active learner has a choice of the situation out of the given $M$ situations from which he or she learns the word-object pairs. Suppose that the active learner chooses the $j^{\text {th }}$ situation by the probability $q_{j}$. Let us denote the $N \times M$ matrix of the conditional probability by $P=\left\{p_{i j}\right\}_{i j}$ and the $N \times 1$ vector of the choice probability by $q=\left(q_{1}, q_{2}, \ldots, q_{M}\right)^{T}$. With this notation, the marginal probability of word-object pairs is given by the vector $P q \in \mathbb{R}^{N}$. According to our mathematical anal-

Figure 2: Word frequency in a corpus aggregated from the CHILDES transcripts.
ysis in the previous section, the minimal probability of objects decides the number of samples required to complete the word learning, the best choice for the active learner is given by the choice probability

$$
\hat{q}=\arg \max _{q} \min (P q) .
$$

This minimal probability, $\min (P \hat{q})$, gives the theoretical upper bound for the minimal number of samples $f_{W, \epsilon}(\min (P \hat{q}))$, as $P$ is not known before empirical learning, and the active leaner also needs to estimate $P$ from the sample. For a given matrix $P$, the optimal $\hat{q}$ can be computed by the iterated linear programming algorithm (See also Appendix for the detail).

As a baseline for the passive learner, we consider the average $\min (P q)$ with the uniform distribution over the vector $q$, whose lower bound is given by the Jensen's inequality

$$
\int_{q \in \mathbb{S}^{N}} \min (P q)(N-1)!\mathrm{d} q \geq \min \left(P \mathbf{1}_{N} / N\right)
$$

where the integral is taken over the $N-1$ dimensional unit simplex $q \in \mathbb{S}^{N}$. For a sufficiently small $x \ll 1$ and $y \ll 1, f_{W, \epsilon}(x) / f_{W, \epsilon}(y) \approx y / x$. Thus, the rate $R=\min (P \hat{q}) / \min \left(P \mathbf{1}_{N} / N\right)$ gives a good estimate for the rate of efficiency $R$, by which the active learning with the optimal probability $\hat{q} R$ times faster than the passive learning with a fixed probability $q$.

## Empirical evaluation

To evaluate the potential impact of the active leaning, we study the SUN database (Xiao, Hays, Ehinger, Oliva, \& Torralba, 2010) as an empirical object distributions in an collection of real-life scenes. The SUN database (retrieved on September 25 th in 2016) has $N=3,458$ objects and $M=1,111$ scenes in it. This data is supposed
to give the $N \times M$ matrix $P$ in which each column is the conditional probability of the objects given each scene. If the scene choice probability is the uniform distribution $q=\mathbf{1}_{N} / N$, the $\min (P q)$ was $8.30 \times 10^{-9}$. Meanwhile, with the optimal $\hat{q}$, the $\min (P \hat{q})$ was $1.95 \times 10^{-6}$, which implies the active learning was approximately $\min \left(P \mathbf{1}_{N} / N\right) / \min (P \hat{q})=235.3$ times faster than the baseline passive learning. The marginal probability distributions of objects for the baseline and optimal $q$ are shown in Figure 3. The difference between the two marginal distributions is visible at their tails - the tail for the uniform $q$ decreases like an exponential function, but that for the optimal $\hat{q}$ decreases as a power function (linear in the double log plot). This empirical evaluation suggests that the active learning of interest can boost the fast mapping a few orders more efficiently.

Figure 3: The marginal probability of objects for the optimal $\hat{q}$ (line) and its baseline (dots).

## Online active learning

The quantification of the efficiency of active learning is based on the optimal $\hat{q}$ with the knowledge of $P$. This gives an optimistic estimate for the active learner, as the matrix $P$ is not fully known in reality. Here we performed a Monte Carlo simulation to quantify the efficiency of an online active leaner who gradually updates knowledge in the matrix $P$ and estimates $q$ on the basis of the sample estimate of $P$. If this online active leaner is comparable with the optimal active learner with $\hat{q}$, we can treat the performance analysis on the optimal active leaner above (a few orders more efficient) as holding for the online active leaner. For this purpose, we generated a $N \times M$ matrix $P$ with $N=1000, M=100$, which has the elements in each column are Zipfian probabilities $P_{\pi(i)} \propto i^{-a}$ with the random coefficients $a \in[1,1.5]$, where $\pi:\{1, \ldots, N\} \mapsto\{1, \ldots, N\}$ is a random permutation. The online active learner has the uniform
choice probability $q_{1}=\mathbf{1}_{N} / N$. For $k^{\text {th }}$ batch of 1000 steps, the online learner samples the objects according to the probability $P q_{k}$, and constructs the sample probability matrix $\hat{P}_{k}$ according to the sample frequency. After the $k^{\text {th }}$ sampling step, the online learner estimates $q_{k}:=\arg \max _{q} \min \left(\hat{P}_{k} q\right)$. In each run of this procedure, we repeat up to $100 \times 1000$ samples, and obtain one sample for the number of required samples to finish learning all the 1000 objects. With 100 runs, we obtain the Monte Carlo estimate of the online learner shown in Figure 4. Figure 4 shows the sample probability distribution of the number of required samples in the Monte Carlo simulation (circles: histogram, line: smoothed estimate), and its comparable median estimate for the optimal learner (green vertical line) and the passive learner with the uniform $q$ (red vertical line). This simulation result shows that the online learner is as fast as the optimal learner, and is likely to be faster than the passive learner.

Figure 4: The probability distribution of the number of required samples to finish learning for passive (red), optimal (green), and online active learner (blue).

## Discussion

This study has provided mathematical analyses of quantitative aspects of word learning that provide key constraints which any theoretical account for children's word learning should satisfy. We reinspected the past theoretical claim by Blythe et al. (2010) that learning via independent fast mapping was efficient enough to account for the average number of words known by 18-year-olds. Our new analysis extends their analysis to fast mapping with non-uniform word frequency distributions, and shows that even learning via fast mapping is not efficient enough to learn words whose distribution has rarely sampled words-including the Zipf (i.e. power-law) distribution, which describes empirical word frequency distributions from natural language.

Given that this new analysis implies learning would be too slow under realistic distributions, we consider a more efficient learning scheme, in which the learner can choose preferred situations from which words are learned. This type of active control over situations or contexts seems natural with respect to general observations of children's behavior, and has been shown to benefit adult word learners (Kachergis, Yu, \& Shiffrin, 2013), but has not been subjected to theoretical analysis as far as we know. We quantify and evaluate the effect of this type of self-directed learning in word learning. As the least probable word in the distribution determines learning efficiency, we analyzed the active choice for the situations maximizing this key parameter. Analyzing an empirical dataset of the words given situations, we estimate that active learning is over two hundred times more efficient in learning time than passive learning. This result suggests that active choice in word learning can resolve the issue that naturalistic non-uniform word distributions greatly slows passive fast mapping.

Our analyses in this paper utilized one of the simplest learning schemes, fast mapping, in order to highlight the effects of varied word frequency distributions, and of active learning. However, we expect the analytic techniques we employed would also allow analysis of other learning algorithms, including many proposed variants of cross-situational learning. In future work, we will report similar analyses for learning schemes with perhaps greater cognitive plausibility. On this path towards ever more realistic assumptions about the language environment and learners' ability to shape it, we expect to make progress toward a general theoretical framework spanning many proposed word learning schemes.

## Appendix: Iterated linear programming

For a $N \times M$ matrix $P$, write its $i^{\text {th }}$ row by $P_{i}$. Let $I=\{1,2, \ldots, N\}$ be the set of all indices. At the initial step, define

$$
K_{0}:=\emptyset, C_{0}:=\mathbb{S}^{M}, q_{0}:=e_{1}
$$

where $e_{1}:=(1,0, \ldots, 0)^{T} \in \mathbb{R}^{N}$. Then for $0<n \leq N$, define

$$
\begin{aligned}
k_{n} & :=\underset{k \in I \backslash K_{n-1}}{\arg \min } P_{k} q_{n-1}, K_{n}:=K_{n-1} \cup\left\{k_{n}\right\} \\
C_{n} & :=\left\{q \in C_{0} \mid \bigwedge_{k \in K_{n}}\left(P_{k_{n}}-P_{k}\right) q \leq 0\right\} \\
q_{n} & :=\underset{q \in C_{n}}{\arg \max } P_{k_{n}} q
\end{aligned}
$$

until $n=m$ such that $\min _{k \in K_{m}} P_{k} q_{m} \leq \min _{k \in I} P_{k} q_{m}$. The algorithm stops the iterative procedure by outputting $q:=q_{m}$.

# Reference Systems in Spatial Memory for Vertical Locations

#### Abstract

Three experiments investigated the frame of reference used in memory to represent vertical spatial layouts perceivable from a single viewpoint. We tested for the selection of three different reference systems: the body orientation, the visual vertical of the surrounding room, and the direction of gravity. Participants learned and retrieved differently colored objects on a vertical board with body and room orientations varying in relation to gravity and each other systematically. Across all three experiments participants were quicker or more accurate in memory recall when they saw the vertical spatial layout in the same orientation in relation to their body vertical as during learning, irrespective of the direction of gravity or visual room upright. These results indicate that spatial long-term memories for small-scale vertical relations are mainly defined in an egocentric reference system with respect to the body vertical despite the availability of alternative highly salient allocentric reference directions.

# Teaching by Intervention: Working Backwards, Undoing Mistakes, or Correcting Mistakes?

#### Abstract

When teaching, people often intentionally intervene on a learner while it is acting. For instance, a dog owner might move the dog so it eats out of the right bowl, or a coach might intervene while a tennis player is practicing to teach a skill. How do people teach by intervention? And how do these strategies interact with learning mechanisms? Here, we examine one global and two local strategies: working backwards from the end-goal of a task (backwards chaining), placing a learner in a previous state when an incorrect action was taken (undoing), or placing a learner in the state they would be in if they had taken the correct action (correcting). Depending on how the learner interprets an intervention, different teaching strategies result in better learning. We also examine how people teach by intervention in an interactive experiment and find a bias for using local strategies like undoing.

Keywords: teaching, intervention, reinforcement learning

## Introduction

When attempting to teach another agent, people have many tools at their disposal. They may choose to explain (Callanan \& Oakes, 1992), give a demonstration (Brugger, Lariviere, Mumme, \& Bushnell, 2007; Buchsbaum, Gopnik, Griffiths, \& Shafto, 2011; Király, Csibra, \& Gergely, 2013), or offer rewards and punishments for taking certain actions (Knox \& Stone, 2015; Ho, Littman, Cushman, \& Austerweil, 2015). Another way in which people teach a learner is by intervening on the learner or the learner's environment. For example, if a puppy urinates on the carpet when a person is trying to teach the puppy to urinate on a pad, a person might move the puppy to the pad or move the pad to the puppy. When teaching another person a skill like tennis, a teacher might intervene on the trainee mid-movement and either adjust their arm to match the target movement or stop them to start over. The space of possible ways in which a teacher could change a learner's situation for pedagogical purposes is large. This raises several questions: First, what is the effectiveness of different intervention strategies? Second, how could learners interpret interventions and how does the interpretation affect a teaching strategy's efficacy? And, finally, what teaching strategies do people tend to use?

In this work, we examine three teaching by intervention strategies from a reinforcement learning perspective (Sutton
\& Barto, 1998). The first, backward chaining, is motivated by algorithms such as value iteration (Bellman, 1957) that solve multi-stage decision-problems by propagating information about rewards to previous states that lead to those rewards. Intuitively, this is akin to teaching a task by "working backwards", first ensuring that the learner knows how to reach a goal from the penultimate state, and then reach the penultimate state from the antepenultimate state, and so on. We consider this a global intervention strategy since it involves changing the learner's state in a manner that reflects the structure of the entire task, rather than a small part of it. The second strategy, undoing, is motivated by the intuition that interventions prevent learners from executing an undesirable action by having them restart from the state they performed the undesirable action. The third strategy, correcting, intervenes on a learner when she executes an undesirable action (like undoing), but places her in the state she would have gone to if she had taken the desired action. Unlike backwards chaining, undoing and correcting involve local changes to an agent's state.

How could a learner interpret an intervention? In a typical reinforcement learning setting, an agent takes an action in a state, and then the environment rewards or punishes her and moves her to a new state (Figure 1). We formalize four ways that an intervention can be interpreted. First, the intervention may simply reset the learner in a new location from which the next action will be taken. Second, the next state that the learner is moved to could be interpreted as part of a transition in the environment. Third, the intervention could be treated as an interruption in a learner's stream of behavior such that the undesirable action just taken never happened. Fourth, the intervention could be treated as a disruption, in which the intervention is experienced negatively. Each of these accounts may interact with a teacher's training strategy in different ways, meaning that the best teaching strategy may be dependent on the learner's intervention interpretation.

The outline of the paper is as follows. First, we review the reinforcement learning framework. Second, we formalize four different ways that a reinforcement learning algorithm

Figure 1: (a) Standard state, action, reward, next state sequence of a Markov Decision Process at a given time step. (b) Four different interpretations of a teacher intervening to place the learner in state $v_{t}$ in response to a learner's action $a_{t}$ from state $s_{t}$. When interventions are interpreted as reset, transition, or disrupt, $r_{t}$ is respectively determined by the environmental next state, $s_{t}^{\prime}$, the teacher's next state, $s_{t+1}$, or the teacher's intervention, $v_{t}$. When the the intervention is treated as interrupt, no reward experienced and no learning occurs for that time step.
could interpret an intervention and three teaching strategies. Third, we conduct simulations to examine how efficacious different teaching strategies are depending on how a learner interprets their interventions. Fourth, we conduct an experiment to investigate how people teach by intervention. We find that undoing, a local intervention strategy, is often effective and that people tend to teach most often by undoing, occasionally correcting, and rarely backward chaining.

## Computational Modeling

In this section we present the standard reinforcement learning (RL) formalism, discuss the four intervention interpretations, and define the three teaching strategies.
Reinforcement Learning RL describes how an agent interacts with an environment and learns reward-maximizing behaviors (Sutton \& Barto, 1998). Formally, an RL algorithm learns to take actions in a Markov Decision Process (MDP), defined by the tuple $\langle S, A, T, R, \gamma\rangle$ : a set of states in the world $S$; a set of actions for each state $\mathcal{A}(s)$; a transition function that maps state-action pairs to a probability distribution over next states, $P\left(s^{\prime} \mid s, a\right)$; a reward function that maps states to scalar rewards, $R: S \rightarrow \mathbb{R}$; and a discount factor $\gamma \in(0,1]$.

At each time step $t$, an RL agent takes an action $a_{t}$ from a state $s_{t}$, which results in moving to next state $s_{t+1}$ and a reward $r_{t+1}=R\left(s_{t+1}\right)$ (Figure 1). Actions are determined by the agent's policy $\pi$ that maps states to distributions over actions. For a policy $\pi$, the value at each state, $V^{\pi}(s)$, is:

$$
\begin{equation*}
V^{\pi}(s)=E_{\pi}\left[\sum_{k=0}^{\infty} \gamma^{k} r_{t+k+1} \mid s_{t}=s\right] . \tag{1}
\end{equation*}
$$

The optimal policy, $\pi^{*}$, is one that maximizes the value function in every state, $V^{*}(s)=\max _{\pi} V^{\pi}(s), \forall s \in S$. An agent uses state, action, next state, reward tuples to learn an optimal policy.

Q-Learning One algorithm for learning an optimal policy is Q-learning, which is an off-policy temporal difference control algorithm. Under mild assumptions, Q-learning converges to the true action-value function (Watkins \& Dayan, 1992). Moreover, humans and animals both engage in the type of error-driven reward learning found in Q-learning, making it a useful model with which to test different human teaching strategies (Niv, 2009). We use one form of this algorithm, one-step Q-learning, which is defined by the following update rule given a tuple $\left(s, a, s^{\prime}, r\right)$ :

$$
\begin{equation*}
Q(s, a) \leftarrow Q(s, a)+\alpha\left[r+\gamma \max _{a^{\prime}} Q\left(s^{\prime}, a^{\prime}\right)-Q(s, a)\right] \tag{2}
\end{equation*}
$$

where $\alpha$ is the learning rate. We convert the estimated actionvalue function to a policy using the softmax decision-rule $\pi(a \mid s)=\exp \left\{Q(s, a) / \lambda_{Q}\right\} / \sum_{a^{\prime}} \exp \left\{Q\left(s, a^{\prime}\right) / \lambda_{Q}\right\}$, where $\lambda_{Q}$ is a temperature parameter controlling the probability that an agent takes the action estimated to yield the largest reward depending on the relative rewards she could get by taking other actions.

## Teaching by Intervention

Interpreting Interventions The standard RL formulation does not define how interventions should be interpreted. Thus, we posit four different possible interpretations here, depicted in Figure 1. The four interpretations are motivated by formalizing the following two intuitions in different ways. First, a teacher could be treated as a part of the environment such that her intervention directly changes the next state of the learner (possibly stopping the feedback she would have received had she gone to the next state had the intervention not happened). Second, a teacher is distinct from the standard MDP environment, and intervenes as a direct response to a learner having taken an action and ended up in a next state.

Formally, at a time step $t$, the learner in state $s_{t}$ takes an action $a_{t}$ and ends up in new state $s_{t}^{\prime}$. If the teacher does not intervene, $s_{t+1}=s_{t}^{\prime}$. Otherwise, a teacher intervenes to place the learner in state $v_{t} \in S$. For all intervention types, $s_{t+1}=v_{t}$. However, if the teacher's intervention is interpreted as a reset, then the learner performs a Q-learning update using the tuple $\left(s_{t}, a_{t}, s_{t}^{\prime}, R\left(s_{t}^{\prime}\right)\right)$, meaning that she still receives the reward she would have gotten had she reached $s_{t}^{\prime}$ as the next state. If it is interpreted as a transition, then the learner updates with $\left(s_{t}, a_{t}, v_{t}, R\left(v_{t}\right)\right)$, meaning that she gets the reward had she taken the action that would move her from $s_{t}$ to $v_{t}$. If it is an interruption, then the learner does not update the state-action value function the state-action pair that was intervened on, and she takes her next action in $s_{t+1}=v_{t}$. If it is interpreted as a disruption, then the learner updates with $\left(s_{t}, a_{t}, v_{t},-1\right)$.
Teaching Strategies We discuss three teaching strategies: backward chaining, undoing, and correcting. A teacher using backward chaining has an $n$-length trajectory $J=<$ $\left(s_{1}, a_{1}\right), \ldots,\left(s_{n}, a_{n}\right)>$ that she uses to teach the learner. We denote the states in the trajectory as $S_{J}=\left\{s_{i}: i=1,2,3 \ldots, n\right\}$. The teacher also has a utility function over different interventions, where initially $U_{0}\left(s_{i}\right)=i$ for $i=1,2,3, \ldots, n$ and $U_{0}(s)=-\infty$ for $s \in S \backslash S_{J}$. On each time step, the teacher's utility function is updated as:

$$
U_{t+1}\left(s_{t}\right)=\left\{\begin{array}{l}
U_{t}\left(s_{t}\right)-1 \text { if }\left(s_{t}, a_{t}\right) \in J  \tag{3}\\
U_{t}\left(s_{t}\right) \text { otherwise }
\end{array}\right.
$$

Teachers only intervene when the agent performs an action inconsistent with the trajectory (i.e. $\left(s_{t}, a_{t}\right) \notin J$ ) and place the agent in a next state according to a softmax decision rule over their utilities: $P(v) \propto \exp \left\{U_{t}(v) / \lambda\right\}$, where $\lambda$ is a temperature parameter. The backward chaining teacher is initially more likely to move the agent closer to the end of a target trajectory, but as the agent shows they can perform the target action in a state the utility of moving the agent to that state decreases. Meanwhile, the relative utility of placing the agent in a slightly earlier stage in the trajectory increases.

A teacher using an undoing strategy has a target policy $\pi^{*}$ : $S \rightarrow A$ that it is attempting to teach. On each time step, if an agent's action $a_{t} \neq \pi^{*}\left(s_{t}\right)$, then $v_{t}=s_{t}$. That is, when an agent takes an incorrect action, that action is undone by the teacher and the agent is placed back in the state she took the incorrect action. A teacher using a correcting strategy also has a target policy $\pi^{*}$ that it is attempting to teach. However, if an agent's action $a_{t} \neq \pi^{*}\left(s_{t}\right)$, then $v_{t}=\arg \max _{s} T\left(s \mid s_{t}, \pi^{*}\left(s_{t}\right)\right)$. That is, the teacher will move the agent to the state it would have been in had the agent taken the target action.

## Simulations

To understand the interaction of teaching strategy and learner interpretation, we simulated the performance of a RL agent for each combination in a gridworld task.

Teacher's Reward Function

| $*$ |  |  |  |  |  |  |

Learner's Reward Function

Experiment Interface

Figure 2: Task used for simulations and experiment. Asterisks (*) indicate absorbing states, both providing reward to the learner, whereas the teacher received reward if the learner entered the right door, but was punished if the learner entered the left door. The teacher received a mild punishment whenever the learner entered a garden tile.

## Task

The task we used is shown in Figure 2. It consists of a $7 \times$ 4 gridworld where the learning agent always starts a round in the center tile of the first row. At any given location, a subset of the four cardinal directions is available to the learning agent (e.g. at the bottom edge, "down" is not available as an action). On each episode, the learning agent starts in the bottom-middle tile and the upper-right and upper-left corners of the gridworld are absorbing states.

In our task, the teacher and learner have different rewards for the learner's actions in the MDP. In particular, the two absorbing states (goals) both have $\mathrm{a}+10$ reward for the learner, but for the teacher, only one has +10 while the other has -10 . Additionally, there are several non-absorbing tiles that give the teacher -1 if the learner enters them. These features of the task are visualized in Figure 2.

All simulations used a Q-learning agent with a tabular representation of states $\left(Q_{0}(s, a)=0 \forall s, a, \alpha=.9\right.$, and $\left.\gamma=.95\right)$. Each simulated teacher interacted with the learner for 12

Figure 3: Simulated backward chaining, undoing, and correcting results or different intervention interpretations and intervention probabilities (top three rows). Results of learners trained using participant responses on task (bottom). Total teacher payoff is the net reward of the learner's behavior based on the teacher's reward function during the evaluation phase of each episode.
episodes. Each episode was divided into two phases: a teaching phase and an evaluation phase. During the teaching phase, the simulated teacher interacted with the Q-learner, which selected actions using a softmax rule ( $\lambda_{Q}=.1$ ) and engaged in learning. During the evaluation phase, the learner performed the task without teacher interaction or learning and used a greedy policy. Additionally, the performance was measured with respect to the teacher's payoffs based on her reward function. Each episode phase ended after 25 time steps.

## Teaching Strategies and Interpretations

We tested all combinations of teaching strategy and intervention interpretation (\{backwards chaining, undoing, correcting $\} \times\{$ resetting, transitioning, interrupting, disrupting $\})$. In natural situations, it is not likely that teachers intervene every time a learner takes an incorrect action. Thus, we tested the performance of the models given different probabilities of intervening given that the learner performed an incorrect action: $0.25,0.50,0.75,1.0$. This allowed us to evaluate the robustness of different teaching method and intervention interpretation combinations when feedback is imperfect. Each combination of teaching strategy, intervention type, and intervention probability were simulated 1000 times and teaching performance was based on the evaluation phase.

## Results and Discussion

Simulation results are plotted in Figure 3. When interaction probability is high, undoing is most effective. This is be-
cause interventions act as impassable obstacles to the learning agent, which, combined with a discount rate, makes taking incorrect actions less beneficial than alternative actions that change the state and lead to reward. However, an exception is when the learner interprets interventions as disrupting, where the average performance of the undoing teaching strategy decreases quickly as intervention probability drops. This is because the teacher is less likely to serve as an obstacle, which makes it less likely that the agent will learn that incorrect actions are less efficacious. Across all interpretations, undoing outperforms correcting because undoing implicitly teaches the learner that the garden tiles are negative, whereas, correcting does not. Undoing also leads to more learning experience because correcting allows the agent to progress on the task without actually taking target actions.

When the probability of intervention is high ( $1.0-0.75$ ), the backward chaining strategy performs as well as or worse than the undoing strategy. Unlike undoing, a global strategy like backward chaining's efficacy is robust to less frequent interventions. This is because these interventions ensure that the learning agent has mastered a subset of states and acquired an accurate value representation as opposed to acting as a constraint on transitions in the environment.

The different intervention types also interacted with the teaching strategies in important ways. First, undoing shows identical patterns regardless of whether the intervention type is resetting, transitioning, or interrupting. When it is disrupting, learners reach maximum performance even more

Figure 4: Experimental results. (a) Boxplot of proportion of correcting, undoing, and other interventions performed by individual participants. For many participants, the majority of their interventions were to undo the learner's action. (b) Graphical visualization of teacher-learner interaction during an episode ( $\varepsilon=0.8$ ) illustrating local interventions. Yellow numbers indicate order of interventions. (c) Graphical visualization of participant interventions for actions taken from the same state. For each episode, each participant has one pseudo-count that is divided among all of their interventions in that episode. The number in each tile represents the sum of these pseudo-counts over participants. The intervention probability is the proportion of times that action was subsequently intervened upon.
quickly. Second, for the backward chaining strategy, all strategies but transitioning led to learners acquiring policies that approached the target behavior. This is likely because the transitioning interpretation results in learners using the teacher's interventions as a way to "teleport" to a desirable location on the grid and not properly learn the task.

## Experiment

How do people teach using interventions? Do they use a global strategy like backwards chaining or a local one like undoing or correcting? Our simulations suggest that undoing is the best teaching strategy if teachers intervene when the learner makes a mistake with high probability. However, backwards chaining works better when the teacher intervenes infrequently. Alternatively, it seems intuitive to intervene such that the learner is shown the correct state she should have gone to, and human teachers might use this strategy despite its sub-optimality with Q-learners. To explore these possibilities, we had human teachers interact with agents that were pre-programmed to improve over time. This gave us the opportunity to view how people would teach by intervention independent of the learning mechanism.

## Experimental Design

Participants and materials Thirty-five MTurk participants took a dog training study that used the interface shown in Figure 2. On each trial, the dog would start at a tile and then walk to an adjacent tile. If the participant did not click on the dog at any point during its movement or within 1 s of the dog entering the next tile, the next trial would start. If the participant clicked on the dog, then the dog "paused" and they could drag it to any tile on the gridworld and drop it. The dog then "unpaused" and the subsequent trial would then start at that tile. When the dog reached either "dog bowl," an animated dog treat would appear to indicate that the dog had experienced a reward. Entering either dog bowl tile ended an episode.
Procedure Before the main task, participants completed training trials that taught them how to intervene on the dog's behavior by picking it up. For the main experiment, they were told that they were trying to train a dog to perform a task on its own. The task was for the dog to only go to its own dog bowl, located in the upper-right tile, while avoiding their neighbor's dog bowl, located in the upper-left tile, and also avoiding the two lawns. Thus, the participants' goal in the task maps onto the teacher reward function shown in Figure 2. They had 12
"days" (i.e. episodes) in which they could train the dog, and they were told that each day ended once the dog became tired after 25 steps or became satiated by eating a dog treat. Each trial, the dog was programmed to execute the target policy with a probability of $1-\varepsilon$ and a random action otherwise. $\varepsilon$ started at 1.0 for the first episode and then decreased by 0.1 each subsequent episode until $\varepsilon=0.0$. This gave the impression that the dog was improving over time regardless of the intervention strategy used.

After the task was completed, participants were asked to answer several questions regarding their strategy, how well the dog responded, task difficulty, expected training efficacy, expected efficacy with a real dog, dog ownership, dog training experience, and several demographic questions.

## Results

Intervening People make relatively sparse, local interventions that match the undoing model. Participants intervened on learners' behavior more when the learner performed a nontarget action than when they performed a target action (nontarget: $\mathrm{M}=0.66$, S.D. $=0.22$; target: $\mathrm{M}=0.06$, S.D. $=0.10$; paired t-test: $t(34)=13.77, p<.001)$. Additionally, the proportion of non-target actions that were intervened upon was between 0.5 and 0.75 , the regime where backward chaining and undoing perform comparably. Interventions were also fairly local and close to the final state that resulted in the learner's action (Average Manhattan Distance between next state and intervention: $\mathrm{M}=1.64$, S.D. $=0.49$ ). This indicates that backwards chaining was not often used as a strategy since that strategy requires making more global interventions. Finally, as Figure 4a reveals, many participants performed undoing interventions in which an agent that took a non-target action was placed back into its original position (Correcting: $\mathrm{M}=0.15$, S.D. $=0.14$; Undoing: $\mathrm{M}=0.59$, S.D. $=0.24$; Other: $\mathrm{M}=0.27$, S.D. $\left.=0.19 ; \chi^{2}(2)=335.89, p<.001\right)$.

Teaching Q-learners To compare human and model strategies, we used participants' responses to train Q -learners in the same task. We approximated how participants would have taught real learners by sampling from their responses to a learner's action in the task whenever a simulated learner took the same action. If a particular participant never observed an agent's take a simulated action, the default response was to not intervene. These results are plotted in Figure 3 for comparison with the simulation results.

## Discussion

Our simulations revealed important interactions among teaching strategy, intervention interpretation, and intervention probability. In particular, undoing, which involves local changes to an agent's state, is an especially effective strategy only when interventions are frequent, while backward chaining, which involves state-changes reflecting the global structure of the task, is moderately effective regardless of intervention frequency. Incidentally, when people teach by intervention, they typically engage in undoing, but they do it
less often than they should to train Q-learners (66\%). Generally, people make moderately frequent local interventions.

As this is a preliminary investigation into teaching by intervention, this work has limitations. We use Q-learning as the learner, but other RL algorithms may respond better to human interventions. And given previous work showing that people often teach with communicative intent (Shafto, Goodman, \& Griffiths, 2014; Ho et al., 2015), it may be that the standard RL framework is inadequate for capturing peoples' relatively sparse, local interventions. Future work will also need to test a wider range of MDP tasks. Nonetheless, these simulations and models are a first step towards understanding the everyday phenomenon of teaching by intervention in humans.

#### Abstract

SOB-CS is an interference-based computational model of working memory that explains findings from simple and complex span experiments. According to the model's mechanism of interference by superposition, high similarity between memory items and subsequently processed distractors is beneficial because the more a distractor is similar to an item, the more they share similar units, leading to less distortion of the memory item. When time allows, SOB-CS removes interfering distractors from memory by unbinding them from their context. The combination of these two mechanisms leads to the prediction that when free time is long enough to remove the distractors entirely, similarity between items and distractors should no longer be beneficial to memory performance. The aim of the present study was to test this prediction. Adult participants performed a complex-span task in which the free time following each distractor and the similarity between items and distractors were varied. As predicted by the model, we observed a positive effect of the similarity between items and distractors, and a negative effect of pace on the mean working memory performance. However, we did not observe the predicted interaction. An analysis of the errors produced during recall showed that longer free time reduced the tendency of distractors to intrude in recall much less than the model predicted. The SOB-CS model accounted well for the data after a substantial reduction of the removal-rate parameter.

Keywords: Working Memory, SOB-CS model; interference by superposition; removal mechanism

## Introduction

Working memory (WM) is the system responsible for holding information available for ongoing cognition (Baddeley \& Hitch, 1974; Miyake \& Shah, 1999). It is often tested with complex-span tasks (Barrouillet, Bernardin, \& Camos, 2004), which combine an immediate memory test with a concurrent processing demand: some items (e.g., letters or words) are provided one at a time for subsequent recall in order and several distractors are also presented in-between items. The concurrent processing of distractors impairs memory, compared to a simple-span task that consists only of the immediate memory test. There has been ongoing debate about the reasons why distractors affect WM performance. The present study contributes to this question by testing a prediction of the interference-based connectionist model SOB-CS (Oberauer, Lewandowsky, Farrell, Jarrold, \& Greaves, 2012).

According to SOB-CS, forgetting is due to interference between items and distractors. The model is based on a two-
layer connectionist network that associates a distributed item representations with distributed position markers, for instance associating the first item of the sequence with position 1 , through Hebbian learning (Anderson, 1995). Each association is registered in a two-dimensional weight matrix coding for the position and the item representations. During each processing step, SOB-CS assumes that distractors are encoded in the same way as items and associated to the position of the preceding item. In other words, SOB-CS suggests that items and distractors are superimposed in the same weight matrix, leading to a distortion of items by distractors which in turn causes forgetting. In this way, the model is able to reproduce interference between items and distractors according to their similarity: the more a distractor is similar to an item, the more feature values they share, leading to less distortion of the memory item. Therefore, this model predicts that high similarity between an item and the following distractor is beneficial to WM performance.

Oberauer, Farrell, Jarrold, Pasiecznik, and Greaves (2012) reviewed studies that have investigated item-distractor (I-D) similarity effects. They showed that phonological similarity between items and distractors is beneficial if the material was pronounceable non-words (non-words were used in order to ensure that participants do not encode stimuli by their meanings). Oberauer et al. did four experiments in which participants had to remember a list of four non-words items. The two distractors intervening after each item were also nonwords and had to be read aloud. The phonological similarity between the items and the distractors was manipulated. In the first three experiments, distractors were similar to the preceding item whereas in the fourth experiment distractors were similar to the following item. The findings of experiments 1,2 and 3 showed a positive effect of phonological similarity between items and distractors which meshes well with the mechanism of interference by superposition implemented in SOB-CS. Moreover, experiment 4 confirmed the hypothesis of SOB-CS suggesting that distractors are associated to the preceding item and not to the following item: no beneficial effect of I-D similarity was observed when similar distractors preceded, rather than followed, the items to which they were similar.

The SOB-CS model also proposes an explanation for the cognitive load effect (Barrouillet, Portrat, \& Camos, 2011). This effect has been observed in several studies showing that WM performance depends on the proportion of time during which distractors capture attention (Barrouillet, Bernardin, Portrat, Vergauwe, \& Camos, 2007; Barrouillet et al., 2004, 2011). According to decay-based theories (Baddeley, 1986; Towse \& Hitch, 1995; Barrouillet et al., 2011), the cognitiveload effect can be explained as follows: forgetting is mostly due to the time-based decay of the memory traces when distractors are processed. In order to avoid forgetting, memory traces can be reactivated when free time is available between distractors. A sole interference mechanism cannot account for such a positive impact of free time on WM performance. Hence, in SOB-CS, the cognitive load effect is explained as follows: forgetting is counteracted by a removal mechanism in such a way that each distractor that has just been encoded is "removed" during free time. The removal process consists of an unbinding, by Hebbian anti-learning, of the association between each distractor and the study context, thereby rendering the context signal more effective as a retrieval cue for the memoranda. SOB-CS suggests that the strength of removal exponentially depends on the time devoted to it. This mechanism leads to the prediction that the more free time elapses after each distractor, the more time is available for removing the interfering distractor that just has been encoded and hence the better the WM performance.

To sum up, two mechanisms are important in SOB-CS to specifiy the effect of distractors on WM performance. First, according to the mechanism of interference by superposition, distractors which are similar to the preceding item should distort that item less than dissimilar distractors, leading to better performance at recall. Second, the mechanism of "removal" leads to the prediction that distractors are unbound from WM during free time in order to clear memory from irrelevant information. The combination of these two mechanisms gives rise to an interesting hypothesis which is at the heart of the present paper: if free time is long enough to entirely unbind an irrelevant distractor from WM, there is no reason to observe an effect of I-D similarity as distractors would not be present in WM anymore.

## Overview of the experiment

The aim of our experiment was to test this prediction of SOB-CS concerning both the removal and the interference by superposition mechanisms. To do that, our experiment replicates and extends the second experiment presented in Oberauer, Farrell, et al. (2012). It consisted of a verbal complex span task in which items and distractors were pronounceable non-words (i.e. words without semantic meanings). The length of the memory list was constant and set to four items. In the high similarity condition, the similar distractor always immediately followed the items to which they were similar and all the items were dissimilar to each other. Then, as memoranda were non-words, serial recall was done by reconstruc-
tion among a candidate set containing the four list items, four of the distractors and four not presented lures (NPLs). The NPLs were non-words which had never been seen by participants in the current experiment.

In their experiment, Oberauer, Farrell, et al. (2012) only manipulated the similarity between items and distractors. We extended that experiment by adding the manipulation of the pace of the distractor presentation to vary the free time available to remove distractors. We tested participants and the SOB-CS model with three paces (fast, medium, slow). To allow comparisons of our findings with Oberauer, Farrell, et al. (2012), the faster pace of our experiment was the pace used by Oberauer, Farrell, et al. (2012). This extension allowed to test the special prediction that the positive effect of I-D similarity decreases as the free time increases.

## Simulation 1 with SOB-CS

To test the prediction that the positive effect of I-D similarity decreases as the free time increases, we reused and adapted the simulation presented in Oberauer, Farrell, et al. (2012).

## Method

The creation of the stimuli was done similarly as in Oberauer, Farrell, et al. (2012): stimuli were generated and organized in 8 dissimilar sets for each trial, each set containing 10 similar stimuli. From these sets, items, distractors and non-presented lures (NPLs) were selected according to the condition of similarity (i.e. high vs low). The recall candidate sets were composed of the four items of the trial, four distractors and four NPLs. The NPLs were added in order to balance the global attractiveness of the candidate sets between similarity conditions. In the high similarity condition, a distractor is attractive for two reasons: it has been processed and it was similar to the items. In the low similarity condition, distractors are therefore less attractive. In contrast to the distractors, NPLs were dissimilar to the items in the high similarity condition, whereas they were similar to the items in the low similarity condition.

In all the simulations presented in Oberauer, Farrell, et al. (2012), which reproduced well the behavioral data, the encoding duration of the distractor was set to 1000 ms . As the pace of the processing task of all their experiments is 1000 ms , no free time was available to remove the distractor. This means that they did not use the removal mechanism in their simulations. In order to replicate the results in this baseline condition (which is the condition with the faster pace in our experiment), we also set the encoding duration of the distractor to 1000 ms . ${ }^{1}$ For the moderate ( 1800 ms ) or slow (2600 ms ) paces, the removal mechanism was used because there were 800 ms or 1600 ms available free time.

[^101]We ran 1000 simulated subjects, each one completing five trials in each condition as in the experiment. Oberauer, Farrell, et al. (2012) used the SOB-CS default parameter values except for the distinctiveness parameter c , which they lowered from 1.3 to 0.45 to approximately move the overall accuracy into the range of data. This new value of parameter c was justified because non-words are less distinctive than well-known words. In our simulation, we did as Oberauer, Farrell, et al. (2012) except that we lowered the c parameter even more from 0.45 to 0.3 . The reason is that, in our experiment, we ensured that each non-word, as an item, a distractor or a NPL, was seen only once by a participant. In contrast, in Oberauer, Farrell, et al. (2012), 100 trials were performed using a set of 36 non-words only. One trial required 16 items, which is almost half the set of non-words. This means that each participant saw each item more than 40 times during the test, which would make them familiar with the non-words as they go along the test. This difference could make their task easier. This is why, in the simulation, it was justified to set the distinctiveness parameter c to 0.3 instead of 0.45 .

## Results: Simulated data

Correct responses Recall responses were scored as correct when a correct item was chosen in its exact serial position. Figure 1 (panel $\mathrm{B}^{2}$ ) presented the percentage of responses correctly recalled by the model as a function of pace and similarity. As expected, the simulation shows an effect of pace ( $0.38,0.75$, and 0.77 at fast, moderate and slow pace respectively) and an interaction effect according to which the beneficial effect of similarity disappears as the pace slows down (i.e. as free time increases). In fact, we can see that at a fast pace the percentage of correct recall is higher when distractors are similar (compared to dissimilar), to the preceding item ( 0.43 vs. 0.33 ) whereas at moderate and slow paces, the difference between similarity conditions is null ( 0.75 vs. 0.75 and 0.76 vs. 0.78 for moderate and slow paces respectively).

We also analyzed three different kinds of errors. An error could be an intrusion of distractor, an intrusion of NPL or a transposition error (an item from the list in a wrong position).
Distractor intrusions Figure 2 (panel B) presents the proportion of distractor intrusions. First, the simulation showed a strong effect of pace: around $20 \%$ of the responses at fast pace contained distractor intrusions whereas distractor intrusions are negligible (less than $2 \%$ ) at moderate and slow pace. It appears that distractors are sufficiently removed after 800 ms , for not being recalled. No effect of similarity and no interaction were observed.

NPL intrusions Figure 3 (panel B) presents the proportion of NPLs intrusions. Even if NPLs are not encoded into WM, the NPLs can be recalled as they can be confused with the memoranda. The more the WM is distorted by distractors,

[^102]the more we should observe confusion errors at recall. We observed that NPLs intrusion decreased when the free time increased as WM is less distorted. We also observed an effect of similarity: there are more NPLs intrusion in the lowsimilarity condition as the NPLs are similar to the items in this condition. This effect is much stronger at fast pace (when distractors are not removed) than at moderate and slow pace. In fact, we observed that the differences of intrusion rates between low-similarity and high-similarity are $0.09,0.02$ and 0.02 for the fast, moderate and slow pace respectively.

Transposition errors Finally, Figure 4 shows the proportion of transposition errors (order errors) for which a small pace effect was observed. At the fast pace, the proportion of transposition errors was increased by $8 \%$ as compared to the slow and moderate pace. No effect of similarity and no interaction were observed.
Summary of the simulation results In summary, the SOBCS model with its standard parameters (except the c parameter) predicts a beneficial effect of I-D similarity, which is present only when there is no removal of the distractors (i.e. in the fast pace condition). As soon as there is free time (800 ms or 1600 ms ), the similarity effect disappears. The analysis of the different kind of errors show that as soon as there is free time, distractor intrusions is negligible. This finding can explain why we do not observe the similarity effect at a moderate and slow pace: distractors are totally removed according to the SOB-CS model. These predictions will now be compared with human data.

## Experiment

## Method

Participants Participants were 34 students from the University of Bristol. They participated voluntarily in 1-hr session in exchange for course credit. Each participant performed the 6 conditions: three different paces (slow, moderate, fast) $\times$ two similarity conditions (low and high).
Material Participants were presented with four non-words (e.g "zaff") for memorization, each followed by a pair of nonword distractors. The memoranda were presented in red and the distractors in black. Participants were asked to read aloud all the non-words as soon as they appeared but to only memorize the red ones in serial order.

Items and distractors were sampled from a set of nonwords selected from the ARC Nonword Database (Rastle, Harrington, \& Coltheart, 2002). A database of 720 non-words was used to ensure that participants never saw a non-word more than once. Each non-word was pronounceable, composed of one syllable and four letters. The 720 non-words were organized in 240 rhyming groups, each containing three non-words (e.g., "baff, daff, haff" was a rhyming group).

The candidate set for recall was constructed such that its similarity structure was the same for both conditions (low and high similarity). Whatever the similarity condition, partici-

Figure 1: Proportion of correct responses. Error bars are 95\% confident intervals for within-subject comparisons.

Figure 2: Proportion of distractor intrusions. Error bars are $95 \%$ confident intervals for within-subject comparisons.
pants saw four items, four stimuli similar to each item and four stimuli dissimilar to the items. In the high-similarity condition, the four stimuli similar to each item were the distractors whereas in the low conditions they were notpresented lures (NPLs).

In the high similarity condition, one stimulus from four different rhyming groups was chosen at random to be an item, and the other two stimuli of each rhyming group were used as the pair of distractors that immediately followed that item, such that each pair of distractor was similar to their preceding item. The NPLs, for the recall set candidates, were chosen at random from 4 other rhyming groups, such that NPLs did not rhyme with any item or distractors.

In the low similarity condition, four groups were used to create the list of items and NPLs, such that each NPL was similar to an item. Two stimuli from each of four other rhyming groups were chosen at random to serve as distractors. In this way, no pair of distractors rhymed with any item on the low-similarity condition.

For all conditions, we ensured that the four to-bemaintained items were dissimilar to each other.
Procedure A MATLAB program using Psychophysics Toolbox (Brainard, 1997; Pelli, 1997) coded by Oberauer and collaborators (2011) was reused with some modifications to display stimuli and record responses. Each trial started with a black centered fixation cross presented during $1,500 \mathrm{~ms}$, followed by a computer-paced presentation of items and distractors. Items always appeared during 800 ms followed by a

Figure 3: Proportion of NPLs intrusions. Error bars are 95\% confident intervals for within-subject comparisons.

Figure 4: Proportion of order errors. Error bars are $95 \%$ confident intervals for within-subject comparisons.

400 ms blank. Distractors appeared at the rate of one stimulus per $1,000 \mathrm{~ms}$ ( 800 ms on, 200 ms off) in the fast condition, $1,800 \mathrm{~ms}$ ( 800 ms on, 1000 ms off) in the moderate condition and $2,600 \mathrm{~ms}$ ( 800 ms on, $1,800 \mathrm{~ms}$ off) in the slow condition. After the last distractor, 12 recall candidates simultaneously appeared on the screen in blue, each in a blue frame. They were displayed at random in a $3 \times 4$ matrix. Participants selected recall choices by clicking inside the items' boxes in the order in which they were presented. A sound indicated that a response has been recorded. They were asked to guess if they could not remember an item. Each participant completed 30 trials, 5 in each condition, in a random order. They were also prompted to take self-paced breaks every six trials. In addition, there were four practice trials at the start with four different conditions: similar/fast, dissimilar/moderate, similar/slow and dissimilar/fast.

## Results: human data and comparisons with simulated data

We ran a two-way ANOVA on the mean proportion of correct responses and different types of errors over trials with similarity (high and low I-D similarity) and pace (slow, moderate and fast) as within-subjects factors.

Correct responses Figure 1 (panel A) shows that, as predicted by the model, there was an effect of similarity $\left[F(1,33)=31.2, p<.001, \eta_{p}^{2}=.48\right]$ and an effect of pace $\left[F(2,33)=12.6, p<.001, \eta_{p}^{2}=.27\right]$. However, contrary to SOB-CS predictions, no interaction was observed
$[F(2,33)<1]$. In fact, even at slow pace, we observed a positive effect of high similarity versus low similarity condition on recall performance.
Distractor intrusions Figure 2, panel A, shows a small effect of pace on distractor intrusions $[F(2,33)=3.18, p=$ $\left..047, \eta_{p}^{2}=.08\right]$ with $27 \%, 26 \%$ and $24 \%$ of distractor intrusions among responses at fast, moderate and slow pace respectively. In contrast, the model predicted a strong effect of the pace with almost no intrusion of distractors at medium and slow pace compare to $20 \%$ at fast pace. This discrepancy suggests that participants did not remove distractors as much as the model did. No similarity effect $[F(1,33)=2.69, p=$ $\left..11, \eta_{p}^{2}=.07\right]$ and no interaction $[F(2,33)<1]$ was observed on the distractor intrusion, as predicted by the model.
NPL intrusions We observed a strong effect of similarity on NPL intrusions $\left[F(1,33)=77.3, p<.001, \eta_{p}^{2}=.70\right]$ and a small pace effect $\left[F(2,33)=4.5, p=.014, \eta_{p}^{2}=.11\right]$ (Fig. 3, panel A). Here again, the model predicted a much stronger pace effect as compared to the experimental data. No significant interaction was found $\left[F(2,33)=2.24, p=.11, \eta_{p}^{2}=\right.$ .06] suggesting that the effect of similarity on NPLs is constant over the pace whereas the model predicts a stronger effect of similarity at fast pace.
Transposition errors No similarity and no pace effect on the transposition errors were found [respectively; $F(1,33)<$ 1 and $\left.F(2,33)=1.27, p=.28, \eta_{p}^{2}=.04\right]$ (Fig. 4, panel A). No significant interaction was found $[F(2,66)=1.27, p=$ $\left..28, \eta_{p}^{2}=.03\right]$. In line with these data, the model predicted no effect of the similarity on the transposition errors. However, the model predicted a small effect of pace between the fast and the two other paces.

## Discussion

The present results replicated the observations found in Experiment 2 of Oberauer, Farrell, et al. (2012) suggesting that forgetting in WM is partly due to interference by superposition. First, whatever the experimental condition, the mean proportion of distractor intrusions was higher than the proportion of NPLs ( 0.25 vs. 0.1 on average). This result demonstrates that distractors, unlike NPLs, are encoded into WM which is a necessary prerequisite for studying distractor interference. Moreover, evidence in favor of the interference by superposition mechanism was provided by replicating the strong benefit of high over low I-D similarity.

However, we observed a discrepancy between some of the model predictions and the data. SOB-CS only fits well the data in the fast condition that is similar to Oberauer, Farrell, et al. (2012)'s experiment, where no removal was used in the simulation. As soon as there is free time and hence removal, the SOB-CS simulation erroneously predicted an interaction between pace and I-D similarity. The error analyses revealed that this difference between model and human seems to be due to an overestimation of the removal strength by the model compared to the experimental findings.

In the following section, we present the results of a grid search on the removal parameter $r$ in order to identify a better $r$ value to reproduce the human data.

## Estimation of the removal parameter

Several experiments (Oberauer, 2001, 2002) estimated that removing part of the contents of working memory takes between 1 and 2 s . In addition to the time devoted to the removal, the strength of removal depends also on a rate of removal controlled by the free parameter $r$. The greater the value of $r$, the faster associations between the distractor and its position are removed. Therefore, in SOB-CS, the removal parameter $r$ was set to 1.5 , which implies that the rate of antilearning for removal has reached $95 \%$ of its asymptote after 2 s. According to the previous experimental analysis, it seems that distractors are not removed as quickly as in the model. To search for a value for the $r$ parameter that would better fit the data, we conducted a grid search on a range between 0 and 1.5 with a step size of 0.1 . The Root-Mean-Square Error (RMSE) was calculated for each parameter value. This measure represents the discrepancy between the model prediction and human data. The lowest RMSE corresponds to the best model. We found that the best model is the one with $r$ equals to 0.1 instead of the standard value 1.5 . If $r$ is set to zero, meaning no removal at all, an important loss of fit is observed as the model does not predict the pace effect anymore. The dashed lines of the panel B of all Figures shows the simulation results with $r$ set to 0.1 . First, the pace and the similarity variables do not interact anymore. Second, the main effect of pace on accuracy and error rates is about as large as in the data. Globally, we observed that the proportion of the different error types fits well the human data. Our result is in contradiction with the conclusion from previous studies (Oberauer, 2001, 2002) that removal takes only 1 to 2 s , as with this new $r$ parameter, removing completely irrelevant information would take about 30 s instead of 2 s .

## General Discussion

In this paper, we aimed to contribute to the debate regarding the reasons why distractors affect working memory performance by testing predictions of SOB-CS. More specifically, we investigated the I-D similarity effect after various amounts of free time. Human results confirm several predictions of SOB-CS. First of all, our results show that distractors are actually encoded in working memory since they were more often recalled than not-presented lures. Then, experimental data reproduced the positive effect of a high similarity between items and distractors originally found by Oberauer, Farrell, et al. (2012). This finding is predicted by the mechanism of interference by superposition of SOB-CS. Finally, we also observed that memory performance increases at a slower pace than predicted by the removal mechanism.

However, results disconfirm one prediction from the model with its standard parameter values: the data show that the ID similarity effect does not diminish with longer free time.

When simulating this experiment with the SOB-CS computational model, the similarity effect disappears when there is 0.8 s or more of free time available, because the model strongly removes distractors. In fact, we observed that at moderate and slow paces, distractors are totally removed according to SOB-CS. The total removing of the distractors cancels the recall difference between similar and dissimilar conditions. Contrary to this expectation, human data still showed distractor intrusions at moderate and slow pace.

Searching for a removal rate able to reproduce the experimental data resulted in a much lower estimate ( $r=0.1$ instead of $r=1.5$ ), which could reproduce the observed similarity effect at all three levels of pace. The removal mechanism was supported, because $r=0.1$ fit better than $r=0$. What are the implications of our removal rate estimate, which is much lower than that in the orignal model? Either, we can consider that $r=0.1$ is the parameter value that holds generally, implying that removal is much slower than thought so far. A way to verify this option would be to simulate other complex span task experiments to test whether their results can be reproduced by SOB-CS with $r=0.1$. Or, there is something particular to delete the material of our experiment that would require a low removal strength. In future research, a comparison of the size of the pace effect across experiments could shed some light on that. In fact, the comparaison of the pace effect of our experiment with all the other experiments can help to determine if our experiment had an exceptional low pace effect or if the removal strength needs to be lowered.

According to decay-based models of working memory, such as TBRS (Barrouillet et al., 2007) or TBRS* (Oberauer \& Lewandowsky, 2011), removal does not exist and free time is used to retrieve and maintain the to-be-remembered items. The maintenance of memory items can be viewed as the strengthening of the item-position bindings of the memory items and also as the strengthening of the representations of individual non-words themselves (i.e., item memory). Decaybased models predict the pace effect which has been observed many times. In fact, the more free time the more opportunity to maintain memory items. In such a model, the positive effect of high similarity between items and distractors, that is not accounted for by decay-based models, can be explained by the assumption that retrieving an item in order to refresh it is easier if it is less distorted by distractors. This process of retrieving would be required whatever the duration of the free time. The effect of similarity on retrieval therefore would lead to a beneficial effect of similar distractors whatever the pace. However, for the moment, decay-based computational models, such as TBRS* do not implement interference by superposition. In the future, it would be interesting to replace the removal mechanism by a mechanism of maintenance in SOB-CS.

## Acknowledgments

We would like to thank Louise Kenney who participated in the data gathering. We also acknowledge the French Regional

Council "Région Rhône-Alpes" which provided a PhD grant to V.H. We acknowledge the Université Grenoble Alpes who gave a grant allowing V.H. to go to the University of Bristol during three months in order to collaborate with S.L.

#### Abstract

The current study investigated the relationship between children's spatial ability and their scientific knowledge, skills and understanding. Children aged $7-11$ years $(N=123)$ completed a battery of five spatial tasks, based on a model of spatial ability in which skills fall along two dimensions: intrinsic-extrinsic; staticdynamic. Participants also answered science questions from standardised assessments, grouped into conceptual topic areas. Spatial scaling (extrinsic static spatial ability) and mental folding (intrinsic dynamic spatial ability) each emerged as predictors of total science scores, with mental folding accounting for more variance than spatial scaling. Mental folding predicted both physics and biology scores, whereas spatial scaling accounted for additional variance only in biology scores. The embedded figures task (intrinsic static spatial ability) predicted chemistry scores. The pattern was consistent across the age range. These findings provide novel evidence for the differential role of distinct aspects of spatial ability in relation to children's science performance.

Keywords: spatial ability; science; STEM; children.

## Introduction

Large-scale longitudinal studies spanning the past 50 years provide convincing evidence that spatial ability in adolescence predicts later science, technology, engineering and mathematics (STEM) achievement; both in academic and career outcomes (Wai, Lubinski \& Benbow, 2009). As well as often cited examples of scientific discoveries resulting from creative spatial thought, a growing body of research with adults and adolescents highlights a link between spatial ability and scientific reasoning (e.g, Kozhenikov \& Thornton, 2006). However, with a few exceptions (e.g Tracy, 1990), the relationship between
spatial ability and science learning in younger children has been largely neglected. This is important to address, given that early science learning involves specific areas of conceptual understanding, and because knowledge of how spatial ability and science relates in younger children has implications for early intervention. The focus of this study was therefore to investigate the relationship between a range of spatial skills and primary-school aged children's scientific knowledge, skills and understanding.

## Spatial ability

Spatial ability, which relates to "the location of objects, their shapes, their relation to each other, and the paths they take as they move" (Newcombe, 2010, p30), has long been recognised as an ability at least partly independent of general intelligence, reasoning and verbal ability (Hegarty, 2014). As well as being apparently distinct from other cognitive abilities, spatial thought itself is generally conceptualised in a multidimensional fashion, consisting of several separate but correlated skills. Two categories of multidimensional models have emerged: ones based in the psychometric tradition (e.g. Carroll, 1993) and other more recent, theoretically driven models (e.g, Uttal et al., 2013).

Psychometric analyses of spatial ability have often resulted in inconsistent findings, with the number of identified factors ranging between two and twelve (Hoffler, 2010). Uttal et al. (2013) argue that some of the inconsistencies result from factor analysis models not being theory-driven. In contrast, Uttal et al.'s (2013) model is based on top-down, theory driven understanding of spatial skills, and draws upon developments in cognitive neuroscience. They propose that spatial skills can be
categorised along two dimensions: static-dynamic and intrinsic-extrinsic. Intrinsic spatial abilities and extrinsic spatial abilities broadly map onto a within-object and between-object classification, respectively. Intrinsic/extrinsic skills can be further categorised as either static or dynamic abilities; dynamic abilities include transformation or movement, whilst static skills do not.

Intrinsic-static skills involve the processing of objects or shapes without further transformation or movement of parts of the object or shape. Tasks that measure this skill often require this processing to occur amidst distracting background information. For example, in disembedding tasks, participants search for a specified 2D shape in a larger distracting image. Intrinsic-dynamic skills involve the processing, and manipulation or transformation of objects or shapes. 2D and 3D mental rotation fit into this category.

Extrinsic-static skills require the processing and encoding of the spatial relations between objects or configurations of objects, without further manipulation or transformation of these relations. The extrinsic-static category includes the ability to find corresponding locations between shapes of equal proportion but differing sizes (e.g. scaling and map use). Extrinsic-dynamic skills involve the apprehension, processing and manipulation of more than one object, or the relationship between objects and frames of reference. Spatial perspective taking, in which a participant visualises what an object would look like from a different viewpoint, is an extrinsic-dynamic skill because it involves the manipulation of the relationship between an object and another frame of reference/viewpoint.

## Spatial ability and science

Spatial skills support understanding and learning of conceptual areas that are very spatial in nature (e.g, astronomy) yet even apparently non-spatial topics are often represented in a spatial format.

Most prior research with adults point to visualisation skills as being related to science learning: the ability to mentally transform spatial information about single objects, assessed through intrinsic-dynamic skills such as mental rotation and mental folding. For example, studies report a link between intrinsic-dynamic spatial skills and conceptual understanding in aspects of biology (e.g. Garg, Norman, Spero \& Mashewari, 1999), chemistry (e.g. Stull, Hegarty, Dixon \& Stieff, 2012) and physics (e.g., Kozhenikov \& Thornton, 2006). In Stull et al. (2012), for instance, 3D visualisation positively correlated with undergraduate students' ability to translate between different diagrammatic representations of chemical structures.

Other spatial skills within Uttal et al.'s (2013) model may play a role in science learning. However, this relationship has been largely neglected to date; the role of extrinsic-static skills such as scaling, for example, has yet to be addressed.

## Spatial ability and science in development

Research relating spatial ability and science learning in younger children is sparse (e.g. Jarvis \& Gathercole, 2003;

Tracy, 1990). Tracy (1990) assessed science performance in a sample of 10 - and 11-year-old students who were split into high and low spatial ability. The study revealed that the high spatial ability group outperformed the low spatial ability group. However, this study did not include any measure of IQ or other cognitive factors, and thus did not discount general ability as an alternative explanation. It also used a composite spatial measure.

One unpublished study that compared the role of different intrinsic-dynamic spatial ability measures on scientific understanding in children, and controlled for verbal ability, found that mental folding, but not mental rotation, predicted five-year-olds' performance in a task involving understanding of force and motion. However, this was still limited to intrinsic-dynamic skills (Harris, 2014).

There is also some mixed evidence to suggest that spatial skills may be more important during the early stages of science learning, rather than later stages (Hambrick et al., 2012). During initial learning a learner may use spatial processing to establish mental maps and models or to problem solve (Mix et al., 2016). With experience, domainspecific knowledge may become more important. Such a hypothesis is supported in the science literature by the finding that visuospatial working memory is less predictive of 14 -year-old versus 11-year-old students' science performance (Jarvis \& Gathercole, 2003), and that mental folding ability predicted children's but not adults' understanding of forces in the previously described study by Harris (2014). The relationship between spatial thinking and science performance, and how this varies between the ages of 7 and 11 , has hitherto remained unclear.

## Current Study

Although prior research indicates that spatial ability predicts aspects of science learning in older populations, little research has been conducted with younger children. Research that has done so, has either focused on visualspatial working memory only, used a composite of spatial ability measures, or has focused only on single object-based manipulation (intrinsic-dynamic spatial skills). Furthermore, no research to date has used and compared a cross-sectional sample to determine if this relationship varies across development.

The aim of the current study was to examine the relationship between 7 and 11-year-olds' performance in a range of spatial ability measures, based on the Uttal et al. (2013) model, and their performance in a science assessment covering aspects of biology, chemistry and physics.

## Methods

## Participants

The initial sample consisted of 127 participants who were recruited from a large, ethnically diverse London primary school. Three pupils did not go on to complete the study
because they were unsuitable for the study due to having a special educational need or an insufficient level of English. Due to missing data, four further participants (one participant per year group) did not have a full set of scores. Three of those participants were missing data from one task only, and so their missing scores were estimated by calculating the mean for their respective year group. The fourth participant, who was missing several variables, was excluded from the analysis. Thus, four participants were excluded in total. The final sample consisted of 123 participants in UK Years 3-6: Year 3 ( $\mathrm{N}=32$, mean (s.d.) age $=8.0$ ( 0.28 ) years), Year $4(\mathrm{~N}=31$, mean (s.d.) age $=9.0$ (0.32) years), Year $5(\mathrm{~N}=31$, mean (s.d.) age $=10.0$ (0.33) years), Year 6 ( $\mathrm{N}=30$, mean (s.d.) age $=11.0$ (0.30) years). Parental consent was obtained for all participants.

## Measures

## Intrinsic-Dynamic Spatial: Mental Rotation

In this mental rotation task (based on Broadbent, Farran \& Tolmie, 2014), children were shown two upright cartoon monkeys, above a horizontal line, on a computer screen, and one monkey below a line which was rotated by varying degrees $\left(0^{\circ}, 45^{\circ}, 90^{\circ}, 135^{\circ}, 180^{\circ}\right)$. One monkey above the horizontal line had a blue left hand and a red right hand, and the other monkey had the reverse pattern and was a mirror image of the other. Children were asked which of the two monkeys at the top of the screen matched the monkey at the bottom of the screen, which had been rotated. This task began with six practice items, in which the monkey below was not rotated ( $0^{\circ}$ trials) and then progressed to 36 experimental trials $\left(4 \times 0^{\circ}\right.$ trials, $8 \times 45^{\circ}$ trials, $8 \times 90^{\circ}$ trials, $8 \times 135^{\circ}$ trials and $8 \times 180^{\circ}$ trials).

## Intrinsic-Dynamic Spatial: Mental Folding

This mental folding task (Harris et al., 2013) required children to imagine folds made to a piece of paper, without physical representation of the folding action itself (see Figure 1). Children were shown a shape at the top of a computer screen which contained a dotted line and an arrow. The dotted line represented the imaginary fold line and the arrow indicated where the paper should be folded to. Beneath this item on the screen, children were shown four images of how the item at the top might look after being folded at the dotted lines, only one of which was correct. Children first completed two practice items. Answers to practice questions were checked by the researcher, and if a child had an incorrect answer, they were given one further attempt of that trial. The experimental trials then began, where children had 14 novel items to work through. The test progressed automatically as the child clicked one of the four images at the bottom of the screen. Accuracy and response time were recorded.

## Intrinsic-Static Spatial: Embedded Figures Task

The Children's Embedded Figures Task (CEFT: Witkin et al., 1971) consists of complex figures in which a simple form is embedded (see Figure 1). Children were shown an
image constructed of colourful geometric shapes and asked to locate either a simple house or tent shape 'hidden' within the image. Children were shown the house or tent shape as a cardboard form; it was kept by the child for the first three trials of each block and hidden thereafter. For the first part of the test ( 11 items ) children located a triangular tent shape within each image, the simpler of the two shapes, and for the other half of the test ( 14 items) children located a house shape. Children were given a score of 1 for correctly locating the shape hidden within the figure. Accuracy and response times were recorded using a laptop computer.

## Extrinsic-Static Spatial: Scaling

Our novel spatial scaling task was based on a similar task by Frick and Newcombe (2012). Children were required to find equivalent corresponding locations on two grids, when one was varied in size relative to the other by a predetermined scale factor (see Figure 1). The task was presented to children as a game which involved pirates' treasure maps. Treasure maps were printed on yellow paper and mounted in a large ring bound pad. Each page contained one yellow map with a grid printed in black. Nine (out of 18) items contained grids which separated the map into $6 \times 6$ sections, whereas the other nine items contained grids which separated the map into $10 \times 10$ sections. For each trial, one target section of the printed grid map was coloured in black (the treasure); the target section varied across trials. Participants were also presented with four maps on a touch screen computer, which each had one black square coloured. One computer map contained a black square at a location which corresponded to the printed map; the locations of the black squares on the other three incorrect computer options were systematically chosen. The larger printed maps were either unscaled (1:1), or scaled to either $1: 4$ or $1: 8$, relative to the maps on the computer screen. Participants first completed two practice items after which they completed the main 18 trials of the test. Six items were presented at each scale factor.

## Extrinsic-Dynamic Spatial: Perspective Taking Task

This task was identical to one developed by Frick et al. (2014) which involved spatial perspective taking in which children were required to visualise what photographs would look like when taken from cameras placed at different positions and angles relative to their viewpoint. The child first completed four practice questions involving actual Play Mobil characters, and then one practice question on a computer, which showed a character taking a photograph of two shapes from the same perspective as the child. The child selected the correct option, of four, from below the main image, which showed what the photograph would look like by pressing a touch screen computer. If a child made an error on the practice items, they were given a second attempt. On passing the practice questions, the task continued with the experimental items, where they again chose the correct image out of four options. These varied per the number of objects in the layout (one, two or three)
and the angular difference between the photographer's and the child's perspective $\left(0^{\circ}, 90^{\circ}\right.$ or $\left.180^{\circ}\right)$.

## Science Assessment

The science assessment consisted of two paper-based tests, which children completed in class groups in two separate sessions under the supervision of the researcher. The assessment was curriculum-based and all questions were taken from an online database of past science UK standardised test questions ("Test Base", 2017, January 31 ${ }^{\text {st }}$ ) designed to assess the science curriculum in this age range. The test included approximately equal amounts of biology, chemistry and physics content from a selection of topics appropriate to this curriculum stage.

Each paper had a total possible score of 50 marks leading to a total science mark of 100 . The assessment included questions which varied in difficulty, which again mapped onto curriculum descriptors. Paper one contained questions of low to medium cognitive demand, and paper two contained questions of high cognitive demand. Questions focused on one conceptual sub-topic, e.g., magnetism or changing state. Questions were further sub-divided into items that were either: factual/recall items (e.g. label a diagram; recall a function); problem solving items, which drew on conceptual knowledge; or items that were in the context of hypothetical experiments, thus drawing on procedural skills.

Figure 1: significant spatial predictors (left to right): mental folding task, spatial scaling task ( $1: 8,6 \times 6$ trial), embedded figures task (locate a triangular 'tent' trial).

## Control Variables

The British Picture Vocabulary Scale-III (BPVS-III; Dunn, Dunn, Styles, \& Sewell, 2009) was included as a measure of verbal ability.

## Procedure

All children first completed the two paper-based science assessments, in two sessions administered by the researcher in class groups, within the child's own classroom. Spatial ability was then assessed within two separate sessions. Children were first tested in a computer-based group session of no more than 10 children where they completed the mental folding task and the monkey mental rotation task, in a counterbalanced order. The BPVS, CEFT, spatial perspective taking task and scaling task were then completed in an individual testing session with the researcher, which lasted approximately 30 minutes per child. The order of testing in the individual sessions was also counterbalanced to control for fatigue and order effects.

## Results

A series of multiple regression analyses were conducted to determine the amount of variance in science scores that was accounted for by each of the spatial ability measures. There were no significant gender differences ( $\mathrm{p}>.05$ for all); therefore, participants were treated as one group in the subsequent regression analysis. A separate analysis was run for total science score and for each area of science (physics, biology, chemistry). In each of the models, the covariates (age, BPVS raw score) were added first (steps 1-2). All spatial measures were subsequently entered in a single block, using forward step-wise entry, to determine the best model of spatial ability predictors. Beta values refer to the final model with all variables entered.

Entered in the first step of each model, age in months significantly predicted each science total. Age was most strongly predictive of physics sub-score, with this initial step accounting for $27 \%$ of the variance, $\Delta F(1,121)=45.52$, $p<.001$. Age accounted for $21 \%$ of the variance in total score, $\Delta F(1,121)=31.27, p<.001,13 \%$ of the chemistry scores, $\Delta \mathrm{F}(1,121)=17.75, p<.001$ and $8 \%$ of biology scores, $\Delta F(1,121)=11.03, p<.001$. In the final overall models, after additional variables were entered, age remained as a significant predictor of total score $(\beta=.122, t$ $=2.03, p=.044)$ and physics score $(\beta=.320, t=4.24, \mathrm{p}<$ .001 ), but not biology score ( $\beta=.010, t=.10, p=.916$ ) or chemistry score $(\beta=.102, t=1.23, p=.223)$.

BPVS raw score was entered in the second step of each model and was a significant predictor. BPVS scores were most strongly predictive of total science score, accounting for an additional $37.6 \%$ of the score variance, $\Delta F(1,120)=$ 106.16, $p<.001,25 \%$ of the biology scores, $\Delta F(1,120)=$ $46, p<.001,21 \%$ of the chemistry scores, $\Delta F(1,120)=$ $36.93, p<.001$ and $15 \%$ of the physics scores $\Delta F(1,120)=$ 29.78, $p<.001$. In the final model, BPVS scores remained significant predictors of total science score $(\beta=.567, t=$ $8.9, p<.001$ ), biology score ( $\beta=.443, t=5.38, p<.001$ ), chemistry score $(\beta=.485, \mathrm{t}=5.93, p<.001)$ and physics score $(\beta=.375, \mathrm{t}=4.85, p<.001)$.

The step-wise analysis of spatial measures to predict total science score resulted in mental folding being entered in
step three and spatial scaling being entered in step four of the regression model. Mental folding accounted for an additional $6 \%$ of the variance in total science score, above the previously entered covariates $\Delta F(1,119)=20.62, p<$ $.001, \beta=.211, t=3.54, \mathrm{p}=<.005$. The scaling task accounted for an additional $2 \%$ of the variance in total science scores, $\Delta F(1,118)=6.8, p<.010, \beta=.162, t=2.60$, $p=.010)$.

Step-wise entry of spatial measures predicting biology scores retained mental folding and the scaling task only, in steps three and four. Mental folding accounted for an additional $6 \%$ of the variance in biology scores, $\Delta F(1,119)$ $=11.65, p<.001, \beta=.195, t=2.52, p=.013$ ). Spatial scaling accounted for an additional $3 \%$ of the variance in biology scores, above the previously entered covariates $\Delta F(1,118)=5.50, p<.021, \beta=.190, t=2.34, p=.021)$.

Only the mental folding task was retained as predictor of the physics score $(\beta=.198, t=2.8, p=.006)$ following step-wise analysis, and was entered in step three of the model. It accounted for an additional $4 \%$ of the variance in physics scores $\Delta F(1,119)=7.82, p=.006)$.

The CEFT was the only emerging predictor of chemistry scores $(\beta=.173, t=2.27, p=.025)$. It accounted for an additional $3 \%$ of the variance in chemistry scores $\Delta F(1,119)$ $=5.130, p=.025$ ). Any remaining spatial tasks not reported did not significantly predict any additional unique variance in science ability beyond those spatial measures included in the above models ( $p>.05$ for all).

To determine if age interacted with any of the spatial ability measures, a further four models were constructed in which the covariates were again entered in step 1, followed by the spatial ability measures found to be significant for that science measure, followed by interaction terms (age in months*spatial measure). No significant interactions with age were found ( $p>.05$ for all).

## Discussion

This study revealed that spatial ability predicted children's performance in a curriculum-based science assessment. That is, after controlling for age, gender and verbal ability, spatial ability accounted for $8 \%$ additional variance in total science scores. This builds upon longitudinal research linking spatial ability to STEM outcomes in adults (Wai et al., 2009) as well as correlational research that has associated spatial ability with various aspects of science learning in adults (e.g., Kozhevnikov et al., 2006). It also expands upon the existing findings from child data (Tracy, 1990; Harris, 2014) by investigating a broader range of spatial measures and science topic areas and, also, comparing a wider age range of children within one study.

Mental folding, an intrinsic-dynamic spatial skill, accounted for the most variance in total overall science scores, relative to the other spatial tasks. This is likely to be due to it being a predictor of both physics and biology topics, whereas spatial scaling was not. It is likely that the relationship with physics scores is driven, in part, by
questions on topics such as magnetism, forces and motion, which required visualisation of how objects move and interact; this suggests that children who are more skilled at visualising paper folds are also better at predicting the direction of various types of forces acting on objects.

The role of mental folding in relation to biology scores is less likely to be directly related to the visualisation skill, as in physics, discussed above. One possibility is that the ability to flexibly maintain and manipulate spatial information, as measured through the folding task, may also be related to mental model construction and use. The mental models children possess for the conceptual topics within biology may be spatially-based. For example, when recalling the function of roots, children may recall a spatial mental model of a plant, which is integrated with verbal/propositional information.

Although mental rotation falls into the same category (Uttal et al., 2013) as mental folding (which was a strong predictor), mental rotation accuracy did not feature in any of the final regression models. The two measures correlated only moderately $(r=.294)$. This may be because there are differences between folding and rotation, despite them both being intrinsic/dynamic measures. For example, rotation is a rigid, intrinsic transformation and folding is a non-rigid, intrinsic transformation (Atit, Shipley \& Tikoff, 2013). Further research is needed to investigate this distinction.

Spatial scaling, an extrinsic/static skill, also emerged as a predictor of total science scores, although it contributed less to this model than folding because it was significant only for biology questions. One interpretation of the role of scaling is that it predicted performance because children who perform well on this task are also more able to determine the correspondence between representations of scientific concepts at different scales. Children may, for example, in the classroom, need to determine the correspondence between: an actual plant; scaled-up versions of plant diagrams on an interactive whiteboard; or scaled-down, abstract printed diagrams.

The CEFT, an intrinsic-static spatial skill, was a significant predictor of chemistry scores, but did not feature in the other final regression models. Intrinsic-static spatial skills relate to the processing of objects without further transformation: the arrangements of parts of the object (subparts) as well as the size and orientation objects. This could relate to chemistry items including diagrams which require inspection and discrimination between sub-parts of objects (e.g, 3 beakers with ice cubes, which either have 1,2 or 3 layers of insulation).

An analysis of age-based interactions revealed that the relationships described were steady across development. We had predicted that spatial skills would contribute more to science performance for younger children, than older children, based on prior research (e.g., Hambrick et al., 2012), which would suggest that as domain-specific knowledge increases, spatial abilities play less of a role in science. It may be that, although older children are more experienced in science, the knowledge they have available
for immediate recall may be restricted to topics that they are currently covering.

One limitation of the study was that we only included the BPVS as a control for general level of ability. One might argue that the spatial tasks are also capturing a more general problem solving ability. However, the differential role of various spatial skills revealed in the analyses demonstrate that spatial ability is having an impact on science performance versus it being a general problem solving ability proxy. However, further research should include other measures of general cognitive ability. Second, the nature of the questions, drawn from standardised assessments, meant that it is difficult to determine if the relationships observed relate to scientific knowledge/understanding, or application of knowledge in scientific problem solving. Further studies are planned to systematically include a range of question types for comparison across categories of items.

In summary, the current study provides evidence for a distinctive role for mental folding (intrinsic-dynamic spatial ability), spatial scaling (extrinsic-static spatial ability) and the CEFT (intrinsic-static spatial ability) in children's science learning. The findings have implications for how we can move forward to support children in the science classroom through spatial training and interventions.

#### Abstract

When people move together, as they dance, march or flirt, it increases affiliation between them. But what about 'moving together' produces affiliation: the movements themselves, or the social context of moving 'together'? We instructed pairs of participants to listen to music and move their arms or legs according to shapes appearing on screen. They either carried out the same movements, or when one moved their arms the other moved their legs. They either saw shapes on one laptop, or each had their own laptop. Surprisingly, participants did not like each other more if they carried out the same movements, but affiliation did increase if they danced looking at the same screen. Rather than their movements, instructions, intentions or perceptual experiences, here it is the social context of the actions that produces affiliation, a surprising finding that is not easily accounted for by the dominant theories of mimicry and behavioural synchrony.

Keywords: synchrony; coordination; mimicry; affiliation; joint action

## Introduction

People have danced, marched and moved together across cultures and history (McNeill, 1995). One reason, suggested by the literature, is that mimicry and synchronous movement acts as a form of 'social glue', increasing liking when two people mimic each other's gestures (Chartrand \& van Baaren, 2009), walk in step with each other (Wiltermuth, 2012), tap in synchrony (Hove \& Risen, 2009), or move together to a common beat (Reddish, Fischer, \& Bulbulia, 2013).

Dance as one particularly social form of human coordination (Dunbar, 2012; Tarr, Launay, Cohen, \& Dunbar, 2015), usually takes place in a shared social context: people in the same room, co-present with others, are listening to the same music. Similarly, demonstrations of motor mimicry increasing affiliation also take place in the shared social context of an experiment. What is the contribution of these two factors, a shared social context and similarity in movement, in changing affiliation when people dance together? From research to date this is not clear, as the two factors are confounded in dance as it typically occurs in society, and mimicry as it is typically studied in the laboratory. Which provide the psychological conditions for dancing 'together'?

The recent invention of the "silent discos" separates these factors and raises an interesting question. At these events, each person wears a set of wireless headphones that can be connected to different DJs playing different pieces of music. So two people next to each other may be engaging in similar, synchronised bodily movements, or not. Each person may or may not know if the person next to them is listening to the same music. What conditions will produce affiliation between the dancers: the similarity between their movements, or the knowledge that they are dancing together to the same music? We created an experimental version of this situation to find out. Rather than manipulating shared music, however, we manipulated shared social context.

This question does not just relate to our specific understanding of silent discos, of course, but raises much broader questions about the function of bodily mimicry for the affective states of social relationships. The dominant prediction from the psychological literature is that movement similarity causes affiliation. One proposed mechanism is that action observation activates a representation of a similar motor plan in the observer (Chartrand \& Bargh, 1999). This mirroring has been linked to a particular set of visuo-motor neurones in the brain known as the 'mirror system' (Di Pellegrino, Fadiga, Fogassi, Gallese, \& Rizzolatti, 1992; Mukamel, Ekstrom, Kaplan, Iacoboni, \& Fried, 2010), which are claimed to contribute to social cognition and affiliation (Gallese \& Goldman, 1998; Pineda, 2009). Supported by many experimental findings, these theories predict that what is required to increase affiliation between two silent disco dancers is a match between their bodily movements.

However, there are two reasons to hypothesize that social context may play an important part in the relationship between affiliation and mimicry. Firstly, imitation can be modulated by social factors such as eye contact (Wang, Newport, \& Hamilton, 2010), group membership (Yabar, Johnston, Miles, \& Peace, 2006), or the circumstances under which people meet (Miles, Griffiths, Richardson M., \& Macrae, 2010). Secondly, one lab experiment has shown that affiliation can be increased by action contingency alone. Catmur and Heyes (2013) asked participants to perform either a hand or a foot movement at random. In response, they either saw the same action that they had just performed onscreen, or the opposite one. The actions onscreen either occurred contingently, every time participants acted, or noncontingently, sometimes appearing and sometimes not.

Figure 1. (a) In the joint condition, participants' headphones were plugged into a splitter and they shared a screen. In the parallel condition, participants had two separate screens and their headphones were plugged in separately. In response to a shape appearing on screen, participants either moved the same limb at the same time as each other, or when one moved a hand the other moved a foot (or vice versa). (b) Laboratory layout in the parallel context condition. In the joint condition the screen was placed in the middle.

Participants' pro-social feelings were influenced by the contingency of their actions, but not by the match between the actions they made and the actions they saw.

This leads to the prediction that for our two dancers at a silent disco, what will increase affiliation is the social context that leads them to interpret their actions as linked and contingent upon each other - that they are dancing 'together'. In contrast, the prediction from the behavioural coordination literature is that affiliation will be higher when the participants' movements are the same.

To test these predictions, we instructed pairs of participants to listen to music on headphones and to perform the same or different movements in one of two conditions: in the joint social context, participants danced 'together' looking at a single computer screen that guided their movements. In the parallel social context, they each had their own screens, side by side, showing the same movement instructions. Afterwards, we measured participants' levels of affiliation to tease apart the contribution of social context and movement similarity in producing liking.

## Methods

We performed two experiments manipulating movement similarity and social context between pairs of participants. In the first experiment, as well as using a single screen, the joint social context was additionally established by giving participants the task of first untangling their headphone cables before plugging into their shared display. In our second experiment, we aimed to replicate our methods, but with the untangling task removed, so that the joint social context was established by the shared display alone. Since the experiments and analyses are identical in every other regard, we describe them together here.

## Participants

We estimated an effect size of $d=0.7$, following Lumsden, Miles and Macrae (2014) for affiliation effects arising from mimicry, and an a priori power analysis using $G^{*}$ Power (version 3.1.9.2; Faul, Erdfelder, Lang, \& Buchner, 2007) suggested a sample size of 76 to achieve $85 \%$ power (with $\alpha$ $=0.05$ ). To be conservative, Experiment 1 tested 80 participants ( 58 females; mean age $=24.66$ years; $\mathrm{SD}=6.84$ years, 29 non-UK nationals) and Experiment 2 tested 82 participants ( 62 females; mean age $=21.8, \mathrm{SD}=6.1,45$ nonUK nationals), recruited from the UCL Psychology Subject Pool. No participants were excluded. Participants in both studies were compensated through course credit or a monetary reward of $£ 4$. It was ensured that the members of each dyad did not know each other prior to the experiment.

## Ethics Statement

Ethical approval was obtained from the UCL Research Ethics Committee. All participants provided written informed consent before the beginning of the study and were fully debriefed upon completion.

## Procedure

Experiments had a $2 \times 2$ (social context: joint or parallel; movements: same or different) between-subjects design with pairs randomly assigned to conditions (Figure 1). In Experiment 1, participants in the joint condition were first given the task of untangling headphone cables together then plug them in. In the parallel condition, the headphones were already plugged into separate laptops. In Experiment 2, the untangling task was not included in either condition.

Participants wore headphones and stood 1 m apart from each other, 2.5 m away from a table, in a square marked on the floor (Figure 1). In the parallel social context, there were two screens (diameter: 27 cm , diagonal: 33.78 cm ) 1 m apart on the table that showed identical stimuli throughout the experiment. In the joint social context, there was one screen midway between participants.

In the same movement condition, both participants were given same shape-movement instructions (e.g., circle $=$ leg movement and triangle $=$ hand movement). In the different movement condition, one participant had the mapping reversed. Shapes were presented randomly on the left, right or middle of the display, indicating the direction that participants were to move their limbs. After a practice stage, participants danced for $4: 50 \mathrm{~min}$ to shapes appearing every 1.2 seconds, matching the tempo of the song 'I turn my
camera on' by Spoon. Participants were then led into different rooms. We measured affiliation in two ways. First, participants responded to a 15 item subset of the Subject Impressions Questionnaire (SIQ) from the Intrinsic Motivation Inventory (Ryan, Koestner, \& Deci, 1991). Second, we measured affiliation with the Inclusion of Other in Self (IOS) scale (Aron, Aron, \& Smollan, 1992), in which participants chose between 7 pairs of differently overlapping circles to represent their relationship with the other participant. Finally, as a manipulation check, we asked how much the participants attended to each other, and if they felt like they were dancing 'together'. The experiment lasted for approximately 30 minutes. All measures and manipulations have been reported here, and analysis did not begin in each experiment until we had collected our target of 80 participants in each.

## SOCIAL CONTEXT <br> joint parallel

MOVEMENT
same different

Figure 2. The main effects of social context and movement conditions on two measures of affiliation: SIQ and IOS. There were no significant interactions between the effects. Red and blue lines show the distribution of scores in each condition, with dotted lines giving mean. Grey lines show the Bayesian estimate of distribution of the difference between conditions; grey areas show the $95 \%$ credibility intervals.

## Results

Across two different measures we found strong evidence that affiliation was increased by a joint social context, but was unaffected by movement similarity. We employed a Bayesian analysis of our results, since in addition to avoiding some of the problems of null hypothesis significance testing (Kruschke, 2010), these analyses are able to estimate the relative strength of evidence for and against null and alternative hypotheses (Wagenmakers, Wetzels, Borsboom, \& van der Maas, 2011). Analyses were conducted in R using the BayesFactor package (Morey \& Rouder, 2015) and default parameter values. For our analyses, we used the default Cauchy prior with a scale of $\sqrt{2} / 2$, which is seen as appropriate under a broad array of situations (see Rouder, Speckman, Sun, Morey \& Iverson, 2009), following the emerging practice in this application of Bayesian techniques (e.g. de Moliere \& Harris, 2016), and compared against the null hypothesis that the conditions had no effect.

Figure 2 presents the distribution of SIQ and IOS scores across our manipulations and to the right of each plot, Bayesian credibility intervals (Kruschke, 2010) for the differences between conditions. These analyses suggest that between the social context conditions there is difference between mean SIQ and ISO scores, but no difference between the movement similarity conditions. Since there was no evidence in our analyses for an interaction between social context and movement conditions, the main effects are plotting in Figure 2.

To quantify the strength of these effects further we calculated Bayes factors. On SIQ scores, a Bayesian Type II ANOVA found very strong evidence in favour of a main effect of social context (Bayes factor: 300:1) over the null hypothesis, but evidence against a main effect of movement similarity in favour of the null hypothesis (Bayes factor 6:1) and against there being a difference between the two experiments (Bayes factor 5:1). There was also evidence against any interaction effects between conditions (Bayes factors between 3 and 4:1). A similar pattern of likelihoods was found for IOS scores. There was strong evidence in favour of an effect of social context (Bayes factor 101:1), evidence against an effect of movement condition (Bayes factor 4:1), evidence against a difference between experiments (Bayes factor 5:1), and against any interaction effects (Bayes factors between 3 and $4: 1$ ).

The conclusions we reached from Bayesian analyses were echoed by more orthodox null hypothesis testing. We ran a 2 (movement condition) x 2 (social context) x 2 (experiment) ANOVA. There was a main effect of social context on SIQ scores $\left(F(1,154)=16.58 ; p<.001, \eta_{\mathrm{p}}{ }^{2}=.1\right)$ and on IOS scores $\left.F(1,154)=13.78 ; p<.001, \eta_{\mathrm{p}}{ }^{2}=.08\right)$. But there was not a significant main effect of movement similarity on either measure, and no interaction between social context and movement conditions (all $F \mathbf{s}<1$ ).

Our manipulation check showed that there is strong evidence that participants in the joint social context felt that they were 'dancing together' more (Bayes factor 900:1), but no evidence that this was affected by movement condition
(Bayes factor 0.68:1). There was weak evidence that joint social context resulted in participants paying more attention to each other (Bayes factor 3:1), but evidence in favour of the null hypothesis and against an effect of movement condition on attention (Bayes factor 6:1).

Why was there no effect of movement similarity? One possibility, the 'attention only' account, is that participants' movements did not influence their affiliation because they simply didn't pay attention to each other, but if they had, then movement similarity would have had an effect. Logically, on this account, the more attention participants paid to each other's identical movements, the larger the increase in affiliation would be. And the more they paid attention to each other's dissimilar movements, the larger the decrease in affiliation would be. However, when we looked at the attention participants paid to each other, there was no such pattern of results. In fact, an increase in participants' attention to one another did not affect SIQ and increased it for both similar and dissimilar movements for ISO.

In the case of IOS scores, attention was positively related to affiliation in both the same movement (Bayes factor 70:1) and, crucially, in the different movement condition as well (Bayes factor 50:1). Moreover, the evidence was against a model for ISO scores with attention, movement condition and an interaction between them, over a model that just included attention (Bayes factor 12:1). In the SIQ scores, there was no evidence that attention to others was related to affiliation (Bayes factor $0.35: 1$ ), and strong evidence against the hypothesis that a model with SIQ scores, movement condition and an interaction between them was preferred over the null hypothesis (Bayes factor 50:1).

We ran correlational analyses between our measure of 'attending to others' and the two measures of affiliation overall, and splitting the data according to social context and movement, to see if those relationships changed between conditions. We calculated Zou's (2007) 95\% confidence intervals for differences between conditions. In each case, the CI encompassed 0 , suggesting that the correlations did not differ between conditions, supporting the conclusions drawn from Bayesian analysis.

## Discussion

We found two surprising results. Firstly, participants did not like each other more if they had been performing the same actions, despite the clear prediction from a host of behavioural coordination studies in the literature. Secondly, they did feel closer to each other if they had been moving together in a joint social context. This joint context was established merely by attending to a common display. If participants moved their bodies in the same way, in the same synchronised fashion, but attended to two displays a few degrees apart, then they did not feel increased affiliation towards each other.

Standard mimicry and imitation theories cannot account for these results. Their prediction is that, ceteris paribus, when participants make the same movements, their affiliation should be higher than when they are making different or
incongruent movements. However, our results did not support this prediction, and Baysian analyses strongly suggested that the likelihoods were in favour of there being no effect of movement similarity at all.

How can we explain both our finding that affiliation is dependent on social context, but also past findings that it is caused by motor mimicry? One possibility follows the associative sequence learning model, which holds that 'mirror systems' are the byproducts of learning sensorimotor contingencies in a social context (Catmur, Walsh, \& Heyes, 2009). From infancy, we perceive and perform the same actions as others in the context of rewarding social interactions (Heyes, 2001). These contingencies are learnt, and in adulthood, they continue to produce mimicry, associated with pro-social feelings. Critically, as Cook, Dickinson and Heyes (2012) showed, these sensorimotor contingencies become tied to the context in which they are learned. So, crucially for our results, the sensorimotor contingencies learned from multiple social interactions would only be re-evoked in a social context. This provides a plausible explanation of why only our joint dancing condition affected affiliation: only when participants shared a screen, they perceived themselves to be in a social situation in which their actions were contingent upon one another.

Elsewhere in the literature, it has been shown that forms of joint action and joint attention can have widespread cognitive consequences. For example, there is interference between the stimulus-response mappings of two people engaged in a Simon task together (Sebanz, Knoblich, \& Prinz, 2003). When someone believes that another person is looking at the same stimuli as them, it changes their visual attention (Richardson D., Street, Tan, Hoover, \& Ghane Cavanaugh, 2012) and memory encoding (Shteynberg, 2010; He, Lever, \& Humphreys, 2011). Pro-social feelings are also increased when two people attend to the same stimuli (Fridlund, 1991; Wolf, Launay, \& Dunbar 2015). It seems plausible that our participants who shared a screen cognitively framed their activity in a particular manner (Huhn, Potts, \& Rosenbaum, 2016), as a shared, joint activity, and from this, changes in affiliation were produced.

The interrelated roles of movement similarity and social context cannot be determined from previous results in the literature. Past experimental studies have either confounded social context with movement similarity, failed to manipulate it explicitly, or used reduced, artificial stimulus-response tasks. Indeed, our findings suggest that many past results linking motor mimicry with affiliation may have occurred, in part, because the experimental situation has established a social context in which behavioural coordination is interpreted as contingent. And we would predict that in a silent disco, if two people do not share the same music, and do not interpret their actions as shared and contingent, they will not become friends as quickly.

## Acknowledgments

We thank Aastha Chadha, Michelle Huh and Ashley Kleeberg for their help with collecting data for these experiments. This research was supported in part by an ESRC transformative research grant (ES/M000680/1) awarded to G. Orgs and D. Richardson.

# Modeling Sources of Uncertainty in Spoken Word Learning 

Matthias Hofer (mhofer@mit.edu), Roger Levy (rplevy@mit.edu)<br>Department of Brain and Cognitive Sciences, 43 Vassar St<br>Cambridge, MA 02139 USA

#### Abstract

In order to successfully learn the meaning of words such as bin or pin, language learners must not only perceive relevant differences in the speech signal but also learn mappings from words to referents. Prior work in native (Stager \& Werker, 1997) and second (Pajak, Creel, \& Levy, 2016) language acquisition has found that the ability to perceptually discriminate between words does not guarantee successful word learning. Learners fail to utilize knowledge that they can otherwise use in speech perception. To explore possible mechanisms accounting for this phenomenon, we developed a probabilistic model that infers both a word's phonetic form and its associated referent. By analyzing different versions of the model fitted to experimental results from Pajak et al. (2016), we argue that a mechanism for spoken word learning needs to incorporate both perceptual uncertainty as well as additional, taskspecific sources of uncertainty.

Keywords: word learning, rational model, probabilistic inference, phonological similarity, speech representations

## Introduction

From the perspective of a learner of English, successfully learning the meaning of novel words such as bin or pin requires the ability to perceptually discriminate between similar-sounding words. Creating distinct, non-overlapping representations of the input is necessary because the words need to be mapped onto different classes of referents. This requires perceptual sensitivities to the phonological contrasts critical for the discrimination (Pater, Stager, \& Werker, 2004). In the case of bin and pin this contrast is along the voicing dimension (phonemes $b$ and $p$ differ in voice onset time). Studies in infant native-language (L1) acquisition have shown that while these perceptual abilities are present in 14 month old infants, they do not guarantee successful word learning (Stager \& Werker, 1997; Pater et al., 2004). In a series of experiments conducted by Stager and Werker (1997), infants that were able to perceptually discriminate between two similarsounding words, such as dih and bih, failed to utilize this knowledge during word learning (experiment 4). When first habituated to label/object pairings, infants did not reliably detect when the assignment of words to objects switched (experiment 1) and they failed to notice mispronunciations when an object that had before been introduced as $d i h$ was later referred to as bih (experiment 2). The authors interpreted their findings as infants being unable to attend to fine phonetic detail during word learning and argued that it constitutes a feature of linguistic development.

The same pattern of results has more recently been demonstrated for second-language (L2) learners. A study by Pajak et al. (2016) compared the performance of subjects of two different linguistic backgrounds in a perceptual discrimination and a word learning task. To create a situation paralleling
that of L1 acquisition in infants, the researchers used a miniature language with word pairs at three levels of phonological similarity whose phonology, modeled after Polish, was novel and unfamiliar to all participants: Dissimilar words differed in multiple phonemes (e.g., tala / kenna); similar word pairs differed in one phoneme (e.g., tala / taja); and highly-similar words differed only along a single phonetic dimension, either in length (short vs. long, e.g., tala / talla) or place of articulation (alveolopalatal vs. retroflex, e.g., gotça / gotsa). In order to examine the role of L1-specific differences in task performance, Pajak and Levy (2014) collected data from both Korean speakers, who are sensitive to length contrasts but not to the alveolopalatal vs. retroflex distinction, and from Mandarin speakers, who show the opposite pattern. To ensure that subjects were naive to the stimuli used in the experiment, the researchers tested separate groups of subjects on the perceptual discrimination and the word learning task.

Similarly to results from Stager and Werker (1997), the study found that the ability to perceptually discriminate similar-sounding words in the perceptual task did not successfully translate to the word learning task on a group level, nor did subjects' L1-specific perceptual advantages. Taken together, these findings suggest that the difficulty in learning similar-sounding words, especially during early lexical acquisition, is a general property of learning rather than a developmental stage (Pajak et al., 2016; Perfors \& Dunbar, 2010). At present, little is known about the learning mechanisms that give rise to these difficulties. Here we seek to provide an account of such a mechanism in the form of a probabilistic model developed with the goal of reproducing the results from Pajak et al. (2016)'s original study. While we are not aware of any computational modeling work, the exists prior work addressing these issues on a conceptual level. The failure to utilize perceptual knowledge during word learning has previously been attributed to increased cognitive load (Werker, Fennell, Corcoran, \& Stager, 2002; Stager \& Werker, 1997). While discrimination only requires storage and comparison of perceptual input in phonological short-term memory, word learners must additionally attend to the referent stimulus and integrate label/referent information over the course of learning to infer probable associations. This lowers the resolution of auditory processing (Mattys \& Palmer, 2015), which contributes to the failure of distinctly representing similar-sounding input. We will explore these verbal theories by analyzing which of the proposed components are necessary to account for the observed effects in the study by Pajak et al. (2016), which we will briefly describe in the next section.

## Pajak et al. (2016)'s experiment

In a between-subjects design, ninety subjects, approximately equally split into speakers of Korean and Mandarin, participated in either a perceptual discrimination or a word learning task. Stimuli consisted of 16 bisyllabic consonant-vowel-consonant-vowel (CVCV) nonce words, split into similarity classes as described above. ${ }^{1}$ Perceptual discrimination was tested in an ABX task. Subjects listened to three consecutive words, e.g., talla ${ }_{[A]}$, taja $_{[B]}$, and talla ${ }_{[X]}$, and had to decide which of the first two words sounded more similar to the last one. In the word learning task, each of the 16 labels was associated with a single referent in the form of a visual image and participants' goal was to learn which words were associated with which referents. The experiment consisted of four training blocks (each with 128 trials) and four interleaved testing blocks (each with 64 trials). In each trial, two pictures were presented side by side, corresponding to the referents for labels A and B. Similarly to the ABX task, subjects then heard a label X and had to decide which referent it belonged to. Error feedback was provided to the subjects during the training phase but not during the test phase. The stimulus triplets used in the discrimination task and in the test phase of the word learning task were identical, which made it possible to compare accuracy for triplets across the two tasks.

## Computational Model

A computational analysis of spoken word learning must take into account the goal of the computation, the information available to the learner, and show how this information maps onto appropriate behavioral responses (Anderson, 1990). We suggest that learning novel words requires the learner to perform statistical inference on at least two distinct levels. While the ultimate goal of learning is to infer concepts, or label/referent associations, from a stream of observations, the learner must concurrently infer the label's phonetic form from the acoustic input, since it is not explicit in the speech signal. These two layers of inference give rise to a hierarchical probabilistic model, visually depicted in Figure 1, which we used to model spoken word learning and, using a variation of the generative process, model results from the perceptual discrimination tasks. Model behavior is influenced by three distinct factors: perceptual noise, which affects both discrimination and word learning when processing speech input, taskspecific factors that lower the resolution of auditory representations of speech sounds during word learning (Mattys \& Palmer, 2015), and overall memory capacity.

## Formal characterization of the model

Each word and its corresponding referent define a concept, denoted $c$. To simplify our analysis, we assume that the referent stimulus is observed unambiguously. In our model, observing the referent stimulus is therefore identical to observ-

[^103]ing the concept directly, because of the one-to-one relation between referents and concepts. The a priori probability of choosing any concept is uniform. Corresponding labels are then sampled from the conditional probability $p(\mathbf{l} \mid c)$, whose probability mass is uniform across all possible labels in the language $\mathcal{L}$ and zero otherwise.
\[

\operatorname{Pr}(\mathbf{l} \mid c)= $$
\begin{cases}\frac{1}{N} & \text { if } \mathbf{l} \in \mathcal{L}  \tag{1}\\ 0 & \text { otherwise }\end{cases}
$$
\]

Label $\mathbf{l}$ is a sequence of phonemes of the form $p_{1} p_{2} p_{3} p_{4}$ composed of pre-specified consonant and vowel primitives. Phonemes are represented mathematically as multivariate Gaussian distributions in one of two separate (phonetic) feature spaces, one for consonants and one for vowels. Following prior approaches to the representation of speech sounds (Richter, Feldman, Salgado, \& Jansen, 2016; Bailey \& Hahn, 2005), the feature dimensions of these phonetic spaces correspond to subsegmental features such as manner, place, length, and voicing, or to the first two vowel formants. Distributions are centered around a fixed category mean $\bar{\mu}\left[p_{i}\right]$, a vector of means indexed by the corresponding phoneme. Covariance matrices $\bar{\Sigma}_{w}[i]$, one shared across vowels and one across consonants, are indexed by $i$ only (corresponding to whether the phoneme is of type C or V ).

Conditioned on a choice for label l, we can generate a sequence of phones $s_{1} s_{2} s_{3} s_{4}$, which can be seen as its discrete and noisy realizations of the label's phonemes:

$$
\begin{align*}
\operatorname{Pr}\left(s_{i} \mid p_{i}\right) & =\mathcal{N}\left(\bar{\mu}\left[p_{i}\right], \bar{\Sigma}_{w}[i]\right)  \tag{2}\\
\operatorname{Pr}(\mathbf{s} \mid \mathbf{I}) & =\operatorname{Pr}\left(s_{1} s_{2} s_{3} s_{4} \mid p_{1} p_{2} p_{3} p_{4}\right)  \tag{3}\\
& =\operatorname{Pr}\left(s_{1} \mid p_{1}\right) \operatorname{Pr}\left(s_{2} \mid p_{2}\right) \operatorname{Pr}\left(s_{3} \mid p_{3}\right) \operatorname{Pr}\left(s_{4} \mid p_{4}\right)
\end{align*}
$$

The covariance matrix that determines variability in the realization of speech sounds is specified through the following scalar-matrix-vector multiplication:

$$
\begin{equation*}
\bar{\Sigma}_{\text {task }}[i]=\alpha_{\text {task }} \mathbf{I} \bar{v}[i]^{\text {population }} \tag{4}
\end{equation*}
$$

The scalar $\alpha_{\text {task }}$ allows us to reflect task-specific sources of uncertainty (word learning vs. discrimination). We note that the parameter for word learning, $\alpha_{w}$ can be written as the product of a perceptual 'baseline' acuity parameter for the discrimination task times a constant factor: $\alpha_{w}=c \alpha_{d}$. Assuming pairwise independence across all feature dimensions, the covariance matrix is fully specified by its diagonal elements, encoded in the population-specific diagonal vector $\overline{\mathrm{V}}[i]^{\text {population }}$. Phonetic acuity along those feature dimensions is inversely proportional to variance: the higher phonetic acuity, the lower the variance. This allows us to model differences in L1 background (Korean vs. Mandarin) with respect to perceptual sensitivities along these feature dimensions. For example, for Korean speakers:

Figure 1: Graphical representation of the word learning model. Circles indicate random variables (variables shaded in gray are observed during learning); squares indicate fixed model parameters. To simplify our representation, the model does not include a referent node, which is deterministically generated by sampling from the concept.

$$
\begin{aligned}
\overline{\mathrm{v}}[1]^{\text {Korean }} & =\overline{\mathrm{v}}[3]^{\text {Korean }}=\left(\tau_{F 1_{K}}{ }^{-1} \tau_{F 2_{K}}{ }^{-1}\right)^{T} \\
\overline{\mathrm{v}}[2]^{\text {Korean }} & =\overline{\mathrm{v}}[4]^{\text {Korean }}= \\
& \left(\tau_{\text {length }_{K}}{ }^{-1} \tau_{\text {place }_{K}}{ }^{-1} \tau_{\text {voicing }_{K}}{ }^{-1} \tau_{\text {manner }_{K}}{ }^{-1}\right)^{T}
\end{aligned}
$$

The vowel feature space consists of the first two formants F1 and F2. Consonant space consists of the dimensions voicing, place, manner, and length (Bailey \& Hahn, 2005). All acuity parameters are set to 1 (corresponding to a unit Gaussian variance), except for $\tau_{\text {length }}$ and $\tau_{\text {place }}$, which are population-specific free parameters in the model. As a simple approximation, means in $\bar{\mu}\left[p_{i}\right]$ are evenly spaced across perceptual space. Along each phonetic dimension, we defined a number of subsegmental features (e.g., 'voiced' and 'unvoiced' along the voicing dimension). Phonetic category means can then be written as the vectors composed of these features (the mean of phoneme $f$, for instance, is represented as [unvoiced, labial, fricative, short]). Although not fully accurate in its details, the coarse grained nature of this setup is sufficient with respect to the word pairs used in Pajak et al. (2016)'s experiment. ${ }^{2}$

Word learning model In word learning, subjects engage in consecutive training and test blocks. Each training trial $t$ consist of an observed label/referent pair $\left\{\mathbf{s}_{t}, c_{t}\right\}$. For simplicity we assume that learners discard the negative, second

[^104]exemplar presented to them and only learn from the positive pairing. The learner's goal is to infer probable associations between referents $c$ and labels $\mathbf{I}$, in other words, compute the posterior probability over labels given the observed stimulus and referent $\operatorname{Pr}\left(\mathbf{l}_{t} \mid \mathbf{s}_{t}, c_{t}\right)$ according to:
\[

$$
\begin{equation*}
\operatorname{Pr}\left(\mathbf{l} \mid \mathbf{s}, c, \bar{\Sigma}_{w}\right)=\frac{\operatorname{Pr}\left(\mathbf{s} \mid \mathbf{l}, \bar{\Sigma}_{w}\right) \operatorname{Pr}(\mathbf{l} \mid c)}{\sum_{\mathbf{l}} \operatorname{Pr}\left(\mathbf{s} \mid \mathbf{l}, \bar{\Sigma}_{w}\right) \operatorname{Pr}(\mathbf{l} \mid c)} \tag{5}
\end{equation*}
$$

\]

The output of this computation is then used as a prior for the next trial. To model the difficulty of integrating multiple memory traces over time, one simple approach is to assume an upper bound on the number of memory traces that can be integrated, denoted $m_{c}$. We formalized this intuition by discarding samples from trials $t \geq m_{c}$ (no further updating of probabilistic representations occurs).

After computing $\operatorname{Pr}\left(\mathbf{l} \mid \mathbf{s}_{1}, \ldots, \mathbf{s}_{T}, c_{1}, \ldots, c_{T}, \bar{\Sigma}_{w}\right)$ for the training block, in the test phase, the learner compares two alternative tuples $\left\{c_{A}, \mathbf{s}_{X}\right\}$ and $\left\{c_{B}, \mathbf{s}_{X}\right\}$ to assess which referent is more probable under $\mathbf{s}_{X}$. This is achieved by computing $\operatorname{Pr}\left(c_{A} \mid \mathbf{s}_{X}, \bar{\Sigma}_{w}\right)$ and $\operatorname{Pr}\left(c_{B} \mid \mathbf{s}_{X}, \bar{\Sigma}_{w}\right)$ by integrating over $\mathbf{l}$ :

$$
\begin{equation*}
\operatorname{Pr}\left(c \mid \mathbf{s}, \bar{\Sigma}_{w}\right)=\frac{\sum_{\mathbf{l}} \operatorname{Pr}\left(\mathbf{s} \mid \mathbf{l}, \bar{\Sigma}_{w}\right) \operatorname{Pr}(\mathbf{l} \mid c) \operatorname{Pr}(c)}{\sum_{c} \Sigma_{\mathbf{l}} \operatorname{Pr}\left(\mathbf{s} \mid \mathbf{l}, \bar{\Sigma}_{w}\right) \operatorname{Pr}(\mathbf{l} \mid c) \operatorname{Pr}(c)} \tag{6}
\end{equation*}
$$

Discrimination model In the discrimination task, subjects perceive a stimulus triplet $\left\{\mathbf{s}_{A}, \mathbf{s}_{B}, \mathbf{s}_{X}\right\}$ and decide whether X is more similar to A or to B . We hypothesize that subjects use the generative process outlined above to judge similarity, where they independently determine the likelihood that the stimuli were sampled from two alternative generative models (Tenenbaum \& Griffiths, 2001), described in the following:

$$
\begin{align*}
& \operatorname{Pr}\left(\mathbf{s}_{A}, \mathbf{s}_{B}, \mathbf{s}_{X} \mid \mathbf{l}_{1}, \mathbf{l}_{2}\right)=  \tag{7}\\
& \quad \sum_{\mathbf{l}_{1}}\left[\operatorname{Pr}\left(\mathbf{s}_{A} \mid \mathbf{l}_{1}\right) \operatorname{Pr}\left(\mathbf{s}_{X} \mid \mathbf{l}_{1}\right) \operatorname{Pr}\left(\mathbf{l}_{1}\right)\right] \sum_{\mathbf{l}_{2}}\left[\operatorname{Pr}\left(\mathbf{s}_{B} \mid \mathbf{l}_{2}\right) \operatorname{Pr}\left(\mathbf{l}_{2}\right)\right]  \tag{8}\\
& \operatorname{Pr}\left(\mathbf{s}_{A}, \mathbf{s}_{B}, \mathbf{s}_{X} \mid \mathbf{l}_{1}, \mathbf{l}_{2}\right)= \\
& \quad \sum_{\mathbf{l}_{1}}\left[\operatorname{Pr}\left(\mathbf{s}_{A} \mid \mathbf{l}_{1}\right) \operatorname{Pr}\left(\mathbf{l}_{1}\right)\right] \sum_{\mathbf{l}_{2}}\left[\operatorname{Pr}\left(\mathbf{s}_{B} \mid \mathbf{l}_{2}\right) \operatorname{Pr}\left(\mathbf{s}_{X} \mid \mathbf{l}_{2}\right) \operatorname{Pr}\left(\mathbf{l}_{2}\right)\right]
\end{align*}
$$

The likelihood $\operatorname{Pr}(\mathbf{s} \mid \mathbf{l})$ is the same as in Equation 3 but with covariance matrix $\bar{\Sigma}_{d}[i]$ specific to the perceptual discrimination task.

Response probability Both experimental paradigms use a two-alternative forced choice task (2-AFC) to assess subjects' knowledge. Subject either compare two posterior probabilities over concepts given labels (word learning task) or the likelihoods that the stimulus triple was generated by one of two alternative generative models (discrimination task). In

Figure 2: Comparison of the $M_{+} A_{+}$model to experimental results for the L1 Korean population (top) and for the L1 Mandarin population (bottom). Error bars are standard errors. Accuracy scores are percentage correct in the discrimination task and during the test phase of the word learning task.
both cases, choices are modeled using a Bernoulli distribution and the probability of choosing one alternative over the other is computed using Luce's choice rule (Luce, 1959). Response parameter $\beta$ controls the stochasticity of responses.

## Results

We fitted the model to aggregate subject data from Pajak et al. (2016)'s word learning and perceptual discrimination tasks. Free model parameters included task-specific phonetic acuity for word learning ( $\alpha_{w}$ ) and for discrimination $\left(\alpha_{d}\right)$, four population-specific acuity parameters ( $\tau_{\text {length }_{K}}, \tau_{\text {length }_{M}}$, $\tau_{\text {place }_{K}}, \tau_{\text {place }_{M}}$ ), the response parameter ( $\beta$ ), as well as the memory capacity parameter ( $m_{c}$ ).

Table 1: Results from fitting four versions of our model to the experimental data. Fits are quantified using the product of RMSEs to the word learning and discrimination data across the two speaker populations.

| Model | n.p. | w.l. | w.l.b. | disc. | all |
| :--- | :---: | :---: | :---: | :---: | :---: |
| $M_{-} A_{-}$ | 6 | 0.089 | 0.138 | 0.179 | 0.407 |
| $M_{-} A_{+}$ | 7 | 0.029 | 0.140 | 0.017 | 0.186 |
| $M_{+} A_{-}$ | 7 | 0.076 | 0.098 | 0.172 | 0.347 |
| $M_{+} A_{+}$ | 8 | 0.025 | 0.099 | 0.018 | 0.142 |

To assess which model components are necessary to account for the experimental data, we fitted four alternative ver-
sions of the model that were composed out of two binary factors: the presence $(+)$ or absence $(-)$ of memory constraints $m_{c}(\mathrm{M})$ and the presence of task-specific, non-perceptual uncertainty in the form of separate $(+)$ or shared $(-)$ perceptual acuity parameters across tasks (A), where in the case of shared parameters: $\alpha_{w}=\alpha_{d}$. We also considered separate response rule parameters $\beta$ for word learning and discrimination but found that the improvements were only minimal.

The models were fitted to the data by minimizing the product of six separate error terms. For each group of L1 speakers (Mandarin vs. Korean), we calculated the root mean squared error (RMSE) between model predictions and experimental results, resulting in three separate error terms for (i) overall discrimination accuracy across trial types [disc.], (ii) overall word learning accuracy across trial types [w.l.], and (iii) word learning accuracy across blocks and trial types [w.l.b.]. For each of the four models, Table 1 shows the RMSE for these three scores (averaged across Korean and Mandarin speakers) and their sums [all]. Column [n.p.] indicates the fitted model's number of free parameters.

## The necessity of separate acuity parameters

Pajak et al. (2016)'s main finding was that the difference in accuracy between tasks was mediated by similarity. In other words, performance takes a greater hit from increased perceptual similarity in the word learning task compared to discrimination. The study also found that L 1 -specific perceptual

Figure 3: Figure (a) shows how the $M_{-} A_{+}$model fails to account for the time course of learning. Figure (b) and (c) show comparisons of the $M_{+} A_{+}$model to L1 Korean speakers and L1 Mandarin speakers. Error bars indicate standard errors.

Figure 4: Results for the $M_{-} A_{-}$model (top) and for the $M_{-} A_{+}$model (bottom; both Korean only; results are qualitatively similar for Mandarin speakers)
advantages that are manifest in the discrimination task cannot be utilized in word learning. Model variants $M_{-} A_{-}$and $M_{+} A_{-}$, missing the additional acuity parameter $\alpha_{w}$, were not able to account for these observations. Figure 4 (top) illustrates this point by showing overall results for Korean speakers. One key observation for the $M_{-} A_{-}$model is that, when sharing a single perceptual acuity parameter between the two tasks, the original pattern of findings reverses and the discrimination model performs worse than the word learning model. ${ }^{3}$ The reasons for this are twofold. All other things being equal, there is more uncertainty in the generative process for discrimination (see Equation 7 and 8) than there is in word learning. In discrimination, subjects need to infer the phonetic form of three auditory stimuli, compared to a

[^105]single stimulus in word learning. Moreover, the word learning model can profit from additional information in the form of label/referent representations, gradually sharpening over the course of learning. The fact that perceptual uncertainty alone (in the form of a shared acuity parameter across models) cannot account for the superiority of discrimination performance over word learning suggests that word learning is influenced by additional sources of uncertainty. The bottom of Figure 4, which depicts results for the $M_{-} A_{-}$model, illustrates that adding an additional phonological acuity parameter that is specific to word learning is sufficient to account for both discrimination as well as word learning results.

## Accounting for the time course of word learning

In Pajak et al. (2016), word learning performance only improved over a certain number of trials, resulting in learning curves to asymptote after roughly the second learning block. Reproducing this pattern while simultaneously accounting for the results presented above was an important aspect of our modeling efforts. While model $M_{-} A_{+}$provides an almost ideal fit to aggregate results from discrimination and word learning (see Figure 4), underlining the importance of incorporating acuity factor A into the model, it fails to capture the time course of learning (see Figure 3a).

The only model that fit the entire range of empirical findings was the $M_{+} A_{+}$model. Figure 2 shows that the model is a good fit, both qualitatively as well as quantitatively, to aggregate accuracy scores for both Korean and Mandarin L1 speakers. In particular, simulated data successfully reproduce the lack of L1-specific advantages in word learning compared to discrimination. Figures 3 b and 3 c show that the added memory constraint allows the model to better account for the shape of the learning curve. Models without this component are not able to reproduce this pattern. Table 1 further shows that adding such memory constraints also slightly improves fits to the aggregate word learning data [w.l.] compared to the same model where they are absent.

## Discussion

Recent work by Pajak et al. (2016) suggests that the difficulty of learning label/referent associations for similar-sounding words is a general feature of learning rather than a developmental stage unique to infancy. In working towards a computational theory that could account for this phenomenon, we developed a probabilistic model capable of learning label/referent pairs while at the same time inferring the label's phonetic form. We fitted and compared four versions of the model to data from Pajak et al. (2016), contrasting different factors that are thought to influence performance.

We found that, besides structural differences in the way the generative models for word learning and for discrimination are set up, a single multiplicative factor operating on perceptual uncertainty was sufficient to account for the major differences between perceptual discrimination and word learning. A second additional factor, representing long-term memory constraints, was only necessary to account for the time course of learning.

## Task-related sources of uncertainty

Conceptually, the acuity factor combines sources of uncertainty unique to the word learning task, such as attention to the referent stimulus and the encoding of label/referent exemplars over the course of learning. An interpretation broadly consistent with our model and with previous work (Stager \& Werker, 1997; Mattys \& Palmer, 2015) is that, although originating from post-perceptual sources, the locus of this added uncertainty is perception itself, operating through lowering attention to phonetic detail. On this view, the model's discrimination acuity parameter can be interpreted as representing various sources of perceptual uncertainty, ranging from the transduction of the speech signal at the periphery to phoneme recognition. Word learning-specific sources of uncertainty can be interpreted as a multiplicative factor on perceptual uncertainty, which, multiplied together, constitute the model's word learning acuity parameter. This added factor also accounts for the finding that L1-specific perceptual advantages cannot be utilized in word learning. The overlap of highly-similar word pairs in perceptual feature space is so large that potential advantages along the length and place feature dimensions are washed out.

Another important insight comes from models that lack this separate acuity parameter, which suggest that the discrimination is actually harder than word learning. This makes sense when considering that the generative model for the discrimination task must infer the phonetic form of three stimuli instead of a single stimulus. As a consequence, perceptual uncertainty affects the discrimination task more severely. In the absence of other factors that independently operate on the generative model for word learning, this leads to relative performance benefits in the word learning task.

## Memory constraints

While distinguishing between two major sources of uncertainty might alone be sufficient to account for time-averaged
results, it is not enough to account for the time course of learning in Pajak et al. (2016), which showed that learning stagnates after the second training block. The fact that these performance deficits are specific to word learning suggests that they are due to memory-related processes. We found that incorporating capacity constraints in the form of an upper bound on memory was necessary to fully account for the observed effects.

## Conclusion

Our model is a first step in addressing the question of what are the factors that make the learning of similar-sounding words hard. In particular, the model is consistent with the original explanation given by Stager and Werker (1997); Werker et al. (2002). According to this view, word learning is an inherently hard information processing problem and the difficulties of learning similar-sounding words are a consequence of optimally distributing limited resources across the perceptual and memory-related processes involved in learning.

# Knowledge of Cross-Linguistic Semantic Diversity Reduces Essentialist Beliefs about Categories 

Kevin Holmes<br>Colorado College

Erin Luby<br>Colorado College

Sarah Husney
Colorado College

#### Abstract

The words of different languages partition the world in strikingly different ways. Yet many people are unaware of such differences, believing that some of the words of their native language pick out discrete categories based in nature. We investigated whether knowledge of cross-linguistic semantic diversity-putatively inherent to bilingualism-can reduce such essentialist beliefs. In three experiments, we found (a) that bilinguals were less likely than monolinguals to judge membership for animal categories in essentialist terms, (b) that explicit exposure to cross-linguistic semantic diversity, independent of bilingualism, yielded similar effects, and (c) that this manipulation reduced essentialist beliefs about social categories as well. Together, our findings suggest that learning about how languages differ in their semantic systems-a form of metalinguistic knowledge-can lead people to think about categories more flexibly. Implications for research on language and thought, and for ameliorating the negative consequences of social essentialism, are discussed.

# Decisions based on verbal probabilities: Decision bias or decision by belief sampling?

#### Abstract

We examined decisions based on verbal probability phrases, such as "small chance," "likely," or "doubtful" (we call these phrases verbal probabilities). Verbal probabilities have communicative functions called directionality and can be categorized into positive (e.g., "likely" or "probable") or negative (e.g., "unlikely," "doubtful") phrases in terms of their directionality. Previous studies have shown that the directionality of phrases affects decisions. Although such decisions seem biased, we argue that they are not. We hypothesize that since a speaker has the option to choose the directionality used during communication, the selected directionality becomes relevant information to a decision maker, and is taken into account in making decisions. We modeled these processes using the Decision by Belief Sampling (DbBS) model. We found that the observed data could be well explained by our hypothesis, and that the DbBS model could be one of the best potential models for decisions based on verbal probability information.

Keywords: Verbal probabilities; decisions based on verbal probabilities; directionality; decision by belief sampling.

## Introduction

In the research on judgment and decision making, topics pertaining to probabilities, such as probability judgment and decisions based on probability information, have been some of the most studied. In the present study, we shall discuss decision making based on different kinds of probability information.

Probability information can be expressed in various forms. The most basic of these expressions is numerical probability, such as " $20 \%$." Probability information is also expressed with verbal phrases such as "it is likely," "it is doubtful," or "it is certain. ${ }^{11}$ In the present study, we examined decisions based on verbal probabilities and analyzed how the difference in expressions affected cognitive processes.

Particularly, we focus on the communicative functions of verbal probabilities. Teigen and Brun (1995) showed that verbal probabilities have communicative functions, called

[^106]directionality, which change the listeners' focus. Verbal probabilities can be categorized into positive or negative phrases in terms of their directionality. Positive phrases (e.g., "small chance," "likely," "certain") make listeners focus on the occurrence of uncertain events. In contrast, negative phrases (e.g., "unlikely," "doubtful," "uncertain") make listeners focus on the non-occurrence of uncertain events. Previous studies have shown that the directionality affected decision making. Here, we introduce one of the most intriguing studies, the "Marianne study" (Study 1) in Teigen and Brun (1999). This experiment involved a task describing the probable effectiveness of a treatment with either a positive phrase ("there is some possibility that the treatment will be helpful in her case") or a negative phrase ("it is quite uncertain that the treatment will be helpful in her case"). Participants rated how likely they would recommend this treatment to a patient (Marianne) based on these phrasings, using a 4-point scale (1: absolutely yes, 4: absolutely not). Numerical translations for positive and negative phrases answered by different participants were $31.7 \%$ and $31.3 \%$. Based on these results, the two phrases should have conveyed highly similar degrees of certainty for the effectiveness of treatment. However, the participants gave highly different decision ratings depending on the probability expressions. Mean ratings for positive and negative phrases were, 1.78 and 2.78 , respectively (when scores of 1 or 2 were jointly regarded as "Yes" decisions, the proportions of "Yes" decisions for the two phrases were $90.6 \%$ and $32.4 \%$, respectively).

Ostensibly, the results in Teigen and Brun (1999) may have suggested a decision bias produced by the difference in probability expression, perhaps another form of the framing effect (Teigen \& Brun, 2003). In the following sections, we shall claim that the effect of different probability expressions on decisions is not a decision bias, and that such decisions derive from a decision maker's inferences regarding background information based on speaker's choice of directionality. Furthermore, we model this decision processes using a Decision by Belief Sampling model.

## Speaker's choice of directionality and listener's inferences in communication

In communication, speakers will select an expression according to situational factors. McKenzie and Nelson (2003) and Sher and McKenzie $(2006,2008)$ argued that a speaker's reference point affects her/his choice of expression when conveying quantitative information, such as the amount of water in a glass (e.g., "half full" or "half empty"). In a task examining this phenomenon, it was found when the glass (a 500 ml capacity) had 250 ml of water, participants used the description of "half full" when the glass had previously 0 ml of water more often than when the glass had previously 500 ml of water. It was also found that a listener could infer the speaker's original reference point (e.g., the amount of water originally in the glass before more was added or removed) based on the selected expression. Honda and Yamagishi (2017) found analogous tendencies in communication using verbal probabilities. Imagine trying to convey that an uncertain event had a $50 \%$ chance of occurrence using verbal probabilities. Honda and Yamagishi (2017) showed that when a speaker's prior expectation of the event occurrence was lower (higher) than $50 \%$, they tended to prefer positive (negative) phrases. Honda and Yamagishi (2017) also found that listeners could infer the speaker's expectation based on the phrases used. When a positive phrase was presented, listeners tended to infer that speaker's prior expectation of the probability was lower than when a negative phrase was presented.

These findings indicate that the selected phrase implicitly conveys important information for decision making. For example, given that a speaker follows the above regularity, $50 \%$ conveyed by a positive (negative) phrase implies "good (bad)" situation relative to the speaker's expectation. Thus, the findings of Teigen and Brun (1999) (i.e., participants tended to recommend a treatment conveyed by a positive phrase more than one conveyed by a negative phrase) suggest that in making decisions, participants took into account the relevant information (i.e., relatively "good" or "bad" situations) implied by the directionality chosen.

## Model of decision making based on verbal probabilities: Decision by Belief Sampling

As described above, previous findings suggest that different phrases implicitly convey information about the relative status of the decision situation, and people utilize this information in making decisions. In the present study, we model such decision processes based on the Decision by Sampling model (DbS, Stewart, 2009; Stewart, Chater, \& Brown, 2006). In the DbS model, subjective attribute values are constructed by a series of binary, ordinal comparisons to a sample of attribute values that reflect the immediate decision context and real-world distribution. The subjective value for a target is calculated as follows:

$$
\begin{equation*}
\mathrm{r}=\frac{R-1}{N-1} \tag{1}
\end{equation*}
$$

where $\mathrm{r}(0 \leq \mathrm{r} \leq 1)$ denotes the subjective value for a target, and R denotes the rank of the target within the decision

Figure 1. Summaries of DbBS. (A) Probabilistic belief regarding an uncertain event. This is represented by the density function of the beta distribution. (B) Mean of belief. (C) Entropy of belief. (D) Skewness of belief. (E) Subjective value in DbBS. This is represented with the cumulative distribution function of the beta distribution.
sample of N items. In this model, if the decision sample differs, $r$ varies in the relationship between $R$ and the decision sample. Imagine the subjective value for $40 \%$. When decision samples are $10 \%, 20 \%, 30 \%, 30 \%$, and $50 \%$, the subjective value is $\mathrm{r}=(5-1) /(6-1)=0.8$. In contrast, in decision samples of $20 \%, 30 \%, 70 \%, 80 \%$, and $90 \%$, the subjective value is $r=(3-1) /(6-1)=0.4$. That is, even when the target has the same attribute value, the subjective value varies depending on decision samples. Previous studies have shown that decision samples affect an evaluation of the target value and the evaluation for the same target varies depending on the samples (e.g., Stewart, Chater, Stott \& Reimers, 2003; Stewart, Reimers, \& Harris, 2014).

In the present study, we propose a decision model, Decision by Belief Sampling (DbBS), based on the DbS model. Figure 1 summarizes DbBS. Here, we introduce
basic two assumptions: Firstly, the decision maker (DM) refers to memory samples in making decisions, and these samples represent the DM's probabilistic belief of event occurrence. For example, imagine the probable success rates of medical procedures for both a serious disease and appendicitis, respectively. Generally, people believe that the probability of success in treating a serious disease is low compared to the probable success of treating appendicitis (Honda \& Matsuka, 2014). We assume that the DM refers to memory samples according to her/his probabilistic belief. We represent these beliefs using beta distributions. Figure 1 (A) shows four examples of a DM's subjective beliefs regarding uncertain events. We can discuss the features of probabilistic belief based on its statistical characteristics such as mean, entropy (i.e., uncertainties about successes or failures), and skewness of beta distributions (see Figure 1 (B), (C), and (D)). Example 1 represents the belief such that an event will occur or not with high uncertainty and without skewness. Likewise, in Examples 2 and 4, the DM has the belief such that the event will happen with low or high probability with relatively low uncertainty and positive or negative skewness. Example 3 represents the belief that an event has around $50 \%$ of occurrence with low uncertainty and without skewness. Thus, beta distributions can represent extensive kinds of beliefs about uncertain events. Secondly, we assume that a subjective value for a target is constructed by the comparison between the target value and memory samples. Figure 1 (E) shows subjective values calculated by the DbBS model (i.e., equation (1)). Given that beta distributions represent beliefs about uncertain events, subjective values correspond to values in the cumulative distribution functions (CDF) of beta distributions. As is apparent, depending on the beliefs, the subjective values differ even for the same target probability. One of the most notable features in the DbS (or DbBS ) model is that subjective values are highly affected by the skewness of distributions in decision (or memory) samples (Brown \& Matthews, 2011). Therefore, subjective values highly differ between beliefs with high probability and those with low probability (see Examples 2 and 4 in Figure 1).

We believe that the DbBS model can clarify the following points regarding decisions based on verbal probabilities. First, the DbBS model can clarify the implicit assumptions (i.e., beliefs about uncertain events) people have in making decisions. Although Honda and Yamagishi (2017) showed that listeners have different assumptions depending on the directionality of verbal probabilities, it remains an empirical question whether people have such assumptions in making decisions. Using the DbBS model, we can examine this question. Second, the DbBS model will provide a new perspective on phenomena regarding decisions based on verbal probabilities. For example, we can discuss whether the influence of directionality on decisions reflects decision bias.

According to previous findings (Honda \& Yamagishi, 2017) and the assumptions of the DbBS model, our hypothesis is as follows: DMs refer to different memory
samples depending on the directionality of verbal probabilities because the selected directionality become relevant information to DMs. In particular, DMs refer to memory samples with lower probability when presented with positive phrases than when presented with negative phrases. As a result, decision patterns differ between positive and negative phrases. For example, even when DMs think that a probability of an uncertain event is $30 \%$ when presented with a verbal probability, the subjective value for the probability will be higher when presented with a positive phrase than a negative phrase, because DMs have lower memory samples (see Examples 2 and 4 in Figure 1 (A) and (E)).

## Behavioral experiment

In order to examine the above hypothesis, we conducted behavioral experiments about decisions based on verbal probabilities.

## Method

Participants Japanese undergraduates $(\mathrm{N}=60)$ participated as part of their course work.
Tasks, materials, and procedure We conducted two tasks: a decision task and a task measuring the membership function for verbal probabilities. The decision task was based on the Marianne study (Study 1) in Teigen and Brun (1999). The cover story was as follows:

Your friend has periodically been suffering

Table 1. Verbal probabilities used in the experiment.

| Verbal probabilities | $\mathrm{M}_{\text {peak }}$ | $\mathrm{SD}_{\text {peak }}$ |
| :--- | :--- | :--- |
| positive phrases |  |  |
| It is almost certain that * | 0.957 | 0.037 |
| There is a good chance that * | 0.779 | 0.126 |
| It is possible that * | 0.418 | 0.167 |
| It is likely that * | 0.540 | 0.164 |
| There is a small possibility that * | 0.346 | 0.129 |
| There is some possibility that * | 0.232 | 0.116 |
| There is a slight hope that * | 0.121 | 0.115 |
| There is a tiny hope that * | 0.074 | 0.097 |
| negative phrases |  |  |
| There are minor concerns that * | 0.602 | 0.167 |
| It is quite doubtful that * | 0.494 | 0.188 |
| It is not certain that * | 0.532 | 0.165 |
| It is uncertain whether * | 0.466 | 0.178 |
| It is quite unlikely that * | 0.433 | 0.141 |
| There is little hope that * | 0.177 | 0.088 |
| It is unlikely that * | 0.137 | 0.103 |
| It is almost impossible that * | 0.027 | 0.038 |

[^107]from migraine headaches, and is now considering a new method of treatment based on acupuncture. The treatment is rather costly and long-lasting. The friend asks if you think the friend should give it a try. Fortunately, you happen to know a physician with good knowledge of migraine treatment, whom you can ask for advice.
Participants were presented with a verbal probability by the physician (e.g., "It is likely that the treatment will be helpful in that case."). Considering this information, participants were asked to rate how much they would recommend that their friend try this treatment, using a scale that was labeled "do not recommend at all" on the far left and "recommend very much" on the far right. This rating scale contained 101 points $(0-100)^{2}$.

We also measured membership function of verbal probabilities based on Budescu, Karelitz, and Wallsten (2003). Participants were presented with a single verbal probability and 11 probability values ( $1 \%, 10 \%, 20 \%, \ldots$, $90 \%$, and $99 \%$ ) simultaneously and asked to rate the degree (i.e., membership value) to which the verbal probability describes each probability, using a scale that was labeled "not at all" on the far left and "absolutely" on the far right. Therefore, this task measures the degree of certainty attributed to a verbal probability. This rating was recorded with 101 points $(0-100)$.

For these two tasks, we used eight positive and eight negative phrases based on Honda and Yamagishi (2017). Table 1 shows the sixteen phrases used in the experiment.

We conducted the two tasks individually using a computer. In both tasks, a single phrase was randomly presented and participants answered the question. In the decision task, participants answered the question for each phrase once. When measuring membership function, participants answered the question for each phrase twice.

## Results and discussion

Numerical representation of verbal probabilities According to Wallsten, Budescu, Rapoport, Zwick, and Forsyth (1986), we assumed that the degree of certainty attributed to a verbal probability could be represented with a membership function. Peak (the probability with the highest membership value) is one of the most discriminative features of membership functions (Budescu et al., 2003). Accordingly, we assumed that the peak of the membership function represented the degree of certainty for a verbal probability felt by a participant. Since participants rated membership values twice for each phrase, the mean of the membership values was regarded as the membership value for the phrase. Table 1 shows means and SDs of peaks for 16 phrases.
Decision ratings for aggregated data First, we examined the aggregated data. Figure 2 shows the relationship

[^108]between the mean degrees of certainty for phrases (peaks of the membership function) and decision ratings for 8 positive and 8 negative phrases. As is apparent, even though positive and negative phrases were perceived to be analogous in the degree of certainty, decision ratings differed such that participants tended to answer with higher ratings for positive phrases. Therefore, the findings of Teigen and Brun (1999) were essentially replicated in the present study.

Model-based analyses for individual data Next, we analyzed the individual data using the DbBS model. In our DbBS model, we assumed that subjective value of certainty conveyed by a phrase corresponds to the CDF in the beta distribution. Therefore, we estimated two parameters ( $\alpha$ and $\beta$ ) of the beta distribution whose CDF best explains the decision ratings. The two parameters were estimated by a grid search in the range of 0.1 and 10 , with increments of 0.1 . That is, we estimated the parameter using 10000 sets. The parameter set with which the model showed the highest $r^{2}$ between model predictions and decision data was regarded as the best model. We searched the best parameter sets for positive and negative phrases, respectively, for each participant.

We found that the DbBS model generally explained the observed decisions well. The medians of $\mathrm{r}^{2} \mathrm{~s}$ between model predictions and observed data for 60 participants were 0.77 and 0.66 for positive and negative phrases, respectively. In the following analyses, when the model fittings in both positive and negative phrases for a participant showed more than 0.3 in r $^{2}$, we used her/his data. With this criterion, we used data from 45 out of 60 participants ( $75.0 \%$ ). Figure 3 shows five examples of decision ratings and model fittings for positive and negative phrases.

Figure 2. Relationship between subjective degree of certainty for phrases (peak of the membership function) and decision rating.

A

Figure 3. Examples of observed decision rating (points) and model fitting (line) for five participants. (A) shows data for positive phrases. (B) shows data for negative phrases.

Figure 4. Summaries of model-based analyses. (A) Scree plot for within-cluster sum of squares (WSS) in K-Means clustering. (B) Three clusters on decision sample. The black line denotes mean of cluster. The grey line denotes individual data. (C), (D), and (E) show distributions of statistics (mean, entropy, and skewness) in each cluster. (F) Proportions of data in positive and negative phrases that were categorized into each cluster.

Next, we examined participants' memory samples in detail with the following procedures. First, we clustered shapes of beta distributions using probability densities. In particular, patterns of probability densities ${ }^{3}$ for 45 (number

[^109]of participants) $* 2$ (positive and negative phrases) $=90$ data sets were clustered using the K-Means method. We used scree plots for the within-cluster sum of squares (WSS) for each cluster in order to determine the number of clusters (see Figure 4(A)). We adopted three clusters for the following two reasons. Firstly, the reduction of WSS was relatively sharp with up to three clusters. Secondly, since
there were at least 13 data for every cluster, we can assume that each cluster does not necessarily represent rare memory samples.

Figure 4 (B) shows three clusters of memory samples. The black line denotes mean of cluster, and the grey line denotes individual data. Using individual data, we calculated the mean, entropy, and skewness. Figure 5 (C), (D), and (E) show distributions of these statistics in each cluster. Figure $4(\mathrm{~F})$ shows the proportions of data that were categorized into one of the three clusters by positive or negative phrase. The decision patterns were explained with the different assumption between positive and negative phrases. When presented with positive phrases, decision patterns were well explained with the assumption that participants referred to memory samples with low probability (see cluster 1 in Figure 4). In contrast, for the negative phrases, decision patterns were explained under the assumption that participants referred to samples with high probability (see clusters 2 and 3 in Figure 4).

Taken together, we found that the DbBS model generally explained decisions based on verbal probabilities. It was also found that decision patterns were well explained under the different assumptions between positive and negative phrases. For positive (negative) phrases, decision patterns were well explained under the assumption that participants referred to memory samples with low (high) probability. Therefore, our hypothesis was corroborated.

## General discussion

In the present study, we examined decisions based on verbal probabilities. Particularly, we examined whether the DbBS model explained the decision processes. We found that the DbBS model explained the decision patterns well.

Observed differences in memory samples were essentially in accord with our hypotheses based on previous findings about the speaker's choice of directionality in communication (Honda \& Yamagishi, 2017). As previously noted, decisions affected by directionality seem like evidence of decision bias because people make different decisions even when positive and negative phrases convey analogous probabilities. Our present findings answer the question, "Why are people affected by directionality when making decisions?" Our answer is: people take into account the information conveyed by the selected directionality, and as a result refer to different memory samples. Therefore, decisions affected by directionality are not examples of decision bias, but decisions according to different memory samples.

# Semantic diversity, frequency and learning to read: A mini-mega study with children 

Yaling Hsiao<br>University of Oxford

Kate Nation

University of Oxford

#### Abstract

Children who read more tend to be better readers than children who read less. Reading exposure captures not only the number of times words are experienced but also the breadth of the contexts words appear in. Using a large children's corpus of written language, we quantified the former as word frequency and the latter as Semantic Diversity (SemD) (Hoffman et al., 2013). SemD was indexed using Latent Semantic Analysis to calculate the degree of semantic dissimilarity between the contexts in which each appeared. We selected 300 words that varied in SemD for a visual lexical decision and naming task with 9 -year-old children ( $\mathrm{N}=114$ ). Results showed that both frequency and SemD were associated with performance, independently accounting for variation in speed and accuracy. Those words high in frequency and high in SemD were read more efficiently. These findings show that factors beyond frequency are important in determining children's word reading.

#### Abstract

Attempts to connect individual differences in statistical learning with broader aspects of cognition have received considerable attention, but have yielded mixed results. A possible explanation is that statistical learning is typically tested using the two-alternative forced choice (2AFC) task. As a meta-cognitive task relying on explicit familiarity judgments, 2AFC may not accurately capture implicitly formed statistical computations. In this paper, we adapt the classic serial-recall memory paradigm to implicitly test statistical learning in a statistically-induced chunking recall (SICR) task. We hypothesized that artificial language exposure would lead subjects to chunk recurring statistical patterns, facilitating recall of words from the input. Experiment 1 demonstrates that SICR offers more finegrained insights into individual differences in statistical learning than 2AFC. Experiment 2 shows that SICR has higher test-retest reliability than that reported for 2AFC. Thus, SICR offers a more sensitive measure of individual differences, suggesting that basic chunking abilities may explain statistical learning.

Keywords: statistical learning; chunking; language; language acquisition; implicit learning; learning; memory, serial recall; individual differences

## Introduction

Statistical learning is understood as the process by which individuals implicitly track the distributional regularities in an input, leveraging recurring statistical patterns to facilitate cognitive processing (see Frost, Armstrong, Siegelman \& Christiansen, 2015, for a review). In recent years, validating the theoretical link between the behavior observed in labbased studies of statistical learning and broader aspects of cognition-such as working memory, language processing, and social learning-has garnered extensive interest. However, Romberg and Saffran (2010) noted that although typical tests of statistical learning demonstrate that individuals appear sensitive to statistical structure, such evidence on its own provides little insight into the process of learning, and the nature of the representations that
consequently arise. The lack of a mechanistic understanding of statistical learning was further suggested to complicate attempts to tie this ability to other aspects of cognition, such as language acquisition.

Indeed, endeavors to relate individual variation in statistical learning to other facets of cognitive processing have yielded mixed results. For example, whereas some findings report that statistical learning abilities significantly correlate with verbal working memory and language comprehension (Misyak \& Christiansen, 2012), others find no reliable relationship with language skills (Siegelman \& Frost, 2015). These conflicting reports could suggest either that statistical learning is not meaningfully related to other aspects of cognition, or alternatively, that the measures used to assess statistical learning may not capture its full extent nor the scope of individual variation in this behavior.

In many studies, statistical learning is typically tested using a two-alternative forced-choice task (2AFC), in which learners are presented with pairs of stimuli and are asked to identify which of the two items were present during familiarization. As such, a possible limitation of the 2AFC task is that it is inherently meta-cognitive in nature, requiring the participant to make an explicit response (a button press) based on a "gut feeling" about implicitly acquired statistical regularities. Thus, as suggested by Franco, Eberlen, Destrebecqz, Cleeremans and Bertels. (2015), 2AFC may therefore more accurately reflect explicit decision-making processes rather than the actual underlying statistical learning mechanisms. Relatedly, although the 2AFC task is assumed to serve as an accurate proxy for the learning of statistical structure, the strategy for successful performance on this task may differ from that required for successfully detecting statistical regularities in the input stream (Siegelman, Bogaerts, Christiansen \& Frost, 2017). Lastly, even though 2AFC may yield useful mean estimates of performance at the group level, the additional cognitive complexity associated with 2AFC performance is likely to introduce error variance such that individual scores may not optimally reflect individual differences in statistical learning ability (Siegelman \& Frost, 2015).

Because of these limitations, a unified theoretical framework that situates statistical learning within broader cognitive processing has thus far remained out of reach. In the current paper, we propose a new measure that implicitly tests statistical learning. Our novel task aims to offer more direct insights into what is being learned in statistical learning-based experiments, while at the same time aligning such learning with the wider learning and memory literature.

Recent theoretical considerations suggest that basic abilities for chunking may subserve many aspects of learning and memory, particularly within the domain of language processing (Christiansen \& Chater, 2016). Our perspective builds on classic memory studies demonstrating that the number of items that can be held in memory significantly increases when successfully chunked into larger units (Miller, 1956; Cowan, 2001). This underscores the potential contribution of chunking processes to the successful learning and retention of new material. For example, when tasked with remembering the novel sequence of letters ailcpaphrtleca, preserving the letters in memory poses a considerably greater challenge than successfully recalling the same set of letters chunked into larger coherent units, such as in the sequence catapplechair. Due to our extensive experience with language, the same set of letters can be more easily retained by exploiting our ability to chunk them into words (i.e. "cat", "apple", and "chair"), which in turn can subsequently be deconstructed to retrieve the individual letters. Our novel task takes advantage of similar chunking processes.

Here, we leverage the general capacity for chunking in a statistically-induced chunking recall task (SICR) as a novel implicit measure of statistical learning. We refashion a central tool in the chunking and memory literature-serial recall (e.g., Miller, 1956)—for use in statistical learningbased tasks. Subjects are exposed to six trisyllabic nonsense words using the classic Saffran, Newport and Aslin (1996) paradigm. After training, participants are aurally presented with syllables from the input and asked to recall them out loud. Critically, the experimental items in our task consisted of the concatenation of two words from the input language (Word A + Word B), and control items consisted of the exact same six syllables in a random configuration, like in the example above. Our hypothesis is that if subjects have statistically chunked the syllables in the input stream into words, then recalling a string consisting of two words should yield more accurate recall of the presented syllables than recalling the same set of syllables in a random order. Crucially, our task is scored on a syllable-by-syllable basis rather than assigning a binary 0 or 1 score as in the 2 AFC task, enabling the calculation of subjects' sensitivity to trigrams and serial position. This yields a richer set of performance data than the 2 AFC task, thus providing a more detailed picture of each subject's individual sensitivity to different kinds of information in the input.

In the current paper, we conducted two experiments to determine the efficacy of SICR in capturing statistical learning behavior, and the formation of the word-level
representations from accrued statistics. In Experiment 1, we compare 2AFC performance to SICR, showing that the latter provides a useful, memory-based measure of implicit statistical learning. To be able to relate statistical learning to specific aspects of language and cognition through individual differences studies requires a performance measure that is stable across time. Because recent research has cast doubts on the reliability of the 2AFC task in the context of the classic Saffran-style paradigm (Siegelman, Bogaerts \& Frost, 2016), we conducted a test-retest study of our SICR task in Experiment 2. We conclude with a discussion of the methodological and theoretical implications of SICR, and how future use of this task may help in establishing a definitive relationship between statistical learning and cognition more broadly.

## Experiment 1: Comparing statistically-induced chunking recall (SICR) with 2AFC

Experiment 1 investigated whether chunking might account for the word-level representations gleaned in statistical learning experiments using the classic Saffran et al. (1996) paradigm. In addition to these theoretical considerations, we also sought to assess the methodological efficacy and sensitivity of both the established 2AFC task, and our novel SICR task in assessing statistical learning. Through exposure to the input, we predict that syllables that regularly co-occur in the input will be chunked into words, which should yield higher recall accuracy of the chunked words than the same syllables heard in a random order.

## Method

Participants 69 native English-speaking undergraduates from Cornell University ( 34 females; age: $M=19.78$, $S D=1.62$ ) participated for course credit.

Materials The input language consisted of 18 syllables (bi, bu, di, du, ga, ka, ki, la, lo, lu, ma, mo, pa, po, ri, ta, ti, to), combined into six trisyllabic words: kibudu, latibi, lomari, modipa, tagalu, topoka. Seventy-two randomized blocks of the six words were concatenated into a continuous speech stream using the MBROLA speech synthesizing software (Dutoit et al., 1996). Each syllable was approximately 200 milliseconds long, separated by 75 milliseconds of silence.

For the 2AFC task, six additional foil words were pseudorandomly generated, avoiding the reuse of transitional probabilities from the target words above: dikabi, kigala, lopadu, mamoti, polubu, tatori.

The stimuli for the SICR task consisted of 24 six-syllable items. The twelve experimental items were composed of two adjacent words from the input (e.g., kibudulatibi), and the twelve corresponding foil items consisted of the same set of syllables in pseudorandom order (e.g., kibudulatibi $\rightarrow$ tidubibulaki), avoiding preexisting transitional probabilities from all other syllable combinations in the experiment. Additionally, 125 -syllable practice items were included, which were constructed in the same manner as the 24 items
reported above, but using one full word and the first bigram of a second word.

Procedure The experiment consisted of three distinct tasks. First, subjects were familiarized with the artificial language. To ensure active engagement, a cover task based on Arciuli \& Simpson (2012) was administered. In addition to each of the six words in the experiment, three variants of each word containing a syllable repetition was included in the training stream (e.g., tagalu $\rightarrow$ tatagalu, tagagalu, tagalulu). Participants were instructed to click the space bar when they noticed a repeated syllable. Each of the three variants of the words appeared 4 times, yielding 72 repetitions. In total, training lasted 11 minutes.

After training, participants' knowledge of the artificial language was tested using both the standard 2AFC task, and our SICR paradigm. The order of these two tasks was counterbalanced such that half of the subjects were given 2AFC first, and half were given SICR first. In the 2AFC task, each of the 6 target words were aurally presented with one of the 62 AFC foil words, and subjects were asked to report which of the two trigrams had been present during training. There were 36 2AFC trials in all, in which each target word appeared alongside each foil once.

In the SICR paradigm, 12 five-syllable practice trials were administered prior to the 24 six-syllable items to familiarize subjects with the task, and to ensure that the amount of post-test exposure to the words would be the same regardless of whether subjects did 2AFC first, or SICR first. In this task, participants were told that we would be gauging their ability to recall the syllables from the experiment. Each item was aurally presented, after which subjects were prompted to recite back each syllable in the sequence to the best of their ability. Importantly, at no point in the experiment were subjects informed that they were partaking in a language experiment, nor was their attention directed to the presence of structure.

## Results and Discussion

The mean accuracy of correctly choosing the word over the foil in the 2AFC task was $66 \%(M=.66, S D=0.13)$, which is significantly greater than chance, $t(68)=11.11, p<.001$. These results are comparable with other studies that utilize 2AFC to assess statistical learning, which typically report performance within the range of $60 \%$ (Frost et al., 2015).

Scoring for the SICR task was done on a syllable-bysyllable basis, enabling analysis of both the overall strings, and the individual words composing the strings. When comparing the number of syllables accurately recalled for the experimental items $(M=42.7, S D=10.68)$ to the number of syllables recalled for random items ( $M=31.19$, $S D=10.29$ ), participants accurately recalled significantly more syllables for the experimental items than the random items, $t(68)=13.85, p<.0001$. A similar pattern was observed for trigram performance: participants accurately recalled significantly more of the experimental trigrams ( $M=8.68$,

Figure 1: a) Average SICR performance. Participants recall significantly more syllables when the test items consist of two concatenated input words, and significantly more trigrams within the experimental six-syllable items. b) Serial position curves for experimental and random items.
$S D=4.25$ ) than items consisting of random trigrams ( $M=3.58, S D=3.02$ ), $t(68)=13.72, p<.0001$ (Figure 1a). Additionally, the serial position curves for the experimental and random items can be found in Figure 1b. These results confirm our hypothesis that through exposure to the distributional regularities in the input, individuals appear to have successfully chunked co-occurring syllables into larger units, and the formation of these word-level representations of the input leads to markedly better memory for experimental items.
Interestingly, our analyses revealed no significant correlations between 2AFC and any of our SICR measures $(r(67)=0.21, p=.084$ for experimental items, and $r(67)=0.18$, $p=.4$ for experimental trigrams. For the score distributions of the two tasks, see Figure 2). However, this finding mirrors recent results by Franco et al. (2015), who also found no correlation between 2AFC accuracy and their Rapid Serial Auditory Presentation task (RSAP), a detection task intended to serve as a more implicit measure of auditory statistical learning. Similar to SICR, RSAP works by exposing subjects to an artificial speech stream composed of trisyllabic words, after which subjects were tasked with detecting a target syllable embedded within strings of target words from the training corpus. Unlike explicit measures like 2AFC, RSAP and SICR are implicit measures in which no reference is made to a desired discrimination, and thus may be more sensitive to the acquired statistical regularities, including information about

Figure 2: The distributions of SICR (experimental-random items), 2AFC scores as compared to chance, and syllable recall for experimental items.
which the participant lacks awareness. Thus, 2AFC and SICR may be picking up on different aspects of statistical learning - decision-making processes based on learned information and underlying mechanisms, respectively which may contribute to the low correlation between the two measures.

Notably, our analyses revealed a strong order effect for 2AFC performance: individuals who performed SICR prior to 2 AFC exhibited significantly higher 2 AFC scores, $t(68)=$ $12.06, p<.0001$. Compared to the means of those who completed 2 AFC first, a $7 \%$-point increase in 2 AFC performance was observed for participants who did SICR first. This may account for why our participants on average performed higher on 2 AFC than the $60 \%$ typically reported for this type of statistical learning. By contrast, SICR was unaffected by the order in which it was performed $(t(68)=0.22, p=.59$ for experimental items, $t(68)=-0.22$, $p=.42$ for experimental trigrams). The robustness of SICR is notable given that in both conditions, the amount of postinput exposure was kept the same, ruling out exposure differences as an explanation for the order effects. That is, despite both tasks being granted the same opportunity for post-input learning, only 2 AFC was affected by the additional exposure.

Taken together, several conclusions can be made from the results of Experiment 1. Firstly, our findings support the idea that chunking may serve as the mechanism by which exposure to statistical regularities lead to representational changes in memory. Secondly, our results affirm that SICR can serve as a valid means of testing the acquisition of sequential regularities, with the additional benefit of offering more fine-grained insight into the acquired representations. Finally, the lack of correlation between 2 AFC and SICR may represent fundamental differences between explicit versus implicit measures of learning (Franco et al., 2015). Thirdly, the lack of order effects on SICR performance suggests that it may be a more stable measure of statistical learning ability than 2AFC. To further examine the stability of SICR across time, we assessed its test-retest reliability in Experiment 2.

## Experiment 2: Establishing the test-retest reliability of SICR

To date, varying levels of test-retest reliability for different measures of statistical learning have been found. For instance, using 2AFC as the primary measure, Siegelman and Frost (2015) reported adequate test-retest reliability for auditory verbal adjacent ( $r=0.63$ ), and visual nonverbal adjacent statistical learning ( $r=0.58$ ), and relatively low reliability for auditory nonverbal adjacent ( $r=0.23$ ) and auditory verbal non-adjacent statistical learning ( $r=0.31$ ). The implications of this are twofold: a) that certain types of statistical learning capacities are not stable within individuals and/or b) that certain tasks may lack specificity as to the behavior they aim to capture (Siegelman et al., 2017). Thus, the goals of Experiment 2 were to determine whether SICR provides a reliable measure of individual statistical learning capabilities, and to establish whether the associated hypothesis-that chunking abilities can account for statistical word learning-would replicate.

## Method

The same general method from Experiment 1 was employed, with a few notable exceptions. Subjects were exposed to the same input language, after which SICR was administered to measure word learning. Unlike the previous study, 2AFC was not included in Experiment 2, given existing studies assessing its test-retest reliability. Following the completion of Session 1, participants returned three weeks later and completed the same tasks again in Session 2, mirroring the timespan between test and retest in Siegelman and Frost (2015).

Participants 26 native English-speaking undergraduates from Cornell University (15 females; age: $M=19.31$, $S D=1.32$ ) participated for course credit.

Materials The same input language from Experiment 1 was used. The SICR stimuli consisted of the same 24 sixsyllable items from Experiment 1, half composed of two concatenated words from the input, and the other half their complementary randomized foils.

Procedure The experiment consisted of two tasks. First, subjects were familiarized with the input language, including the same cover task as before. In total, training lasted 11 minutes. The SICR task was identical to Experiment 1, with the exception that participants were given a different randomized input and SICR item order in each session.

## Results and Discussion

As in Experiment 1, participants performed significantly better on the experimental items than on the random items, both in Session 1, $t(25)=5.46, \mathrm{p}<.0001$, and in Session 2, $\mathrm{t}(25)=7.08, p<.0001$. The same results were found for

Table 1: Means and standard deviations of SICR scores

|  | Session 1 |  |  |  | Session 2 |  |
| :--- | :---: | :---: | :---: | :---: | :---: | :---: |
|  | M | SD |  | M | SD |  |
| 6-syllable <br> experimental | 36.42 | 12.48 |  | 40.15 | 12.73 |  |
| 6-syllable | 27.04 | 10.71 |  | 28.0 | 10.38 |  |
| random | 6.89 | 4.41 |  | 8.31 | 4.46 |  |
| Trigrams | 3.0 | 2.65 |  | 2.96 | 2.60 |  |
| experimental <br> Trigrams <br> random | 3.96 |  |  |  |  |  |

performance on the trigrams, with participants recalling significantly more experimental trigrams in both Session 1, $t(25)=6.18, p<.0001$, and in Session 2, $t(25)=7.67, p<.0001$. The mean performance on these measures can be found in Table 1. Thus, the results from both sessions replicated the results from Experiment 1.

Between the two sessions, the test-retest reliability of SICR proved to be very strong. SICR performance was highly correlated across the two sessions. Performance on the recall of six-syllable experimental items was $r(24)=0.81$, $p<.0001$ (Figure 2). This exceeds the correlation coefficient of 0.63 reported for 2 AFC in an auditory statistical learning task by Siegelman and Frost (2015). Recall performance on the six-syllable random items was also highly stable, $r(24)=0.85, p<.0001$. Performance on experimental trigrams $r(24)=0.73, p<.0001$ and random trigrams $r(24)=0.82$, $p<.0001$ was also consistent across the two sessions. However, the correlations of the differences scores (performance on experimental minus random items) were slightly lower, yielding $r(24)=0.46 p=.0192$ for six-syllable recall, and $r(24)=0.53 p=.0053$ for trigram recall. These results suggest that performance on the experimental items may be a better measure of individual differences in statistical learning than the difference scores.

In all, the results of Experiment 2 corroborate our findings from Experiment 1, in which experimental items yield significantly better recall. Our results also confirm the

Figure 3: Correlation between Sessions 1 and 2 recall scores for statistically experimental items.
stability of SICR. Taken together, these findings suggest that SICR proves to be both a theoretically valid and methodologically sound measure of statistical learning.

## General discussion

In this paper, we introduced a novel chunk-based method to implicitly test statistical learning-the SICR task-as an alternative to the standard 2AFC task. The results of our experiments demonstrate that through exposure, subjects' implicit chunking of the distributional regularities in the input significantly amplified their baseline working memory abilities (as captured by performance on the random items), and that the formation of multi-syllabic chunked representations of the input markedly boosted recall. Furthermore, these results appear to be strikingly stable over time and are less subject to order effects than 2AFC, which underscores the promise of SICR as a reliable and multifaceted measure of statistical learning faculties.

SICR offers several methodological benefits that circumvent a variety of issues inherent to 2AFC. Because 2AFC relies on overt decision-making processes about the familiarity of stimuli, it is unclear as to whether 2AFC may thus only be reflective of the more explicit meta-cognitive aspects of statistical learning. 2AFC appears to provide more limited sensitivity to individual differences, as it tends to rely on a binary all-or-nothing score. This lack of granularity in the scoring also makes it more difficult to accurately assess the precise extent of learning.

One important difference between explicit tasks like 2AFC and implicit tasks such as SICR is that they may be respectively characterized as 'direct' versus 'indirect' measures of learning (Franco et al, 2015). Whereas direct measures steer participants' attention toward the relevant discriminations they are expected to make, indirect measures that circumvent the need for explicit instruction may be more sensitive to any knowledge the subject has acquired, including material below the threshold of conscious awareness. That is, although direct and indirect measures should exhibit equal sensitivity to consciously known information, direct measures may not be as adept at capturing the accretion of information of which the learner is not yet fully aware. Furthermore, unlike 2AFC and reaction time tasks, SICR requires both immediate comprehension and production on the part of the learner. The task thus provides the means to capture how exposure to statistical regularities can facilitate memory abilities via improved chunking abilities, which in turn may help the learner to overcome the processing pressures deriving from the Now-or-Never bottleneck (Christiansen \& Chater, 2016). As such, SICR may be seen as an ecological measure of the impact of accrued statistics on the online memory processes used to track verbal input, without the need for participants to rely on explicit decision-making.

Whereas 2AFC relies on a binary scoring method, SICR offers a more granular approach by performing scoring on a syllable-by-syllable basis, allowing the evaluation of sensitivity to trigrams and serial position. The richness of
this dataset may also lend itself to acoustic measurements of production durations and analysis of prosody. Because of the sensitivity of SICR to a number of different individual capacities, and findings suggesting that chunking ability serves as a strong predictor of online language processing skills (McCauley \& Christiansen, 2015), SICR may also be employed compare how individual differences in statistical learning may predict other language learning abilities. Indeed, preliminary results from an ongoing study with 5-6-year-old children ( $N=73$ ) indicate that performance on the experimental items in the SICR task correlates significantly with language skill ( $r=0.41, p<.001$ ), whereas 2AFC performance does not ( $r=0.20, p=.096$ ).

More generally, the basic recall methodology upon which SICR piggy-backs has a long pedigree in the domaingeneral memory literature, including serial recall (e.g., Miller, 1956). Of particular importance is the related work on nonword repetition, which has been established as one of the primary predictors of language ability (e.g., Gathercole et al., 1994). Our SICR measure may be seen as a statistical learning-based variation on a nonword repetition task, in which we manipulate the distributional support for the items to be recalled via artificial language exposure. This interpretation of the SICR task dovetails with evidence that nonwords constructed from phoneme sequences that occur frequently in natural language are repeated more accurately than nonwords based on infrequent phoneme strings (Majerus, van der Linden, Mulder \& Peters, 2004). In a similar vein, recall of random digit sequences has also been shown to reflect natural language statistics (Jones \& Macken, 2015).

In addition to the methodological advantages afforded by this novel method, SICR also points toward a theoretical answer to Romberg and Saffran's (2010) concern about the lack of connection between measures of statistical learning and potential underlying processes and representation. Our proposition, given the efficacy of SICR in capturing statistical learning behavior, is that chunking may be seen as the process by which encountered statistics are used to form concrete, discrete units, thereby effectively segmenting a continuous stream into individual words. As such, the output of statistical learning may thus be seen as individual chunks of varying sizes. This notion is corroborated by previous research suggesting that chunking-based processes enable the recoding of incoming information into gradually higher levels of abstraction, from acoustic input, to words, to multiword units and beyond (Christiansen \& Chater, 2016). Thus, SICR provides both a compelling tool to effectively and ecologically appraise statistical learning, and strives to bridge the statistical learning and chunking memory literatures.

# Minimal covariation data support future one-shot inferences about unobservable properties of novel agents 

Julian Jara-Ettinger (julian.jara-ettinger@yale.edu) ${ }^{\mathbf{1}}$, Hyowon Gweon (hyo@stanford.edu) ${ }^{2}$,<br>${ }^{1}$ Department of Psychology, Yale University, New Haven, CT 06520<br>${ }^{2}$ Department of Psychology, Stanford University, Stanford CA, USA

#### Abstract

When we reason about others' behavior, there are often many equally-plausible explanations. If Bob climbs a tree to get an apple, we may be unsure if Bob found climbing difficult but really wanted an apple; if he found climbing easy and was not particularly excited about the apple; or if he found climbing intrinsically fun and just got the apple because it was convenient. Past research suggests that we solve this problem by obtaining repeated observations about the agent and about the world. Here we argue that, beyond allowing us to sharpen our inferences about agents and the world, covariation data also enables us to do one-shot inferences about novel agents. We show that given minimal covariation data, people can infer objective and subjective properties of a new agent from a single event. We show that a model that assumes that agents maximize utilities matches participant judgments with quantitative precision.

Keywords: theory of mind; social cognition; computational modeling

## Introduction

In our everyday social interactions, we easily learn aspects of people that are directly observable. We hear people's names, see what they look like, and recognize their jobs. But getting to know someone means much more: what they like, what they're good at, and even what they think of themselves. We invest much of our social interactions gathering observable evidence about these unobservable qualities of others, and even plan opportunities that serve specifically this purpose such as interviews with applicants or dates with potential partners.

A growing set of studies suggest that when we reason about others we assume that they act to maximize the rewards that they obtain relative to the costs that they incur (see Lucas et al. 2014 and Jara-Ettinger et al. 2016 for review). If, for instance, we watch an agent walk straight to a coffee shop, we can infer that getting coffee is rewarding (explaining why the agent went there) and that walking is costly (explaining why she took the shortest path). Despite its simplicity, this ability to reason about behavior in terms of costs and rewards, called a Nä̈ve Utility Calculus, supports rich explanations, enabling observers to distinguish between highly motivated agents (high rewards) and poorly motivated agents (low rewards), and supporting reasoning about agents who ignore goals because of a lack of competence (costs are too high) and because of a lack of motivation (rewards are not high enough).

Decomposing behavior into costs and rewards, however, means that action-understanding is usually confounded, even in the simplest scenarios. If, for example, an agent jumps over an obstacle to reach an object on the other side, her behavior
can be explained equally well by appealing to different combinations of costs and rewards. The agent may have found jumping very costly, but the outcome even more rewarding. Alternatively, she may have found jumping relatively easy, and the outcome not particularly rewarding. Or she may have even found jumping rewarding, and not cared about the object. To complicate matters further, agents not only incur costs and obtain rewards, but they also have beliefs about their own costs and rewards, and these beliefs guide their behavior. Imagine, for instance, watching a girl pull out a sword from a stone. While it is trivial to see that her goal was to get the sword (and that it was therefore rewarding), it is difficult to determine how much she wanted the sword (was the reward high or low?), how strong she is (is the cost low for her?), how difficult it is to pull the sword out (is the cost high in general?), or what she thought about her own strength before trying (what did she believe about her own costs?).

The problem of confounded explanations is most obvious when we only have access to a single event. But in more realistic situations, we often watch different people pursue the same goal, and we watch the same person pursue different goals (see, e.g., Figure 1). This covariation most directly allows us to learn about the agent we are observing (Kelley \& Michela, 1980). However, it may also enable us to make stronger inferences about new agents. Returning to the example above, what if you knew that several other people had already tried to pull the sword out and failed, and that the girl decided to try anyway? Even though the information about the girl is the same, you might be more confident about your inferences in this second case: the girl probably really wanted the sword (she probably believes that the cost is in general high), she thought she'd be strong enough to succeed (she believes that the cost may be lower for her specifically), and she was right (our observation of her success suggests the cost was indeed lower for her)!

Here we propose that minimal covariation data about the outcomes of agents' goal-directed actions, combined with our commonsense psychology, enable us to make richer inferences about novel agents. We show that even from a brief history of actions, people can make powerful joint inferences about a new agent's desire, competence, and even beliefs about their own competence, all from a single action. Below we briefly review research that motivates our proposal, we present our theory instantiated as a computational model in a Bayesian framework, and we then present two experiments that test our model predictions.

## Agent-dependent and agent-invariant dimensions of costs and rewards

Costs and rewards are partially objective and agent-invariant (e.g., a high hill is more costly to climb than a low hill, and three cookies are more rewarding than one), and partially subjective and agent-dependent (e.g., some are better than others at hill-climbing, and some like cookies more than others). Thus, to effectively explain an event, we not only need to infer the underlying costs and rewards, but we must also uncover what aspects of the costs and rewards are specific to the agent and what aspects of the costs and rewards are properties of the world and apply to all agents. Decomposing costs and rewards into agent-dependent and agent-independent dimensions not only helps us understand the event better. It also helps us understand new events more easily. If we know what costs and rewards are specific to an agent, then we can use this knowledge to explain the agent's behavior in new events (e.g. if learn that someone is strong, this helps us interpret their successes and failures in new events). If we know what aspects of costs and rewards are properties of the environment, then we can use this knowledge to make sense of new agents acting in this familiar situation (e.g. if we learn that a box is heavy, this helps us interpret the success or failure of new agents when trying to lift the box).

## One-shot learning from covariation information with a Naïve Utility Calculus

Based on these intuitions, we propose that people rely on covariation information to break down costs and rewards into their agent-dependent and agent-independent components, and that, with this decomposition at hand, people rely on their Naïve Utility Calculus to make rich inferences from single events. Returning to the example above, if we already understand that getting the sword is difficult to pull out because many have failed, then, if we a new agent succeed, we can be sure that it was not because the sword was easy to pull out, but because the person was strong; an inference that would have been impossible to make the first time we saw this. Similarly, if the successful agent had already watched others try and fail, we can assume that she also knew the sword as difficult to lift, and so she probably thought she has strong enough to succeed; otherwise, she would not have bothered trying. If she succeeds, then we can also be certain that she really was strong.

Recent work suggests that even infants can use covariation information to infer properties of the world and properties of agents. When one agent successfully activated a toy twice but the other failed twice (suggesting one is more competent than the other), infants attributed their own failure with the toy to their incompetence and sought help from others; conversely, when each agent succeeded twice and failed twice on the toy, infants attributed their failure to the toy, seeking a different one instead (Gweon \& Schulz, 2011). Furthermore, older children (4- and 6-year-olds) use covariation information between characters and activities to generate different
causal explanations for their behaviors (Seiver, Gopnik, \& Goodman, 2012). For instance, if Sally and Anne both tried activity A but not B, children were more likely to appeal to the properties of the activities to explain their actions (e.g., A is more fun than B); but when Sally tried both A and B but Anne tried neither, children appealed more to the characters' attributes (e.g., Sally is older). Furthermore, children generalized these explanations to predict whether the characters would try a new activity, or what another character would do on the same activities. These results suggest that humans, even early in life, are sensitive to the covariation information embedded in others' actions: they infer both the relevant properties of people and the physical world (e.g., toys, activities) and readily use it to explain their actions.

Similarly, children have a Naïve Utility Calculus by age five, with some form of it tracing back to infancy. Even infants have some expectation that agents navigate efficiently (Csibra, 2003) and that this expectation reflects some understanding of cost minimization (Liu \& Spelke, 2016). Also before their second birthday, children understand that both competence and rewards vary across agents (Repacholi \& Gopnik, 1997; Jara-Ettinger, Tenenbaum, \& Schulz, 2015). And by age five, children can explicitly explain behavior by inferring the unobservable costs or rewards, given partial information (Jara-Ettinger, Gweon, Schulz, \& Tenenbaum, 2016).

As reviewed above, the two main accounts that our proposal relies on -understanding covariation, and having a Naïve Utility Calculus- are both available early in life. Although our goal here is to explore this possibility with adults, the developmental research suggests that the abilities our account requires are likely central to social reasoning as they can be traced to our first years of life. The next section describes our computational model that formalizes these intuitions. We use the model to obtain quantitative predictions and compare them against empirical data across two experiments. In Experiment 1 we test if our account explains how we jointly infer properties about agents and the world using covariation information, and how this past information, in turn, supports one-shot learning of objective and subjective properties of novel agents. Because participants in Experiment 1 explicitly make judgments about the covariation in formation, in Experiment 2 we test if this step is critical for people to integrate this information when reasoning about new agents.

## Computational modeling

In order to test our predictions more formally, we implemented a computational model of our account and a simple alternative model that ignores the covariation data when inferring properties of the new agent. The principles of our model apply to any situation in which the outcome of events depend jointly on properties of agents and properties of the world; here, we describe it in the context of our experimental paradigm (see Procedure section in Experiment 1 and Figure 1), where agents with different levels of strength attempt to
lift boxes of different weighs in order to obtain rewards.

## Naive Utility Calculus model

Our implementation is a simplified variation of the Naïve Utility Calculus model (Jara-Ettinger, Schulz, \& Tenenbaum, 2015). Whereas the past models were designed to reason about agents navigating in two-dimensional environments, this model is adapted for reasoning about agents making choices without any spatial information (along the lines of (Lucas et al., 2014)). For a single event, the agent's strength and the box's weight are inferred using Bayesian inference:

$$
\begin{equation*}
p(W, S \mid O) \propto p(O \mid W, S) p(W) p(S) \tag{1}
\end{equation*}
$$

where $W$ is the weight of the box, $S$ is the strength of the actor, and $O$ is the observed outcome (success or failure). For simplicity, we use a deterministic likelihood function where agents can successfully lift a box only when their strength is higher than the box's weight. As such, we represent strength and weight using a common scale, using real values ranging from 0 to 1 .

By providing covariation information, where agents interact with different boxes, Equation 1 enables observers to break down events into agent-dependent (strenght) and agent-invariant (weight) components. With this information at hand, when we watch a single event from a new agent (henceforth the one-shot agent), we compute her preference by relying on the assumption that she is attempting to maximize her subjective utilities (see Introduction). An agent's expected utility for any given box is given by the reward associated with the box times the probability that the agent will be able to retrieve it. As such, an agent's choice reflects a trade-off between the magnitude of the reward, and the probability that the agent will be able to get it if she tried. Given a choice $C$, the posterior probability of the agent's underlying preferences is given by

$$
\begin{equation*}
p(P \mid C) \propto p(C \mid P) p(P) \tag{2}
\end{equation*}
$$

where $P$ represents the rewards associated with each option. For simplicity, we assume that the observer has a uniform prior over the agent's preferences $(\mathrm{p}(P))$, and we compute $p(C \mid P)$ by integrating the observer's prior belief over the actor's strength:

$$
\begin{equation*}
p(C \mid P)=\int_{S} p(C \mid P, S) p(S) \tag{3}
\end{equation*}
$$

where $S$ is the agent's strength, and $C$ is the agent's choice. This intermediate term, $p(C \mid P, S)$, integrates the assumption that the agent is attempting to make choices that maximize her utilities. Finally, the one-shot agent's objective strength is also computed using equation 1 .

## Alternative model

To test the role of the past covariation information in the final (one-shot) trial, we implemented a simple alternative model. In this baseline model we assume that participants ignore the
covariation information and make all judgments about the one-shot agent using that event alone. As such, this model is computationally equivalent to the main model, as it relies on Equations 1-3 to reason about the agent, but it does not use the covariation data to sharpen its estimates.

## Experiment 1

To test our hypothesis that people can use past observations of multiple agents to make one-shot inferences about a novel agent, we designed a behavioral experiment where participants received covariation data about three agents, each of whom attempted to lift four different boxes (see Figure 1). Next, participants watched a single agent choose one of the boxes and either succeed or fail to lift it. After this single event, participants were asked to infer three properties of the agent: her preference, her beliefs about her own strength, and her true strength.

## Methods

Participants 100 adults participants (mean age $=35.95$; range: 19-70) from the US (as determined by their IP address) were recruited using Amazon's Mechanical Turk framework. Participants were randomly assigned to one of 10 conditions (see Procedure).
Procedure Participants read a brief story that consisted of two parts. In the first part (Part 1 in Fig.1), participants learned about a game where, if players could successfully lift a box, they were allowed to keep its contents. Next, participants learned about three players (Circle, Rhombus, Triangle) who played with different boxes. There were five boxes, but the agents only had four coins and interacted with just the first four (Candy, Teddy Bear, Rubber Duck, and Baseball boxes); no one interacted with the fifth box (Yoyo box) and no mention was made about it other than stating that it was an option. For each action of each agent, participants learned whether the agent succeeded or failed; the first agent (Circle) sequentially tried the four boxes (in fixed order as shown in Figure 1), followed by the second (Rhombus), and then the third (Triangle). After each attempt, the cumulative outcomes were summarized visually as in Figure 1. After observing this covariation data, participants were asked to determine how heavy each box was and how strong each agent was. Both types of questions were answered on a numerical scale ranging from 0 to 9 . In the weight questions, 0 indicated very light, 5 indicated average, and 9 indicated very heavy. In the strength questions, 0 indicated very weak, 5 indicated average, and 9 indicated very strong.

In the second part of the task (Part 2), participants learned about a fourth agent (Square) who had also watched the other three agents. Participants learned that this final agent only had enough money to play the game just once. Participants were then shown which box (of the five) the agent selected, and whether she succeeded or failed in lifting it. Crossing agent's choice ( 5 boxes) and outcome (success or failure) produced 10 conditions, to which participants were randomly as-

Part 1

## Part 2

Figure 1: Visual summary of the experiment. Participants were introduced to four agents and five boxes. The first three agents (the square, rhombus, and triangle) interacted with the first four boxes (but not the fifth box). In Experiment 1, after observing these trials (and before seeing the final agent), participants were asked to rate the relative strength of these three agents, and the relative weight of the four boxes. In the second part of the experiment, the final agent (the square) chose one of the five boxes and either succeeded or failed to lift it (producing a total of 10 conditions that we tested across participants). Participants were then asked to determine this agent's preference, strength, and beliefs about her own strength when she made her choice.
signed (see Part 2 in Figure 1). Participants were then asked three questions in the following order. First, participants were asked to rate how much the agent wanted the object in the box using a scale from 0 ("not at all") to 9 ("very much"); Preference. Second, they were asked to rate the agents strength on a scale from 0 ("very weak") to 9 ("very strong"); True Strength. Third, participants were asked to rate the agent's beliefs about their own strength on a scale using an identical scale to the one used in the second question (Perceived Strength).

## Results

Participants' responses from the experiment were $z$-scored within response type (preference inferences, weight inferences, and strength inferences) and then averaged across participants.

First, we looked at people's use of covariation data by looking at their inferences about agents' strength and boxes' weights from Part 1. The model provided very high quantitative fits (Figure 2). On the joint inference over strength

Figure 2: Overall results from Experiment 1. The x-axis shows the model predictions and the $y$-axis shows participant judgments. The left plot shows inferences obtained from the covariation data (see Figure 1). The right plot shows inferences made from the one shot event.
and preference for the first set of agents (see Part 1 in Figure 1), the model showed a correlation of $\mathrm{r}=0.99$ with participant data ( $95 \%$ CI: 0.99-1.00).

Having verified that participants attended to the covariation data in Part 1 and accurately inferred the boxes' weight and the agents' strength, we then looked at whether participants made used this information when interpreting the event from the one-shot agent in Part 2.

Qualitatively, the results from the one-shot learning trial were as expected (see Figure 3). Participants judgments about the agents true strength varied both as a function of the box that she chose, and the outcome. Similarly, inferences about the agent's beliefs about her own strength also varied as a function of the box that she chose to lift.

On the joint inferences about the final agents preference, true strength, and perceived strength (Part 2), participant judgments showed a correlation of $\mathrm{r}=0.86$ with participant data ( $95 \%$ CI: 0.67-0.94).

By contrast, our alternative model, which used the same computations but did not learn from the covariation data, failed to predict the one-shot inferences participants made about the novel agent. Because the model ignores the covariation data, it does not make any predictions about the first set of agents; thus we only report the fit between the alternative model and people's responses in Part 2, about the target agent. The model showed a correlation of $\mathrm{r}=0.40(95 \% \mathrm{CI}$ : $-0.06,0.71$ ) against participant judgments.

## Experiment 2

Experiment 1 established that, when given covariation data, people can infer a novel agent's preference, strength, and perceived strength from a single event. In this experiment participants were explicitly asked to think about the covariation data and judge the strength of each agent and the weight of each box. It is possible that people do not naturally decompose preferences and competence into agent-dependent and agent-independent features, and this only happens when par-

Figure 3: Results from Part 2 of Experiment 1. The x-axis shows the box that the protagonist shows and the $y$-axis shows participant's ratings for the agent's perceived strength and the agent's true strength. Red bars show the conditions where the agent failed to lift the box, green bars show the conditions where the agent successfully lifted the box, and the grey bars show the agent's self-perceived strength. Judgments are zscored within participants and averaged and the vertical bars represent $95 \%$ confidence intervals. People inferred lower strength when the agent failed relative to when the agent succeeded, and these inferences depended on the box that the agent chose.
ticipant's attention is drawn to the information they can use. We test this possibility in Experiment 2. Experiment 2 was identical to Experiment 1 with the exception that participants were not asked about the covariation data and were just asked to rate the one-shot agents preference, true strength, and perceived strength.

## Methods

Participants 100 adult participants (mean age $=35.51$; range: 20-70) from the US (as determined by their IP address) were recruited using Amazons Mechanical Turk framework.

Procedure The procedure was identical to Experiment 1 with the exception that people were not asked to judge the weight of each box or the strength of any of the agents in the first part of the story (shown in Figure 1).

## Results

As in Experiment 1, results from the experiment were zscored within response type (preference inferences, weight inferences, and strength inferences) and then averaged across participants.

Figure 4 shows the results from the experiment. As in Experiment 1, the model fit participant judgments with high accuracy (Figure 4a). On the joint inferences about the oneshot agent's preference, true strength, and perceived strength, participant judgments showed a correlation of 0.88 with participant data ( $95 \%$ CI: 0.72-0.95). Consistent with this, participant responses in Experiment 2 resembled the responses

Figure 4: Results from Experiment 2. (a) Model predictions plotted against participant judgments. (b) Comparison of results from Experiment 1 and Experiment 2.
from Experiment 1. Figure $4 b$ shows the comparison between the results in Experiment 1 and the results in Experiment 2. The two sets of data showed a correlation of $\mathrm{r}=0.92$ ( $95 \% \mathrm{CI}$ : 0.80-0.97).

## General Discussion

Inferences about unobservable qualities of others from single observations are often ambiguous. Across two experiments, we showed that people can rely on past knowledge to make strong inferences about new agents from a single action. Consistent with previous research, Part 1 of Experiment 1 showed that people can decompose ambiguous events into properties of agents and properties of the world by relying on the covariation structure in the data (Kelley \& Michela, 1980; Gweon \& Schulz, 2011; Seiver et al., 2012). We also showed that these representations about the agents and the physical world support powerful one-shot inferences in future events. People accurately inferred an agent's preferences, their true strength (competence), and the agent's beliefs about her own strength, all from a single event. In Experiment 2, we replicated these results and showed that people spontaneously make use of covariation data in new events. Even when people were not asked to explicitly reason about the covariation in events, they made the same inferences about the novel agent as the participants in Experiment 1.

To test our proposal, we presented a computational model that jointly infers properties of agents through Bayesian inference over a model of utility maximization. This model enabled us to generate quantitative predictions and test participants' relative judgments holistically. Overall, we found that our formalization predicted participant judgments with high accuracy. In our experiment, inferences about the final agent were tested across participants. As such, each participant only watched a single event. Thus, the graded inferences about the properties of the novel agent (see Figure 3) are not judgments that are relative to each other, but rather absolute estimates relative to past experiences.

In our experiments we clarified that the one-shot agent the square (see Figure 1)- had seen all other agents. This assumption is critical for our model, as its inferences about the agent's mental states -her preference and her perceived
strength- rely on the assumption that the agent herself had some rational estimate of the weight of the boxes.

Intuitively, if the one-shot agent had not seen the covariation information (and was therefore ignorant about the possible weight of the boxes or the strength of the other agents), then her choice would not be as revealing with respect to the strenght of her preference or her beliefs about her own strength. Consistent with this intuition, our model predicts that if the agent did not see the other agents interact with the boxes, participants should continue to infer the agent's true strength as a function of the selected box and the outcome, but they should now infer the same preference independent of the agent's choice, and they should be unable to infer her beliefs about her own strength. Future work may explore this.

Here we focused on cases where participants bring their knowledge about the world (e.g., weight of boxes) to infer properties of a new agent. As discussed in the introduction, people may also bring knowledge about agents they know to infer new properties of the world. Imagine in our paradigm, for example, if people saw the covariation data in Part 1 first, and then in Part 2, one of the agents from Part 1 interacted with a new box. In this case, our account predicts that people should be able to infer the agent's belief about the weight of the box as well as the true weight of the box from that event. Our paradigm can be flexibly adapted to explore this possibility, and future work might test this prediction.

In our experiment, some participants observed the one-shot agent interact with a new box that no one had tried lifting before (the yoyo box). Participants' inferences suggest that they did not have any prior expectations about the weight of this box (see Figure 3). In our experiment, we were clear that all the covariation agents selected the boxes in a fixed order and they only had four coins, explaining why they never tried to lift the yoyo box. If the agents from the covariation stage had freely chosen which box to play with, then their choices would suggest that the yoyo box has a low reward, or that they thought it was too heavy. In future work we may integrate choice reasoning into the covariation stage to test if people can also integrate this information when reasoning about agents.

One open question is whether the type of account that we proposed here is specific to the social domain. Although our model relies on the assumption that agents maximize utilities, much of the model relies on general principles of Bayesian inferences and inductive generalization. The logic behind these inferences -finding the causes of confounded events, and then using this knowledge to infer hidden causes of new eventsis likely to be common in non-social tasks as well (Kemp \& Tenenbaum, 2009).

In sum, our current work provides a window into the richness and the complexity of how people reason about others. Developmental work on Theory of Mind (Wellman \& Cross, 2001), and even tests of Theory of Mind used with adults (Baron-Cohen, Wheelwright, Hill, Raste, \& Plumb, 2001), often rely on inferences about a single, isolated event. How-
ever, it is important to keep in mind that we are constantly observing others' actions and their outcomes in the physical world, and reason about other people who act on the same (or similar) physical world. Exploring the social-cognitive mechanisms that underlie our ability to learn from others to learn better about others is an exciting direction for future research.

# The Semantics and Pragmatics of Logical Connectives: Adults' and Children's Interpretations of And and Or in a Guessing Game 

Masoud Jasbi<br>masoudj@stanford.edu<br>Department of Linguistics<br>Stanford University

Michael C. Frank<br>mcfrank@stanford.edu<br>Department of Psychology<br>Stanford University

#### Abstract

The development of the ubiquitous logical connectives and and or provides a window into the role of semantics and pragmatics in children's linguistic development. Previous research has suggested that adults and children might differ in their interpretation of or in two ways. First, unlike adults, children might interpret or as logical conjunction, akin to and. Second, children might interpret or as inclusive disjunction while adults interpret it as exclusive. We report experimental studies that probe interpretations of and and or in adults and children using truth value judgements as well as children's spontaneous linguistic feedback. Both truth judgements and linguistic feedback showed that four-year-olds do not interpret or as and. While children's truth judgments suggested that they did not derive exclusivity implicatures, however, their corrective feedback showed signs of sensitivity to the implicature, suggesting that the truth value judgement task could have underestimated children's pragmatic competence. More generally, four-yearolds' interpretation of logical connectives may not be as different from adults as previously supposed.

Keywords: language development; semantics; pragmatics; logical connectives; disjunction; conjunction.

## Introduction

An airport sign reads "If you see something, say something." Taken literally, this is a trivial request, but readers infer an interpretation that goes far beyond the literal meanings of the words. How much of what we interpret is due to literal meaning (semantics) and how much due to our general-purpose inferential abilities (pragmatics)? In this paper, we address this question by investigating adults' and children's interpretation of the logical words and and or.

Despite their simple appearance, and and or have been a major source of insight into the contributions of semantics and pragmatics to language interpretation. The meaning of and has always been unambiguously associated with logical conjunction. For example, "There is a cat and a dog in the house." is true when the house has both a cat and a dog but false if only one or neither. The meaning of or, however, has two interpretations: inclusive disjunction and exclusive disjunction. The inclusive interpretation suggests the house has either a cat, a dog, or both. The exclusive one suggests only a cat or dog, not both. Until Grice (1975), it was generally assumed that or is ambiguous between these two meanings.

Grice (1975) argued against this ambiguity account. He maintained that the core meaning of or is inclusive disjunction but we often derive an exclusive interpretation (exclusivity implicature) by reasoning about what the speaker could have said. If the speaker meant to communicate that both a cat and a dog are in the house, s/he could have used the connective and. S/he chose or instead, so s/he did not mean
to communicate that both animals are in the house. In the Gricean account, the exclusivity implicature is not part of or's meaning, but rather the result of our reasoning on speaker's connective choice.

The advent of Gricean pragmatics shifted the focus of research in child language to the differences between adults and children in semantic vs. pragmatic aspects of interpretation. In a series of influential studies, Stephen Crain and colleagues argued that unlike adults who have an implicature-rich exclusive interpretation of or, children as young as three years old, interpret the meaning of or as inclusive disjunction (Chierchia, Crain, Guasti, Gualmini, \& Meroni, 2001; Crain, 2012). They argued that children develop the semantics of or before its pragmatics: they interpret or as inclusive disjunction but fail to enrich it with the exclusivity implicature the way adults do. Therefore, the main difference between children and adults is that children interpret or as inclusive, but adults interpret it as exclusive.

Recent investigations have added a new level of complexity to this line of research. Tieu et al. (2017) and Singh et al. (2016) argued that a large group of children in their studies (30-40\% of the participants) interpreted or as logical conjunction. In other words, these children did not differentiate between and and or. They argue that this conjunctive interpretation of $o r$ is due to non-adult-like pragmatic reasoning: children interpret $A$ or $B$ as $A$ or $B$ or both, but not only $A$, and not only $B$; therefore both $A$ and $B$.

The current paper seeks to fill two gaps in the current literature. First, previous research has focused on children's interpretation of and and or in complex sentences - for example with other logical words such as quantifiers every and none. In this paper we test children and adults' understanding of and and or in simple existential sentences like "There is a cat or a dog." Second, previous research has tested children and adults using the binary truth value judgment task (Crain \& Thornton, 1998). In such tasks participants are asked whether a puppet's statement is right or wrong. In this study, we allow participants to make use of three options: wrong, kinda right, and right. Katsos \& Bishop (2011) argued that ternary judgment tasks are better suited for assessing children's pragmatic competence.

This paper addresses two main questions. First, do children interpret or as logical conjunction (similar to and)? Second, do children understand or as inclusive disjunction, or exclusive disjunction? We conduct two experiments to answer these questions. Experiment 1 tests adults' interpreta-
tions and sets the benchmark for our child study. Experiment 2 investigates children's truth value judgments in a guessing game as well as their spontaneous linguistic feedback in the same task. Considering the first question, neither children's truth value judgement nor their linguistic feedback support the hypothesis that a large group of them interpret or as logical conjunction. For the second question, children's judgments suggest that unlike adults, they do not derive exclusivity implicatures and interpret or as inclusive disjunction. However, children's spontaneous linguistic feedback shows signs of sensitivity to the exclusivity implicature of or.

The next two sections present experiments 1 and 2 and the last section discusses the implications of these findings for theories of semantic and pragmatic development. For further details of the methods as well as the data and statistical analyses, please visit the paper's online repository ${ }^{1}$

## Experiment 1: Adults

## Methods

Participants We recruited 52 English speaking adults online using Amazon's Mechanical Turk (MTurk).

Materials and Design The experimental game included several cards with cartoon images of either one or two animals. The animals included a cat, a dog, and an elephant. Figure 1 shows two example cards. The game also used three types of guesses: simple (e.g. There is a cat), conjunctive (e.g. There is a cat and a dog), and disjunctive (e.g. There is a cat or a dog). Pairing the cards with the guesses resulted in 6 types of card-guess scenarios. Figure 1 shows examples for four critical scenarios. Overall, the animal labels used in the guess and the animal images on the card may have no overlap (e.g. Image: dog, Guess: There is a cat or an elephant), partial overlap (e.g. Image: Cat, Guess: There is a cat or an elephant), or total overlap (e.g. Image: cat and elephant, Guess: There is a cat or an elephant). Crossing the number of animals on the card, the type of guess, and the overlap between the guess and the card resulted in 12 different trial types.

Procedure The experiment had three phases: introduction, instruction, and test. In the introduction, participants saw six sample cards and read that they will play a guessing game with them. Then a blindfolded cartoon character named Bob appeared on the screen and they were told that in each round of the game, they will see a card and Bob is going to guess what animal is on it. We emphasized that Bob cannot see anything. We asked participants to judge whether Bob's guess is wrong, kinda right, or right. In the instruction phase, participants saw a card with the image of a dog and were told that Bob guessed There is a cat on the card. All participants (correctly) responded with wrong.

In the test phase, participants saw one trial per trial type for the total of 12 trials. Within each trial type, the specific card-guess scenario was chosen at random. The order of trial types was also randomized.

[^110]| Guess |  | One Animal (1T) | Two Animals (2T) |
| :---: | :---: | :---: | :---: |
| AND | There is a cat and a dog. | $8$ | $\begin{gathered} 50 \\ 50 \end{gathered}$ |
| OR | There is a cat or a dog. |  | \% |

Figure 1: Critical trials with example cards.

## Results

Here we focus on the results of the critical trial types, pictured in Figure 12 We identify these trials using two features: 1. the connective used for guessing (AND vs. OR) 2. the number of true conjuncts/disjuncts, which corresponds to the number of animals on the card. When only one animal is on the card, only 1 conjunct/disjunct is true (1T) and when two animals are on the card, both conjunct/disjuncts are true (2T).

Adult responses differed both by the connective used and the number of true conjuncts/disjuncts (Figure 2). First, the response pattern in AND trials is different from the one in OR trials. For AND, the responses were on the extremes of right and wrong while for OR, they were distributed on kinda right and right. This pattern suggests that adults interpret and and or differently. Second, the responses were different between the trials where one disjunct/conjunct was true (1T) and those where both disjuncts/conjuncts were true (2T). This difference was greater for conjunction than disjunction. Adults showed a small preference for the use of disjunction when only one disjunct was true. This pattern suggests a small preference for an exclusive interpretation of $o r$ in the guessing game.
Individual Responses In order to understand how participants interpret disjunction, Tieu et al. (2017) and Singh et al. (2016) categorized participants as a function of their responses to the disjunctive trials. Here we perform a similar analysis. In this study, none of the adults considered a disjunctive guess wrong when one or both of the animals were on the card. However, the participants' kinda right and right responses divided them into four categories.

The largest group of participants (23 out of 52) considered the disjunctive guess right when one animal was on the card

[^111]

Figure 2: Adult judgments in critical trials of Experiment 1. Error bars represent $95 \%$ confidence intervals.
(1T), but kinda right with both animals were present (2T). This pattern is consistent with an interpretation of "or" with an exclusivity implicature. The use of disjunction when both disjuncts are true is not wrong but it is nevertheless infelicitous and not completely right. For these participants, kinda right captures the violation of such a pragmatic expectation.

The other 29 participants divided almost equally into three groups. Ten participants rated disjunctive guesses as right in both scenarios where one or two animals were on the card. This pattern is consistent with an inclusive interpretation of or, in which adults do not derive an exclusivity implicature. It is also compatible with some adults being tolerant towards violations of the exclusivity implicature.

Nine other participants rated disjunctive guesses as only kinda right in both one-animal and two-animal trials. In other words, disjunctive guesses were dispreferred regardless of the outcome. This response pattern is consistent with the violation of another pragmatic expectation in the context of a guessing game: the guesser must choose the most specific guess possible. Under this expectation, guesses that cover several possible outcomes are punished. A disjunctive guess never picks a specific outcome and it is possible that for these participants, kinda right captures the violation of this specificity expectation.

Finally, nine participants ( $17 \%$ of participants) reported a disjunctive guess as right when both animals were on the card, but only kinda right when only one of the animals was on the card. In other words, these participants preferred the guess when both disjuncts where true rather than only one. It is possible to interpret such a response profile as some adults interpreting or as logical conjunction. However, it is also possible that these adults considered the goal of the game to be choosing the right animals and did not think the choice of the connective should matter for the purposes of the guessing

Figure 3: Children's judgments for critical trials in Experiment 2. Error bars represent 95\% confidence intervals.
game. In other words, they may have interpreted a right guess as one that picks the correct animals out of the possible set of animals in the game, regardless of the connective used.

The analysis of individual response profiles shows that there is a good deal of variability in the response profiles of adults. However, since we have not systematically manipulated the possible interpretations mentioned above and accounted for noise and chance variation, we remain cautious in our interpretation of participants' response profiles here.

## Discussion

In this study, we tested adult interpretations of the connective words and and or in the context of a guessing game. Adult participants interpreted these words differently and depending on how many disjuncts/conjuncts were satisfied. Overall, a guess with and was considered right if both conjuncts were true and wrong if only one was true. A guess with or was not wrong in either case, yet adults were more likely to consider it as right when only one of the disjuncts was true. Grouping individuals based on their response profiles, we found that some participants dispreferred disjunctive guesses whether one or both disjuncts were true, some considered them better when both disjuncts where true, and some others considered them right in either case.

The results are consistent with the dominant view on the division of labor between semantics and pragmatics in the interpretation of connective words. The semantics of and is captured by logical conjunction and or by inclusive disjunction. And is true when both conjuncts are true and false when only one is true. $O r$ is true in both cases but is not the best option as a connective when both disjuncts are true. In Experiment 2 we examine preschool children's interpretation of these connectives in the context of the same guessing game.

## Experiment 2: Children

## Methods

Participants We recruited 42 English speaking children from the Bing Nursery School at Stanford University. Children were between $3 ; 02$ and $5 ; 02$ years old (Mean $=4 ; 04$ ).

Materials and Design We used the same set of cards and linguistic stimuli as the ones in Experiment 1. The study used 8 trial types and 2 trials per trial type for a total of 16 trials. The trials were balanced to include the same number of one-animal and two-animal cards, the same number of simple and connective guesses, and the same number of expected true vs. false judgments. However, we made a few changes to make the design more suitable for children. Instead of Bob, a puppet named Jazzy played the game with the children. Jazzy wanted to guess what animals were on the cards without seeing them. So he had a sleeping mask on his eyes during the game. Children knew that Jazzy likes guessing but they did not know why Jazzy would choose to guess the way he does; namely, sometimes with simple sentences and sometimes with conjunctions or disjunctions. To introduce a three-valued reward scale similar to the verbal responses wrong, kinda right, and right, we placed a set of red circles, small blue stars, and big blue stars in front of the children. These tokens were used to reward the puppet after each guess.

Procedure The experiment was carried out in a quiet room and the sessions were videotaped. There was a small table and two chairs in the room. Children sat on one side of the table and the experimenter and the puppet on the other side facing the child. The groups of circles, small stars, and big stars were placed in front of the child from left to right. A deck of six cards was in front of the experimenter. Similar to the adult study, participants sat through three phases: introduction, instruction, and test.

The goal of the introduction phase was to show the animal cards to children and make sure they recognize the animals and know their names. The experimenter showed the cards to the children and asked them to label the animals. All children recognized the animals and could label them correctly. In the instruction phase, children went through three example trials. The experimenter explained that he is going to play with the puppet first so that the child can learn the game. He removed the six introduction cards and placed a deck of three cards face-down on the table. From top to bottom (first to last), the cards had the following images: a cat, an elephant, a cat and a dog. He put the sleeping mask on Jazzy's eyes and explained that Jazzy is going to guess what is on these cards. He then picked the first card and asked the puppet: "What do you think is on this card?" Jazzy replied with "There is a dog". The experimenter showed the cat-card to the child and explained that when Jazzy is not right he gets a circle. He then asked the child to give the puppet a circle. Rewards were collected by the experimenter and placed under the table to not distract the child. The second trial followed the same pattern except
that the puppet guessed right and the experimenter invited the child to give the puppet a big star. In the final trial, the puppet guessed that there is a cat on the card when the card had a cat and a dog on it. The experimenter said that the puppet was $a$ little right and asked the child to give him a little star.

In the test phase, the experimenter removed the three instruction cards and placed a deck of 16 randomized cards face-down on the table. In all trials of the study, the face of the card was shown to the child after the puppet's guess. The experimenter explained that it was the child's turn to play with the puppet.
Offline Coding of Linguistic Feedback We also coded children's spontaneous linguistic feedback to the puppet when they saw the card. There were four types of feedback: 1. None, 2. Judgments, 3. Descriptions, and 4. Corrections. None refers to cases where children did not provide any linguistic feedback. Judgments refers to linguistic feedback such as you are right!, yes, nope, you winned. Such feedback expresses whether the puppet was right or not. Descriptions were cases that the child simply mentioned what was on the card with no added lexical item or prosodic stress: cat!, dog and elephant!', There is a cat and a dog! etc. Finally, corrections referred to feedback that provided corrections to what the puppet had said using extra words or prosodic stress. Examples include: cat AND dog (with emphasis placed on and), Both!, The two are!, Just a cat!, Only cat.

## Results

Figure 3 shows the results for the critical conditions in Experiment 2. Comparing the AND and OR trials (Figure 3 rows), we see that children distinguish between and and or in cases where one animal is on the card but not when both are. Given that the one-animal conjunction trials (top left) and the one-animal disjunction trials (bottom left) differ in truth conditions, the difference in response patterns suggests that children at this age have a different semantic knowledge for and and or. The two-animal conjunction and two-animal disjunction trials (top right and bottom right) do not differ in truth values, and the responses also show no difference.

In the one-animal and two-animal trials, children show different response patterns when the guess contains the conjunction word and (top right vs. top left) but not when or is used (bottom right vs. bottom left). Since the truth values of oneanimal and two-animal trials differ for conjunctive guesses but not disjunctive ones, the results suggest that children have different semantic knowledge for and and or. The similarity of the disjunctive guesses in one-animal and two-animal trials (bottom right vs. bottom left) can be interpreted as a lack of exclusivity implicatures in children.
Statistical Modeling We used the R package $\{r \operatorname{stan}\}$ for Bayesian statistical modeling. We fit separate ordinal mixedeffects logistic models for children's and adults' judgments. The response variable had three ordered levels: wrong, kinda right, and right. The trial types One-Animals-OR, Two-

Figure 4: Coefficients capturing the relevant comparisons across conditions across the two experiments (see text). Error bars represent $99 \%$ regions of highest posterior density.

Animals-OR, One-Animal-AND constituted the (dummycoded) fixed effects of the model with Two-Animal-AND set as the intercept. The model also included by-subject random intercepts. The priors over trial types and the random intercepts were set to $\mathcal{N}\left((0,10)\right.$. We also included parameters $C_{1}$ and $C_{2}$, the two cutpoints delimiting the logistic for 1) wrong and kinda right and 2) kinda right and right responses, drawn with the prior $\mathcal{N}(0,1)]^{3}$ All four chains converged after 3000 samples (with a burn-in period of 1500 samples)

We make inferences based on the highest-posterior density (HPD) intervals for the coefficients estimated from each model. Because predictors are dummy-coded, we can examine contrasts of interest by computing the difference between coefficients for pairs of conditions we wish to contrast (Figure 4). Overall, adults' and children's estimated coefficients are similar in sign to one another, though adults are more extreme. The one notable exception to this pattern is for the contrast or, $1 T$ vs. $2 T$, which shows the comparison between the disjunctive trials: both disjuncts are true vs. only one disjunct is true. On average, children are more positive for disjunction on two-animal trials, while adults are more negative. These estimates reflect the exclusivity implicature that adults compute, leading them to judge two-animal trials as more kinda right.

Individual Responses Children showed a wide variety of response profiles for disjunction trials. This was partly because each child responded to two trials per trial type: two one-animal disjunction trials and two two-animal disjunction trials. The largest group ( 10 out of 42) responded with right to all four trials. Six children responded with right to all trials except one one-animal trial that they responded to with kinda right. Six other children responded with kinda right to both one-animal trials and right to both two-animal trials.

However, the main goal of analyzing the response profiles

[^112]was to find children that demonstrated conjunctive readings of or. In order to find such children, we adopted a (lenient) measure: any preference for or when both disjuncts were true was considered a conjunctive profile. More specifically, either the child responded with wrong when one disjunct was true but kinda right or right when both were true; or, the child responded with kinda right when one disjuncts was true but right when both were true. We found 10 children ( $24 \%$ of participants) that matched this profile. In Experiment 1 we found nine adults ( $17 \%$ of participants) who matched such a profile. Furthermore, as explained earlier, such a response profile is also compatible with a different construal of the guessing game in which the goal is to pick the right animals regardless of the logical connective. Therefore, we conclude that the analysis of participants' response profiles did not provide any evidence for the hypothesis that a large group of four-year-old children interpret or as logical conjunction.

Linguistic Feedback We next examined children's linguistic feedback to the puppet (Figure 5). In all critical trials, we found similar proportions of None responses: no comment on the puppet's guess and only rewarding the puppet. However, the proportions of other feedback categories differed between trial types. We performed chi-squared tests of homogeneity to compare the feedback distributions.

In the AND trials, a comparison of the feedback distribution in one-animal and two-animal conditions was statistically significant $(\chi(3,167)=35.99, p<.0001)$, indicating different feedback for true vs. false sentences. In the OR trials, we find a similar significant difference between oneanimal and two-animal trials, suggesting children's sensitivity to the exclusivity implicature of $\operatorname{or}(\chi(3,166)=11.11, \mathrm{p}=$ 0.01 ). In both cases, children's corrective feedback increases for false (AND - one animal) and infelicitous trials (OR - two animals). There was no significant difference between these false and infelicitous trials $(\chi(3,166)=3.19, \mathrm{p}=0.36)$.

The one-animal disjunctive trials (bottom left) showed the highest proportion of Descriptions. These are trials in which the guess is correct but not specific enough: it leaves two possibilities open. These trials were significantly different than the one-animal trials for conjunction $(\chi(3,166)=24.29$, $\mathrm{p}<.0001$ ). Finally, the two-animal conjunctive trials (top right) showed the highest proportion of Judgments such as you are right!. This is not surprising given that in these trials represent the most optimal guessing scenario. These trials had a significantly different feedback distribution from the matching disjunction trials $(\chi(3,167)=42.37, \mathrm{p}<.0001)$.

## Discussion

This study did not find evidence for the hypothesis that a large group of four-year-old children interpret the disjunction word or similar to its conjunctive counterpart and. To the contrary, both children's judgments and their linguistic feedback suggested that they differentiate these two connectives. Instead, children's judgments largely mirrored those of adults. We take this as a sign of children's adult-like semantics for

Figure 5: Children's Linguistic Feedback to Conjunction and Disjunction Trials. Error bars represent $95 \%$ confidence intervals.
and and or. Considering pragmatic inferences with or, children's truth value judgments did not differentiate between trials where one disjunct was true and those where both were true. However, their linguistic feedback to the puppet did differentiate these two trial types. Children provided more corrective feedback when both disjuncts were true, indicating sensitivity to the exclusivity implicature of or.

## General Discussion

We began with two questions. First, do adults/children differentiate or from and? Second, do adults/children interpret or as inclusive disjunction or exclusive disjunction? We presented two studies to address these questions.

For the first question, we reported truth value judgement results as well as results from children's linguistic feedback that suggested both adults and children differentiate or from and. Crucially, children showed different judgments for false vs. true guesses, suggesting that they understand the core semantics of these connectives.

For the second question, adult truth value judgments of or were split between an inclusive and an exclusive interpretation in the guessing game, with a slight advantage for the exclusive interpretation. Children's judgments suggested that they interpret or as inclusive disjunction and do not derive an exclusivity implicature. However, children's spontaneous linguistic feedback in the same task showed signs of sensitivity to the exclusivity implicature of or. In other words, when both disjuncts were true children considered the guess right but corrected the puppet with utterances such as cat AND dog, both!, the two are!.

Based on the truth value judgement results, it is possible to conclude that children, unlike adults, do not derive an exclusivity implicature for or. However, children's spontaneous
linguistic feedback raises another possibility: while the truth value judgement task reflected children's semantic knowledge well, it could have underestimated children's pragmatic competence. We would like to explore this possibility more systematically in a future study.

Overall, our results point to the importance of assessing the semantics and pragmatics that children assign to connectives across a wide variety of contexts and using different measures. Although individual experimental trial types can appear consistent with multiple interpretations, the profile of responses across trial types can be revealing of the underlying representations. More broadly, the investigation of how children acquire semantic representations for logical connectives - and in particular, how they infer an inclusive semantics for or - is an important puzzle for future investigations of early word learning.

## Acknowledgements

We would like to thank Eve V. Clark and Christopher Potts for their generous help and advice on this project. We would also like to thank the staff and children at Stanford's Bing Nursery School. This work was supported by NSF \#1456077 and the Stanford University fellowship to Masoud Jasbi.

# Maintaining Credibility When Communicating Uncertainty: The Role of Communication Format 

Sarah C. Jenkins (s.jenkins.12@ucl.ac.uk) and Adam J. L. Harris (adam.harris@ucl.ac.uk)<br>Department of Experimental Psychology, University College London, 26 Bedford Way, London, WC1H 0AP, UK<br>R.M. Lark (mlark@bgs.ac.uk)<br>British Geological Survey, Keyworth, Nottingham, NG12 5GG, UK

#### Abstract

Research into risk communication has commonly highlighted the disparity between the meaning intended by the communicator and what is understood by the recipient. Such miscommunications will have implications for perceived trust and expertise of the communicator, but it is not known whether this differs according to the communication format. We examined the effect of using verbal, numerical and mixed communication formats on perceptions of credibility and correctness, as well as whether they influenced a decision to evacuate, both before and after an 'erroneous' prediction (i.e. an 'unlikely' event occurs, or a 'likely' event does not occur). We observed no effect of communication format on any of the measures pre-outcome, but found the numerical format was perceived as less incorrect, as well as more credible than the other formats after an 'erroneous' prediction, but only when low probability expressions were used. Our findings suggest numbers should be used in consequential risk communications.

Keywords: verbal probability expressions; numerical probabilities; risk communication; trust; expertise; credibility

## Introduction

Science is suffering from a 'crisis of trust' (House of Lords, 2000); preserving and cultivating the public's trust has never been more important for the scientific community (Nature, 2010). Uncertainty is an inescapable part of any scientific endeavour, but the presence of it creates doubt in the minds of the public and it is often used as a reason to delay taking action (Lewandowsky, Ballard, \& Pancost, 2015). Effectively communicating information regarding risk and uncertainty thus represents a significant problem for scientists.

Methods for communicating risk and uncertainty include using verbal probability expressions (VPEs; e.g. 'possible', 'likely'), numerical expressions (e.g. '20\% likelihood'), or mixed expressions (e.g. 'unlikely [20\% likelihood]'). Budescu and Wallsten (1995) proposed that the choice of format for communicating likelihood information should be governed by the congruence principle: the precision of the communication should be consistent with the degree of certainty that can reasonably be expected for estimates about the event described. Much research has investigated the pitfalls of using VPEs to communicate uncertainty using the 'how likely' translation approach, whereby people are asked to translate a VPE to a corresponding numerical probability

This has highlighted the variability in people's usage and interpretations (e.g., Budescu \& Wallsten, 1985), as well as the influence of other contextual and cultural factors (e.g., Bonnefon \& Villejoubert, 2006; Harris \& Corner, 2011; Harris, Corner, Xu, \& Du, 2013; Teigen \& Brun, 1999, 2003; Weber \& Hilton, 1990). Such variability clearly highlights the potential for a reduction in perceived credibility of the communicator, if there is a disparity between the meaning intended by the communicator and that which is understood by the recipient.
A commonly suggested solution to the problems of miscommunication is to use a dual-scale, mixed format expression to communicate risk and uncertainty, for example 'It is unlikely (less than 33\%)' (e.g., Budescu, Broomell, \& Por, 2009; Budescu, Por, Broomell, \& Smithson, 2014; Harris \& Corner, 2011; Harris et al., 2013; Patt \& Dessai, 2005; Witteman \& Renooij, 2003). Using such a 'verbalnumerical' (V-N) format was found to increase correspondence between people's interpretations and the IPCC guidelines, an effect that replicated across 24 countries (Budescu et al., 2014). However, when shown a histogram of potential outcomes and asked to complete probability statements (e.g., "It is unlikely that the lava flow will extend to a distance of _km'), the so-called 'which outcome' approach to studying VPEs (e.g., Teigen, Juanchich, \& Riege, 2013), participants tended to complete the sentence with a distance that exceeded any represented in the histogram, both for 'unlikely' and 'unlikely ( $20 \%$ chance)' (Jenkins, Harris, \& Lark, 2016; see also Juanchich \& Sirota, 2016). If such phrases are seen as appropriate for communicating an outcome with a $0 \%$ chance of occurring, the mismatch between this and an intended communication of ' $20 \%$ likelihood' could adversely affect confidence in subsequent communications.

Aside from the terms used, a further problem arises from people's general understanding of uncertainty and probability. Uncertainty is often perceived by the public as an 'indicator of ignorance', when in fact it should be seen as a source of actionable knowledge (Lewandowsky et al., 2015). Scientific forecasts are probabilistic (at best) and thus it is, for example, not possible to predict with certainty the probability of a volcanic eruption on a given day. Even if an event is predicted to be 'likely' to occur, the very fact it is not certain means that it might still not happen. In the same vein, even if an event is predicted as 'unlikely' to occur (e.g. 20\% likelihood; Theil, 2002), it does not mean the event will
definitely not occur, given that one in five times it will (on a frequentist interpretation of probability). The expectation of what will happen is largely driven by the directionality of the expression (Teigen \& Brun, 1995, 1999); in that phrases which have negative directionality (e.g. 'unlikely') focus one's attention on the non-occurrence of the event, whereas those with positive directionality (e.g. 'likely') focus on the occurrence of the event. If the outcome is 'opposite' to what was predicted, the predictions are often seen as 'erroneous', which could have a knock-on effect on perceived credibility.

Despite recent calls to use a dual-scale communication format, research has yet to explore the effect of using mixed expressions on the perceived credibility of the communicator. Neither, perhaps more importantly, has it investigated the consequences of 'erroneous' predictions on credibility. Given a major function of risk communication is providing trustworthy information, confidence in the source of the information is key (Kasperson, 2014). After all, even if the information is understood as intended, it is of no use if the communicator is not perceived as credible and thus is not trusted enough to inspire action on the basis of the communication. Indeed, credibility has been found to influence risk perceptions. Trust is negatively associated with perceived risk (Sjöberg, 2001), as well as directly affecting behaviour (Wachinger, Renn, Begg, \& Kuhlicke, 2013).

Longman, Turner, King, \& McCaffery (2012) explored the effect of numerical formats on accuracy of understanding, perceived risk, and source credibility judgements for two different sources of risk information (clinician / pharmaceutical company). The risk estimate was presented either as a either a point ( 20 out of 100), small range ( $16-24$ out of 100) or large range ( $8-32$ out of 100). Range information resulted in reduced understanding and the large range was perceived as more risky compared to a point estimate. Experts using point estimates were viewed as more credible. Gurmankin, Baron and Armstrong (2004) investigated the effect of verbal and numerical statements of risk (percentage / fraction) on trust and comfort in a physician in a hypothetical medical communication. They found subjects were more trusting of, and more comfortable with, numerical versions of the information, though this effect decreased with lowering levels of numeracy, highlighting the importance of including a numeracy measure in the current study.

The importance of investigating the credibility of the communicator cannot be understated. Whilst an accurate understanding of information is clearly desirable, it is people's actions (on the basis of the communication) which matter, given they will have the most consequences for the individual. Therefore an investigation into the effects of communication format should also consider the effect of communication format on people's actions. Doyle, McClure, Paton, \& Johnston (2014) found that fewer people suggested evacuating when the risk of a volcanic eruption was described using verbal terms than when using numerically equivalent terms, suggested to be a result of the fact that VPEs are viewed as more ambiguous, though again the study did not
consider mixed-formats, or the influence of 'erroneous' predictions.

Although previous research has demonstrated the V-N format aids understanding in risk communications (Budescu et al., 2014), it may not be the preferred format for the recipient. Indeed, there may be a discrepancy between what people favour (for instance the preference for receiving information in numerical form, Erev \& Cohen, 1990) and what experts can suitably provide. Using a numerical point estimate (e.g. 15\%) to describe the chance of a natural hazard (which are, by nature, highly uncertain) might be perceived as overly precise according to the congruence principle (Budescu \& Wallsten, 1995) and thus not credible.

A deeper understanding of the effects of using different communication formats and the consequences of 'erroneous' predictions is therefore clearly required, such that the public's trust in science can be built and maintained. We thus sought to examine whether initial perceptions of credibility in the communicator differed according to communication format over two studies featuring low and high probability events. We also investigated whether these perceptions changed after an 'erroneous' prediction (i.e. the 'unlikely' outcome occurred, in Study 1, or the 'likely' outcome did not occur, in Study 2). Ascertaining the effect of these factors is instructive for developing effective risk communication strategies.

## Study 1

## Method

## Participants

300 Native English speakers ( 146 male) aged between 18 $72(M d n=33.5)$ were recruited from Prolific Academic (PA; www.prolific.ac). Participants received $£ 0.75$ for participating.

## Design

A $4 \times 2$ mixed design was used. Communication format was in the low probability domain and had four levels, manipulated between participants: verbal- "unlikely", numerical- " $20 \%$ likelihood", V-N- "unlikely ( $20 \%$ likelihood)" and N-V- " $20 \%$ likelihood (unlikely)." Outcome (pre/post) was a within-participants variable.

Perceptions of trust, expertise, correctness and decision to evacuate were rated on five-point scales. Expertise was operationalised as 'How knowledgeable does the expert seem?' from 1 - 'Not at all knowledgeable' to 5 - 'Extremely knowledgeable'. Trust was operationalised as 'How much do you trust that the expert is giving you complete and unbiased information?' (Dieckmann, Slovic, \& Peters, 2009), from 1 'Not at all' to 5 - 'A great deal'. Decision to evacuate, based on Doyle et al. (2014), was rated from 1- 'Definitely should evacuate today' to 5 - 'Definitely should not evacuate today'. Participants also then had to indicate why they made that decision. Correctness was rated from 1 - 'Not at all correct' to 5 - 'Completely correct'.

## Materials and Procedure

After consenting to participate, participants indicated their age, gender and Prolific ID before reading the introductory text. The introductory text informed participants that they would see a geological scenario and be asked to make a series of judgements about this. On the next screen, participants read a vignette about a current volcanic eruption, in which lava flows were expected. A volcanologist presented a communication about the probability of the lava flows travelling a certain distance:
"Mount Ablon has a history of explosive eruptions that
have produced lava flows. An eruption is currently
underway and lava flows are expected. Volcanologists
from Ablon Geological Centre are communicating
information about the volcano. A volcanologist has
suggested that, given the volcano's recent history, there
is a $\mathbf{2 0 \%}$ likelihood (unlikely) that the lava flow will
extend 3.5 km from the point of eruption."
Participants then provided initial ratings of expertise and trust in the expert's prediction of events. On the subsequent screen, participants were informed that the capital city was at risk of the volcanic eruption and asked to rate whether to evacuate the city today or not (Doyle et al., 2014). A mass evacuation was described as being 'very expensive and extremely disruptive to residents'.

Participants were then informed on the following screen that the unlikely outcome did in fact occur. They were asked to provide further trust and expertise ratings, as well as rating how correct the volcanologist's prediction was in light of the outcome. The next screen then showed a similar communication by a volcanologist about Mount Ablon, set two years on, with participants asked the two evacuation questions, as before.

Finally participants completed a numeracy scale (Lipkus, Samsa, \& Rimer, 2001), with two additional questions from the Berlin Numeracy Test (Cokely, Galesic, Schulz, Ghazal, \& Garcia-Retamero, 2012) included to increase variability in scores, given previous studies using PA have found it to be a highly numerate sample. After completing the study, participants were given a code to claim their reward, thanked and debriefed.

## Results

There was a significant correlation between trust and expertise ratings, both pre-outcome, $r=.69, p<.001$ and post-outcome, $r=.74, p<.001$. For ease of exposition, we averaged the measures to create a single measure of credibility. The data were entered into a 4 (communication format) $\times 2$ (outcome) $\times 2$ (numeracy) ANOVA, unless stated otherwise.

Given the highly skewed distribution of responses, participants with scores of eight or under were classed as low numeracy and those with nine or above classed as high numeracy. However, given there was only one effect of (or interaction involving) numeracy across Studies 1 and 2, this variable is only considered further in that single instance.

## Credibility Ratings

Mean credibility ratings, by communication format, are plotted in Figure 1, which suggests that pre-outcome there was little difference between formats. All communication formats suffered from a loss of perceived credibility postoutcome, but there was less of a reduction in the numerical format. Correspondingly, there was a main effect of outcome, $F(1,292)=218.60, p<.001, \eta_{p}^{2}=.43$, and format, $F(3,292)$ $=5.77, p<.01, \eta_{p}^{2}=.06$, but this was qualified by a significant interaction between outcome and format, $F(3,292)=6.87, p$ $<.001, \eta_{p}^{2}=.07$. Simple effects analyses confirmed no effect of format pre-outcome $F(3,296)=0.38, p=.77$, and a significant effect of format post-outcome $F(3,292)=8.02, p$ < .001. It is worth noting, however, that the reduction in credibility was still significant even in the numerical condition, $t(73)=3.66, p<.001, d=0.43$.

Figure 1. Effect of Communication Format on Perceptions of Credibility Before and After an 'Erroneous' Prediction (Error Bars Represent $\pm 1$ SE) - Study 1 - Low Probability.

## Decision to Evacuate

Mean evacuation ratings both pre- and post-outcome, by communication format, are displayed in Table 1, which shows a slight difference between communication formats prior to the outcome. Post-outcome, there was a shift to being more certain about evacuating today. There was a main effect of outcome, $F(1,292)=98.19, p<.001, \eta_{p}^{2}=.25$ and format, $F(3,292)=5.59, p<.01, \eta_{p}^{2}=.05$. Participants were more certain about evacuating today in the verbal condition and least certain decision in the N-V condition. There were no significant interactions (all ps > .12).

## Correctness Ratings

A one-way ANOVA revealed a significant effect of communication format on correctness ratings, $F(3,292)=$ 26.32, $p<.001, \eta_{p}^{2}=.22$, corresponding to the differences in the credibility ratings. From Table 1, the numerical format was seen as 'least incorrect' and the verbal format seen as most incorrect.

## Study 2

## Method

## Participants

299 Native English speakers were recruited from Amazon MTurk. 17 cases were removed for failing the attention check, leaving a final sample of 281 participants ( 138 male) aged between $18-74$ ( $M d n=32$ ). Participants received $\$ 0.60$ for participating.

## Design, Materials and Procedure

As in Study 1, except communication format was set in the high probability domain: verbal - "likely", numerical - " $80 \%$ likelihood", V-N - "likely ( $80 \%$ likelihood)" and N-V-" $80 \%$ likelihood (likely)". In addition, post-outcome, the likely event did not occur.

## Results

Trust and expertise ratings were again correlated (preoutcome: $r=.60, p<.001$; post-outcome: $r=.74, p<.001$ ). We combined the two measures as in Study 1. The data were analysed as in Study 1.

## Credibility Ratings

Mean credibility ratings, by communication format, are plotted in Figure 2, which shows before the outcome there was little difference between formats, as in Study 1. Postoutcome, all communication formats suffered from a loss of perceived credibility, with no notable difference between formats. The outcome and format interaction of Study 1 was not replicated, $F(3,273)=2.53, p=.06$. The main effect of outcome was significant, $F(1,273)=221.23, p<.001, \eta_{p}^{2}=$ .45, and the effect of format was marginally significant, $F$ (3, 273) $=2.59, p=.053, \eta_{p}^{2}=.03$. A post-hoc Gabriel test revealed there were no significant differences between formats (all $p \mathrm{~s}>.08$ ). Highest perceptions of credibility were in the numerical condition ( $\mathrm{M}=3.91, \mathrm{SE}=0.08$ ), and the lowest were in the verbal condition $(\mathrm{M}=3.63, \mathrm{SE}=0.08)$.

## Decision to Evacuate

Mean evacuation ratings for both pre and post-outcome (by communication format) are displayed in Table 1, which shows little difference between formats both pre and postoutcome. Indeed, there was no significant effect of outcome ( $p=.07$ ) nor format $(p=.20)$ on the decision to evacuate. There was a significant effect of numeracy, $F(1,273)=5.08$, $p<.05, \eta_{p}^{2}=.02$, with the high numeracy group more certain about evacuating ( $\mathrm{M}=2.08, \mathrm{SE}=0.10$ ), compared to the low numeracy group ( $\mathrm{M}=2.39, \mathrm{SE}=0.10$ ). There were no significant interactions (all ps > .15).

## Correctness Ratings

Again there was a significant effect of communication format on correctness ratings $F(3,273)=4.90, p<.01, \eta^{2}{ }_{\mathrm{p}}=.05$. As in Study 1, the numerical format was seen as 'least incorrect' and the verbal format seen as most incorrect (see Table 1).

Figure 2. Effect of Communication Format on Perceptions of Credibility Before and After an 'Erroneous' Prediction(Error Bars Represent ${ }_{-} 1$ SE) - Study 2 - High Probability.

## General Discussion

Pre-outcome, people did not perceive any of the volcanologists to be more credible than others using different communication formats, nor was there an effect of format on decision to evacuate. However, post-outcome, credibility was sensitive to an 'erroneous' prediction, with lower ratings in all formats. In Study 1 (low probability), the numerical format was affected least by this, and there was a trend for numerical-led communications (numerical and $\mathrm{N}-\mathrm{V}$ ) to be least affected in Study 2.

It is surprising that there was no initial difference between communication formats on perceptions of credibility in either probability domain, given the findings of Longman et al. (2012) that an expert who used a point estimate was seen as more credible. We would have expected numerical communications to have been rated as more credible, as the decision to use a precise numerical estimate could be thought to reflect a level of confidence and certainty in the prediction. Indeed, people expect experts to provide their knowledge in a precise manner (Shanteau, 1992).

In Study 1, the finding of most interest was the presence of a format $\times$ outcome interaction, whereby the numerical format lost least credibility following the occurrence of the unlikely event. These findings could be partly attributed to the directionality of the expression (Teigen \& Brun, 1995, 1999). Although both V-N and N-V formats featured a negatively directional expression ('unlikely'), it was accompanied by the positively directional phrase ' $20 \%$ likelihood', which may have cancelled out the effect of the negative directionality. Although no significant interaction was observed with high probability expressions, the results followed a similar trend, with numerical and $\mathrm{N}-\mathrm{V}$ expressions least affected.

We were surprised not to replicate Doyle et al.'s (2014) findings that more people chose to evacuate when given a risk communication featuring a numerical expression as opposed to a VPE. Although we found an effect of format in Study 1, it was in the opposite direction to the original study. A large number of responses to the question of 'why' people made their evacuation decision mentioned themes such as 'better to

Table 1. Evacuation and Correctness Ratings for Studies 1 \& 2

| Study | Measure | Outcome | Communication Format- Mean Rating (SE) |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  |  |  | V | V-N | N | N-V |
| 1 (Low Probability) | Evacuation Decision | Pre | 3.87 (0.09) | 3.87 (0.09) | 3.93 (0.09) | 3.87 (0.09) |
|  |  | Post | 2.41 (0.13) | 2.65 (0.13) | 3.31 (0.13) | 2.83 (0.12) |
|  | Correctness | Post | 1.61 (0.15) | 2.06 (0.14) | 3.35 (0.14) | 2.51 (0.14) |
| 2 (High Probability) | Evacuation Decision | Pre | 1.99 (0.17) | 2.19 (0.16) | 2.42 (0.16) | 2.11 (0.16) |
|  |  | Post | 2.08 (0.16) | 2.34 (0.15) | 2.47 (0.15) | 2.32 (0.15) |
|  | Correctness | Post | 1.80 (0.13) | 2.08 (0.13) | 2.45 (0.13) | 2.31 (0.13) |

be safe than sorry'. There was little cost to the participant to adopt this approach, which could have been a factor in the high proportion of people choosing to evacuate immediately. Whilst Doyle et al. (2014) attributed their results to the ambiguity of VPEs, we argue that our results could also be explained using this reasoning. Participants may have felt that the choice to use a VPE in the risk communication reflected a level of uncertainty in the outcome, with the communicator 'hedging their bets', and thus felt that it was better to adopt a conservative stance and evacuate, 'just in case'. Indeed, this is in line with the appropriate response of increased uncertainty providing an impetus to be concerned and an even greater reason to act (Lewandowsky et al., 2015). Additionally, if an 'unlikely' event were to occur, it would be far more consequential than if a 'likely' event did not occur.

The lack of an influence of numeracy on nearly all of our measures was somewhat unexpected, given the fact that numeracy has been demonstrated to influence effects of communication format (Gurmankin et al., 2004), and information format (e.g. frequencies versus percentages, Reyna, Nelson, Han, \& Dieckmann, 2010).

Further research should seek to explore the effect of the precision of the communication format. Chess, Hance \& Sandman (1988) claimed being open about levels of uncertainty would lead to enhanced credibility and trustworthiness. The current study only explored point numerical estimates (e.g. '20\% likelihood'), rather than more specific point estimates (e.g. '23\% likelihood'). Including range estimates (both small and large) would allow for a better understanding of the benefits of including numbers in risk communications. Whilst Longman et al.'s (2014) findings suggest that range estimates will have a negative effect on understanding and perceived credibility, others have found that range estimates are perceived as more useful and more honest (Dieckmann, Mauro, \& Slovic, 2010; Johnson \& Slovic, 1995).

## Conclusion

This study provides a different perspective to examining the effectiveness of risk and uncertainty communications, moving away from merely how the information is understood. Trust is fundamental to improving these communications (Slovic, 1993), and our work contributes to this somewhat neglected area of research.

The present research provided a systematic comparison of the effect of differing communication formats on the credibility of the communicator in the context of geological risk communications. Identifying instances in which the communication format has a significant impact on the audience's perceptions of the communicator is key to building and maintaining public trust in science, as well as improving the effectiveness of risk communication. Our findings show that the numerical format is viewed as more correct and is most robust against reductions in credibility following an 'erroneous' prediction. The present results thus suggest numbers should be included in these communications wherever possible.

#### Abstract

The problem of stability has long been a limiting factor in developing neural networks that can grow in size and complexity. Outside of particular, narrow parameter ranges, changes in activity can easily result in total loss of control. Human cognition must have reliable means of acting to stay within the stable ranges of sensitivity and activation. Learning is one such mechanism, and population dynamics are another. Here, we focus on another, often overlooked stability mechanism: cellular homeostasis through metabolism dynamics. We ran a visual change detection experiment designed to strain network stability while minimizing any learnable patterns. We fit the data using models with and without cellular energy levels as a factor, finding that the model influenced by its past history of energy use was a closer fit to the human data.

Keywords: Homeostasis; attention; visual change detection; neural modeling

## Introduction

The stability of learning and development depends partly on the stability of the learner's underlying cognitive machinery. A system that is not tethered to a baseline level of activity is vulnerable to being excited out of control or perishing through complete inaction. A number of mechanisms have been uncovered that promote basic stability in neural systems across multiple timescales. For instance, neurons coupled to one another via patterns of local excitation and lateral inhibition, can interact over fractions of a second to stably form and maintain "peaks" of activation around a core value of interest (e.g. Thelen, Schöner, Scheier, and Smith, 2001). As patterns in the short term persist, memory traces can be formed that are able to project the influence of these patterns over much longer timescales, leading to overall stability across similar situations.

Stability can also be driven at a level even below that of populations of neurons. Cellular metabolic processes allow individual neural units to contribute to the stability of a population coded representation by, observing and acting on their own changes in activity, and doing so at multiple timescales. The Hebbian rule, relating changes in correlations in the activity of neurons to their degree of co-activation, under-specifies the adjustment mechanisms needed for higher order stability. Oja (1982) derives an additional term, that, if included in the instantaneous rate of Hebbian weight change, will remain within some stable range of activity while maintaining the correlation. It was suggested that this term could
be thought of as a form of intrinsic "leakage" rate, $\eta$, of the materials available to the synapse.

This initial modification to the Hebbian rule was largely abstracted, however, from the precise biological interpretation. The cellular mechanism would need to toggle the adaptation of a neural unit between "labile" and "stable" dispositions toward changing connection strengths (Bienenstock, Cooper, \& Munro, 1982). One suggested candidate for this process is brain-derived neurotrophic factor (BDNF) (Glaser \& Joublin, 2011). Using Calcium levels as a proxy for the instantaneous levels of change at a synapse, neural units coding for changes in the level of BDNF can dynamically alter the underlying synaptic excitation/inhibition levels of cells. For instance, blocking input channels to the retina using a tetrodotoxin can affect cellular activity in ways that suggest homeostatic forces (Turrigiano, 2011). Strong excitatory inputs, when blocked, allow for a period of higher than normal activity once unblocked; likewise, the opposite is shown when inhibitory inputs are blocked. More generally, energy stores build up in the blocked neurons when receiving lower than normal input (and thus experiencing lower than normal activity themselves), or when allowed to fire higher than normal, stores are depleted. When a baseline level of energy is restored, normal conditions are eventually achieved again, but the effect in the meantime is one of an internal, cellular homeostatic force.

In the present study, we use a visual change detection paradigm to explore the capacity of the cognitive system to adapt to changes in task demands. Our model of the data are more detailed than that described by Oja (1982), but more abstract than a chemically detailed BDNF explanation. Our goal was to create perturbations of cognitive homeostasis that can produce interesting behavioral level data suitable for modeling effects beyond those observable in cellular recordings. The specifics of two computational models are then introduced for capturing the new behavioral effects. Simulations show that the model with a cellular energy term outperforms a version without one. We conclude with a discussion on the merits of including energy terms in basic neural models as a part of establishing a common language of conservation across the brain, even when exploring cognition at the level of behavior.

## Change Detection

The change detection paradigm is a useful way of studying the cognitive operations necessary for several processes relevant to homeostasis. A typical trial in a change detection task consists of a sample set of items to remember, followed by a test set of items and a response prompt. The paradigm is simple yet challenging to model (Johnson, Spencer, Luck, \& Schöner, 2009); so we opted for a highly simplified version with only one feature dimension of change: color. By changing anywhere from zero to six colors per trial, however, we still allowed for a straightforward manipulation of homeostasis across trials, disturbing the balance of expectation, ability, and adaptation constantly throughout our task.

## Experiment

We designed a change detection experiment with the intention of placing participants in situations of rapidly changing cortical energy levels as might be consistent with a BDNF homeostatic response. The task was also designed as a situation where homeostatic control would potentially be beneficial to task performance. Two presentations of colored squares were given to participants per trial, and the number of changes between presentations was reported, changing from zero to six changes unpredictably trial by trial. No overall learnable trial-to-trial pattern was available to participants that would aid them in answering correctly, so that there was no advantage to adopting complex expectations.

## Method

Participants were recruited from the Simon Fraser University psychology department subject pool, where they received course credit for 30 minutes of participation. We asked participants to think of 6 color patches as alien creatures that would change form over the course of a trial. The job of the participant was to correctly classify the number of changes as part of a national effort to better understand these aliens. Of the 33 subjects, 30 were retained for analysis. Three participants were dropped for failing to complete 106 trials of the task.

Each trial involved a masked presentation sequence designed to eliminate any relevance of spatial position of stimuli, so that color alone was the sole feature dimension of change detection. Subjects were instructed to view a fixation cross for two seconds at the start of each trial. A set of six colors was then presented for four seconds, long enough to ensure an ability to briefly encode the colors in memory. The screen was then masked to block effects of afterimages for two seconds, and a second set of colors was presented. The orientation of the colors was a vertical $2 \times 3$ grid rather than the horizontal $3 \times 2$ grid in the first presentation, to remove any clear or objective correspondence between spatial locations in the first and second presentations. All colors were also scrambled in positions, in addition to the display positions being rotated.

The second color display was left on the screen for either $2.5,3.0,3.5$, or 4.0 seconds (counterbalanced across trials
per participant) to allow for different amounts of time for any homeostatic system to adjust cellular activity rates now that the changes, if any, were visible. The intention of the time manipulation was that there would not be sufficient time to make a homeostatic adjustment in one timeframe, but enough in another, and thus that the required time for homeostatic adjustment could be identified by changes in accuracy.

A second mask was then presented for two seconds, whereafter the participant was given any amount of time to report the number of changes on a number line on screen. Participants were given explicit feedback about their answer in the form of a blue mark for the correct answer in addition to the red mark indicating the chosen response. Figure 1 depicts a graphical representation of the task procedure.

Twelve perceptually equidistant colors were assigned to each participant, offset from each other by a random amount. Color coordinates were obtained from a slice of CIEL*a*b* color space, with luminance set to a constant $L=75$. Only coordinates in this color space that have a representation in RGB can be displayed on a monitor, so all but the largest circular portion of the color space satisfying this constraint was removed (Johnson et al., 2009; Lehky \& Sejnowski, 1999). These twelve colors were then used consistently for a participant's entire experiment. Every trial randomly sampled from the participant's set of twelve colors as needed. A "zero changes" trial, for example, only required six colors (the same set of six twice), whereas a "six changes" trial required all twelve colors (two different sets of six).

Trials were counterbalanced with a customized Latin square in order to equally distribute the number of times each possible number of changes in colors (0-6) was the correct answer, while also equally distributing the number of oneback differences between correct answers on the current and previous trial. Figure 2 shows the actual number of total trials across participants of each combination of these variables. The four possible display times for the second color array were evenly distributed within each of these trial types (i.e., within each bar in Figure 2. Display times not shown in Figure).

The partial Latin square was necessary due to mathematical constraints in designing a distribution of trials that attempted to fit both criteria. Each trial is part of a one-back link to its previous trial but also to the next trial, so any change has a cascade of consequences for the options on other trials. Also, certain one-back differences are impossible; for example, if the number of changed colors on a trial is three, then the one-back difference cannot possibly be 6 , because that would mean the correct answer on the previous trial was "3 changes" which is not possible. There were 9 impossible combinations like this overall, forming a triangle of missing bars in Figure 2 (upper right portion of figure).

Trial orders were generated by a Monte Carlo algorithm that simulated many solutions to the overall trial order problem. The algorithm respected the constraints described above, while also introducing randomness in order to limit

Figure 1: The presentation sequence of a trial. A fixation cross appears for 2 seconds. A sample set of 6 colors to be remembered is then presented for 4 seconds. A diffuse colored mask intended to cancel out sensory correlation with the subsequent test array is then presented for 2 seconds followed by a set of 6 color patches rotated by $90^{\circ}$ (and completely scrambled with no correlations in positions before vs. after masking). A final colour mask is then presented for 1 second in advance of the unconstrained response phase. Subjects would click on a value for their estimate of the number of changes, marked in red, and the correct value marked by blue.
trial order confounds between participants. A unique solution was found for each participant. Solutions were defined as trial orders where the total number of trials was nearly equal for each of the seven possible correct answers (so as many trials have an answer of " 4 " as have an answer of " 2 "), and where the number of trials was also nearly equal for each of the seven possible one-back changes in correct answer. The shape depicted in Figure 2 was the algorithm's consistent solution to this problem, with only very minor differences and asymmetries between participants.

## Experiment Results

The average error across all trials and all subjects was 1.5 units (number of color changes, out of 6). A mixed effects model with subject as a grouping factor showed no significant improvement in change detection over the course of the experiment $(t=1.6, p=0.11)$. In accordance with our goal of exploring sensitivity to swings in cognitive energy and activation over time, we also checked for a lag-one correlation in responding over the course of the experiment. Lag-one in this case is being measured as the correlation between responses on trial t and responding on trial t -1, i.e. the correlation between the list of responses and itself shifted one trial sooner. When this correlation is positive, it suggests that answers were given in long "runs" where a high answer would be followed by more high answers and similarly for low. When the lag-one correlation is negative, it suggests a degree of "ping-ponging" back and forth between high and low (number of changes) successive answers more often than would be expected by chance. A lag-one of zero suggests no particular persistent carryover effects of responding from one trial to the next.

For this analysis, it was necessary to control for any lagone correlation that may have been inherent to the trial order itself. Figure 2 shows how, despite equal distribution of changes and differences in changes in colors across trials, patterns exist between these two variables. To control for such patterns during the analysis, we looked for lag-one correlation only in those trials we knew had a symmetric pattern of changes compared to previous trials: ones where the answer was exactly three changes ("Correct Answer $=3$ " set of
bars in Figure 2). Within this restricted data set, we found a positive correlation ( $\beta=0.11, t=2.74, p<0.01$ ) in the responses between trials, indicating a minor preference for repeated "runs" of responding that was not related to any experimental design.

Timing differences in the second color presentation phase of the task did not correspond to significant differences in performance. Differences were expected, but any homeostatic effects may simply be too rapid (or too slow / occurring by memory only during the answering phase) to be distinguished by the difference between 2.5 and 4 seconds of presentation.

## Model

We tested two models against our behavioral data: one biologically inspired model (in line with with the BDNF principles discussed by Glaser and Joublin, 2011) capturing cellular homeostatic principles, and the same model but with the cellular homeostatic term removed. Each was simulated in Matlab using the exact order and content of trials and color values seen by each of the 30 participants in turn. These models provide continuous real number outputs between 0 to 6 , but were forced to choose exact whole number answers for number of changes, as the humans were. Especially for the model that accounted for the C.H. model, the effect of feedback could have contributed differently to the next trial's behavior if whole number answers were not required, so to ensure the most human-like between-trial patterns, model answers were also rounded.

Since our goal was to capture the levels of errors and inaccuracy in human behavior, and the difficulties of the task being between-trial consistency, we fed the signal for the number of changes on a trial to the models directly, so that the target measure of the fit was focused on the specific pattern of errors made by each human on each of their trials. Each model was fit to human responses using the method described below, which tested enough detail to capture these homeostasis straining effects over time, as well as patterns of variance in errors.

Figure 2: Histogram of different trial types in the experiment. Every trial had a correct answer, and all but the first trial had a one-back difference between its correct answer and the correct answer on the previous trial. Some of these combinations were impossible (see text). The shape seen here equally distributes correct answers overall, and also equally distributes changes between trials overall, while avoiding the impossible trial types. Bars are not perfectly symmetrical due to partial randomization between participants to avoid trial order effects. Some small asymmetries between bars are visible due to the necessity of using a Monte Carlo algorithm for this task.

## Cellular Homeostasis Model

The primary model of interest displayed homeostasis as a result of cellular energy resisting extreme response rates by becoming depleted after heavy use or energized after low use. The neuron's energy reserves were its only way of tracking information across trials. Its output on a trial is given by:

$$
O_{t}=a s_{t} E_{t}+b+\varepsilon n
$$

where $s_{t}$ is the stimulus on the trial (the number of changed colors), $\varepsilon$ is normally distributed noise, $a, b$, and $n$ are freely fitted coefficients, and $E$ is cellular energy, calculated per trial as:
$E_{t}=E_{t-1}+\frac{\left(O_{t-1}-3\right) c}{\tau}-\frac{\left(E_{t-1}-1\right) \frac{c}{3}}{\tau}$
The fourth free parameter of the model is $c$ in the energy equation above. $\tau$ was not parameterized and was always set to a constant value of 10 . The $O_{t-1}-3$ represents the fact that three was the most central response out of options 0-6, so any values below this were considered "low" answers that helped relatively gain cellular energy, and any values above this were "high" answers that relatively depleted energy reserves. The third term represents relaxation of the system to neutral energy over time, but $1 / 3$ slower than the rate of energy change from responding (Toyoizumi, Kaneko, Stryker, \& Miller, 2014). Setting $E_{t-1}-1$ causes energy to relax toward a neutral value of 1 , where it would have no effect on the cell's output. All model answers were rounded to the nearest integer from 0-6 - the only valid answers in this task - on a per-trial basis. This was also true of the mathematical model
variant below.
The energy term mimics the predictions of the BDNF chemical cell model, with as much abstraction as necessary to allow for easy application to typical cognitive behavioral data. As in the BDNF model, a decision neuron firing at a relatively low rate ( $0-2$ changes in this task) builds up energy and fires faster than normal for a brief period in response, while a neuron firing relatively energetically (4-6 changes in this task) will progressively deplete energy and fire more slowly for a time in response.

## Simple Mathematical Model

The second model had no biological motivation, but serves as a baseline comparison with the C.H. model. It replicates the C.H. model in structure, but with the energy term removed. This model had no means by which to account for previous trials, as the model had no form of memory/hysteresis. It did, however, still have all of the information needed to perform perfectly at the task according to task instructions (rather than fit to human answers). A perfect score could be achieved with parameter values $a=1, b=0$, and $n=0$. Thus, lower performance by this model at fitting human data would be due to a lesser ability to capture human sources of error and trial to trial effects (theoretically irrelevant and distracting from optimal performance) only. The model is given by:

$$
O_{t}=a s_{t}+b+\varepsilon n
$$

## Fitting Method

We created three dimensional histograms of responses for humans and models to fit and compare results. Every trial across subjects was sorted into histogram bins according to the correct answer on that trial ( 0 to 6 ), the difference between the correct answer on that and the correct answer on the previous trial ( -6 to 6 ), and the participant's (real or simulated) response ( 0 to 6 ). This produced $7 \times 13 \times 7$ set of possibilities ( 637 histogram bins). The first two dimensions represent objective trial types (ones built into the design and based on actual stimuli) and since these were not perfectly evenly distributed due to mathematical constraints (see Figure 2), we weighted the importance of cells from the combinations that had more more data points, using weighted least squares:

$$
\text { Fit }=\sqrt{\frac{1}{637} \sum_{s, d, r}\left(\sum_{s, d}\left(N_{H_{s, d}}\right)\left(H_{s, d, r, \text { model }}-H_{s, d, r, \text { human }}\right)^{2}\right)}
$$

where $H$ is the histogram, and $s, d, r$ are stimuli at time of response ( t ); difference in $\operatorname{stimuli}(\mathrm{t})$ - $\operatorname{stimuli}(\mathrm{t}-1)$; and response, respectively. This method captures information about trial to trial effects, main effects, interactions, general task accuracy, and patterns of variance, all in one measure.

This histogram method was chosen for the objective function to avoid the problem that fitting averaged descriptives like accuracy or standard deviation of responses, which could lead to degenerate model patterns: a mean might be fitted by $100 \%$ of model answers at exactly the mean without realistic variance, for example. Fitting the entire histogram of all relevant measures allowed for the model with the richest detailed pattern of fits across every measure.

Figure 3: Change responses versus change responses on the previous trial, where the current trial had 3 changes. C.H. is the Cellular Homeostatic Model.

The models have differing numbers of free parameters (4 vs. 3), yet due to the dynamical nature of the cellular energy model, its maximum likelihood cannot be easily calculated, and simulations take non-trivial time to perform. Ultimately, the main concern of an overly complex model is failure to generalize, so instead of scoring parsimony, we ruled out over-fitting directly using cross-validation. For each model, we split the subject pool in half, and separately fit each half. We then recorded the fits for each half using only the best parameters found from fitting the other half. All results reported below are exclusively these generalization results, removing our concerns about hidden differences in generalization ability between the three and four parameter models.

We fit a 7 value range for each parameter in a grid covering all of reasonable parameter space for the task, separately for each half of participants as above. We then focused more closely near each best fit at higher precision until precision increases stopped yielding better fits.

## Model fitting results

The best fitting parameters for the cellular homeostasis model were $a=-0.4, b=3.5, c=0.92$, and $n=1.4$. The best fitting parameters for the simple mathematical model were $a=-0.45, b=3.5$, and $n=1.5$.

The average cross-validation weighted least squares error for the cellular homeostasis model was 8.335 , while the average cross-validation weighted least squares error for the simple mathematical model was 9.436 . Since these values already account for the greater potential for over-fitting with four versus three parameters, they can be compared at face value: the energy term meaningfully accounts for human behaviors above and beyond slope, intercept, and noise terms.

Although the magnitude of the effect is somewhat modest,
it is noteworthy to point out again that the simple mathematical model was able to achieve $100 \%$ objective accuracy at the task as per the task instructions by simply fitting parameters $a=1, b=0$, and $n=0$, a combination that was within the tested range of reasonable parameters during fitting. Thus, the lower performance of the simpler model is purely a result of more poorly fitted patterns of human error, possibly error in response to patterns of trials that threw off homeostatic neutrality, since the better fitting energy term in the homeostasis model varies by activity on previous trials.

Ultimately, the exact cause of the better fits of the cellular homeostasis model are unclear. Analysis of the full threedimensional fitting histogram suggested noticeable differences between the two models and between models and human data, but these differences were too diffuse and opaque to easily interpret.

Lag-one correlations on trials with three color changes also fit human data better in the homeostasis model than in the simple mathematical model. Where $\beta_{\text {human }}=0.11$, $\beta_{\text {cellularmodel }}=0.05$ and $\beta_{\text {simplemodel }}=0$ (see Figure 3). These correlations highlight the lag-one effects in particular, but lag-one effects are also built into the 3-dimensional histograms used for the main fitting results.

## Discussion

Behavioral stability is often approached from the perspectives of neural population dynamics or higher-level verbal or executive control theories. Stability is also attainable, however, through more microscopic means, at an intra-cellular or synaptic level. This source of homeostasis in cognition and behavior is, by itself, simple. Activity is most likely stabilized around a static resting level, at least within the timescales afforded by a particular task. This does not necessarily match the flexibility or possible sophistication of higher level stabilizing mechanisms.

Cellular homeostasis is, however, an appreciable effect, especially when studied in a task that eliminates distracting forces and pushes the boundaries of a system's homeostasis. Even in less specialized situations, however, cellular effects are likely continuing to function and can contribute toward an understanding of behavior. This form of homeostasis may generally be playing a silent and under-appreciated role in a wide variety of cognitive activities, providing a small but important level of baseline stability that can act as a foundation for more targeted systems like learning mechanisms to explore more freely without risk of losing control of a system.

Our findings require significant further investigation to establish an exact pattern of behavior that is being captured by the cellular energy term of our model, and followup experiments are necessary to confirm those mechanisms once identified. In the meantime, we suggest cognitive modelers more often consider including cellular energy terms in neural models of not only cellular-level effects, but behavioral effects as well. All cognitive processes involve neurons, so even modest effects of such a cellular system may be of great impor-
tance collectively, for a range of effects at different levels of complexity and abstraction.

#### Abstract

Bounded and unbounded events differ in whether they include an inherent endpoint (Bach, 1986). Even though this distinction can be important for the way events are identified and processed, the literature on event cognition has not focused on such abstract aspects of event structure. In the present study, we asked whether viewers are sensitive to the distinction between bounded and unbounded events in a category learning task. Our results show that people were more successful in forming the category of bounded events than that of unbounded events. We discuss implications of this finding for event cognition.

Keywords: event structure; endpoint; boundedness

## Introduction

Our experience of the world is intrinsically dynamic. To make sense of the complex flow of changes in our environment, we break continuous streams of experience into separate entities and classify such entities into different types.

Much work has focused on how people segment continuous experience into discrete units, i.e. events. The term "event" refers broadly to a temporal segment that has "a beginning and an ending" (Zacks \& Tversky, 2001). People identify the boundaries of an event through tracking changes in perceptual features such as direction, location, or speed of action (e.g. an arrow hitting a target); more importantly, people encode events based on conceptual features, especially the goal-directedness or causal structure of the corresponding experience (e.g. a person on diet hitting a target; Zacks \& Swallow, 2007). Event boundaries have a privileged status in memory and provide anchors for later learning and describing (Swallow, Zacks, \& Abrams, 2009). In particular, the endpoint is conceptualized as a critical event component. For instance, when comparing two events, the resultant state (e.g. whether a ball knocked over the whole tower or just a few blocks) has more psychological weight than other perceptual features (e.g. the moving direction of the ball) (He \& Arunachalam, 2016). In the well-studied domain of motion events, the goal of motion is more accurately encoded in both language and memory as opposed to other components such as the source (Lakusta \& Landau, 2005, 2012; Papafragou, 2010; Regier \& Zheng, 2007; Wagner, 2009). In addition, people tend to fill the gap between successive events within a causal chain by generating rapid inferences about the endpoint of the first
event. In a study by Strickland and Keil (2011), after watching videos of someone launching an object (e.g. kicking a soccer ball) followed by the object's directed motion (e.g. the ball flying into the goal), participants mistakenly reported that they saw the moment of contact, i.e. the endpoint of the launching event, even when it was actually omitted from the display.

Despite the richness of the literature on event segmentation and the salience of endpoints in event perception, the nature of event endpoints has been less discussed. In most event-segmentation studies, the stimuli are actions by an intentional actor (e.g. a person putting up a tent) and the endpoint is taken to be obvious and welldefined (e.g. the moment the tent is put up). In studies of motion events, the endpoint appears similarly self-evident (and is typically the moment that a moving entity reaches the goal). However, across a broad range of events, the notion of endpoint is not always straightforward. Consider the following situations described by the two sentences in (1):
(1) a. The child played the Moonlight Sonata.
b. The child played the piano.

There is subtle difference between (1a) and (1b). The event in (1a) comes to an end when the last note of the sonata was played. In contrast, it is hard to specify how or when the situation in (1b) ends - the child could stop playing at any point. The endpoint is inherent in the former event but is arbitrary in the latter. Such contrasts have been discussed extensively in the linguistic literature on aspect (i.e., the linguistic encoding of the internal temporal profile of events). In this literature, the distinction between the two sentences in (1) is captured by assuming that (1a) encodes an experience as a "bounded" event but (1b) encodes it as an "unbounded" event (Bach, 1986; Harley, 2003; Jackendoff, 1991). Bounded events have an internal structure with a "built-in terminal point" (Comrie, 1976), "climax" (Vendler, 1957) or "culmination" (Parsons, 1990), while unbounded events are homogenous, lacking internal development (Krifka, 1998). This linguistic distinction presumably has a non-linguistic counterpart in the way events are perceived and understood but to date, this connection has not been explored in detail.

Inspired by the rich linguistic research on how event endpoints are encoded in language (see Filip, 2004; Krifka, 1998 , etc.), one can further identify two major types of consideration that determine whether an event is bounded or
not. First, intuitions about boundedness may be due to the nature of the action. In particular, some actions lead to a change of state in the affected object, such that the endpoint is the resultant state (bounded events); other actions do not affect the object in a perceptible way or the change lacks a well-defined resultant state (unbounded events). The contrast is shown in the following example:
(2) a. The child dressed the teddy bear.
b. The child patted the teddy bear.
(2a) describes a bounded event - the teddy bear was dressed when the child finished. (2b) describes an unbounded event-no predictable result followed from the child's patting. Although both events involve the same object, the difference in actions leads to the contrast in boundedness.

Second, intuitions about boundedness may be due to the nature of the affected object. Sometimes, there is a homomorphism between the affected object and the time course of the event (Dowty, 1991; Krifka, 1989), such that the changes in the object track or "measure out" the way the event develops (Tenny, 1987). When the object itself is quantified, the event is bounded. The contrast can be illustrated by the example below:
(3) a. The child ate a pretzel.
b. The child ate cheerios.
(3a) depicts a bounded event- the event unfolds as the pretzel changes and it ends at the moment when the pretzel is gone. (3b) depicts an unbounded event that lacks an inherent endpoint-the child could stop at any time.

To sum up, bounded and unbounded events differ in whether they have an inherent endpoint. Two major components, i.e. the nature of the action and the affected object, might determine whether an inherent endpoint is available. So far the literature on event perception has not explored the role of boundedness in determining event boundaries, and little is known about whether viewers are sensitive to such abstract aspects of event cognition. One suggestive piece of evidence comes from work focusing on how events are counted. Bounded events are naturally counted in terms of how many inherent endpoints have been achieved. Lacking an inherent endpoint, unbounded events are counted according to spatio-temporal criteria. Returning to the example in (1), imagine that the child paused for a break and then resumed her playing in both situations. The event of playing the Moonlight Sonata still occurred once, but the child played the piano twice. When counting events like (1a), adults look for the inherent endpoint regardless of the pauses (Barner, Wagner \& Snedeker, 2008) but 3-to-5-year-olds tend to over-generalize spatio-temporal criteria and count the number of pauses (Wagner, 2006; Wagner \& Carey, 2003).

In the present paper, we explore viewers' sensitivity to the distinction between bounded and unbounded events (defined in terms of the availability of an inherent endpoint, as in (2) and (3) above). Specifically, we ask whether viewers can group events into the bounded vs. unbounded category in a category learning task. Drawing on the linguistic literature in which the category of unbounded
events is definitionally dependent on the category of bounded events (such that boundedness and unboundedness form a positive-negative pair), we ask whether there is an asymmetric relation between the two types of event in nonlinguistic cognition. If so, the category of bounded events might be learned by observers more easily compared to that of unbounded events.

## Experiment 1

Experiment 1 was a category learning task. Participants were exposed to minimal pairs of bounded and unbounded events (defined by the availability of an inherent endpoint) and had to extract what was shared by different events of the same category and extend this information to new events.

## Method

Participants Forty adults participated in the experiment. All were undergraduates at the University of Delaware and received course credit for participation. Data from an additional group of 2 adults were collected but excluded because these adults were color-blind and failed to identify an important test feature (a red frame) consistently.

Stimuli Twenty pairs of videos were created, such that each pair showed a bounded and an unbounded event (see Table 1). Within each pair, the videos had the same duration (range: $4.5 \mathrm{~s}-13 \mathrm{~s} ; \mathrm{M}=7.98 \mathrm{~s}$ ) and involved the same actor but differed minimally from each other in one of two ways that involved boundedness. For half of the pairs, the bounded and unbounded events within a pair involved the same object but differed in terms of the nature of the action performed on the object: the bounded event displayed an action that caused a clear and temporally demarcated change of state in the object (e.g. fold up a handkerchief) while its unbounded counterpart did not involve such a change (e.g. wave a handkerchief). For the other half of the pairs, the bounded and unbounded events within a pair involved the same action but differed in terms of the nature of the affected object: the bounded event involved a single object (e.g. draw a circle) but its unbounded counterpart involved either an unspecified plurality of objects or a mass quantity (e.g. draw circles).

To ensure that all video stimuli would illustrate the contrast in boundedness presented in Table 1, a new group of 18 adults from the same population was asked to watch a subset of the clips and describe what happened in a full English sentence. For this norming task, the events in Table 1 were split into 2 lists, such that each list included only one member of each pair and an equal number of bounded and unbounded events. Each of the 18 participants was randomly assigned to one of the two lists. Their descriptions were coded for the verb used to describe the action and the noun phrase used to describe the affected object(s). As expected, differences in boundedness within a pair that were due to the nature of the action were reflected in verb choices: bounded stimuli elicited verbs of change of state (e.g. "dress a teddy bear") $98.3 \%$ of the time and unbounded stimuli
elicited verbs denoting activities (e.g. "pat a teddy bear") $93.1 \%$ of the time. Similarly, differences in boundedness within a pair that were due to the nature of the object were reflected in noun phrase choices: bounded events elicited count nouns with definite or indefinite articles (e.g. "eat the/a pretzel") $98 \%$ of the time and unbounded events elicited bare plurals, mass nouns, or related devices (e.g. "eat cheerios") $92.4 \%$ of the time.

For purposes of Experiment 1, the video stimuli were arranged into three basic lists corresponding to the three phases of the experiment (see Table 1). For the initial learning phase, we selected 8 pairs of events ( 4 in which boundedness was due to the Action and 4 in which boundedness was due to the Affected Object) and arranged them into a pseudorandomized presentation list in which a single video was played in the center of the screen and the two videos within a pair appeared in immediate succession (the order of bounded-unbounded events within pairs was counterbalanced within the list).

For the later testing phase, we arranged 8 of the remaining pairs of videos (see Table 1) into 2 lists. Each list contained one video from each pair. We counterbalanced whether the event was bounded or unbounded and whether source of boundedness was the action or the object across lists.

For the final (short) surprise testing phase, we used the last 4 pairs of videos, arranged into 2 lists. The same counterbalancing was used as in the (main) testing phase.

Procedure Participants were randomly assigned to one of two conditions. In the Bounded condition, the videos of bounded events shown in the learning phase were given a red frame while their unbounded counterparts were given a black frame. In the Unbounded condition, the reverse assignment occurred.

In the learning phase for both conditions, participants were asked to watch a few videos and to pay attention to those appearing within a red frame. Their task was to figure out what kind of videos were given the red frame and to decide whether a new video could have the red frame or not.

In the testing phase, participants saw a new set of videos and for each one they were asked: "Could the video have a red frame or not?" (test question) In the surprise testing phase, participants were unexpectedly asked: "Could the video have a black frame or not?" (surprise question) This question was included to probe whether participants formed any hypothesis about the secondary event category present within the experiment, even though it was not the target of the study.

After the end of the session, participants were asked to write down what kind of videos could have a red frame. This was used as an additional source of information about the category that participants had just formed.

Table 1: Videos used in Experiment 1.

| Phase | Boundedness Source | No. | Bounded Events | Unbounded Events |
| :--- | :---: | :--- | :--- | :--- |
|  |  | 1 | fold up a handkerchief | wave a handkerchief |
| Learning | Nature of Action | 2 | put up one's hair | scratch one's hair |
|  |  | 3 | pile up a deck of cards | shuffle a deck of cards |
|  |  | 4 | group pawns based on color | mix pawns of two colors |
|  |  | Nature of Affected | 6 | draw a balloon |
|  | Object | 7 | eat a pretzel | draw circles |
|  |  | 8 | flip a postcard | tie knots |
|  |  | 9 | dress a teddy bear | eat cereal |
|  |  | 10 | roll up a towel | flip pages |
| Testing |  | 11 | fill a glass with milk | pat a teddy bear |
|  |  | 12 | scoop up yogurt | twist a towel |
|  |  | 13 | peel a banana | shake a bottle of milk |
|  |  | 14 | blow a balloon | stir yogurt |

## Results

An ANOVA was performed on the proportion of correct responses to all questions with Source of Boundedness (i.e. Nature of Action vs. Nature of the Affected Object) as a within-subjects factor. No significant difference was found $(F(1,39)=.042, p=.838)$. Therefore, answers to questions targeting the two sources of boundedness were collapsed for further analysis.

Results from Experiment 1 are shown in Figure 1. The proportion of correct responses to test questions was significantly higher in the Bounded $(\mathrm{M}=92.50 \%)$ than in the Unbounded condition ( $\mathrm{M}=76.25 \%$ ) $(t(38)=3.563$, $p$ $=.001)$. No significant difference in the proportion of correct responses to the surprise questions in the two conditions was found $(t(38)=-.831, p=.411)$.

An ANOVA was conducted on the proportion of correct responses with Question Type (Test vs. Surprise) as a within-subjects factor and Condition (Bounded vs. Unbounded) as a between-subjects factor. There was a significant effect of Question Type $(F(1,38)=19.795, p<$ 0.0001 ), no significant effect of Condition $(F(1,38)=$ 2.247, $p=.142$ ), and an interaction between the two factors $(F(1,38)=7.833, p=.008)$. The participants were more accurate in test questions than in the surprise questions in the Bounded condition $(t(19)=6.114, p<.00001)$ but not in the Unbounded condition $(t(19)=1.022, p=.320)$.

Figure 1: Proportion of correct responses in Experiment 1. Error bars represent standard error.

Answers to the last open question asking about the target category focused on 3 aspects of the stimuli-organization, neatness and intention. Organization was the most frequent hypothesis ( 29 out of the 40 answers). Specifically, modifiers such as "organized", or "structured" were used to describe bounded events while "unorganized", or "lacking structure" were given for unbounded events. Neatness was the second most frequent hypothesis ( 15 out of the 40 answers). Words used for bounded events included "neat", "tidy" and "clean" while those for unbounded events included "messy" and "untidy". Lastly, intention was mentioned in 9 out of the 40 answers. Bounded events were depicted as aiming "to achieve a goal", or being "on
purpose" while unbounded events were "lacking an end or purpose", "random".

## Discussion

Performance in test questions directly showed that, given the same contrastive examples in the learning phase, the participants were better at forming the category of bounded events compared to that of unbounded events. Furthermore, in the Bounded condition, learning was focused, with participants being less successful in the surprise compared to the test questions; however, no such asymmetry was found in the Unbounded condition. Further intuitions about boundedness were found in answers to the last open question about the nature of the target (red-frame) stimuli. The most frequent hypotheses referred to the organization of the stimuli. This suggests that participants attended to the internal structure of events when forming hypotheses about the meaning of the to-be-acquired category.

## Experiment 2

In Experiment 1, participants might have benefited from the presentation of paired videos in the learning phase. By showing 2 successive videos with minimal differences, the contrast between bounded and unbounded events was highlighted. Experiment 2 asked whether the category of bounded or unbounded events could be efficiently extracted in a less supportive learning context.

## Method

Participants A new group of forty undergraduates at the University of Delaware were recruited. Data from an additional adult were collected but excluded because he failed to understand the task and did not finish all the questions.

Stimuli and Procedure The stimuli and procedure were identical to those in Experiment 1 with one exception. In the learning phase, the sequence of the 16 videos was pseudorandomized such that any 2 videos within a pair were separated by at least 5 other videos. This made it impossible to detect the contrast between bounded and unbounded events by simply comparing 2 consecutive videos.

## Results

As in Experiment 1, no difference in the proportion of correct responses was found between the two sources of boundedness $(F(1,39)=1.595, p=.214)$. The answers were thus collapsed in the following analysis.

Results from Experiment 2 are shown in Figure 2. Test questions elicited a significantly higher proportion of correct responses in the Bounded ( $\mathrm{M}=84.38 \%$ ) than in the Unbounded condition ( $\mathrm{M}=68.13 \%$ ) $(t(38)=3.365, p$ $=.002$ ). There was no significant difference between the two conditions in the proportion of correct responses to the surprise questions $(t(38)=-1.129, p=.266)$.

An ANOVA conducted with Question Type as a withinsubjects factor and Condition as a between-subjects factor showed a significant effect of Question Type $(F(1,38)=$ $7.095, p=.011$ ), no significant effect of Condition $(F(1,38)$ $=.646, p=.427$ ), and an interaction between Question Type and Condition $(F(1,38)=7.839, p=.008)$. The participants performed better in test questions than in surprise questions in the Bounded condition $(t(19)=4.174, p=.001)$, but not in the Unbounded condition $(t(19)=-.093, p=.927)$.

Figure 2: Proportion of correct responses in Experiment 2. Error Bars represent standard error.

Answers to the open question about the nature of the target category still mainly referred to organization, neatness and intention. These were mentioned in 16,8 and 7 out of the 40 answers respectively. In addition, repetition was used to describe unbounded events in 5 answers. Completion appeared in 3 answers about bounded events.

As is clear from Figures 1-2, performance on the test questions was better in Experiment 1 than in Experiment 2. This was confirmed in an ANOVA that used the proportion of correct responses on the test questions as the dependent measure, and included Condition (Bounded vs. Unbounded) and Experiment ( 1 vs. 2) as between-subjects factors. The analysis showed main effects of Condition, $(F(1,76)=$ 23.940, $p<.0001$ ), and Experiment $(F(1,76)=5.986, p$ $=.017)$, and no interaction between the two factors $(F(1,76)$ $=.000, p=1.000$ ). (Results were similar when accuracy on both test and surprise questions was used as the dependent measure.)

## Discussion

Results from Experiment 2 showed a learning advantage for the category of bounded compared to unbounded events. This pattern was similar to Experiment 1, even though performance in Experiment 2 was worse compared to the earlier study, presumably because of the lack of direct contrast between bounded and unbounded events during the learning phase.

## General Discussion

Our findings provide direct evidence for viewers' sensitivity to the abstract feature of boundedness in event cognition. In that sense, the present data go beyond prior work on how bounded and unbounded events are individuated and counted (Barner, Wagner \& Snedeker, 2008; Wagner, 2006; Wagner \& Carey, 2003). Furthermore, our results demonstrate that there is an asymmetry between bounded and unbounded events, such that it is easier to form the category of bounded compared to unbounded events. Our results raise the possibility that unboundedness is asymmetrically dependent on boundedness during event perception and apprehension, and that bounded - but not unbounded - events form a natural class.

The present data leave several directions open for further research. An important direction concerns the exact nature of the conjectures underlying participants' groupings of events into boundedness categories. The notion of boundedness is broad and can be subject to more abstract considerations than the present discussion has suggested. For instance, the inherent endpoint that defines bounded events can provided by a salient intention (Depraetere, 2007). To take an isolated example, even though the action of warming a soup does not have a clearly defined endpoint, it is often construed as culminating at the point at which the soup has reached someone's favorite temperature. In our study, it seems unlikely that intentionality was the feature responsible for participants' success in the Bounded condition. We asked a new group of 10 people to rate the degree of intentionality for all the videos used in the experiments on a scale from 1 (totally unintentional) to 7 (intentional). There was no significant difference between scores for bounded events $(M=5.829)$ and unbounded events $(M=5.704)(t(9)=1.059, p=.330)$.

Finally, a number of researchers has drawn close parallels between object and event systems from a semantic perspective, such that the property of boundedness in the domain of events has been linked to the issue of quantification in the domain of objects (Bach, 1986; Jackendoff, 1991). In our study, the quantification of the affected object served as a cue for distinguishing bounded events from unbounded ones. It is possible that viewers are better at forming the category of bounded events because it is easier to track a single object compared with an unindividuated substance or objects of a variable number. An interesting further question is whether there is a common notion of boundedness underlying cognitive representations of both events and objects (see Wellwood, Hespos \& Rips, in press) and how distinctions in one domain might generalize to the other.

#### Abstract

Deep understanding of mathematical equivalence is critical for later mathematical understandings. However, research studies and national test results have repeatedly demonstrated that many students fail to develop adequate understanding of equivalence. Recent work from McNeil and colleagues proposes that this failure is partly due to the format of traditional instruction and practice with highly similar problems. Specifically, the change-resistance account (McNeil \& Alibali, 2005) proposes that students struggle with equivalence because they have developed overgeneralized "rules" that affect how they process and approach math problems, (e.g., the operators are always on the left side, the equal sign means to "do something" or "give the answer") and fail to see equations having two separate sides that are being related to one another. Extensive practice with problems in a similar format (e.g., those that present all arithmetic operations on the left side of the equal sign) encourages students to develop ineffective mental models of problem types. We replicate and extend prior work that brings cognitive science research to the classroom. Our findings indicate that applying research-based design principles to arithmetic practice improves student understanding of mathematical equivalence enough to support transfer to novel problem types.

Keywords: Mathematical representations; relational reasoning; mathematics education; randomized control trial

## Introduction

Can a research-based, early elementary intervention help students learn key concepts that may prevent later struggles in algebra? Research suggests that understanding mathematical equivalence is a critical component of algebraic reasoning (Carpenter, Franke, \& Levi, 2003; Charles, 2005; Knuth, Stephens, McNeil, \& Alibali, 2006). However, the majority of US students fail to reason with and apply concepts of equivalence (McNeil \& Alibali, 2005), making encoding errors when remembering mathematical equations (e.g., McNeil \& Alibali, 2004), and interpreting the equal sign to mean "calculate the total"
rather than "two amounts are the same" (e.g., Behr, Erlwanger, \& Nichols, 1980).

Why do so many students lack a relational understanding of the equal sign? McNeil and Alibali (2005) proposed a change-resistance account: traditional arithmetic instruction that focuses on procedures (i.e., solving problems such as $3+4=$ ) promotes a misconception of the equal sign as a request for an answer and interferes with the development of relational understanding. The majority of examples of arithmetic problems in early elementary math curricula show operations (e.g., addition and subtraction) on the left of the equal sign and the "answer" on the right (Seo \& Ginsburg, 2003). Children detect and extract patterns from these examples and ultimately construct long-term memory representations. Although default representations typically speed computation in the problem-solving contexts that children encounter most frequently, these representations may lead to difficulties when patterns are mistakenly transferred to similar, but non-applicable, problem types (e.g., Bruner, 1957).

McNeil and Alibali characterize the representations that develop in early mathematics as "operational patterns" as they reflect an understanding of arithmetic that focuses on the operators (e.g.,,,$+- \times, \div$ ) rather than the relational nature of mathematical equations. Research has identified three types of operational patterns that represent a distorted view of arithmetic and hinder conceptual understanding of the underlying mathematics. First, children learn to expect math problems to have all operations on the left side of the equal sign, with the equal sign immediately before the answer blank on the right, an "operations $=$ answer" problem format (McNeil \& Alibali, 2004). Second, children learn to interpret the equal sign operationally as a symbol to do something (Baroody \& Ginsburg, 1983; Behr et al., 1980). Third, children learn to perform operations on all given numbers in a math problem (e.g., add up all the numbers in an addition problem, McNeil \& Alibali, 2005).

Once entrenched, children rely on these potentially misleading patterns when encoding, interpreting, and solving novel mathematics problems. Students that expect all problems to have operations on the left fail to correctly encode the problem being asked. For instance, after briefly viewing the problem "7 + 4+5=7+_" many children rely on their knowledge of the "operations = answer" problem format and erroneously remember the problem as "7 $+4+5+7=\ldots$ (McNeil \& Alibali, 2004). Students also struggle to interpret what a mathematical problem is asking. When asked to define the equal sign-even in the context of a mathematical equivalence problem-many children treat it like an arithmetic operator (like + or - ) that means they should calculate the total (McNeil \& Alibali, 2005). Finally, entrenched patterns mislead students to solve the problem " $7+4+5=7+\ldots$ " by performing all given operations on all given numbers and put 23 (instead of 9) in the blank (McNeil, 2007; Rittle-Johnson, 2006). These findings support the idea that children's difficulties with mathematical equivalence are partially due to inappropriate knowledge derived from overly narrow experience with traditional arithmetic.

## The ICUE Intervention

Current math practice seems to promote the development of faulty representations, and the change-resistance account's focus on "operational patterns" offers design principles for instruction to improve students' understanding of equivalence. Initially, researchers hypothesized that greater exposure to "non-traditional" arithmetic practice (e.g., presenting operations on the right side of the equation, "_ $=2+4$," [McNeil et al., 2011], organizing practice by equivalent sums [ McNeil et al., 2012], and using relational phrases such as "is equal to" instead of the equal sign in problems [Chesney, McNeil, Petersen, \& Dunwiddie, 2012]). may prevent students from developing operational patterns. Though practice with non-traditional arithmetic in a classroom intervention led to improved outcomes over traditional instruction, a number of students failed to reach proficiency (McNeil, Fyfe, \& Dunwiddie, 2015).

To further promote mastery of equivalence, McNeil and colleagues added additional design features beyond nontraditional arithmetic practice. The current version of the materials, dubbed Improving Children's Understanding of Equivalence (ICUE), consists of second grade student activities that reduce reliance on operational patterns and promote deep understanding of mathematical equivalence through four key components that have independently been shown to be effective:

1. Non-traditional arithmetic practice (Chesney et al., 2012; McNeil et al., 2012, 2015, 2011);
2. Lessons that first introduce the equal sign outside of arithmetic contexts (e.g., " $28=28$ ") before introducing arithmetic expressions (e.g., Baroody \& Ginsburg, 1983; McNeil, 2008);
3. Concreteness fading exercises in which concrete, real-world, relational contexts (e.g., sharing stickers,
balancing a scale) are gradually faded into the corresponding abstract mathematical symbols (e.g., Fyfe, McNeil, Son, \& Goldstone, 2014); and
4. Activities that require students to compare and explain different problem formats and problemsolving strategies (e.g., Carpenter et al., 2003; RittleJohnson, 2006).

## The Current Study: Improving Children's Understanding of Equivalence

A pilot study found the ICUE intervention was successful in improving student understanding of mathematical equivalence (Byrd, McNeil et al. 2015; McNeil, Hornburg, Brletic-Shipley, \& Matthews, under review). The current study sought to replicate the findings with a new population of students and additionally investigate whether the learning transferred to the mathematical practice of generating explanations.

To replicate Byrd et al.'s (2015) pilot study, we compared the full ICUE intervention to a control condition consisting solely of non-traditional mathematical practice and measured students' ability to encode equations, solve problems, and define the relational function of the equal sign.

To test whether the learning transferred to the ability of students to generate mathematical explanations related to arithmetic problems, we gave students performance tasks from the Silicon Valley Mathematics Initiative's (SVMI) Mathematics Assessment Collaborative (MAC). MAC partners with the Mathematics Assessment Resource Service (MARS) to develop tasks that assess core mathematical ideas and practices taught in each grade level. Tasks require students to solve complex math problems as well as give open-ended explanations of their reasoning. For each task, MARS provides scoring rubrics and scorer training procedures, student performance statistics, and examples of common student errors (Foster \& Noyce, 2004).

Our research questions were:

1. Does ICUE promote measurable gains in children's understanding of equivalence?
2. Do the benefits of ICUE activities transfer to generating mathematical explanations?

## Method

## Design

We used a cluster-randomized control trial design to examine the efficacy and generalizability of the ICUE intervention relative to an active control program. Teachers were randomly assigned to use the either the ICUE intervention or Active Control materials. The active control consisted of workbook activities to control for time on task. The active control contained non-traditional arithmetic practice but not the additional components present in ICUE, described above.

Participants. Five second-grade teachers (three treatment, two control) from three California schools used the activities in their classrooms. Class sizes ranged from 21 to 32 , and we analyzed data from 81 students who completed the ICUE activities and measures and 49 students who completed the Active Control activities and measures.

## Procedure and Materials

The procedure for ICUE Treatment and Active Control conditions were identical, differing only in the content of the materials used by teachers and students. Each teacher received training on the study purpose, features of the activities, and strategies for integrating the activities into their typical mathematics curriculum.

Prior to starting the study, participating teachers completed online surveys assessing their mathematics teaching experience and classroom structure and dynamics.

After administering a pretest, teachers used the study materials for approximately 15 minutes twice each week for 16 weeks. In both conditions, teachers were asked to use the study materials to supplement, rather than replace, current instruction, and to limit session duration to 20 minutes.

After completing the 32 sessions, teachers administered the same pretest measure of mathematical equivalence, a proximal transfer measure, two measures of transfer to mathematical explanations, and the Math Concepts subtest of the Iowa Test of Basic Skills.

Active Control. Teachers in the Active Control condition received a set of student workbooks (see Figure 1) and a teacher guide.

Figure 1. Sample workbook page from the Active Control condition materials featuring non-traditional math practice.

ICUE. Teachers in the ICUE Treatment condition received a set of student workbooks (see Figure 2), a teacher guide, and a set of classroom manipulatives including balance scales and flashcards.

## Measures

Pre- and post-test measures of mathematical equivalence. We assessed children's understanding of
mathematical equivalence before and after the interventions using similar measures of equation encoding, equation solving, and defining the equal sign used in previous work by McNeil and colleagues (Byrd et al., 2015; McNeil \& Alibali, 2005; McNeil et al., 2015).

Figure 2. Sample workbook page from the ICUE Treatment condition materials featuring a concreteness fading exercise.

Equation encoding. The encoding measure consisted of recalling four mathematical equivalence problems (e.g., $5+$ $4=3+\ldots$ ) presented one at a time. Each equation was visible for five seconds and students were instructed to remember and write down exactly what they saw after the equation was hidden from view. Responses were coded as correct if the student wrote the equation exactly as shown (i.e., the correct numbers and symbols in the correct order).

Equation solving. The equation solving measure consisted of eight equations with operations on both sides of the equal sign (e.g., $3+5+6=3+$ $\qquad$ ).
Defining the equal sign. The defining the equal sign measure prompted students to write responses to three questions about the equal sign symbol (=): 1) What is the name of this math symbol? 2) What does this math symbol mean? And, 3) Can it mean anything else? Teachers read each question aloud and waited for students to write their responses before moving on to the next question. Responses were coded as relational if the response defined the equal sign as relating two sides of the equation (e.g., two amounts are the same, something is equivalent to another thing). ${ }^{1}$

## Measures of knowledge transfer.

Proximal transfer measure. The proximal transfer measure, used by Byrd et al. (2015), consisted of nine more advanced problems of mathematical equivalence, not strictly aligned with the ICUE intervention. The transfer questions included equations with operations on both sides of the equal sign involving subtraction (e.g., $2+5+3=14$ -
$\qquad$

[^113]larger numbers (e.g., $13+18=\ldots+19$ ), "word problem" items featuring story-to-equation translation, and an "explaining equivalence" problem, which asked students to decide whether the same number should appear in two equations and explain their reasoning.

Distal transfer to mathematical explanations. We selected two MARS items that tested students' understanding of mathematical equivalence, described below. Items were scored by project staff following scorer training, calibration, and reliability procedures established by MARS (Foster \& Noyce, 2004).

Incredible Equations. In this task, students are asked to fill in the missing parts of equations such as "_ $+8+\ldots=$ 16 " and " $11+5=\ldots+8$." Students are asked to explain how they know their answer is correct. When 6,305 students took the task in 2007, the mean score was 6.08 out of 10 with a standard deviation of 2.5 (MARS, 2007).

Agree or Disagree? In this task, students are asked if they agree or disagree with two number sentences: " $8+5=5+8$ " and " $6-4=4-6$ ". Students are asked to explain their answers using words, numbers, or pictures. MARS administered this task to 4,585 second graders in 2004 and found the mean score was 3.10 out of 6 with a standard deviation of 1.94 (MARS, 2004).

Iowa Test of Basic Skills. To make sure any gains in understanding of equivalence do not come at the expense of problem-solving fluency, students completed the Math Concepts subtest of Level 8 of the Iowa Tests of Basic Skills (ITBS), which served as a measure of general mathematical reasoning. Participation in the ICUE Treatment neither helped nor hurt students' performance on this measure, relative to the Active Control group $(t(83)=1.48, n s)$, establishing that the intervention does not improve understanding of equivalence at the expense of general computational fluency.

## Results

## Does ICUE promote measurable gains in children's understanding of equivalence, relative to an Active Control?

We assessed three critical abilities identified by McNeil and colleagues as necessary for success in reasoning about equivalence (Byrd et al., 2015; McNeil et al., under review):

1. Equation encoding: the ability to accurately encode and recreate an equation after seeing it briefly;
2. Equation solving: the ability to solve equations that feature operations on both sides of the equal sign; and
3. Defining the equal sign $(=)$ : the ability to identify " $=$ " as a symbol that signals a relation between two equal numbers or quantities.

Specifically, we examined students' gains in performance on identical pre-intervention and post-intervention tests that assessed the three abilities above. For each of the target abilities, we compared the gains made by students in the

ICUE Treatment condition to those of students in the Active Control condition (Figure 3).

There were no reliable differences between pretest scores for each group, and students in the ICUE Treatment condition made substantially greater gains during the intervention than students in the Active Control condition. The proportion of correct responses for Equation solving items increased by 0.65 for ICUE students, compared to only 0.065 for Active Control students $(t(119)=48.8$, $p<.001$; Cohen's $d>3$ ); the proportion of correct responses for Equation encoding items increased by 0.34 for ICUE compared to 0.26 for Active Control $(t(52)=5.31, p<.001$; Cohen's $d>3$ ); and the proportion of correct definitions of the equal sign increased by 0.38 for ICUE compared to 0.02 for Active Control $(t(125)=8.42, p<.001$; Cohen's $d>3$ ). These results suggest that the ICUE Treatment intervention leads to systematic and measureable gains in children's understanding of and reasoning about mathematical equivalence.

Figure 3. Mean performance gains from pre- to post-test for children in the ICUE and Active Control groups.

## Do the benefits of ICUE activities transfer to more challenging material and generating mathematical explanations?

We explored whether the knowledge that children gained from the intervention activities transferred to problemsolving tasks that were not strictly aligned with the content and goals of the ICUE or Active Control interventions. We first examined performance on a proximal researcherdeveloped measure that included a series of complex equation solving items, word problem items that required translating story content into mathematical equations, and an explaining equivalence item that required students to justify why two sides of an equation were equal (i.e., "Is the number that goes in the the same number in the following two equations? Explain your reasoning."). We compared the performance of ICUE and Active Control students on the measure, which was administered after each group completed all intervention activities (Figure 4).

Figure 4. Mean ICUE and Active Control group performance for researcher-developed transfer items.

Students in the ICUE condition scored reliably higher, on average, than students in the Active Control condition on both complex equation solving items $(t(81)=3.44, p<.01$; Cohen's $d=1.5$ ) and word problem items $(t(129)=5.31$, $p<001$; Cohen's $d=2.5$ ). However, the groups did not differ in their mean performance on the explaining equivalence item $(t(81)=0.15, n s)$.

We also examined transfer to the MARS items. We measured post-intervention performance on the "Incredible Equations" task (scored out of a possible 10 points) and the "Agree or Disagree?" task (scored out of a possible 6 points). As before, we compared performance by students in the ICUE and Active Control conditions, shown in Figure 5. As one teacher from each condition failed to return the MARS posttest materials, results are reported from two treatment teachers and one control teacher.

Students in the ICUE condition performed reliably better than Active Control students on both the Incredible Equations $(t(54)=2.83, p<.05$; Cohen's $d=0.32)$ and Agree or Disagree? tasks $(t(47)=2.36, p<.05$; Cohen's $d=0.43)$.

## Conclusions

A deep understanding of mathematical equivalence is a key building block for later mathematical understandings. However, research studies and national test results have repeatedly demonstrated that many students fail to develop this understanding. The change-resistance account suggests that traditional instruction that relies on extensive practice with problems in a single format may be contributing to students' difficulties by encouraging students to develop ineffective mental models of problem types.

In the current study, we sought to replicate and extend prior work that brings research from the lab into the classroom. The change-resistance account proposes that students struggle with equivalence because they have developed overgeneralized "rules" that affect how they process and approach math problems, (e.g., the operators are always on the left side, the equal sign means to "do something" or "give the answer") and fail to see equations having two separate sides that are being related to one another.

Figure 5. Mean ICUE and Active Control group performance for MARS transfer items.

Overall, our findings indicate that applying researchbased design principles in the form of multiple types of practice improved student understanding of the critical concept of mathematical equivalence.
Our findings replicate Byrd et al. (2015), who found that activities that include the use of the equal sign outside of arithmetic contexts, that start with concrete examples and fade to extractions, and that explicitly prompt students to compare and explain different problem formats and strategies improve student understanding of mathematical equivalence beyond non-traditional arithmetic practice alone.

Students receiving the ICUE materials demonstrated improved performance in equation solving, equation encoding, and providing relational definitions of the equal sign. These improvements did not come at the expense of arithmetic problem-solving fluency, as measured by the ITBS. Further, the learning in ICUE transferred to greater student abilities to solve complex equations and word problems.

Students in both conditions struggled with the researcherdeveloped item that required students to explain equivalence. Their poor performance may reflect confusion with equivalence that persists for more complicated problems with multiple "terms" and different types of operators (both addition and subtraction), a confusion that was reflected in students' explanations of their answers.
The robust improvements on the MARS items supports the possibility that the lack of transfer in the equivalence explanation question was due to confusion regarding multiple terms and operators rather than the ability to generate the explanation. These established items, developed externally, also asked students to explain equivalence, but used blanks, rather than variables, to reflect the unknown entities. On both items, students in the ICUE condition outperformed the students in the active control condition. These findings suggest that the additional practice comparing and explaining different problem formats helped students gain a deeper understanding of not only whether different examples were equivalent, but also why or why not.

Why is it important to test the synergistic effect of research-based design principles? Instructional designers face a large number of decisions in selecting appropriate activities and tasks for students. Though much research seeks to identify how different facets work independently, if research in cognitive science is to extend meaningfully to practice the cumulative effects of using multiple strategies must be tested. Our small-scale cluster-randomized trial suggests that the multi-component ICUE intervention was more effective than an active control of non-traditional arithmetic practice (which in prior work was also more effective than traditional instruction).

Future work, in progress, will test the efficacy of the ICUE intervention in a large-scale cluster-randomized trial with diverse students across the state of California. This work demonstrates how findings in the lab can be successfully implemented in authentic classroom settings to improve student learning outcomes.

#### Abstract

People often prefer simpler explanations because they have higher prior probability. However, simpler explanations are not always normatively superior because they often do not fit the data as well as complex explanations. How do people negotiate this trade-off between prior probability (favoring simplicity) and goodness-of-fit (favoring complexity)? Here, we argue that people use opponent heuristics-relying on simplicity as a cue to prior probability but complexity as a cue to goodness-of-fit (Study 1). We also examine factors that lead one or the other heuristic to predominate in a given context. Study 2 finds that people have a stronger simplicity preference in deterministic rather than stochastic contexts, while Study 3 finds that people have a stronger simplicity preference for physical rather than social causal systems. Together, we argue that these cues and contextual moderators act as powerful constraints that help to specify otherwise illdefined hypothesis comparison problems.

Keywords: Causal reasoning; explanation; probabilistic reasoning; heuristics; judgment under uncertainty.

## Introduction

The principle of parsimony has a long and venerable pedigree. It has been discussed since at least Aristotle, who wrote in his Physics that "nature operates in the shortest way possible," and it has since become one of the core tools in our argumentative arsenal as scientists. Of course, this principle was given its most famous formulation given by William of Occam, who advised against "multiplying entities beyond necessity."

Simplicity is not only a core notion in science and philosophy, but may well be an organizing principle of cognition (Chater \& Vitányi, 2003). People prefer simpler causal explanations (Lombrozo, 2007), category assignments (Pothos \& Chater, 2002), and perceptual organizations (van der Helm \& Leeuwenberg, 1996), and more easily learn simple concepts (Feldman, 2000).

This principle is not arbitrary. Other things equal, simpler explanations are more likely to be true because they have higher prior probability. Consistent with this analysis, Lombrozo (2007) found that people use simplicity as a heuristic for estimating prior probabilities. In her experiments, participants performing simulated medical diagnoses would not accept a complex explanation over a simple one unless the prior probabilities favored the complex explanation by a factor of 4 . Further, participants who had a simplicity bias had distorted memories of the disease base rates, recalling the simpler explanations as having had higher prior
probabilities than they in fact did. Thus, people's preference for simple explanations, though sometimes stronger than normatively warranted, appears to track the probabilistic logic favoring simpler explanations.

Yet, simplicity has its limits because a simple and a complex explanation do not always fit the data equally well. There is generally a U-shaped curve in how simple an explanation ought to be. Too complex, and the explanation has a lower prior probability and overfits the data; too simple, and it does not account for the nuance of the phenomenon (Forster \& Sober, 1994). How, if at all, does cognition perform this trade-off?
We propose that people use opponent heuristics to compare a simpler versus a more complex explanation. This view incorporates Lombrozo's (2007) insight that people use simplicity to estimate prior probability-the $\mathrm{P}\left(H_{i}\right)$ terms in Bayesian hypothesis comparison-but couples it with the idea that people also use complexity to estimate likelihoods-the $\mathrm{P}\left(E \mid H_{i}\right)$ terms that measure the goodness-of-fit of the evidence to the data.
For example, if a patient is sneezing and has a stomach ache, the patient could have a cold. This explanation is simple, but fits the data imperfectly. If we took a random sample of the population, a reasonably large fraction would have a cold at any given time-so this explanation has high prior probability. But among those people who have a cold, how many of them would both be sneezing and have a stomach ache? The facts here are complex, and this simple explanation does not fit very well.

In contrast, the patient could have both allergies and a stomach virus. This explanation is more complex, but fits the data neatly. In a random sample of the population, a fairly small number would have both allergies and a stomach virus. Yet, many of those who do have both diseases would likely be suffering from both sneezing and a stomach ache. Even though the prior probability of this complex explanation is low, it fits the data very well.

In this case, simplicity seems to be associated with our estimate of prior probability and complexity seems to be associated with our estimate of likelihood. Of course, this explanation was engineered to produce these intuitions by relying on specific beliefs we have about these diseases. The opponent heuristic account proposes that people also use simplicity and complexity as cues in cases where they cannot estimate probabilities directly from background knowledge. Study 1 tests this possibility.

Initial evidence for this idea comes from studies of intuitive curve-fitting-a superficially distinct but deeply related problem to causal explanation. For any set of scatterplot data, many different trend curves can be drawn
to explain the data, but statistical theory can tell us which curve has the best predictive power, fitting as much of the underlying signal as possible while fitting little of the noise. Yet, people tend to choose curves that are more complex than they normatively should be, rather than curves that are too simple (Johnson, Jin, \& Keil, 2014), as one would expect if people only have a simplicity heuristic but no complexity heuristic. Indeed, these curvefitting studies uncovered direct evidence of a complexity bias, because participants judged the more complex to be literally closer fits to the data, even when the actual fit was held constant. This finding is also consistent with naturalistic studies of everyday verbal explanations drawn from an Internet corpus, for which the best explanations actually tend to be fairly complex (Zemla et al., 2017).

Why is this pair of heuristics useful? Simplicity is just the absence of complexity. How, then, can a pair of heuristics accomplish any more than a single heuristic, when these two heuristics rely on the same cue? While it may seem more parsimonious to assume that people merely use one cue in a U-shaped manner, it is difficult to specify, for any given problem, where the bend in this $U$ should be. Contextual factors (along with background knowledge) must work to calibrate the strength of these two heuristics, in order to produce a unique solution in any given case. Although there is no reason to think that a context-sensitive dual heuristic solution will give an optimal answer, there is reason to think that it may bring the reasoned closer to the right part of the hypothesis space, compared to either heuristic working alone or to any cookie-cutter U-shaped response to simplicity that is not calibrated to the explanatory problem. The current studies look at two possible contextual factors that might modulate the strength of the two heuristics.

First, we consider the determinism of the causal system. In previous studies of simplicity (Lombrozo, 2007), explanations have been produced for deterministic causal systems. In such systems, it is rational to prefer simple explanations. If disease $A$ always causes symptoms $X$ and $Y$, while disease $B$ always causes symptom $X$ and disease $C$ always causes symptom $Y$, the issue of likelihoods or goodness-of-fit simply does not come up: Disease $A$ perfectly explains the evidence, and so do Diseases $B$ and $C$ together. The only issue is which explanation has the higher prior probability, and the simplicity heuristic tells us that, absent any other information, the answer is Disease $A$. Therefore, there is no reason to invoke a complexity heuristic to countervail against the presumption of a simple explanation.

In contrast, when the causal system is stochastic, the likelihoods become a more crucial part of the computation. If disease $A$ sometimes causes $X$ and sometimes causes $Y$, while disease $B$ sometimes causes $X$ and disease $C$ sometimes causes $Y$, it is difficult to evaluate whether the evidence (symptoms $X$ and $Y$ ) are made likelier by disease $A$ or by diseases $B$ and $C$ combined: It depends on the nature of "sometimes." Yet,
in the real world, it is the exception rather than the rule to have precise quantitative information about these likelihoods in stochastic systems. If people rely on a complexity heuristic in such cases, they would judge the likelihood of the evidence to be higher for an individual with two diseases than for an individual with one disease. Study 2 tests whether stochastic contexts therefore lead to a weaker simplicity preference.

Second, we consider the content domain of a causal system. People seem to have different beliefs about the causal textures of different domains. Whereas people tend to identify physical events as having relatively few causes, social events are often thought to have many causes (Strickland, Silver, \& Keil, 2016). This suggests that people may calibrate their prior expectations to more complex explanations in the social domain, compared to the physical domain. Furthermore, people may even deploy different causal concepts across domains (Lombrozo, 2010). Whereas causal claims about physical systems appear to be evaluated in terms of transference and contact, social causal claims appear to be evaluated counterfactually. This too may reinforce the intuition that physical events typically result from highly specified causal factors, whereas social events result from more complex configurations of counterfactual conditions. Since such complex conditions can seldom be known, social systems are often highly unpredictable.

As a consequence of these domain-specific beliefs, people may rely on simplicity as a cue to prior probability to a differing degree across domains. Whereas simplicity is likely to be a potent heuristic for evaluating explanations of physical causation, it may be a weaker cue for evaluating explanations of social causation, if people have a meta-theory that assigns higher prior probabilities to complex social causal explanations, as compared to physical causal explanations. In addition, if social causal systems are seen as more stochastic, this would increase the importance of the complexity heuristic for evaluating explanations of social causation, as compared to physical causation. With a weaker simplicity heuristic and stronger complexity heuristic, people may have a less pronounced bias toward simple explanations in the social domain. Study 3 tests this idea.

## Study 1

To a Bayesian, the key quantities required to compare two hypotheses are the relative prior probabilities of the hypotheses (the prior odds), and the relative fit of each explanation to the data (the likelihood ratio). Study 1 tests whether people use simplicity to estimate these quantities.

Study 1A seeks converging evidence for Lombrozo's (2007) claim that people assign higher prior probabilities to simple hypotheses. Study 1 B tests whether this heuristic favoring simple explanations might be opposed by a heuristic that assigns higher likelihoods to more complex explanations: Do people believe that complex explanations are better fits to the data?

## Method

Participants in all studies were recruited from Amazon Mechanical Turk. Each study included a series of check questions at the end, and participants were excluded from analysis if they answered more than $33 \%$ incorrectly.

Participants ( $N=80,9$ excluded) were randomly assigned to Study 1A (making judgments about priors probabilities) or to Study 1B (making judgments about likelihoods). In both studies, participants completed four items about diseases, similar to the following problem:
There is a population of elves that lives at Gelfert's Glacier. Sometimes the elves have medical problems such as feverish muffets or wrinkled ears.
A Yewlie infection can cause feverish muffets.
A Yewlie infection can cause wrinkled ears.
Hepz's disease can cause feverish muffets.
Aeona's syndrome can cause wrinkled ears.
Nothing else is known to cause an elf's muffets to be feverish of the development of wrinkled ears.

On the same screen, participants completed a series of 10 true/false questions to ensure comprehension.
Participants in Study 1A were then asked to judge the relative prior probabilities ("Imagine that we randomly select an elf from Gelfert's Glacier. Which of the following types of elves do you think we are more likely to have selected?") on a 10 -point scale, with one end corresponding to the simple explanation ("An elf who has a Yewlie infection only") and one end to the complex explanation ("An elf who has both Hepz's disease and Aeona's syndrome"). Participants in Study 1B were asked to judge the likelihoods ("Imagine an elf who has a Yewlie infection only, and another elf who has both Hepz's disease and Aeona's syndrome. Which elf do you think is more likely to develop both feverish muffets and wrinkled ears?") on the same scale.

## Results and Discussion

Data for all studies were recoded so that negative numbers correspond to the simple explanation and positive numbers to the complex explanation.

Participants in Study 1A used a simplicity heuristic, indicating that a randomly selected elf was more likely to have one disease than two diseases $[M=-2.19, S D=$ 1.78; $t(33)=7.19, p<.001, d=1.23]$. This is consistent with Lombrozo's (2007) studies, where overwhelming prior odds were required before participants would favor a complex over a simple explanation in deterministic cases.

However, the story was different for judgments of likelihoods or goodness-of-fit. Here, participants favored the complex explanation $[M=1.41, S D=2.35 ; t(36)=$ $3.65, p=.001, d=0.60]$. This complexity bias in estimating likelihoods was substantial in magnitude ( $d=$ 0.60 ), though smaller than the simplicity bias in estimating priors ( $d=1.23$ ), at least for these stimuli.

These results shows that people do not blindly prefer simple explanations, but instead calibrate their
preferences according to the question asked. Even though the problem did not include any probability information, participants used simplicity and complexity to estimate different probabilistic quantities in opposing ways.

## Study 2

In any causal system where there is uncertainty about which explanation is correct, the prior probabilities of each explanation must be less than 1 , since otherwise there is no reason to observe any data (as it will fail to move the posteriors). However, the likelihoods differ across deterministic and stochastic systems. In deterministic systems, the evidence is always produced with probability 1 by its causes, whereas in stochastic systems, these likelihoods are less than 1.

If explanatory heuristics exist in part because degrees of uncertainty are difficult to estimate and to use in computations, then a simplicity heuristic will always be a useful tool for estimating priors, since they are always uncertain. However, a complexity heuristic is only useful in stochastic systems, where the likelihoods are uncertain. Thus, both heuristics should be at work in stochastic systems (a simplicity heuristic pushing toward simpler explanations and a complexity heuristic pushing toward more complex explanations), whereas only the simplicity heuristic applies in deterministic systems (pushing toward simpler explanations, without an opposing force pushing toward more complex explanations). This leads to the prediction that people should especially favor simple explanations for deterministic systems.

## Method

Participants ( $N=80$, 14 excluded) completed four items corresponding to the cover stories used in Study 1. For one of these items-in the $100 \%$ condition-the causal system was described as deterministic, in that the diseases always led to their symptoms ( $100 \%$ likelihood):

Tritchet's syndrome always ( $100 \%$ of the time) causes both sore minttels and purple spots.
Morad's disaease always ( $100 \%$ of the time) causes sore minttels, but the disease never ( $0 \%$ of the time) causes purple spots.
When an alien has a Humel infection, that alien will always ( $100 \%$ of the time) develop purple spots, but the infection will never ( $0 \%$ of the time) cause sore minttels.

The other three items corresponded to the $90 \%, 80 \%$, and $70 \%$ conditions, which differed only in the causal system being described as stochastic:
Tritchet's syndrome often ([80/65/50]\% of the time) causes both sore minttels and purple spots.
Morad's disaease often (([90/80/70]\% of the time) causes sore minttels, but the disease never ( $0 \%$ of the time) causes purple spots.
When an alien has a Humel infection, that alien will often (([90/80/70]\% of the time) develop purple spots, but the infection will never ( $0 \%$ of the time) cause sore minttels.

After reading this information, participants were asked about their favored explanation ("Which do you think is the most satisfying explanation for Treda's symptoms?") on a scale from 0 (Tritchet's syndrome only) to 10 (both Morad's disease and a Humel infection). The conditions were balanced across the cover stories using a Latin square, and items were completed in a random order.

## Results and Discussion

Participants strongly preferred the simple explanation [ $M$ $=-3.81, S D=1.95 ; t(65)=15.84, p<.001, d=-1.95]$ given deterministic ( $100 \%$ ) likelihoods. This replicates Lombrozo's (2007) finding that people strongly favor simple explanations in deterministic causal systems.

The key question is whether this preference would differ in the stochastic conditions, where a complexity heuristic would be more likely at play for understanding the likelihoods. To keep the likelihood ratio objectively identical across conditions, the likelihood for the simple explanation must equal the product of the likelihoods for the components of the complex explanation (i.e., $90 \% \times$ $90 \% \approx 80 \%, 80 \% \times 80 \% \approx 65 \%$, and $70 \% \times 70 \% \approx 50 \%$ ). This calculation assumes that people believe diseases to cause their symptoms independently-an assumption that Lombrozo (2007) validated for her very similar stimuli.

As predicted by the opponent heuristic account, the simplicity bias was weaker in each of the three stochastic conditions, although participants still had a robust simplicity preference in each of them $[M=-3.00, S D=$ 2.68, $t(65)=9.09, p<.001, d=1.12$ for the $90 \%$ condition; $M=-2.50, S D=2.58, t(65)=7.86, p<.001$, $d=0.97$ for the $80 \%$ condition; $M=-2.48, S D=2.45$, $t(65)=8.24, p<.001, d=1.01$ for the $70 \%$ condition]. The simplicity bias in the stochastic conditions, while large ( $d$ from 0.97 to 1.12 ), was smaller compared to the deterministic condition ( $d=1.95 ; p \mathrm{~s}>.012$ ), as predicted.

However, this design is subject to concerns about demand characteristics and difficulties with probabilities that are unrelated to the proposed mechanisms. In particular, the deterministic condition set all likelihoods to $100 \%$, whereas the stochastic condition had to set different likelihoods for the simple explanation and for each component of the complex explanation. Could people have relied on a strategy such as comparing these numerical likelihoods ( $100 \%$ vs. $100 \%$ and $90 \%$ vs. $80 \%$ for complex vs. simple), favoring the complex explanation in the stochastic conditions merely because it was superficially associated with higher numbers?

If this were the case, people should be increasingly less biased toward the simple explanation as the difference between the simple and complex likelihoods increased. This difference increases not only between the deterministic and stochastic conditions, but also across the stochastic conditions ( $90 \%$ vs. $80 \%, 80 \%$ vs. $65 \%$, and $70 \%$ vs. $50 \%$ ). Thus, on this deflationary account there should be large gaps not only between the deterministic and stochastic conditions, but also among
the stochastic conditions. In contrast, the opponent heuristic account predicts a qualitative shift between the deterministic condition and the stochastic conditions that introduce uncertainty into the likelihoods.

The data are more consistent with the latter prediction, as suggested by the similar effect sizes of the simplicity bias across the three stochastic conditions. There is a significant difference between the $100 \%$ and $90 \%$ conditions, where we shift from deterministic to stochastic $[t(65)=2.61, p=.011, d=0.32]$. However, the difference between the $90 \%$ and $80 \%$ conditions reaches only marginal significance $[t(65)=1.88, p=.064, d=$ 0.23 ] and the difference between the $80 \%$ and $70 \%$ conditions is nowhere near significant $[t(65)=0.04, p=$ $.97, d=0.01]$. The deflationary account would predict equally large differences across these sets of conditions.

Thus, determinism may play a role in striking the balance between the simplicity and complexity heuristics. These results also resolve a puzzle about Lombrozo's (2007) findings. Given that people are reasonably wellcalibrated in evaluating explanations in the real world, it is surprising to see such a striking simplicity bias as one finds in her studies, with prior odds of 4-to-1 required to override a simplicity preference when the evidence is perfectly consistent with either hypothesis. Study 2 found that in more ecologically realistic conditions, where the evidence is not perfectly predicted by any explanation, people are more likely to hedge their bets. People may thus make more accurate explanatory inferences in realistic, stochastic environments.

## Study 3

A second contextual factor that may influence preferences of simple and complex explanations is a system's content domain. People believe that physical events have fewer causes than social events (Strickland, Silver, \& Keil, 2016) and use causal concepts relying on physical transference for physical systems but complex counterfactual conditions for social systems (Lombrozo, 2010). Thus, Study 3 tests the possibility that people would use these expectations to calibrate their explanatory inferences, favoring simpler explanations in physical causal systems compared to social systems.

## Method

Participants ( $N=479$, 89 excluded) read 12 items across four content domains (physics, biology, artifact, and social), which were deterministic for half of participants and stochastic for the other half. These items had the same format as the items used in Study 2, but the content was replaced with various items in physical (ultraviolet waves, subatomic particles), biological (disease, agriculture, dieting), artifact (robots, clocks, toys), and social (team dynamics, child behavior, and romantic attraction) causal systems. Participants then made explanatory judgments on the same scale as Study 2. Items were completed in a random order.

|  | Deterministic | Stochastic |
| :--- | :---: | :---: |
| Physical | $-2.76(2.10)$ | $-2.15(2.40)$ |
| Biological | $-2.59(2.19)$ | $-2.15(2.28)$ |
| Artifact | $-2.32(2.41)$ | $-1.81(2.53)$ |
| Social | $-1.81(2.71)$ | $-1.22(2.59)$ |

Table 1: Means (SDs) in Study 3.

## Results and Discussion

Table 1 shows the effects of both moderators (negative scores reflecting an overall simplicity preference). First, as in Study 2, participants favored the simple explanations more strongly for deterministic than for stochastic systems $[t(388)=2.52, p=.012, d=0.26]$. Thus, the shift seen in Study 2 was not unique to unfamiliar stimuli, or specific to reasoning about diseases. Rather, it is a general pattern used across many content domains.

Second, the ordering of the means across domains was consistent with predictions. Critically, participants had a much stronger simplicity preference in the physical than in the social domain $[t(389)=8.62, p<.001, d=0.38]$. The biological and artifact domains fell in between, with the strongest preference for the physical, followed by the biological, artifact, then social domains. (Keil, Lockhart, \& Schlegel, 2010 find similar patterns in a different task.)

Together, the results of Studies 2 and 3 help to resolve the puzzle of how people could rely on a single cue-an explanation's simplicity-to do two logically independent jobs: estimating the prior and likelihood of an explanation. If contextual moderators can influence the weighting of the simplicity and complexity heuristics, then a reasoner could reach different conclusions about simplicity and complexity in different contexts, in ways which are broadly adaptive.

However, there are lingering puzzles about what determines the strength and even direction of simplicity and complexity preferences. For example, one might have expected inferences to more strongly favor the simple explanations than they did here, given the strong simplicity preferences found for the artificial items in Study 2. The more moderate inferences here may have occurred because the items were seen as more reflective of the real world-where true determinism is rareleading participants to hedge their bets. Alternatively, participants here could be recruiting background knowledge, relying more on memory rather than reasoning. In that case, the strong simplicity preferences found for artificial items in Studies 1 and 2 may better reflect the underlying reasoning processes.

## General Discussion

We set out to understand how people use simplicity to constrain their evaluation of explanations, making tractable an otherwise ill-defined computational problem. Usually, simplicity is a good cue for an explanation's
prior probability (intuitively, simple causes require fewer stars to align in order to occur) while complexity is a good cue for an explanation's likelihood or fit to the evidence (since complex causes have more opportunities to cause each aspect of the evidence). Study 1 found direct evidence for both of these opponent heuristics, directly asking about participants' priors and likelihoods.

However, our explanatory strategies must be definite enough to provide both a unique answer for a given explanatory problem, but also flexible enough to provide different answers to different problems. The opponent heuristics strategy solves this dilemma by modulating the inference depending on context. Study 2 showed that people shift toward complex explanations in stochastic contexts (because such contexts render a complexity heuristic more computationally relevant), and Study 3 showed that people favor simple explanations to varying degrees across domains, in ways that track people's general expectations about the causal textures of these domains: People believe that physical systems are more linear, whereas social systems are more subject to branching, and people correspondingly favor simple explanations to a greater degree for physical systems.

Explanatory Logic. We view these opponent heuristics as one part of a broader explanatory logic-a set of heuristics and strategies that people use for evaluating explanatory hypotheses across a variety of processes in light of our cognitive and informational limitations (Johnson, 2017). Here, we focused on causal explanation and previous work has found similar effects in visual curve-fitting (Johnson, Jin, \& Keil, 2014), both tasks requiring people to evaluate competing hypotheses (causes, trend lines) for available data (effects, data points). However, many other processes also take this form, including categorization (which category best explains the features?), theory-of-mind (which mental state best explains the behaviors?), language (which meaning best explains the utterance?), and memory (which past events best explain the details I recall?).

In ongoing work, we have been looking at simplicity heuristics in some of these other processes. For example, people can belong to several categories simultaneouslyyou can be a feminist bank teller, a Jewish woman, or a gay cognitive scientist. When explaining particular traits, people tend to favor social categorizations that invoke fewer categories simultaneously, but this bias is weaker when the categories are more loosely (i.e., stochastically) associated with the relevant features (Johnson, Kim, \& Keil, 2016). Similarly, people favor mental-state explanations that invoke relatively fewer goals to explain a particular behavior, but this simplicity preference is weaker when the goals are more stochastically associated with the behaviors (Johnson, 2017). Thus, opponent simplicity heuristics appear to pervade cognition.

The Adaptive Value of Opponent Heuristics. Our empirical argument for opponent heuristics has required us to engineer situations where people make errors.

Nonetheless, we maintain that under more ecologically realistic conditions, these heuristics often serve us well and help to make explanatory reasoning possible.

If you have a well-specified prior distribution and likelihood function, then you can do no better than normative Bayesian inference. Our participants fell short of this standard, making inferences that were unreasonably biased toward simple explanations and influenced by normatively irrelevant factors.

Yet, in the real world, we often lack access to substantial information about probability distributions. We often are confronted with novel situations in which we cannot calculate but must simply guess, based on what little we can glean from the immediate problem and what minimal cues we can bring to bear from our previous experience. It may be true that people seldom encounter cases where they must diagnose an elf, deciding among unfamiliar diseases on the basis of make-believe symptoms, but it is true in real-world medical decisionmaking that we are often faced with highly limited information. Doctors have built up a corpus of statistical knowledge about some familiar diseases, and medical scientists may have some evidence to bring to bear on less familiar ones. Yet, no one has joint probability information about all combinations of diseases and symptoms. We must rely on iffy assumptions and fallible heuristics to make any real progress, even in a highly constrained problem domain such as medical diagnosis.

In other cases, probabilities may be even less evident. When making geopolitical forecasts, assessing the reasons for a friend's odd decision, or debating philosophical conundrums, there may be little relevant prior information, and it may be impossible to model the probabilities with any degree of confidence. This is known as radical uncertainty or Knightian uncertainty (Knight, 1921), and some thinkers argue that many sources of uncertainty are not quantifiable using probabilities (e.g., Levi, 1974; Mises, 2008/1949). In cases of Knightian uncertainty, the best we can do is to adopt rules that work reasonably well most of the time, much as David Hume has argued that our inductive habits are justified by habit rather than logic (Hume, 1977/1748). The use of simplicity and other explanatory heuristics appears to be one such adaptive habit.

This is not to claim that our explanatory habits are untethered to the world. On the contrary, simplicity is usually an excellent principle to use because there are often multiple explanations, varying in complexity, which fit the data equally well. In such cases, the priors generally do favor simple explanations, so a simplicity heuristic is reasonable. But when the explanations vary in likelihood, simplicity will lead us astray, as complex explanations are often better fits to the data. Opponent heuristics allow us to harness both of these general facts to our advantage, while avoiding computations that may be intractable and, in Knightian cases, even impossible.

#### Abstract

Mathematics is critical for making sense of the world. Yet, little is known about how people evaluate mathematical explanations. Here, we use an explanatory reasoning task to investigate the intuitive structure of mathematics. We show that people evaluate arithmetic explanations by building mental proofs over the conceptual structure of intuitive arithmetic, evaluating those proofs using criteria similar to those of professional mathematicians. Specifically, we find that people prefer explanations consistent with the conceptual order of the operations (" $9 \div 3=3$ because $3 \times 3=9$ " rather than " $3 \times 3=9$ because $9 \div 3=3$ "), and corresponding to simpler proofs (" $9 \div 3=3$ because $3 \times 3=9$ " rather than " $9 \div 3=3$ because $3+3+3=9$ "). Implications for mathematics cognition and education are discussed.

Keywords: Mathematics cognition; philosophy of mathematics; explanation; reasoning; concepts and categories.

## Introduction

People track statistical regularities and use these regularities to make sense of the world. Some statistical learning abilities emerge early: Infants use statistics to extract complex visual features (Fiser \& Aslin, 2002) and form categories (Gómez \& Lakusta, 2004). Statistical generalizations are also critical for sense-making in higher cognition. For example, adults and children prefer simpler causal explanations in part because they have higher prior probabilities (Bonawitz \& Lombrozo, 2012; Johnson, Valenti, \& Keil, 2017; Lombrozo, 2007).

Yet, we also seem to track other truths that do not rely on statistical regularities-Platonic, logically necessary regularities such as mathematical truths. From early on, people use mathematical truths to make sense of the world: Even young infants know that if two puppets venture behind a screen, and one comes out, then only one puppet remains behind (Wynn, 1992). Without an understanding of mathematics (i.e., $2-1=1$ ), this eventand many others-would be inexplicable. Mathematical explanation grows even more essential in adulthood, as consumers must account for their spending, programmers must understand the logic of their code, and CEOs must explain their bottom line. For this reason, educators increasingly emphasize the explanatory function of mathematics (Schoenfeld, 1992). For example, the Common Core Standards (2010) state that "one hallmark of mathematical understanding is the ability to justify...why a particular mathematical statement is true or where a mathematical rule comes from" (p. 4).

But to what extent, and by what mechanisms, can
people track such mathematical regularities? Here, we claim that people use a sophisticated set of mechanisms to evaluate mathematical explanations. We argue that people (1) are sensitive to the conceptual structure of arithmetic, (2) construct mental proofs over this structure, and (3) evaluate those proofs using principles that mirror the history, philosophy, and practice of mathematics.
Just as there are intricate connections among concepts in physics and biology, so are mathematical concepts richly structured (Whitehead \& Russell, 1910). For example, geometric facts are grounded in facts about analysis (Bolzano, 1817), and arithmetic facts in set theory (Frege, 1974/1884). More basically, subtraction can be viewed as grounded in addition, multiplication in addition, division in multiplication, and so on (Figure 1; see also Dedekind, 1995/1888; Tao, 2016). Although these concepts need not be viewed asymmetrically, these asymmetries may be psychologically natural. For example, people may follow the principle that more fundamental operations begin with small things and assemble larger things, rather than vice versa. This would make addition more fundamental than subtraction (which breaks larger things into smaller pieces).

We explored the intuitive conceptual structure of mathematics using a simple method-asking people to evaluate mathematical explanations. Consider the explanation " $9 \div 3=3$ because $3+3+3=9$." In one sense, this is a terrible explanation because it is tautological-both facts are necessarily true and logically equivalent. However, we propose that people are willing to evaluate explanations of this sort, and do so as if constructing a mental proof of the explanatory target (here, " $9 \div 3=3$ ") from the putative explanation (" $3+3+3=9$ "), over the conceptual structure in Figure 1. For example, to evaluate " $9 \div 3=3$ because $3+3+3=9$," one would first derive a multiplication fact (" $3 \times 3=9$ ") from the addition fact, and then derive the division fact from that intermediate multiplication fact. We test two principles that people might use for evaluating implicit mental proofs.

First, people may be sensitive to the asymmetric nature of mathematical explanation (Bolzano, 1817; Kitcher, 1975). For example, consider the explanation " $4-2=2$ because $2+2=4$." Although tautological, if this explanation respects a perceived conceptual order, it may be seen as superior to an explanation that does not, such as " $2+2=4$ because $4-2=2$." That is, a statement may be explained in terms of a logically equivalent statement, if that explanation helps to highlight the more conceptually primitive facts grounding it.

Figure 1: Proposed intuitive structure of arithmetic.
Note. Numbers correspond to the proof rules in Table 1, with forward proof rules flowing in the direction of the arrows and reverse proof rules flowing against the direction of the arrows.

| Rule | Input | Output |
| :---: | :---: | :---: |
| Addition/Subtraction Conversion |  |  |
| 1F | $X+Y=Z$ | $Z-X=Y$ |
| 1R | $Z-X=Y$ | $X+Y=Z$ |
| Addition/Multiplication Conversion |  |  |
| 2F | $\Sigma_{Y} X=Z$ | $X \times Y=Z$ |
| 2R | $X \times Y=Z$ | $\Sigma_{Y} X=Z$ |
| Multiplication/Division Conversion |  |  |
| 3F | $X \times Y=Z$ | $Z \div X=Y$ |
| 3R | $Z \div X=Y$ | $X \times Y=Z$ |
| Multiplication/Exponent Conversion |  |  |
| 4F | $X \times X=Z$ | $X^{2}=Z$ |
| 4R | $X^{2}=Z$ | $X \times X=Z$ |
| Exponent/Root Conversion |  |  |
| 5F | $X^{2}=Z$ | $\checkmark Z=X$ |
| 5R | $\sqrt{ } \mathrm{Z}=X$ | $X^{2}=Z$ |

Table 1: Hypothesized rules for mental proofs.
Second, people may prefer explanations that involve fewer steps because such proofs more readily confer understanding (Descartes, 1954/1684; Hardy, 2004/1940; Kitcher, 1983) and are less prone to error (Hume, 1978/1738). For example, " $9 \div 3=3$ because $3+3+3=9$ " might be seen as a worse explanation than " $9 \div 3=3$ because $3 \times 3=9$," since the proof for the former explanation requires two steps (addition to multiplication, multiplication to division) whereas the latter requires only one step (multiplication to division), even though both proofs proceed in the same conceptual order. We test whether people scale their explanatory judgments to proof complexity. If so, this would be evidence not only that people use complexity as a criterion to judge explanatory
quality, but also that people spontaneously construct proofs over the conceptual structure depicted in Figure 1.

Our model assumes that people evaluate these explanations by constructing and evaluating a proof of the explanatory target from the base, using the transformation rules given in Table 1. These correspond to the forward ( F ) and reverse (R) version of each arrow in Figure 1 (see Rips, 1983 for a related idea in propositional reasoning). Proofs are evaluated by assuming a rule cost is incurred for applying each rule, and that the total proof cost is the sum of the costs of the individual rules invoked in the proof. If people are sensitive to proof complexity, then they should prefer proofs with smaller costs. To capture the idea that people prefer explanations consonant with the conceptual order, our model allows forward and reverse rules to have different costs: We predict that reverse rules carry a higher cost than forward rules. That is, a proof has a higher cost to the extent that it uses more rules in general, and more reverse rules in particular. Equivalently, short proofs flowing with Figure 1's arrows would correspond to better explanations than long proofs flowing against the arrows (see examples below).

## Method

We recruited 97 participants from Amazon Mechanical Turk in exchange for a small payment ( $50.5 \%$ female, $\left.M_{\text {age }}=34.0\right)$. Participants were excluded from data analysis if they gave inappropriate answers to the check questions ( $N=6$; see below for details).

Participants rated a series of 30 mathematical explanations. For each explanation, participants were asked "How satisfying do you find this explanation?" on a scale from 0 ("not at all satisfying") to 10 ("very satisfying"). These explanations consisted of all possible pairings of addition, subtraction, multiplication, division, exponent, and root operations, where the constituents were 3 s ; examples are given in Table 2 in the Appendix. For example, across different blocks, participants completed a pair of multiplication/exponent items:

$$
\begin{aligned}
& 3^{2}=9 \text { because } 3 \times 3=9[\text { forward }] \\
& 3 \times 3=9 \text { because } 3^{2}=9[\text { reverse }]
\end{aligned}
$$

Because there are 15 ways of pairing these 6 operations with each other, and two orders (forward and reverse), participants completed a total of 30 items. The forward and reverse items were presented in separate blocks, with the order of the items randomized within each block. The order of the blocks was also randomized.

Check questions were included after the test questions to detect participants who were responding randomly. These always included two items for which one of the equations was false (e.g., " $4+3=7$ because $4+3=2$ " or " $743+259=1,002$ because $743+259=713 "$ ) and two items for which the numbers differed between the two equations (e.g., " $26 \times 47=1222$ because $678-234=444 "$ ). Participants with average answers to these questions that were above the scale midpoint were excluded from data analysis.

## Results

Participants were sensitive to both criteria of conceptual order and proof complexity. We first describe the results relative to the qualitative predictions of the model in order to explain how the model works, and then assess the quantitative fit at both the group and individual levels.

Qualitative model predictions. We anticipated that people would penalize explanations to the extent that the most direct proof requires applying a large number of rules (see Tables 1 and 2), and that application of 'reverse' rules would correspond to a greater penalty. These two principles are captured by (1) computing the shortest distance between the two operations in Figure 1, and (2) penalizing the explanation for each arrow along that shortest path, with arrows in the 'reverse' direction receiving a larger penalty (we call this penalty $R$ ) than arrows in the 'forward' direction (a smaller penalty of $F$ ).

For example, consider explaining a root formula in terms of division (e.g., " $\sqrt{ } 9=3$ because $9 \div 3=3 "$ ). According to our model, people would rate this explanation by producing a mental proof of ' $\sqrt{ } 9=3$ ' from $' 9 \div 3=3$ '. As noted in Table 2, this requires the application of three rules: 3 R (to derive ' $3 \times 3=9$ ' from ' $9 \div 3=3$ '), 4 F (to derive ' $3^{2}=9$ '), and finally 5 F (to derive ' $\sqrt{ } 9=3$ '). Two of these rules are forward and one is backward, so the total penalty is $2 F+1 R$-since this is a relatively high penalty, we would expect this explanation to be rated poorly. In contrast, addition would be seen as an excellent explanation of subtraction, because a subtraction formula (e.g., ' $9-3-3=3$ ') can be derived from addition (' $3+3+3=9$ ') using only one forward rule ( 1 F ), leading to a penalty of only $1 F$. The penalty scores for several of the explanations are given in Table 2 in the Appendix, along with the rules required to perform these proofs.

This model captures several patterns in the means (Table 3 in the Appendix). First, for each operation, we can consider which explanation was rated highest (i.e., the highest mean in each row of Table 3). For the addition operation, which is not conceptually dependent on any of the other operations, its highest rated explanations were subtraction and multiplication-the closest downstream operations. For both subtraction and multiplication, addition is the highest rated explanation, consistent with the topology of Figure 1, wherein both operations depend directly on addition. Similarly, for explaining division and exponentiation, multiplication is highest rated, consistent with Figure 1, in that both operations depend directly on multiplication. Finally, for roots, exponentiation was seen as the best explanation, again consistent with the direct dependence of roots on exponents.

More generally, our model predicts a central role of multiplication and a peripheral role of subtraction. As Figure 1 shows, multiplication is a central node in the conceptual structure of arithmetic-most roads lead to (or from) multiplication-but subtraction is on the periphery. This prediction is borne out by the data. Multiplication is both the most easily explained operation (i.e., the highest
mean in the rightmost column of Table 3) and the operation that explains the most (i.e., the highest mean in the bottom row of Table 3). In contrast, subtraction is least easily explained and explains the least.

Group-level model fitting. We model the results in terms of the sum of the rule costs, shown in Table 2. This analysis assumes that the cost of each rule is determined only by whether it is a forward or reverse rule. Thus, one free parameter $R / F$ is used, reflecting the extent to which $R$ rules were penalized more heavily than $F$ rules.

We modeled the explanation ratings in terms of the summed rule costs, where only the $R / F$ parameter was free to vary. These scores were good predictors of the explanation ratings, $r(28)=-.86, p<.001$. The best fitting value for the $R / F$ parameter was 1.18 , indicating that the explanatory cost of applying reverse rules that go against the conceptual grain of mathematics is $18 \%$ higher than the explanatory cost of applying forward rules. This supports our conjecture that forward explanations (e.g., explaining subtraction in terms of addition) are preferred to their logically equivalent reverse explanations (e.g., explaining addition in terms of subtraction).

This asymmetry between forward and reverse rules is also evident from looking at the means in Table 3. For example, explanations of subtraction in terms of addition were rated more satisfying than explanations of addition in subtraction, since the former grounds an operation in a more psychologically basic operation whereas the latter does the opposite. Since there are five rules in Table 1, there are five directly reversible pairs, as well as four pairs of operations (addition/division, addition/ exponentiation, addition/root, and multiplication/root) that are connected by applying two or more rules in the same direction (see Proof column in Table 2). Averaging across these pairs, the forward explanations were seen as more satisfying than the reverse, $t(90)=3.90, p<.001$.

Individual-level model fitting. Our model also captures individual participants' explanatory judgments. To test the proof complexity factor, we calculated, for each participant, the correlation between the explanatory judgment for each of the 30 items and the number of rules required for that item's proof (i.e., the sum of the $F$ and $R$ columns in Table 2). This parameter-free model captured a substantial amount of the variance within each participant's response pattern, with a mean correlation of -. 46 between number of rules and explanatory judgment (Fisher-transformed to a $z$-score before averaging, and inverse-transformed back to a correlation). Furthermore, almost all participants ( $95.6 \%$ ) had a negative correlation, demonstrating that the excellent model fit at the group level is not due to a small subset of participants, but instead generalizes across almost all participants.

Although this parameter-free model is useful in showing that considerable within-subject variability can be explained via proof complexity, it is less useful for testing asymmetries between the forward and backward rules, since this requires estimating the relative penalties
associated with each rule. To do so, we conducted a linear regression for each participant, using ten dummy-coded variables to represent whether each of the ten rules figures in each item's proof. For example, for the item explaining division in terms of subtraction, the dummy variables for rules $1 \mathrm{R}, 2 \mathrm{~F}$, and 3 F were set to 1 , and all others set to 0 . For each participant, we calculated the regression weights for each rule, reflecting the relative penalty associated with each rule (thus, all regression weights would be expected to be negative), and these weights (averaged across participants) are depicted in Figure 2.

Figure 2: Regression coefficients on each rule.
Note. These coefficients represent the explanatory 'cost' of a given rule appearing in the proof of the explanation. Error bars represent $95 \%$ confidence intervals, calculated over participants.

Mirroring the group-level findings, Figure 2 reveals higher costs for reverse rules than for forward rules, leading to more negative regression coefficients for the reverse rules. This was true for rules 1 F and $1 \mathrm{R}(95 \% \mathrm{CI}$ [ $0.28,1.15]$ for the difference in regression coefficients), rules 3 F and $3 \mathrm{R}(95 \% \mathrm{CI}[0.13,0.81])$, rules 4 F and 4 R ( $95 \%$ CI $[-0.02,0.58]$; marginally significant), and rules 5 F and $5 \mathrm{R}(95 \% \mathrm{CI}[0.17,0.85])$. This difference was not significant for the addition/multiplication rules 2 F and 2 R ( $95 \%$ CI $[-0.41,0.39]$ ), perhaps because repeated addition of the same addends is uncommon except in the context of multiplication. Overall, these findings are consistent with the best-fitting value of the $R / F$ parameter of 1.18 in the group-level analysis, indicating a higher explanatory cost for reverse rules than for forward rules.

## Discussion

Mathematical knowledge is critical for explaining patterns in both the physical and symbolic worlds, and for building an understanding conceptually dependent mathematical facts. Here, we proposed that people evaluate mathematical explanations (e.g., " $9-3-3=3$ because $3+3+3=9$ ") by building a proof from the explanatory base (" $3+3+3=9$ ") to the explanatory target (" $9-3-3=3$ ") using a set of transformation rules (e.g., deriving subtraction from addition). Supporting this idea, participants
preferred explanations that obeyed the conceptual order of mathematics and which required fewer derivational steps.

Where might these intuitions come from? One possibility is that they are rooted in a more basic understanding of the natural numbers (e.g., Carey, 2009; Dehaene, 1997; Rips, Bloomfield, \& Asmuth, 2008) that begins to emerge early in development. For example, addition and subtraction are intimately related to counting, both in development (Rips et al., 2008) and in mathematics (Tao, 2016). This is because the natural numbers are constructed by using the successor function (e.g., 9 is the successor to 8 ). Such psychologically and mathematically primitive mechanisms may underlie lateremerging explanatory intuitions.

Alternatively, could it be possible that people simply parroted explanations as introduced in school? This possibility is unlikely for two reasons. First, multiplication was strongly preferred over subtraction as an explanation. This pattern is consistent with our claims about conceptual structure but conflicts with this alternative account, since subtraction is typically learned before multiplication. Second, we doubt most people have ever heard (for example) division explained in terms of addition, exponential, roots, etc., so differences across these explanations must be due to a chaining mechanism of the type we proposed.

Might analogous results hold beyond arithmetic explanations? Indeed, people have a rich intuitive understanding of other mathematical domains such as geometry (Dillon, Huang, \& Spelke, 2013), suggesting that people have intuitive theories of Platonic regularities across a variety of domains. Moreover, the proof construction and evaluation principles may be the same used in more general deductive reasoning processes (Rips, 1994; but see Johnson-Laird \& Byrne, 1991), in which case our method may generalize. Our studies focused on simple arithmetic operations (e.g., Ashcraft, 1992), but future work could extend this inquiry to other areas of mathematics (such as geometry), populations (such as children or expert mathematicians), or domains (such as dependencies among physics concepts or among mental states) to further map our intuitive theories.

The ontological implications of this work are within the domain of philosophy. For now, we merely contrast two possible views. According to the dominant Platonist view (e.g., Frege, 1974/1884), mathematical truths are 'out there' in the world. On the Platonist view, our results reflect aspects of mathematical structure that have been internalized from the world. However, others with Kantian views argue that mathematical cognition reflects structure imposed on the world by our minds rather than anything intrinsic in the world (Kant, 1998/1781; Mill, 2002/1843; see Lakoff \& Núñez, 2000). On the Kantian view, our results reflect the intrinsic structure of our minds themselves, which we impose on the world.

As for the instructional implications of these findings, we believe mathematics educators are best-positioned to
make the assessment. However, we do make some tentative suggestions. First, mathematical proof may not be intrinsically unintuitive-it may instead be the level of abstraction of many proofs that masks intuitive understanding. If so, introducing simple deductive proofs of simple arithmetic relationships at an earlier educational stage could lay an intuitive foundation for more formal proofs later on (see Carpenter, Franke, \& Levi, 2003). Second, people use the conceptual structure of mathematics to understand derivative concepts in terms of more basic ones. Educators may wish to emphasize these abstract connections, in conjunction with more concrete applications, in order to tap into this intuitive understanding; for example, explaining division both as a way to divide resources and as the inverse of multiplication. Finally, our methodology might be used to assess the explanatory trade-offs between different kinds of examples. Studying explanatory preferences in adults may provide a simple laboratory for testing out explanatory methods that might be used in educational settings, prior to undertaking expensive and risky intervention studies. This method could be used not only to illuminate mathematical understanding, but also the conceptual structure of other domains.

# Statistical and Mechanistic Information in Evaluating Causal Claims 

Samuel G. B. Johnson \& Frank C. Keil<br>(sgbjohnson@gmail.com, frank.kei@ @yale.edu)<br>Department of Psychology, Yale University, New Haven, CT 06520 USA

#### Abstract

People use a variety of strategies for evaluating causal claims, including mechanistic strategies (seeking a step-bystep explanation for how a cause would bring about its effect) and statistical strategies (examining patterns of cooccurrence). Two studies examine factors leading one or the other of these strategies to predominate. First, general causal claims (e.g., "Smoking causes cancer") are evaluated predominantly using statistical evidence, whereas statistics is less preferred for specific claims (e.g., "Smoking caused Jack's cancer"). Second, social and biological causal claims are evaluated primarily through statistical evidence, whereas statistical evidence is deemed less relevant for evaluating physical causal claims. We argue for a pluralistic view of causal learning on which a multiplicity of causal concepts lead to distinct strategies for learning about causation.

Keywords: Causal reasoning; concepts and categories; information evaluation; statistical reasoning.

## Introduction

Causal knowledge is crucial for understanding and controlling the world, and strategies for evaluating causal claims are central to gatekeeping that crucial knowledge. Humans seem especially prone to two strategies-a mechanism strategy, on which we consider potential mediating causal links as evidence favoring a causal connection; and a statistical strategy, on which we look for correlations between a cause and effect. For example, Jack is assessing the risk that smoking causes cancer. He can assess this claim mechanistically by considering the plausibility of potential mediating mechanisms that explain relationship between smoking and cancer. Or he can assess the claim statistically by observing whether the frequency of cancer is higher in a population that smokes compared to a population that does not.
There is ample evidence that people use both of these strategies, though different theoretical approaches to causal cognition emphasize different types of information.

According to mechanism-based approaches to causal cognition, we learn about causal relations primarily by searching for generative mechanisms through which causes can produce their effects. Several convergent lines of evidence are consistent with causal relations being represented in terms of underlying mechanisms (see Johnson \& Ahn, in press). Knowledge of underlying mechanisms affects whether discounting or conjunction effects occur in causal attribution (Ahn \& Bailenson, 1996), whether the Markov principle is applied to causal networks (Park \& Sloman, 2013), and whether causal chains are judged to be transitive (Johnson \& Ahn, 2015).
If we learn about causation by searching for plausible
mechanisms, then people would seek out evidence of underlying mechanisms when determining whether one thing causes another. Indeed, people do sometimes assess causal hypotheses by forming a mechanistic narrative that would lead from $X$ to $Y$ and assessing the plausibility of that narrative (e.g., Fernbach, Darlow, \& Sloman, 2011; Kahneman \& Tversky, 1982; Taleb, 2007). For example, Jack might imagine some physiological mechanism by which smoking and lung cancer could be connected, then evaluate the plausibility of these steps. Moreover, people prefer mechanism evidence overwhelmingly in causal attribution - that is, in determining which cause to assign to an effect (Ahn, Kalish, Medin, \& Gelman, 1995).

In contrast, statistics-based approaches to causal learning emphasize the role of statistical knowledge in inferring causal relationships. These theories hold that causal relationships are primarily discovered through information about the co-occurrence of the cause and effect, although individual theories differ in the details of how these inferences work (e.g., Cheng, 1997; Gopnik et al., 2004; Griffiths \& Tenenbaum, 2005). These theories do not necessarily claim that causal relations are represented in terms of statistical patterns, but often hold that causal relations are represented in terms of abstract causal powers underlying the connection between cause and effect, which are then inferred through statistical means (Cheng, 1997; Pearl, 2000). Nonetheless, statistical approaches do claim that causal relations are primarily learned through co-occurrence information, and there is abundant evidence that people are often able to learn from statistical evidence (e.g., Gopnik et al., 2004; Steyvers, Tenenbaum, Wagenmakers, \& Blum, 2003).

Moreover, statistical evidence could be an antidote to the shallowness of people's knowledge of causal mechanisms: Even though people do use mechanism knowledge in evaluating causal relationships when it is available, we do not seem to have extensive knowledge of mechanisms. People greatly overestimate their knowledge of how everyday devices such as flush toilets work, revealing misconceptions and pervasive gaps in understanding (Rozenblit \& Keil, 2002). People's beliefs in mechanisms underlying causal relationships are more likely to take the form of generic or highly unspecified 'placeholders', akin to our beliefs in abstract category essences (Medin \& Ortony, 1989). Such skeletal representations are difficult to square with a strong mechanism view on which people seek a detailed understanding of how causal relationships work and use that understanding to guide inference, but they might seem to be more consistent with statistical approaches to causal thinking on which covariation is used to infer the
existence of abstract underlying mechanisms without being committed to particular mechanistic details.

The mechanism and the statistical approaches, however, need not be in conflict and can be mutually compatible with a third approach known as causal pluralism (Cartwright, 2004; Danks, 2005; Hitchcock, 2003; Lombrozo, 2010; Waldmann \& Mayrhofer, 2016). According to this approach, people might use a multiplicity of causal concepts and a concordant variety of learning strategies in systematic, context-dependent ways. Some prima facie support for the pluralistic position comes from experiments where people used mechanism and statistical evidence in an interactive manner (Fugelsang \& Thompson, 2000; Spellman, 1996).

Yet, little is known about contextual factors that lead each type of evidence to predominate. Here, we look at two dimensions along which causal relations can vary-in its level of abstraction and its domain. Because people seem to use different sorts of causal concepts for representing these relations, we anticipated that people may also use different strategies to learn about these relations. If you need to decide whether something is a banana, the best question to ask would be about its shape, whereas if you need to decide whether something is a peach, the best question would be about its texture. And just as we must consult our concept of 'banana' when deciding whether something is a banana and our concept of 'peach' when deciding whether something is a peach, we must consult our concept of 'cause' when deciding whether a relationship is causal. When we deploy different causal concepts across contexts, this can lead to different learning strategies.
General and Specific Causation. General causal claims refer to generic causal patterns ("Smoking causes a person to get lung cancer"), whereas specific claims refer to concrete occasions when a pattern was instantiated ("Smoking caused Jack to get lung cancer"). The inferences supported by general and particular claims differ in several ways. General claims are associated with more essentialist inferences (Cimpian \& Erickson, 2012) and, in the domain of human behavior, with more neuroscientific rather than psychosocial explanations (Kim, Ahn, Johnson, \& Knobe, 2016). Might these claims also differ in the evidence used for their evaluation?

General claims refer to an entire category of causal relationships (i.e., a set of event pairs), whereas specific claims refer to an instance of that category (one single event pair in that set). Thus, general claims necessarily quantify over multiple instances and intrinsically carry statistical content, whereas specific claims do not. We suggest that this conceptual difference could lead statistical evidence to be privileged more for general rather than specific causal claims.
This pattern of evidence preferences can lead to nonnormative behavior. If we are not privy to the particulars of Jack's case, the only strategy for evaluating a tokencausal claim will be to look for a more general causal
pattern between smoking and cancer-to evaluate the general claim. Thus, evidence relevant for evaluating the general claim would be equally relevant for evaluating the specific claim. Imagine that a tobacco company is being sued under one of two different circumstances: (1) a class action suit (the plaintiffs' lawyers arguing that "Smoking causes a person to get lung cancer"), or (2) Jack's single party action (his lawyers arguing that "Smoking caused Jack to get lung cancer"). In both cases, jurors might be confronted with mechanism evidence, such as a biologist's testimony concerning biochemical mechanisms, or with statistical evidence, such as an epidemiologist's testimony comparing cancer rates across populations. It seems difficult to justify a difference between these two cases in jurors' relative weighing of mechanistic and statistical testimony. Yet, if people rely on different processes for evaluating general and specific claims, then the jurors may well behave differently.

Causation across Domains. People use different intuitive theories of causality across domains. Whereas physical causation is typically conceptualized in terms of force propagating down branching causal chains, social and biological causation are thought of as webs of interconnected influences. People tend to identify physical events as having one cause but many effects, whereas social events are seen as having many causes and many effects (Strickland, Silver, \& Keil, 2016; see also Johnson, Valenti, \& Keil, 2017). Likewise, even young children seem to view biological systems as causally interacting parts in homeostatic balance (Keil, 1989). Thus, the simple, linear causal pathways thought to be at play in the physical world give way to more complex causal structures in the social and biological domains.

Similarly, social (e.g., psychological or economic) causation is often goal-directed (Lombrozo \& Carey, 2006) or equipotential (Heider, 1958)-the same ends can often be brought about through many different means. For this reason, people's causal theories of social (and likely biological) systems often focus on counterfactual dependence (Lombrozo, 2010), whereas their theories of physical systems are characterized more by ideas about physical force and transference of conserved quantities.

Given the relatively linear and force-based conceptions of physical causation, and the relatively web-like and dependence-based conceptions of causality in biological and social causation, people may use a more deterministic concept of physical causation and a more stochastic concept of social and biological causation (Johnson, Valenti, \& Keil, 2017). Thus, people may rely more on mechanistic strategies when learning about physical systems and more on statistical strategies when learning about biological and social systems.

Overview of Studies. Two studies test differences in evidence-seeking between general and specific causal claims, with the studies differing in the framing of the claims. After testing this hypothesis about general versus specific causation, we present an analysis of evidence-
seeking preferences across domains, aggregating across studies. In the General Discussion, we assess the prospects for a pluralistic view of causal learning.

## Experiment 1

In Experiment 1, we tested what kind of information people thought most relevant for assessing general causal claims (e.g., "Eating polar bear liver causes a person to become dizzy") and specific causal claims ("Eating polar bear liver caused Bill to become dizzy"). The mechanism view holds that we learn about causal relationships primarily by searching for underlying mechanisms, leading to a preference for mechanism evidence, whereas the statistical view holds that we learn about causal relationships primarily through contingency information, leading to a preference for statistical evidence. In contrast to both positions, we predicted that, whatever people's baseline preferences for one or the other type of evidence, the preference for statistical evidence would be stronger when evaluating general rather than specific claims.

## Method

We recruited 80 participants from Mechanical Turk, and excluded 5 from data analysis because they incorrectly answered more than $33 \%$ of the check questions.

Participants saw either the general or specific version of each of 24 causal claims, presented in a box. For each item, participants were asked "Which of the following types of evidence would be most helpful to you in determining whether the statement in the box is true?" as a forced-choice. For the polar bear item, the options read:

Statistical: "Measurements of the frequency of dizziness of many people after they eat or do not eat polar bear liver."
Mechanism: "An explanation of why eating polar bear liver would cause a person to become dizzy."
Anecdotal: "Knowing whether there is another occasion on which a person ate polar bear liver and then they felt dizzy."
We assumed that few people would choose the weak anecdotal evidence, and used this option to assess the degree to which participants used poor causal reasoning. The order of the options was randomized for each item, and the items were presented in a random order.

## Results and Discussion

As shown in Table 1, statistical evidence was chosen more frequently when evaluating general compared to specific claims. Due to non-normality, Mann-Whitney $U$ tests were used to compare the number of items for which participants chose each evidence type in each condition.

These tests showed that statistical evidence was chosen for more items when evaluating general claims than when evaluating specific claims [ $U=496.5, p=.028, r=.25$ ]. This corresponded to relatively fewer mechanism responses for the general claims than for the specific claims and fewer anecdotal responses for the general
claims than for the specific claims. Thus, responses shifted relatively more toward statistical evidence for the general than for the specific claims.

This result indicates that people use pluralistic causal learning strategies. Specifically, it appears that the conceptual differences between general and specific claims had downstream consequences for evidenceseeking preferences: Because general claims quantify over instances, statistical evidence is seen as more relevant to evaluating such claims, compared to specific claims, and mechanism evidence is seen as less relevant.

Table 1: Results of Experiments 1 and 2

|  | Statistical | Mechanism | Anecdotal |
| :--- | :---: | :---: | :---: |
| Exp. 1 |  |  |  |
| General | $55.3 \%$ | $36.8 \%$ | $7.9 \%$ |
| Specific | $41.6 \%$ | $47.5 \%$ | $11.0 \%$ |
| Exp. 2 |  |  |  |
| General | $62.0 \%$ | $30.4 \%$ | $7.6 \%$ |
| Specific | $47.6 \%$ | $41.4 \%$ | $11.0 \%$ |
| Domain Analysis |  |  |  |
| Physical | $47.5 \%$ | $46.6 \%$ | $5.9 \%$ |
| Biological | $53.6 \%$ | $38.9 \%$ | $7.5 \%$ |
| Psychological | $51.6 \%$ | $36.0 \%$ | $12.4 \%$ |
| Economic | $53.7 \%$ | $34.7 \%$ | $11.6 \%$ |

Note. Entries indicate the proportion of choices of each evidence type in each experiment. For the domain analysis, the proportion of participants choosing each evidence type was calculated for each item in Experiments 1 and 2, and those proportions were averaged across all items in each domain.

## Experiment 2

Experiment 2 sought to generalize the effect of general versus specific causation to contexts where it is known that the events in the specific causal relationship actually occurred. That is, participants in Experiment 1 evaluated claims such as "Smoking cigarettes caused Jack to get lung cancer" without knowing whether or not Jack in fact smoked and whether or not he had cancer. In such contexts, both statistical and mechanism information may seem irrelevant, since a crucial part of evaluating this claim is establishing first that the cause and effect both occurred. In contrast, Experiment 2 examined contexts where it is known that both cause and effect occurred (e.g., by prefacing the causal claim with the statement "Jack smoked cigarettes, and then Jack got lung cancer"), where the primary concern is distinguishing causation from coincidence (see Cartwright, 2017) and where the available evidence would be seen as more relevant.

## Method

We recruited 80 participants from Mechanical Turk, and excluded 5 from data analysis because they incorrectly
answered more than $33 \%$ of the check questions.
Participants responded to a new set of 24 causal claims. The format of these items differed from Experiment 1 in that contextual information was given for each claim, establishing that the cause and effect occurred. This information was printed above the box containing the claim. For example, one general item read (background information in regular typeface, claim in italics):

Researchers sometimes observe that a person consumes large amounts of meat, and then that the person develops kidney stones.
Consuming large amounts of meat causes a person to develop kidney stones.
The specific version of that item read:
Researchers observed that Tom consumed large amounts of meat, and then that Tom developed kidney stones.
Consuming large amounts of meat caused Tom to develop kidney stones.
The procedure was otherwise identical to Experiment 1.

## Results and Discussion

Although participants preferred statistical information overall, this preference was far stronger when evaluating general than when evaluating specific claims $[U=481.5$, $p=.019, r=.27]$, consistent with Experiment 1. They correspondingly chose mechanism evidence less frequently for general than for specific claims and anecdotal evidence less frequently for general than for specific claims, as shown in Table 1.

These two experiments together are consistent with the idea that people use different learning strategies depending on what causal concept they are consulting. However, there are other differences between general and specific causation that could plausibly account for some of the variance. First, the reference class from which the statistical evidence is drawn may be more relevant for the general than the specific claim, and second, plurality may have been more salient for the general than for the specific claims. We conducted an additional experiment with artificial stimuli to rule out these two alternative explanations, in which both the general and specific claims were prefaced by a statement about the reference class (e.g., "There is a group of 100 Garbotrons"), with the general claim then made about the entire group and the specific claim about an arbitrary member of that group. This equated the reference class and the salience of plurality, yet produced a similar shift across conditions.

These experiments do not fully tease apart whether the difference is due to a statistics preference for general claims or a mechanism preference for specific claims. We conducted two additional studies to answer this question, one in which participants answered an open-ended question about what evidence they would want to use, and another in which participants rated the two types of evidence on independent scales. Consistent with our claim that these differences arise due to more stochastic
representations of general causation, the condition differences were significant for statistical evidence but not for mechanism evidence in both cases.

## Domain Differences

In Experiments 1 and 2, we drew our causal claims from four domains-physical, biological, psychological, and economic-across which causal representations are likely to differ. People typically conceptualize physical causation as flowing in branches, with each event having few causes but many effects, and social (and perhaps biological) causal systems as interconnected webs, in which events have many causes and many effects (Strickland et al., 2016). Similarly, people may use more transference-based (or mechanistic) causal concepts in the physical domain, and more dependence-based (counterfactual or statistical) causal concepts in the social domain (Lombrozo, 2010). Thus, physical systems may be seen as more deterministic and social systems as more stochastic. According to the pluralistic position, these conceptual differences across domains could translate into different learning strategies: We would expect relatively greater reliance on statistical information for social and biological systems and less for physical systems.

We tested this possibility by comparing preferences for statistical evidence across all 48 items used in Experiments 1 and 2, collapsing across the general and specific versions. For each item, a statistics preference score was computed by taking the difference between the proportion of participants choosing statistical evidence for that item and the proportion choosing mechanism evidence for that item. An ANOVA on these scores with domain (physical, biological, psychological, or economic) as a between-items variable uncovered a marginally significant main effect of domain $[F(3,44)=2.22, p=$ $\left..099, \eta_{\mathrm{p}}^{2}=.13\right]$, with the preference for statistics evidence smallest for the physical items $[M=0.01, S D=0.17]$, followed by the biological $[M=0.15, S D=0.19]$, psychological $[M=0.16, S D=0.21]$, and economic $[M=$ $0.19, S D=0.17]$ items. Independent-samples $t$-tests revealed that items from the physical domain had a smaller statistics preference than did items from the combined other domains $[t(46)=-2.56, p=.014, d=$ 0.85 ], while the biological, psychological, and economic domains did not differ from one another [ $t \mathrm{~s}<1, p \mathrm{~s}>.50$ ].
This result further supports the pluralistic position, suggesting that differences in causal concepts used across domains translated into different learning strategies.

## General Discussion

Cognition requires us to attend to and integrate various sources of information into coherent representations of the world. Our representations of causal systems are particularly critical because they allow us to predict and understand events, and to plan interventions on the world to achieve goals. Humans use two distinct strategies for making inferences about causal claims-evaluating the
plausibility of mediating causal mechanisms, and evaluating statistical evidence for contingencies between cause and effect. What factors lead people to favor one strategy over the other?

First, general causal statements, which refer to a category of causal events, are seen as more compatible with statistical evidence than are specific causal statements, which refer to only an individual causal event. We hypothesized that this would occur because representations of general claims intrinsically include statistical content, and people would seek evidence that conforms to their representation of the causal concept.

Second, statistics were seen as more relevant for biological and social systems than for physical systems, whereas mechanistic evidence was more important for physical systems. We predicted this effect because causal representations vary across domains. Whereas physical systems are seen as more linear and force-based, social and biological systems are seen as more branching and counterfactual-based (Lombrozo, 2010; Strickland et al., 2016). Thus, concepts of biological and social causation would be more stochastic than concepts of physical causation, leading people to favor statistical evidence.

Causal Pluralism. Our causal representations subserve a variety of cognitive functions, and exhibit a concordant variety of properties that sometimes appear contradictory (Johnson \& Ahn, in press). For instance, causal representations seem to have many of the properties of associations (Shanks, 1987), yet causal inferences exhibit directional biases that are inconsistent with symmetric associative representations (Waldmann \& Holyoak, 1992). These shortcomings of associative theories have led to the suggestion of causal models or Bayesian networks as the representation over which causal reasoning operates (e.g., Pearl, 2000; Sloman, 2005). Yet, other evidence suggests that people often fail to make the transitive inferences predicted by Bayesian networks (i.e., that $A$ causes $C$, given that $A$ causes $B$ and $B$ causes $C$ ), and that these failures occur when the connection between $A$ and $C$ is not seen as a coherent, schematized mechanism (e.g., sex causes pregnancy, which causes nausea, but sex does not cause nausea; Johnson \& Ahn, 2015). Thus, causal representations appear to have some association-like properties, some network-like properties, and some schema-like properties. Add to this evidence that causal relations are represented with some properties of forces (Wolff, 2007), icons that support mental simulation (Hegarty, 2004), and metacognitive placeholders (Rozenblit \& Keil, 2002), and it becomes clear that people do not represent causation using one unified representation (see Markman \& Dietrich, 2000).

Despite the overwhelming evidence for representational pluralism, it does not follow that people use distinct strategies for learning about different varieties of causal concepts. People may not tailor their learning strategies to the representation at hand, but could instead apply a single learning strategy across all types of causal systems,
such as statistical learning algorithms (Pearl, 2000).
However, the current experiments demonstrate learning patterns that are not only pluralistic, but appear to be tailored to the underlying representation. In the cases of specific causation we used, there is no prior knowledge, so the only option is to learn about the general causal relation anew. If the best strategy for learning about the general claim is statistics, then the best strategy for learning about the specific relation is also statistics. Yet, participants shifted dramatically from statistics when learning about specific claims-a signal that they had applied a heuristic, matching statistical representations of general claims to statistical information. Therefore, any view of causal learning and representation that focuses on a single representation or learning mechanism will fail to capture important aspects of our causal thinking.

In addition to clarifying the debate between mechanism and statistical views of causation, causal pluralism may also be a helpful framework for thinking about debates over causal semantics. Theories of causal semantics embrace diverse accounts based on physical forces (Wolff, 2007), on probability (Good, 1961), and on logic (Lewis, 1973). Teasing these accounts apart has been difficult because they often make similar empirical predictions (Barbey \& Wolff, 2007; Goldvarg \& JohnsonLaird, 2001; Sloman, Barbey, \& Hotaling, 2009).

However, in a pluralistic framework, it may not only be difficult but in fact impossible to capture all of causal semantics using a single representational format. Our causal representations differ not only in reference (general or specific) and domain (physical, biological, social), but along many other dimensions as well, in potentially interconnected ways-among deterministic, chaotic, and indeterministic systems; among the past, present, and future; between observed, unobserved, and unobservable causes and effects; between categorically or continuously valued causes and effects; and among various potential causal structures. A useful strategy going forward may be to investigate the manner in which such variation in causal meaning propagates to causal learning processes.

# Touch Screen Text Entry as Cognitively Bounded Rationality 

Jussi Jokinen<br>Aalto University, Espoo, Finland

#### Abstract

Typing on a smartphone is an everyday activity that involves various cognitive and behavioural processes. This paper models touch screen text entry as cognitively bounded rationality. The model aims to maximise error-free text throughput, while being constrained by its architecture and task environment. Empirical data are used to calibrate the model, which demonstrates adequate fit. The model is used to explore how strategic choices under given constraints affect text entry performance. The preliminary model presented here serves as a confirmation that touch screen text entry can be modelled as cognitively bounded rationality. Future extensions by integration into richer cognitive architectures are outlined.

# Using Measurement Models to Understand Eyewitness Identification

#### Abstract

Much research effort has been expended improving police lineup procedures used in collecting eyewitness identification evidence. Sequential presentation of lineup members, in contrast to simultaneous presentation, has been posited to increase witness accuracy, though analyses based in Signal Detection Theory (SDT) have challenged these claims. A possible way to clarify the effect of presentation format on witness accuracy is to develop SDT-based measurement models, which characterise decision performance in terms of psychologically-relevant parameters, particularly discriminability and response bias. A model of the sequential lineup task was developed with a "first-above-criterion" decision rule, alongside a simultaneous model with a "maximum familiarity" decision rule. These models were fit to a corpus of data comparing simultaneous and sequential lineup performance. Results showed no difference in discriminability between the procedures and more conservative responding for the sequential lineup. Future work will examine criterion setting in the sequential lineup and model alternative decision rules.

Keywords: Eyewitness identification; Signal Detection; memory

## Introduction

Typical six-person lineups used in police investigations consist of one suspect, whom police believe may be guilty of a crime, and five known-innocents called variously "fillers' or "foils", selected to resemble the suspect in specified ways (Clark, 2012). A witness may identify (ID) a person from the lineup or reject the lineup ("the person I saw is not here"), and may provide a confidence rating for their choice. In experimental mock-crime studies, a lineup is referred to as target-present (TP) if it includes the person observed by the witness at encoding (the "culprit") or targetabsent (TA) if it is composed entirely of fillers.

Possible decision outcomes are expressed as rates or proportions over a series of trials. From a TP lineup, witnesses may correctly ID the culprit, incorrectly ID a foil or incorrectly reject the lineup. From a TA lineup, witnesses may correctly reject the lineup or incorrectly ID a foil, known as a false alarm.

The members of a lineup may be presented simultaneously, where the witness makes a single decision, or sequentially, where the witness makes a yes/no decision for each member before seeing the next. In experimental studies, the sequential procedure terminates once an ID is made, although variations of the procedure are used in applied settings (Horry, Palmer \& Brewer, 2012). Whether presentation format affects witness accuracy has received significant research attention (Steblay, Dysart \& Wells, 2011). Initial work by Lindsay and Wells (1985) found that the sequential procedure produced a marked reduction in false ID rate, a desirable outcome, and a slight reduction in correct ID rate compared to the simultaneous procedure. Numerous subsequent studies and two meta-analyses (Steblay et al., 2011) have supported this pattern of results and, although the effect has not always been found (Dobolyi \& Dodson, 2013) and seems to have weakened with time (Moreland \& Clark, 2016), evidence for sequential superiority has been persuasive enough for the procedure to be adopted in the United Kingdom and in many jurisdictions in the United States (Clark, 2012).

## Signal Detection Theory Advantage

Recently, researchers have advocated the use of analyses based in Signal Detection Theory (SDT) to evaluate lineup procedures (Mickes, Flowe \& Wixted, 2012). SDT is an approach used to analyse decision performance in a wide variety of areas in which a target, such as an enemy jet on radar or a tumor on an x-ray, must be discriminated from similar non-targets under conditions of uncertainty. In its most basic form, it characterises decision performance as resulting from two sources; discriminability ( $d$ '), related to how well a witness can distinguish targets from non-targets, and response bias or criterion (c), related to overall willingness to make a decision (MacMillan \& Creelman, 2005). Claims of superior performance for the sequential procedure have been based on findings of a higher ratio of correct ID rates to false ID rates - the so called "diagnosticity ratio" - compared to the simultaneous procedure (Steblay et al., 2011). However, Mickes et al.
(2012) have shown that diagnosticity confounds discriminability and response bias. In fact, analysis of lineup data using SDT reveals that there are a range of different diagnosticity ratios associated with the same lineup procedure and that, necessarily, the ratio increases as response bias becomes more conservative, i.e. as people reject more frequently (Wixted \& Mickes, 2012). SDT avoids this problem by computing all empirical or hypothetical correct ID/false ID pairs, which can then be plotted and analysed. Further, formal modelling of the task allows estimation of the entire response curve from estimated parameters - allowing tests of hypotheses about the impact of system variables such as lineup member similarity on theoretically relevant parameters.

## Measurement Models

A measurement model uses theoretically-derived mathematical functions to link observed behavioural data to psychological constructs. Psychologically meaningful model parameters are estimated by fitting the model to observed data (Farrell \& Lewandowsky, 2010).

Palmer and Brewer (2012) sought to address the need for formal modelling of the lineup task by fitting a SDT compound detection model (SDT-CD; Duncan, 2006) to a corpus of studies that compared simultaneous and sequential lineup data. The 'compound' aspect of SDT-CD refers to the fact that a lineup can be decomposed into two decision tasks; target detection (is the target present?) and target identification (if the target is present, which member is the target?). Results showed that the simultaneous and sequential lineups did not significantly differ in terms of discriminability but that the sequential procedure led to more conservative responding.

However, there were critical aspects of the analyses conducted by Palmer and Brewer (2012) that may have affected their results. First, the SDT-CD model was developed to account for simultaneous presentation of stimuli - it does not directly model the sequential procedure. For this reason, we develop and apply a formal model of the sequential procedure. Second, the best-fitting parameter values reported by Palmer and Brewer (2012) may not have been optimal as they appear not to have been estimated by an optimization procedure. For this reason, we fit the two models using a computational optimization routine. Third, given distinct models of simultaneous and sequential procedures, it is important to explore the dependence of each task on the criterion that is set by the witness. Previous research (Horry et al. 2012) has highlighted the vulnerability of the sequential task to criterion setting so we compare the simultaneous and sequential models in terms of their dependence on the decision criteria.

## New Models

Both the simultaneous and sequential models assume an underlying unequal variance SDT model based on prior recognition memory research (Mickes, Wixted \& Wais, 2007). Figure 1 illustrates this model for a single person
lineup. Each member of a lineup is associated with a particular value of memory strength or familiarity. Foil familiarity on both TP and TA trials is modelled as a random draw from a normal distribution (dashed line in Figure 1) with mean zero and standard deviation one. Target familiarity is modeled as a random draw from a normal distribution (solid line in Figure 1), with a mean $d^{\prime}$ and standard deviation $s$.

A decision is made in relation to a decision criterion, $c$. This functions as a 'choice threshold' and reflects response bias. If familiarity is greater than $c$, the witness will identify the lineup member as the culprit. Otherwise, they reject the lineup. The greater the value of $c$, the more conservative is the decision and the less likely that an ID is made.

The following functions define the hit rate ( $h$ ) and false alarm rate ( $f$ ), where $\Phi($.$) is the normal cumulative$ distribution function:

$$
\begin{aligned}
& h(c)=1-\Phi\left(\left(c-d^{\prime}\right) / s\right) \\
& f(c)=1-\Phi(c)
\end{aligned}
$$

For an $n=1$ lineup, $h$ is the correct ID rate and $f$ is the false ID rate.

Figure 1: Basic representation of the unequal variance signal detection model

Simultaneous Model (SDT-SIM). In a simultaneous lineup, there are $n>1$ members where typically, $n=6$. Let $x_{1}, \ldots, x_{n}$ be the familiarity values of each member of the lineup and let $m$ the maximum of these values. The SDTSIM model implements the decision rule to choose member $k$ if $m>c$ and $m=x_{k}$, otherwise to reject the lineup. For a TP lineup, if a choice is made and member $k$ is the target, a correct ID has been made, otherwise, a foil ID has been made. Any selection on a TA lineup is a false alarm.

Sequential Model (SDT-SEQ). In a sequential lineup, the witness makes a decision for each member, presented in a fixed order labelled by indices, from 1 to $n$. Let $K$ be a subset of these indices, such that $x_{i}>c$ for all $i \in K$. If $K$ is empty then the lineup is rejected, otherwise the witness
chooses member $k$ where $k$ is the smallest (i.e. the first) element in $K$. For a TP lineup, if a choice is made and member $k$ is the target then a correct ID has been made, otherwise an incorrect ID is made. Any selection on a TA lineup is a false alarm.

## Summary \& Aims

Despite recent efforts to apply SDT to eyewitness identification, there has been no attempt to model the sequential lineup task taking account of the differences in the decision rule and the importance of criterion setting for response probabilities. We offer, to our knowledge, the first formal measurement model of the sequential lineup. Further, previous research did not use optimization routines to find the best fitting parameters for the data, and thus the conclusions may be different. Finally, the application of formal models in the eyewitness identification domain highlights the most important factors likely to impact on the rates of false identifications of innocent people and failure to detect the presence of a guilty suspect. In summary, the aims of the present study are:

1. To implement a formal model of the sequential lineup procedure (SDT-SEQ).
2. To reanalyse the data reported by Palmer and Brewer (2012), fitting SDT-SIM to the simultaneous lineup results and SDT-SEQ to the sequential lineup results.
3. To compare SDT-SIM and SDT-SEQ in terms of their dependence on parameter values, particularly decision criterion.

## Method

## Studies Analysed

A corpus of 22 studies $(N=3871)$ assembled by Palmer and Brewer (2012) that directly compared simultaneous and sequential presentation, making 44 data sets in all, was reanalysed. Following Steblay, et al.'s (2011) 'full diagnostic design' inclusion criteria the studies all a) manipulated both presentation format and target presence/absence, b) showed ID performance above chance levels and c) involved only adult participants.

## Statistical Analyses

SDT-SIM and SDT-SEQ were fit using optimization of maximum likelihood (implemented using Matlab FMINCON function). This searches parameter space for values of $d^{\prime}$ and $c$ that best characterise observed decision performance. We report goodness-of-fit in terms of the $G^{2}$ statistic which is a function of the maximum likelihood and distributed as chi-squared.

Statistical Considerations. Due to a lack of confidence rating data in many of the studies analysed, the standard deviation of the target distribution ( $s$ ) was not estimated. Instead, the value of $s$ was fixed to one. This is a plausible
assumption in the eyewitness paradigm where each participant encodes a single study item (the culprit). The greater variance of the target distribution observed in recognition memory research may be attributed to encoding variability across a range of study items (Mickes et al., 2007).

Additionally, Palmer and Brewer (2012), following Duncan (2006), used a relative measure of criterion value with the zero point positioned between the target and lure distributions, i.e. $C=c-d^{\prime} / 2$. Both absolute ( $c$ ) and relative $(C)$ criteria are reported here.

## Results

The new models fit the data well; SDT-SIM could not be rejected for 19 of 22 simultaneous data sets, as indicated by non-significant values of $G^{2}$. The model was rejected for data from Carlson, Gronlund and Clark (2008; Experiment 2), Lindsay and Wells (1985), and Rose, Bull and Vrij (2005). SDT-SEQ was also not rejected for 19 of 22 sequential data sets but was rejected for data from Carlson et al. (2008; Experiment 2), Lindsay and Wells (1985), and Pozzulo and Marciniak (2006). The SDT-CD model was also rejected for data from Carlson et al. (2008; Experiment 2), Lindsay and Wells (1985) and Pozzulo and Marciniak (2006), in addition to Greathouse and Kovera (2009).

Taking the parameter values estimated for each dataset, average values of $d^{\prime}, c$ and $C$ were calculated over the corpus of data, weighted according to sample size. Table 1 displays the summary results obtained by Palmer and Brewer (2012) obtained from fitting the SDT-CD model (equivalent to the SDT-SIM model) to data from both simultaneous and sequential lineups, compared to the summary results obtained by fitting the SDT-SIM model to data from both simultaneous and sequential lineups, and fitting the SDT-SEQ model to data from sequential lineups.

Table 1: Mean weighted parameter values from SDT-CD, SDT-SIM and SDT-SEQ

| SDT-CD | $d^{\prime}$ | $c$ | $C$ |
| :--- | :---: | :---: | :---: |
| Simultaneous | 1.64 | -.06 | -.89 |
| Sequential | 1.74 | .44 | -.43 |
| SDT-SIM |  |  |  |
| Simultaneous | 1.37 | 1.21 | .53 |
| Sequential | 1.33 | 1.53 | .87 |
| SDT-SEQ |  |  |  |
| Sequential | 1.40 | 1.55 | .85 |

The first step in our analysis was to fit SDT-SIM to both simultaneous and sequential datasets, attempting to recover a similar pattern of results to those obtained by Palmer and Brewer (2012). Fitting SDT-SIM to all datasets produced a similar pattern of estimates to SDT-CD, with a significantly higher mean weighted $C$ value for the sequential datasets, as indicated by a Welch two-sample weighted $t$-test, $t(36.42)=$ $-3.89, p<.05$, and no significant difference in mean
weighted $d^{\prime}$ values between simultaneous and sequential datasets, $t(41.67)=.34, p=.73$.
The second step was to compare the parameter values recovered by fitting SDT-CD and SDT-SIM/SEQ. Figures 2 and 3 plot the estimated parameter values recovered for each data set when fitting SDT-CD to both simultaneous and sequential datasets and SDT-SIM and SDT-SEQ to their respective datasets.

Figure 2. $C$ vs $d$ ' estimates for all datasets SDT-CD

Figure 3. $C$ vs $d^{\prime}$ 'estimates for all datasets SDT-SIM/SEQ

The difference in $y$-axis range between Figure 2 and Figure 3 indicate that fitting SDT-SIM and SDT-SEQ to their respective datasets produced higher criterion estimates compared to SDT-CD. Welch two-sample weighted $t$-tests indicated that mean weighted $C$ was significantly higher for SDT-SIM, $t(36.74)=-16.41, p<.05$, and SDT-SEQ, $t(38.91)$ $=-9.87, p<.05$, compared to mean weighted $C$ from SDTCD for simultaneous and sequential datasets respectively. There was no difference in mean weighted $d^{\prime}$ for SDT-SIM compared to SDT-CD as fit to simultaneous datasets, $t(40.33)=1.89, p=.06$, however mean weighted $d^{\prime}$ for

SDT-SEQ was significantly lower than SDT-CD as fit to sequential datasets $t(33.76)=2.11, p<0.5$.
The final stage of the analysis was to compare $C$ and $d$ ' values generated by fitting SDT-SIM and SDT-SEQ to their respective data types, as displayed in Figure 3. Examining Figure 3 reveals a cluster of sequential datasets with higher $C$ values than the cluster of simultaneous datasets. A Welch two-sample weighted $t$-test, $t(35.03)=-3.53, p<.05$, indicated that the mean weighted $C$ value of the sequential datasets as estimated by SDT-SEQ was significantly higher than that of the simultaneous datasets as estimated by SDTSIM.
There are no such patterns evident relative to the horizontal axis, with $d^{\prime}$ values for most of the datasets clustered from approximately 1 to 2 . No significant difference between the mean weighted $d^{\prime}$ values for the simultaneous and sequential datasets was found, $t(41.54)=-$ $.28, p=.81$.

## Discussion

The present study developed and fit two SDT-based formal measurement models of the simultaneous (SDT-SIM) and sequential (SDT-SEQ) eyewitness lineup task to a corpus of data collected by Palmer and Brewer (2012) using an optimization procedure, and compared the model's dependence on the parameters discriminability ( $d^{\prime}$ ) and response bias (c) in order to better understand decision performance on the lineup task.
Fitting SDT-SIM to both simultaneous and sequential data, following Palmer and Brewer (2012), produced similar parameter estimates to those generated by fitting SDT-CD, with results suggesting that the sequential procedure encourages more conservative responding but does not differ in discriminability. Fitting SDT-SIM and SDT-SEQ to their respective data types further reinforced this pattern of results, supporting the conclusions reached by Palmer and Brewer (2012).
Compared to SDT-CD, SDT-SIM and SDT-SEQ produced higher criterion estimates for their respective data types while, while SDT-SEQ also produced lower discriminability estimates. The difference in parameter values between Palmer and Brewer (2012) and the results here is likely due to the task and fitting the models using an efficient optimization procedure rather than grid search.
While no discriminability differences were reported here or in Palmer and Brewer (2012), previous studies using ROC analysis to calculate observed discriminability from rating data have shown a discriminability advantage for the simultaneous lineup (Dobolyi \& Dodson, 2013; Mickes et al., 2012). Results here do not necessarily contradict these findings, as simulations can generate different shaped ROC curves from different ID procedures despite holding theoretical $d^{\prime}$ constant between them (Rotello \& Chen, 2016). The relationship between theoretical $d^{\prime}$ as estimated by SDT-SIM and SDT-SEQ and observed "Area Under the Curve" measures of $d^{\prime}$, as used in ROC analysis, will likely be investigated in future work with new data that includes
confidence ratings. Regarding theoretical discriminability, these results challenge the diagnostic feature detection model (Wixted \& Mickes, 2014) that proposes a discriminability advantage for the simultaneous lineup arising from witnesses’ ability to identify diagnostic features between lineup members.

The more conservative decision criterion observed on the sequential lineup can be explained by differences between its "first-above-criterion" identification rule of SDT-SEQ and the "maximum familiarity" rule of SDT-SIM. This difference becomes evident as the decision criterion is made more lenient. In the limit, the most liberal decision criterion (i.e. always choose) in the sequential lineup results in selection of the first lineup member, leading to chance performance; a correct ID rate of $1 / 6$ for TP lineups and a false alarm rate of $1 / 6$ for TA lineups. In contrast, the "maximum familiarity" rule of SDT-SIM means that, for the most liberal decision criterion, the witness always chooses the most familiar lineup member. If $d^{\prime}>0$, the lineup member with maximum familiarity in TP lineups is more likely than other members to be the target, leading to a correct ID rate greater than $1 / 6$, while for TA lineups the false ID rate remains at $1 / 6$. The effect of this difference is that in order for ID performance to be comparable between simultaneous and sequential lineups, the latter requires a more conservative decision criterion.

Based on the present findings, any performance advantage attributed to the sequential procedure is likely due to a stricter decision criterion, not improved discriminability. This suggests that changes in lineup procedure do not alter underlying memory strength. Rather, the quality of memory information available to a witness is largely determined at encoding by factors such as distance, lighting and exposure time (Maclin, Maclin \& Malpass, 2001). The present findings also do not support of the proposal that performance differences are the result of procedural effects on retrieval or reconstructive memory processes taking place during a lineup decision as these are likely to affect discriminability (Ebbesen \& Flowe, 2002).
Wells (2014) acknowledged the mounting body of evidence showing that any perceived sequential lineup advantage is the result of a more conservative decision criterion but contends that it is more useful in applied settings no matter the source of any performance difference. As other researchers have noted (e.g. Clark, 2012), conservative responding reduces both false IDs and correct IDs. If policy makers consider conservative responding in the lineup task desirable, such an affect could be achieved by simpler means than retraining police to administer lineups sequentially, such as instructing witnesses to be very careful in their choosing or by only counting IDs made at high confidence (Wixted \& Mickes, 2012).

## Limitations

Decision Strategy. The present work uses an absolute decision strategy for both the simultaneous and sequential models, despite the simultaneous lineup's long association
with the so-called relative judgement strategy (Wells, 1984). Wells (1984) proposed that the increased innocent suspect ID rate of the simultaneous procedure may be due to the tendency for witnesses to compare across lineup members, selecting the one that most resembles their memory of the perpetrator relative to the other members, rather than comparing each lineup member directly to their memory of the perpetrator as in the absolute decision strategy (cf. Wixted \& Mickes, 2014). The absolute vs. relative distinction has gained some traction in the literature and has received some empirical investigation, although the superiority of one strategy over the other has not been demonstrated (Fife, Perry \& Gronlund, 2014). In line with our present approach, formal modelling of the relative decision strategy could clarify the utility of the absolute/relative distinction to understanding lineup performance.

One option for implementing relative judgement is to use the difference in familiarity between the lineup member with maximum familiarity ( $m$ ) and the next-most-familiar lineup member, which seems to accord with Wells' (1984) description. The rule would be; if this difference score exceeds a criterion, then choose the lineup member with maximum familiarity, otherwise reject the lineup. We are currently developing a formal model based on this rule.

## Future Directions

Criterion Shift in Sequential Lineup. The present work demonstrates that the sequential lineup decisions are critically affected by the placement of the decision criterion. A further question is whether the decision criterion may change over the course of the lineup. In an attempt to forestall such changes, Horry, Palmer and Brewer (2012) investigated the efficacy of "backloading", telling the witness that they will be viewing more photos than there are lineup members. The results indicated that the more photographs the witness was told to expect, the more conservative were their decision criteria. On nonbackloaded lineups, foil choices increased in the later lineup positions. Because Horry, Palmer and Brewer (2012) fit SDT-CD to the data to generate parameter estimates, future research could explore whether these conclusions remain valid after fitting the SDT-SEQ model to these data.

## Conclusion

This study presents two formal measurement models of the simultaneous and sequential lineup tasks, which were fit to a large corpus of data using computational optimization. The development of a sequential model is particularly noteworthy, it being, to our knowledge, the first of its kind in the eyewitness literature. Results show no difference in discriminability between the two procedures and a more conservative decision criterion in the sequential procedure. The models offer a means to investigate the effects of system variables on eyewitness performance in terms of theoretically relevant underlying parameters, demonstrating the value of formal modelling in applied research.

# A Biologically Constrained Model of Semantic Memory Search 

Ivana Kajić, Jan Gosmann, Brent Komer, Ryan W. Orr, Terrence C. Stewart, Chris Eliasmith<br>Centre for Theoretical Neuroscience, University of Waterloo<br>Waterloo, ON, Canada N2L 3G1<br>\{i2kajic, jgosmann, bjkomer, rworr, tcstewar, celiasmith\}@uwaterloo.ca

#### Abstract

The semantic fluency task has been used to understand the effects of semantic relationships on human memory search. A variety of computational models have been proposed that explain human behavioral data, yet it remains unclear how millions of spiking neurons work in unison to realize the cognitive processes involved in memory search. In this paper, we present a biologically constrained neural network model that performs the task in a fashion similar to humans. The model reproduces experimentally observed response timing effects, as well as similarity trends within and across semantic categories derived from responses. Three different sources of the association data have been tested by embedding associations in neural connections, with free association norms providing the best match.

Keywords: semantic memory; associations; semantic search; spiking neural network; neural engineering framework

## Introduction

The semantic memory system plays an important role in a variety of cognitive functions. It is essential for language comprehension and understanding, and has been referred to as a mental thesaurus, storing knowledge about words, their meaning and relationships among them (Tulving, 1983).

The advent of neuroimaging techniques and observations from brain lesion studies have allowed more specific localization of the brain regions and networks responsible for semantic representation and processing (Huth, de Heer, Griffiths, Theunissen, \& Gallant, 2016; Quiroga, 2012). In particular, the medial temporal lobe and portions of anterior lobes have been identified as essential to the function of semantic memory. Purely computational semantic network models have successfully explained behavioral data (Collins \& Quillian, 1969; Collins \& Loftus, 1975) and have been purported to reveal principles guiding language formation and organization (Steyvers \& Tenenbaum, 2005). Yet, they have been severely limited in their ability to account for the neural realization of such processes. Our understanding of how networks of millions of neurons perform the computations that underly semantic processing is still extremely limited.

We propose a network of simulated spiking neurons that is able to perform the semantic fluency task in a manner similar to humans. While providing a good match with behavioral data, the model also proposes specific neural mechanisms that may be involved in semantic processes. The components of the model are discussed in terms of functionally and neurologically plausible counterparts found in the human brain.

## Search in the Semantic Space

The semantic fluency task has been used to understand how humans search memory when asked to retrieve items se-
mantically related to a given cue (Thurstone, 1938; Bousfield \& Sedgewick, 1944). In a typical trial, a person is instructed to generate members of a category within a given time limit. One common version of the task requires an individual to list all animals they can think of within a fixed timespan of one or more minutes. Response analysis shows they tend to be grouped into clusters corresponding to subcategories (Troyer, Moscovitch, \& Winocur, 1997), such as pets or farm animals. For example, responses might start with the animals an individual is most familiar with, such as cat, $d o g$, rabbit and then continue with a list of farm animals such as cow, chicken and turkey.

To explain the clustering trend observed in the responses, Hills, Jones, and Todd (2012) suggested that individuals generate responses according to the optimal foraging policy (Charnov, 1976). Animals use such a strategy when searching for food in natural environments: after resources in one area have been depleted, animals continue their search for food in a new patch. In the context of the semantic fluency task, an individual listing animals in a specific sub-category would stop listing animals from that category after being unable to generate new items at a certain rate. Search behavior suggestive of optimal foraging has been reproduced with several different representations and algorithms, including a random walk on a semantic network constructed from free association norms (Abbott, Austerweil, \& Griffiths, 2015). Jones, Hills, and Todd (2015) attribute the simplicity of this particular algorithm to the association norms being a direct result of an experimental design that is very similar to the semantic fluency task. They argue that the fundamental memory retrieval processes and representations are obscured by the data underlying the model and the behaviors that are being explained. However, association data from sources other than association norms, like data learned from natural language, have successfully been used to reproduce human response patterns with random walks (Nematzadeh, Miscevic, \& Stevenson, 2016).

Here, we take a first step towards explaining how the memory retrieval processes and representations described above can be realized by a biologically constrained neural network. The proposed model performs the search based on associative weights encoded within connections between neurons, resembling aspects of a random walk while still conforming to constraints of neural computation. The noise resulting from spiking neurons and the diversity in neuron parameter values lead to the response variability. We show that the search patterns observed in the model responses are consistent with the optimal foraging theory and match human behavioral data.

Figure 1: A: Architecture of the neural network model performing the semantic fluency task. Each box represents a population of spiking neurons. B: Neuronal spiking activity in the model recorded from the population cue. Some neurons are actively spiking when representing words dog, cat and donkey (highlighted area 1), while others only spike when representing words $d o g$ and cat (highlighted area 2). The similarity between these spikes and the ideal spike pattern for each word is shown above.

## Biologically Constrained Representation

Brain imaging studies provide evidence in support of semantic representations distributed across networks of neurons in various brain regions (Huth et al., 2016; Rissman \& Wagner, 2012). While many neurons jointly contribute to representations, single neurons can still exhibit preference for certain input stimuli. For example, neurons in the medial temporal lobe show selective responses for higher-level semantic concepts such as places or people (Quiroga, 2012).

Consistent with the notion of a distributed representation, we employ vector-based representations that can be implemented in a network of spiking neurons by means of the Neural Engineering Framework (NEF; Eliasmith \& Anderson, 2003). In the NEF, connection weights between neurons can be analytically computed such that the neural network approximates a desired function.

Given an $n$-dimensional vector representing a preferred stimulus $\boldsymbol{e}$ and some time-varying input $\boldsymbol{x}$, the activity of a single neuron $a_{i}$ can be expressed as

$$
\begin{equation*}
a_{i}=G_{i}\left[\alpha_{i} \boldsymbol{e}_{i}^{\top} \boldsymbol{x}+J_{i}^{\mathrm{bias}}\right] \tag{1}
\end{equation*}
$$

where $G$ represents a spiking neuron model, in this case the Leaky Integrate-and-Fire (LIF) model. The parameter $\alpha$ scales the input and converts the unit of the variable ( $\boldsymbol{x}$ ) to units of current, and $J^{\text {bias }}$ represents background currents.

As a result, if a neuron is driven by an input $\boldsymbol{x}$ that is similar to its preferred direction $\boldsymbol{e}$, the dot product $\boldsymbol{e}^{\top} \boldsymbol{x}$ is larger ( $\boldsymbol{e}^{\top}$ is a transposed vector $\boldsymbol{e}$ ). For a LIF neuron, this translates to a higher input current that drives the neuron to produce a more rapid series of spikes that is transmitted to another neuron. In biological systems, spikes are transmitted across synaptic connections and transformed to post-synaptic current at the site of a receiving neuron. It is important to note that the inputs to the neuron do not have to be characterized as scalar values, as Equation 1 holds for vector inputs.

We can recover the value represented by populations of
neurons by filtering spike trains with a filter $h(t)$ and scaling with decoding weights $\boldsymbol{d}_{i}$ :

$$
\begin{equation*}
\hat{\boldsymbol{x}}=\sum_{i} a_{i} *\left[\boldsymbol{d}_{i} h\right] . \tag{2}
\end{equation*}
$$

The linear filter $h(t)=\tau_{\text {syn }}^{-1} \exp \left(-t / \tau_{\text {syn }}\right)$ models the postsynaptic current. The symbol $*$ denotes convolution, an operation that places such filter at every position where a spike occurs, and sums the result. The decoding weights $\boldsymbol{d}_{i}$ can be analytically computed by a least-squares minimization of the error term $E=\|\boldsymbol{x}-\hat{\boldsymbol{x}}\|$.

To perform a computation, these decoding weights are coupled with the encoding weights $\boldsymbol{e}$ of the receiving neurons. This gives observable connection weights between two neural populations. Specifically, the connections between neurons in the pre-synaptic population $a_{i}$ and the post-synaptic population $b_{j}$ are computed as $w_{j i}=\alpha_{j} \boldsymbol{e}_{j}^{\top} \boldsymbol{d}_{i}$. The group of receiving neurons can also represent a transformed value $f(\boldsymbol{x})$, where $f$ can be a non-linear function. The same optimization method can be used in this case to compute alternative decoding weights $\boldsymbol{d}_{i}^{f}$ to estimate the function.

## Representing Words and Associations

In our model, the vectors $\boldsymbol{x}$ in Equation 1 are 256-dimensional unit vectors that represent animal words. The vectors are generated randomly such that similarity between any two vectors is generally less than 0.1 . This ensures almost orthogonal vectors, with some overlap in representation, meaning the same neurons will be involved in the representation of different words. An example of this representational overlap can be seen in the spike raster plot in Figure 1B, where some neurons fire for all words and some only for a subset. The NEF methods allow us to decode the spiking activity in terms of the words being represented by the neurons with Equation 2 as shown in the upper part of Figure 1B.

Associative relationships between words are represented as linear transformations implemented in the connections be-

Table 1: Utility calculations for different goals and the corresponding actions.

|  | Goal | Utility calculation | Action |
| :--- | :--- | :---: | :--- |
| 1. | Start | goal $\cdot$ start | Set cue to animal, set goal to think |
| 2. | Think | goal $\cdot$ think + response_magnitude -1 | Copy response to cue, add response to responses, set goal to think |
| 3. | Default | 0.4 | Set cue to animal, set goal to think |

tween two groups of neurons. Word vectors are collected row-wise into a single matrix $\boldsymbol{V}$, and associations between pairs of words are encoded into a matrix $\boldsymbol{A}$ such that $A_{i j}$ is the association strength from word $i$ to word $j$. We can then express a new matrix $\tilde{\boldsymbol{A}}=\boldsymbol{V}^{\top} \boldsymbol{A}^{\top} \boldsymbol{V}$ to implement a transformation that multiplies the vector represented by the first group of neurons by the matrix $\tilde{\boldsymbol{A}}$ and transmits the result to the second group. This operation results in a weighted linear combination of vectors that represents words associated with the word represented in the first group of neurons. This method of representing associations is embedded in a large recurrent network to perform the semantic fluency task.
Association Matrices To construct three different association matrices $\boldsymbol{A}$, we use three different sources of associative data: Free Association Norms (FAN; Nelson, McEvoy, \& Schreiber, 2004), BEAGLE (Jones \& Mewhort, 2007) and Google Ngrams (Michel et al., 2011).

The FAN data set has been derived empirically in a free association experiment, where individuals were asked to generate the first word which comes to their mind for given a cue. The data was normed over all participants to yield asymmetric association strengths for over 5,000 words. The Ngram data set contains co-occurrences of sequences of $n$ words extracted from the Google Books Ngram Viewer dataset (Version 2 from July 2012, Michel et al., 2011). This dataset provides occurrence frequencies of n -grams across over 5 million books published up to 2008. We use occurrences of bi-grams to construct an asymmetric association matrix. The BEAGLE dataset has been trained on a 400M-word Wikipedia corpus, yielding unique vector representations for each word. In this data set, similarity between pairs of vectors is computed as cosine similarity, providing a symmetric measure of association strength. We use pre-computed similarities between pairs of animal word-vectors as in Hills et al. (2012).

We take human responses as a reference for the set of animal words and consider only words that are present in all datasets, amounting to 157 animals. The FAN data set contains the smallest vocabulary and is the most restrictive set.

## Proposed Neural Network Model

Using the NEF implemented in the Nengo simulation environment (Bekolay et al., 2014), we constructed a model consisting of approximately 62,000 LIF neurons organized in functional subgroups performing the semantic fluency task. ${ }^{1}$

[^114]The architecture in Figure 1A shows how networks of neurons are organized and connected to perform the task. The model can be divided into two components: the semantic system and the action selection system. In terms of their biological correlates, the semantic system can be mapped to areas of the medial temporal cortex, and the action selection system to the basal ganglia and the thalamus. The action selection system maintains two possible phases: initializing the task and performing the task.

The initialization phase is active only at the beginning of a simulation, where external input is used to drive the goal ${ }^{2}$ population of neurons to represent the vector start. The second phase consists of performing the task itself, and occurs once a cue is provided.

After the task has been initialized, the action selection system (consisting of the basal ganglia BG and thalamus THAL populations) switches to the process of generating word responses within the semantic system. The recurrent action selection system maintains word generation by simultaneously evaluating utilities of actions and selecting the action with the highest utility value. Table 1 shows the mapping between utility calculations and actions utilized by the action selection system. Since the external input initially sets the goal to start, the action selection system will select the first action due to its high utility value. This action will feed the vector animal as input to the population cue, and set the representation in the goal population to think. This action can be interpreted as the instruction "start listing animals".

Next, the semantic system begins to generate associations of the word animal within the association network. The connection between cue and the association network implements the transformation $\tilde{\boldsymbol{A}}$, as described in the previous section.

The association network then represents a vector which is a linear combination of word-vectors associated with animal. For example, there might be a representation corresponding to the vector: $0.5 *$ cat $+0.4^{*} \mathbf{d o g}+0.1 *$ fish. Coefficients represent association strengths between each individual word and the word animal, as derived from the association matrix A. A winner-take-all (WTA) mechanism within the network selects the vector with the largest coefficient, and projects it to the response population. In this example, the response popu-

[^115]lation would now represent the vector cat.
When a response has been generated, the action selection system selects the second action (see Table 1) due to its high utility value. This action projects the word represented in response (e.g., cat) to cue, simultaneously adding it to the representations stored in response memory. The goal continues to be think.

This process within the semantic system continues, with the action selection system selecting the second action most of the time. To prevent the same responses from re-appearing immediately, response memory is implemented as a neural integrator population. It projects inhibitory connections to association network in order to suppress representations of words previously generated as responses.

The last action with a fixed utility value of 0.4 is selected if utilities of all previous actions have evaluated to a lower value. This occurs when the system is unable to come up with a new response (e.g., the WTA mechanism takes too long to decide between two words). While rare, when this situation occurs, the action selection system sets cue to represent the input animal and the goal is set to think.

## Network Parameters

Most parameters in the model have been left at their default values provided by the simulation software Nengo (Bekolay et al., 2014). Table 2 lists the major parameters in the model. Some parameter values (e.g., maximal firing rates) are selected randomly. Each time the model is run, a new set of such parameters are chosen. Such diversity in parameter settings is a first approximation of differences in cognitive processing that may occur across cortical regions of different individuals.

## Results

We ran 141 simulations of the model for each of the three association matrices (Beagle, Ngram, and FAN) and compared them to human data. The number of simulations corresponds to the number of participants in the study by Hills et al. (2012). The simulations were run until the average number of responses produced matched the average number of responses given by human subjects within three minutes.

For each simulation run, we recorded word responses as decoded vector representations in the response population, and inter-item response times (IRT) as times between the onset of the current response and the previous response. Here we consider only relative timings (i.e., the time differences between responses), as mapping to absolute timing (i.e., exact duration of the experiment) would require consideration of the time it takes for other processes to occur, such as visual perception and motor responses, which are not part of this model.

The model responses were evaluated using the same scripts developed for the analysis of the human data, provided in Hills et al. (2012). Each response is assigned an animal category, and the clusters are identified as sequences of responses
within the same category. An animal that could be assigned to two clusters is assigned to both. ${ }^{3}$

The first analysis compares the pairwise similarity of a word and the words preceding it within a cluster (Figure 2A). The similarity is computed as a dot product between two BEAGLE vectors corresponding to the two words in a word pair (Hills et al., 2012). The experimental results in Figure 2A show that the word most similar to the recent word in the patch is the one preceding it, supporting the theory of locality in a memory structure. For the model, this trend is observed with the Ngram and the FAN association matrices, and less so with the BEAGLE association matrix, for which the similarity appears to have a flat trend independent of the position in the cluster.

The second analysis compares the pairwise similarity of subsequent items relative to the position of an item in the cluster (Figure 2B). Human data shows that the lowest pairwise similarity occurs at the cluster transition points, indicated by ' 1 ' on the $x$-axis in the figure. That point shows the similarities between the first word in a cluster and the last word in the preceding cluster. For humans, the mean similarity $\mu$ at the cluster switch is $\mu=0.92$ with standard deviation $\sigma_{\mu}=0.01$. The model using FAN data shows comparable results $\left(\mu=0.93, \sigma_{\mu}=0.01\right)$. For the Ngram and the BEAGLE association matrices this effect is weakly observable $\left(\mu=1.00, \sigma_{\mu}=0.01\right.$ and $\mu=1.01, \sigma_{\mu}=0.01$, respectively), as the word similarity at the transition point remains above the subject's average.

The third analysis concerns the position of a word item within a cluster and the speed of generating a word. The ratio between the average IRT for an item and the participant's mean IRT over the entire task is shown in Figure 2C. Human participants take the most time to produce the first word in a new cluster (reported $t(140)=13.14, p<.001$ ) and least time to produce the second word in a new cluster $($ reported $t(140)=11.92, p<.001)$. This observation is the hallmark prediction of the optimal foraging strategy, suggesting that cluster switches occur when the current IRT increases over the mean IRT value. Figure 2C also shows that the model using the FAN association matrix exhibits the same effects as observed with human responses. It takes significantly more time to generate the first words in a new cluster $(t(140)=4.78, p<.001)$, compared to the second words in the cluster $(t(140)=4.78, p<.001)$.

## Discussion

We have proposed a spiking neural network model that performs the semantic fluency task and shows a good match with human behavioral data. In particular, we embed association data in connections between neurons within a large recurrent network and investigate which source of association information provides the closest match to human performance. Our focus is on identifying plausible, causal neural mechanisms

[^116]Table 2: List of model parameters

| Name | Value (unit) | Explanation |
| :---: | :---: | :--- |
| $d$ | 256 | Dimensionality of word vectors |
| assoc_th | 0.3 (or 0.25) | Default WTA input threshold (Ngram, BEAGLE threshold) |
| $c_{\mathrm{cs}}$ | 3 | Cue to association network connection strength |
| $c_{\mathrm{fs}}$ | 0.2 | Cue feedback connection strength |
| $c_{\mathrm{inh}}$ | -5 | Response memory to association network inhibitory connection strength |
| $\tau_{\mathrm{syn}}$ | 0.1 ms | Synaptic time constant between association network and response |
| $\tau_{\mathrm{syn}}$ | 0.005 ms | Synaptic time constant (default) |
| max_rate | $200-400 \mathrm{~Hz}$ | Range for maximal neural firing rates (default) |

Figure 2: Comparison between model responses for FAN, Ngram and BEAGLE association matrices (blue) and human responses (yellow, reproduced from Hills et al., 2012). A: Pairwise similarity between a word and the words preceding it within the same categorical cluster. B: Pairwise similarity between subsequent words. For example, the bars above ' 1 ' indicate the relative pairwise similarities between the first item in a cluster, and the last item in the previous cluster. $\mathbf{C}$ : Inter-item response times (IRT) between subsequent words. Standard errors of the mean are shown with error bars in all plots.
for performing such tasks. To that end, we have identified computational requirements in terms of processes and relevant neural parameters, and here we discuss how they affect the model's behavior.

The model produces responses in a way that is consistent with predictions made by optimal foraging theory proposed to be used by humans (Hills et al., 2012). It is more likely to switch animal categories when the average similarity of subsequent responses drops below, or gets close to, the overall mean similarity. This effect was observed with all three association matrices, but is most pronounced with the FAN
matrix.
However, the analysis of timing effects allowed us to clearly distinguish between the three matrices. The model using FAN exhibited the same timing effects as observed with human responses. This timing effect was not observed with other association matrices (see Figure 2C). The similarity between cognitive processes involved in free association task and in the semantic fluency task (Jones et al., 2015) is a likely candidate to explain the effectiveness of free norms in matching the experimental data. However, this result could also be seen as support for the plausibility of the proposed neu-
ral mechanisms, as they are able to generate behaviors in accordance with these underlying associations. We expect that a better understanding of cognitive processes involved in free associations could aid understanding of the processes underlying semantic fluency. Our model may prove useful in exploring a variety of possible ways that such associations are neurally realized, as the direct embedding in connection weights as done here is only one possibility.

When building biologically constrained neural models, timing is a highly constrained property of a model. Here, the timing of responses is sensitive to both neural time constants and our characterization of concept representation. This is in contrast to previous models that directly use semantic networks, where timing is a separate and independent parameter. For instance, we identified that a longer synaptic time constant was needed between the association network and the response populations to stabilize the representation. This leads to the prediction that this network will be rich with NMDA receptors in the biological system. These receptors have significantly longer time constants than the more common AMPA receptors. Also, NMDA receptors can be found in the hippocampus, a brain structure located in the medial temporal lobe, whose function has been implicated in semantic and episodic memory.

Our characterization of neural concept representation also has an effect on the timing responses. Specifically, we have observed that the dimensionality of employed vector representations needed to be sufficiently large to achieve experimentally observed timing effects. While we find that $d=256$ suffices for this purpose, a systematic search of dimensionality effects on the performance is needed to see how it affects the behavior. We have tested this model with lower values (e.g., $d=64$ ) and it produced results in support of local search strategy, yet it failed to provide a good match with the timing data. In other work, we have suggested that $d \approx 500$ is necessary for representing human-scale conceptual structures (Eliasmith, 2013), which is consistent with this newer observation.

#### Abstract

Serial stay-or-search problems are ubiquitous across many domains, including employment, internet search, mate search, and animal foraging. For instance, in patch foraging problems, animals must decide whether to stick with a depleting reward vs search for a new source. The optimal strategy in patch foraging problems, described by the Marginal Value Theorem (MVT; Charnov, 1976), is to leave the depleting patch when the local reward rate within a patch matches the overall long-run reward rate. Many species of animals, ranging from birds to rodents, monkeys, and humans, adhere to this policy in important respects, but tend to overharvest, or stick with the depleting resource too long. Here we attempt to determine the cognitive biases that underlie overharvesting in one of these species (the rat). We characterized rat behavior in response to two basic manipulations in patch foraging tasks: to travel time between patches and depletion rate, and two novel manipulations to the foraging environment: the size of reward and length of delays, and placement of delays (pre- vs. post-reward). In response to the basic manipulations, rats qualitatively followed predictions of MVT, but stayed in patches for longer than is predicted. In the latter two manipulations, rats deviated from predictions of MVT, exhibiting changes in behavior not predicted by MVT. We formally tested whether four separate cognitive biases - subjective costs, decreasing marginal utility for reward discounting of future reward, and ignoring postreward delays - could explain overharvesting in the former two manipulations and deviations from MVT in the latter two. All of the biases tested explained overharvesting behavior in the former contexts, but only one bias - in which rats ignore post-reward delays - also explained deviations from MVT due to larger rewards with longer delays and due to introduction of a pre-reward delay. Our results show that multiple biases can explain certain aspects of overharvesting behavior, and, while foraging behavior may be the result of the use of multiple biases, inaccurate estimation of postreward delays likely contributes to overharvesting.

Keywords: foraging; decision-making, subjective utility; delay discounting

## Introduction

Patch foraging refers to situations in which one must decide when to leave a depleting resource patch to search for a
new, likely richer one, that comes at the cost of time and/or effort. The optimal solution in patch foraging is given by the Marginal Value Theorem (MVT; Charnov, 1976): leave when the local reward rate within a patch depletes below the global reward rate across all patches - the average reward rate for the environment. MVT makes two main predictions: i) in patches that contain more reward than average, stay longer to exploit such reward, and ii) when the cost of searching for a new patch is greater (e.g. the time or effort required to travel to a new patch is greater), stay longer in all patches. Many animals, ranging from invertebrates to birds to mammals, qualitatively follow predictions of MVT (Stephens \& Krebs, 1986). However, in most tests, animals, including rats, monkeys, and humans, tend to stay in patches longer than is predicted by MVT (Constantino \& Daw, 2015; Hayden, Pearson, \& Platt, 2011; Nonacs, 1991; Stephens \& Krebs, 1986).

Hypotheses to explain overharvesting include common biases in intertemporal choice, such as i) subjective costs, such as an aversion to leaving the patch (Carter \& Redish, 2016; Wikenheiser, Stephens, \& Redish, 2013); ii) decreasing marginal utility in which large rewards available in a new patch are not viewed as proportionally larger than the smaller, depleted rewards available in the current patch (Constantino \& Daw, 2015); iii) discounting future rewards, in which the value of large rewards available in a new patch are discounted by virtue of being available later, above and beyond the time it takes to travel to the new patch (Blanchard, Pearson, \& Hayden, 2013; Carter \& Redish, 2016; Constantino \& Daw, 2015); and iv) ignoring postreward delays, which causes overestimation of reward rate within the patch due to inaccurate estimation of the time taken to obtain reward (Bateson \& Kacelnik, 1996; Blanchard et al., 2013; Carter \& Redish, 2016; Gallistel \& Gibbon, 2000; Kacelnik, 1997). Although overharvesting is widely observed, there have been few direct investigations into the underlying mechanisms. In this paper, we directly test these hypotheses to rat foraging behavior in an operant chamber based patch foraging task.

First, we characterized rat foraging behavior in response to four manipulations to the foraging environment: to travel
time between patches, rate of reward depletion within patches, scale of reward size and length of delay, and placement of delays (pre- vs. post-reward). Next, we fit formal models representing the four hypotheses to rats' behavior to examine how well each hypothesis explained foraging behavior across all manipulations.

## Methods

## Animals

Adult Long-Evans rats were used (Charles River, Kingston, $\mathrm{NY} ; \mathrm{n}=8$ ). Rats were housed on a reverse $12 \mathrm{~h} / 12 \mathrm{~h}$ light/dark cycle (lights off at 7 A.M.). All behavioral testing was conducted during the dark period. Throughout behavioral testing, rats were food restricted to maintain a weight of $85-90 \%$ ad-lib feeding weight, and were given adlib access to water. All procedures were approved by the Princeton University Institutional Animal Care and Use Committee.

## Operant Foraging Task

This task simulated foraging in a patchy environment, resembling the task used with monkeys by Hayden et al (2011). On a series of trials performed in a standard operant chamber (Med Associates, St. Albans, VT), rats had to repeatedly decide to stay in a patch to continue harvesting a depleting reward source or leave the patch to travel to a new, full patch, incurring a cost of time to travel to a new patch. Rats' decided to harvest from a patch by pressing an activated lever on one side of the front of the chamber, or to travel to a new, full patch by nosepoking at the back of the chamber and then returning to a newly activated lever on the other side of the front of the chamber. To cue the beginning of a trial, lights above the activated lever and the nosepoke illuminated, indicating that the rat could decide to harvest reward from the activated patch (lever press) or to travel to a new patch (nosepoke). The time from start of trial to the decision was recorded as decision time (DT). If the rat pressed the lever to harvest from the activated patch, a cue light turned on in the reward magazine next to the lever following a short handling time delay (HT), and liquid sucrose was delivered when the rat's head entered the magazine. An intertrial interval (ITI) began as soon as the rat entered the reward magazine. To control the reward rate within the patch, the length of the ITI was adjusted based on the DT of the current trial, such that the length of all lever press trials was equivalent. If the rat nosepoked to leave the patch, the lever retracted for a delay period, simulating the travel time, after which, the lever on the opposite side of the chamber extended, representing a new patch from which the rat could harvest.

Each manipulation (travel time, depletion rate, scale, and delay placement) was conducted in separate experiments, with two conditions in each experiment. Rats were trained on each condition for 5 days, and tested for a subsequent 5 days. Conditions within each experiment were
counterbalanced. Details regarding reward size and timing for each experiment can be found in Figure 1. T-tests or ANOVA with repeated measures were used to compare the number of harvests per patch, a proxy for time in the patch, across conditions.

## Models

All models were constructed as Markov Decision Processes. States were represented as trials within patches. A decision to stay in the patch (i.e. harvest from the patch) provided reward for staying in state $s, r_{\text {stay }, s}$, and caused transition to state $s+1$. A decision to leave the patch resulted in travel time delay, $\tau$, followed by the first reward in the next patch, $r_{\text {leave }}$, and associated ITI following the reward, $I T I_{\text {leave }}$. We fit three models based on MVT: a model incorporating a constant subjective cost (subjective cost), a model that accounted for diminishing marginal returns for larger rewards (subjective utility), and a model ignoring postreward delays, as well as a delay discounting model.

For each of the MVT models, we calculated the value of staying in the patch in state $\mathrm{s}, V_{\text {stay }, s}$, as the reward rate within the patch,

$$
\begin{gathered}
T_{s t a y, s}=D T_{s t a y, s}+H T+I T I_{s t a y, s}, \\
V_{s t a y, s}=\frac{r_{s t a y, s}}{T_{s t a y, s}},
\end{gathered}
$$

and the value of leaving the patch in state $\mathrm{s}, V_{\text {leave, } s}$, as the cumulative reward rate across patches,

$$
\begin{gathered}
T_{\text {leave }, s}=D T_{\text {leave } s}+\tau+I T I_{\text {leave }}, \\
R_{s}=p_{\text {stay }, s} * r_{\text {stay }, s}+p_{\text {leave }, s} * r_{\text {leave }}, \\
T_{s}=p_{\text {stay }, s} * T_{\text {stay }, s}+p_{\text {leave }, s} * T_{\text {leave }, s}, \\
V_{\text {leave }}=\frac{\Sigma_{s} p_{s} * R_{s}}{\Sigma_{s} v_{s} * T_{s}}
\end{gathered}
$$

where $R_{s}$ and $T_{s}$ was the average reward and average time for state $s, p_{\text {stay,s }}$ was the probability of choosing to stay in state $s$, and $p_{s}$ was the probability of being in state $s$. Optimal behavior was to leave the patch when $V_{\text {leave }}>=V_{\text {stay }}$ (i.e. when the long-run average reward rate is greater than the local reward rate in the patch). To model rats' behavior, patch leaving distributions were assumed to be normally distributed with respect to $V_{\text {leave }}-V_{\text {stay }}$, with mean $\mu=0$ (i.e. $\left.V_{\text {leave }}=V_{\text {stay }}\right)$ and variance $\sigma^{2}$, a free parameter.

To account for subjective costs, a constant, $c$, representing an aversion to leaving the patch, was added to the model, such that the patch leaving distribution was normally distributed with respect to $V_{\text {leave }, s}-V_{\text {stay,s }}-c$.

For the subjective utility model, the utility for taking action $a$ in state $s$ increased monotonically, but sublinear to the size of the reward, according to a power utility function, dependent on a free parameter, $\eta$,

$$
\begin{gathered}
u_{a, s}=r_{a, s}^{\eta} \\
V_{s t a y, s}=\frac{u_{s t a y, s}}{T_{\text {stay }, s}}, \\
U_{s}=p_{s t a y, s} * u_{\text {stay }, s}+p_{\text {leave }, s} * u_{\text {leave }},
\end{gathered}
$$

$$
V_{\text {leave }}=\frac{\sum_{s} p_{s}^{*} U_{s}}{\sum_{s} p_{s}^{*} T_{s}}
$$

For the ignoring post-reward delays model, delays that occur after receiving reward, but before a decision was made on the next trial (e.g. ITI after reward and DT prior to making next decision), $T_{\text {post }}$, were treated differently than time delays that occured between the decision and receiving a reward (e.g. handling time delay between lever press and reward, or travel time delay between nosepoke and first reward in the next patch). We tested multiple functions for how post-reward delays might have been treated, all in which the increase in perceived time increased monotonically, but sublinear to actual time, including a linear function with slope $<1$, a power function, and an exponential function. The exponential function provided the best fit across all experiments, and was used for further testing:

$$
\begin{gathered}
T_{\text {post }, \text { stay }}=\frac{1-e^{-\alpha^{*}\left(D T_{s t a y, s}+I T I_{\text {stay }, s}\right)}}{\alpha} \\
T_{\text {post,leave }}=\frac{1-e^{-\alpha^{*}\left(D T_{\text {leave }}+I T I_{\text {leave })}\right)}}{\alpha} \\
V_{\text {stay }, s}=\frac{r_{\text {stay }, s}}{H T+T_{\text {post }}}, \\
T_{s}=p_{\text {stay }, s} *\left(H T+T_{\text {post,stay }}\right)+p_{\text {leave }, s} *\left(\tau+T_{\text {post }, \text { leave }}\right) \\
V_{\text {leave }}=\frac{\Sigma_{s} p_{s}{ }^{*} R_{s}}{\sum_{s} p_{s} T_{s} T_{s}}
\end{gathered}
$$

Whereas MVT optimizes all future reward, the delay discounting model, a hyperbolic discounting model, optimizes discounted future reward (i.e. it similarly optimizes future reward, but with less weight to rewards that occur further in the future):

$$
\begin{gathered}
d(t, k)=1 /\left(1+k^{*} t\right), \\
V_{\text {stay }, s}=d(H T, k)\left[r_{\text {stay }, s}+d\left(I T I_{\text {stay }, s}, k\right) \sum_{s^{\prime}} p\left(s^{\prime} \mid \text { stay }, s\right) \sum_{a} p_{a, s^{\prime}} V_{a, s^{\prime}}\right] \\
V_{\text {leave }, s}=d(\tau, k)\left[r_{\text {leave }}+d\left(I T I_{\text {leave }}, k\right) \sum_{s^{\prime}} p\left(s^{\prime} \mid \text { stay }, s\right) \sum_{a} p_{a, s^{\prime}} V_{a, s^{\prime}}\right]
\end{gathered}
$$

where $d(t, k)$ was the hyperbolic discount function of time $t$, with a free parameter, $k . p\left(s^{\prime} \mid a, s\right)$ was the conditional probability of being in future state $s$ ' given action $a$ was taken in state s, $p_{a, s^{\prime}}$ was the probability of taking action $a$ in future state $s$ ', and $V_{a, s^{\prime}}$ was the value of for taking action $a$ in future state $s^{\prime}$.

As the discount parameter, $k$, approached zero (no discounting of future reward), this model converged to MVT; that is, it sought to maximize all future reward. As $k$ increases, future rewards are discounted, such that i) the value of large rewards in a new patch are discounted above and beyond the travel time between patches, and ii) the model sought to maximize reward into the future, but over shorter periods of time.

For all models, one set of parameters was fit to each animal per experiment, to maximize the likelihood of the data from both conditions in that experiment. To test whether the model could explain rat overharvesting behavior in each experiment, we generated predicted patch leaving distributions from the best fit parameters for each
model, then perform a repeated measures ANOVA, to test whether there is an interaction between model predictions and observed behavior (i.e. whether the effect of each experimental manipulation was different between model predictions and observed behavior).

## Results

## Foraging Behavior

Rats were first tested on a manipulation of travel time. With longer travel time, the long-run average reward rate is lower, thus MVT predicts rats should stay in patches longer. Within behavioral sessions, rats encountered three different patch types, which started with varying amount of reward ( 60,90 , or $120 \mu \mathrm{~L}$ ) and depleted by the same rate $(8 \mu \mathrm{~L})$. Between sessions, rats were tested on either a 10 s or 30 s travel time delay following their decision to leave the patch. As predicted by MVT, rats stayed longer in patch types that started with larger reward volume, indicated by more harvests per patch, $\mathrm{F}(2,14)=3145, \mathrm{p}<.001$, and rats stayed longer in all patches with longer travel time, $\mathrm{F}(1,7)=71.4$, $\mathrm{p}<.001$. However, rats overharvested, staying longer in all patches than is predicted by MVT (Figure 1A).

Next, rats were tested on a manipulation of depletion rate. Quicker reward depletion causes the local reward rate to deplete to the long-run average reward rate quicker, such that MVT predicts earlier patch leaving. Within sessions, rats encountered a single patch type (starting volume of 90 $\mu \mathrm{L}$ ), which depleted at a rate of either 8 or $16 \mu \mathrm{~L} /$ trial, tested between sessions. As predicted by MVT, rats left patches earlier when they depleted more quickly, $t(7)=$ $15.835, \mathrm{p}<.001$. But, again, rats stayed in patches longer than is predicted by MVT (Figure 1B).

Rats were then tested on a manipulation of the scale of rewards and time. In one condition, the size of rewards and length of delays was twice that of the other: patches started with 90 or $180 \mu \mathrm{~L}$ of reward, depleted at a rate of 8 or 16 $\mu \mathrm{L} /$ trial, and travel time between patches was 10 or 20 s . Both reward rate within the patch and reward rate across patches were equivalent in the two conditions; thus, MVT predicts no change in behavior. Contrary to predictions of MVT, rats stayed in patches significantly longer when given larger rewards with longer delays, $t(7)=10.039, p<.001$. And, again, rats overharvested in both conditions (Figure 1C).

Lastly, rats were tested on a manipulation of the placement of delays. In one condition, rats experienced no pre-reward delay, and a long post-reward delay (ITI $\sim 10 \mathrm{~s}$, adjusted based on DT). In the other condition, rats experienced a 3 s pre-reward delay, and shorter post-reward delay (ITI $\sim 7 \mathrm{~s}$ ). The duration of each trial did not change, so both the local reward rate within the patch and long-run average reward rate across patches were equivalent between the conditions, and MVT predicts no change in behavior. Rats overharvested in both conditions, but they left patches earlier when part of the delay occurred prior to the reward, $t(7)=7.453, p<.001$ (Figure 1D).

Figure 1: Diagram of each foraging experiment and behavioral data. In diagrams, black boxes represent the start of a trial, at which a decision to lever press or nosepoke must be made. $\mathrm{DT}=$ decision time, $\mathrm{HT}=$ handling time, ITI $=$ intertrial interval. In graphs, black points and lines represent rat data, and red points and lines the optimal behavior predicted by MVT. A) Points represent the mean number of lever presses in each patch from each animal, error bars representing standard error are obstructed by the points. B-D) Each point is the mean number of lever presses in each patch for a single rat, with lines connecting each rats behavior in the two conditions.

## Models of overharvesting

We first tested a model that includes a subjective cost to foraging - a constant that represents a bias towards staying in the patch. Predictions from the model, fit to each rat, are presented in Figure 2. Qualitatively, this model explained rat behavior on the travel time and depletion rate experiments well, producing a predicted number of harvests per patch similar to that exhibited by the rats. However, there was a significant interaction between travel time and predicted vs. observed behavior, $\mathrm{F}(1,7)=7.391, \mathrm{p}=.030$, indicating a difference between how the model vs. the rats responded to the change in travel time. This is likely driven by the model predicting slightly earlier patch leaving in the 30 s travel time relative to rats' behavior. The interaction between depletion rate and predicted vs. observed behavior was not significant, $\mathrm{F}(1,7)=.124, \mathrm{p}=.735$.

As this model only allows for a constant change in the reward rate threshold to leave patches, it is unlikely to account for behavior in which rats select a different threshold between conditions. When rats were given longer rewards with longer delays, they stayed in patches longer, allowing patches to deplete to a lower reward rate before leaving. Similarly, when a pre-reward delay was introduced, rats left patches earlier, at a higher reward rate. The model failed to account for both of these effects (interaction between scale $x$ predicted vs. observed behavior, $\mathrm{F}(1,7)=$ $58.43, \mathrm{p}<.001$; delay x predicted vs. observed behavior, $F(1,7)=48.79, p<.001)$.

Figure 2: Predictions of the subjective cost model for the A) travel time, B) depletion rate, C) scale, and D) pre- vs. post-reward delay experiments. Black points and errorbars represent the mean number of harvests per patch $\pm$ standard error. Colored lines represent the average model predicted number of harvests. The width of the colored line represents the standard error of the predicted number of harvests. There were significant interactions between model predictions and observed behavior in the travel time (A), scale (C), and pre vs. post-reward delay (D) experiments.

We next tested whether diminishing marginal returns could explain overharvesting (Figure 3). Under this
hypothesis, large rewards in a new patch were not valued as proportionally larger to smaller rewards in the current, depleting patch. Predictions from the subjective utility model are presented in Figure 3. As did the subjective cost model, the subjective utility model qualitatively explained overharvesting behavior in the travel time and depletion rate experiments. This was supported by the lack of a significant interaction between travel time and predicted vs. observed behavior, $\mathrm{F}(1,7)=4.501, \mathrm{p}=.072$, although there was a significant interaction between depletion rate and predicted vs. observed, $\mathrm{F}(1,7)=14.12$ ), $\mathrm{p}=.007$.

In the scale experiment, the subjective utility model should estimate a lower reward rate in the environment with larger rewards, and thus predict later patch leaving. However, this model could not explain both general overharvesting, as well as the change in behavior due to scale, $\mathrm{F}(1,7)=112, \mathrm{p}<.001$. Additionally, this model is insensitive to the placement of delays, and failed to predict that rats would leave patches earlier when a pre-reward delay was introduced, $\mathrm{F}(1,7)=77.22, \mathrm{p}<.001)$.

Figure 3: Predictions of the subjective utility model for the A) travel time, B) depletion rate, C) scale, and D) prevs. post-reward delay experiments. There were significant interactions between model predictions and observed behavior in the depletion rate (B), scale (C), and pre- vs. post-reward delay (D) experiments.

Next, we tested whether a delay discounting model that considers future rewards could account for rat overharvesting behavior (Figure 4). As rewards are discounted into the future, the value of the first reward in a new patch was discounted due to the travel time between patches, and the model sought to maximize future rewards over a shorter period of time. The discounting model accurately predicted overharvesting behavior in both travel times; interaction between travel time and predicted vs. observed behavior was not significant, $\mathrm{F}(1,7)=.050$, $\mathrm{p}=$ .830. This model also predicted earlier patch leaving when reward in the patch depleted quicker, but there was significant interaction between depletion rate and predicted vs. observed behavior, $F(1,7)=16.780, p=.005$, indicating that the model-predicted change in behavior is different
from the change in behavior exhibited by rats.
In the scale experiment, when comparing larger rewards with longer delays to smaller rewards with shorter delays, the larger rewards would be discounted to a greater extent. Thus, in this model, the estimate of the overall reward rate would be lower in the environment with larger rewards, predicting that rats would stay longer in this environment. Indeed, this model did predict that rats would stay in patches longer when given larger rewards with longer delays, and the interaction between scale and predicted vs. observed behavior was not significant, $\mathrm{F}(1,7)=.482, \mathrm{p}=.510$. This model also should place lower value on rewards in the patch when there is a longer delay between decision to harvest and obtaining reward. However, there was a significant interaction between pre- vs. post-reward delay conditions and predicted vs. observed behavior, $\mathrm{F}(1,7)=34.650$, $\mathrm{p}<$ . 001 .

Figure 4: Predictions of the delay discounting model for the A) travel time, B) depletion rate, C) scale, and D) prevs. post-reward delay experiments. There were significant interactions between model predictions and observed behavior in the depletion rate (B) and pre- vs. post-reward delay (D) experiments.

Lastly, we tested whether ignoring post-reward delays could explain rats' overharvesting behavior. In this model, time delays that occur after receiving reward, before a decision is made on the next trial (e.g. ITI after reward and DT prior to making next decision), were treated differently than time delays that occur between making a decision and receiving a reward (e.g. handling time delay between lever press and reward, or travel time delay between nosepoke and first reward in the next patch). Time delays that occur after the reward, and before the next decision are assumed to increase monotonically, but sublinear relative to actual time, according to an exponential function. In this model, underestimation of the ITI would cause overestimation of reward rate, and overharvesting. Additionally, in the scale experiment, longer delays would cause greater overestimation of reward rate, and would predict that rats should stay in patches longer when given larger rewards with longer delays. In the pre- vs. post-reward delay
experiment, when the pre-reward delay was introduced, post-reward delays were shorter. In this model, shorter postreward delays would lead to less overestimation of reward rate, and earlier patch leaving.

This model qualitatively explained overharvesting in all four experiments. Additionally, there were no significant interactions between task manipulations and predicted vs. observed behavior (travel time, $\mathrm{F}(1,7)=.416, \mathrm{p}=.539$; depletion rate, $F(1,7)=4.691, p=.067$; scale of reward and time, $\mathrm{F}(1,7)=.047, \mathrm{p}=.835$; pre- vs. post-reward delay, $\mathrm{F}(1,7)=1.985, \mathrm{p}=.202$ ), indicating that there were no differences between rats change in behavior due to experimental manipulation and model predicted change in behavior in all four experiments.

Figure 5: Predictions of the ignore post-reward delays model for the A) travel time, B) depletion rate, C) scale, and D) pre- vs. post-reward delay experiments. Interactions between model predictions and observed behavior were not significant in any of the four experiments.

## Discussion

We characterized patch foraging behavior of one of these species, rats, in a variety of foraging environments, and examined the computational mechanisms of overharvesting. We found that rats, like humans (Constantino \& Daw, 2015), followed the primary qualitative predictions of MVT, leaving patches earlier when the rate of depletion was quicker, and staying longer in patches when travel time was longer. However, as has consistently been observed in other species, they overharvested (or stayed longer in patches than is predicted by MVT). Furthermore, rats deviated from predictions of MVT in other ways, staying longer in patches that provided larger rewards with longer delays, and leaving patches earlier when delays occurred between the decision to harvest from the patch and receiving reward. To examine the cognitive biases that underlie overharvesting, we fit four models to rats foraging behavior in each context: a model including subjective costs, diminishing marginal returns for larger rewards, discounting of future reward, and ignoring post-reward delays, and tested whether predictions of these models were different from rats' behavior. All four models could qualitatively explain rat foraging behavior in response
to a change in travel time and patch depletion rate, but only the 'ignore post-reward delays' model, in which post reward delays are perceived to be shorter than they actually are, could predict both later patch leaving when given larger rewards with longer delays, and earlier patch leaving when a pre-reward delay was introduced. These results suggest that there are multiple cognitive biases that can explain overharvesting in certain contexts, and that foraging behavior may be the result of the use of multiple biases. However, inaccurate estimation of post-reward delays likely contributes to overharvesting.

# Language-users choose short words in predictive contexts in an artificial language task 

Jasmeen Kanwal (jasmeen.kanwal@ed.ac.uk), Kenny Smith (kenny.smith@ed.ac.uk), Jennifer Culbertson (jennifer.culbertson@ed.ac.uk), and Simon Kirby (simon@ling.ed.ac.uk)<br>Centre for Language Evolution, University of Edinburgh<br>3 Charles St., Edinburgh, Scotland EH8 9AD

#### Abstract

Zipf (1935) observed that word length is inversely proportional to word frequency in the lexicon. He hypothesised that this cross-linguistically universal feature was due to the Principle of Least Effort: language-users align form-meaning mappings in such a way that the lexicon is optimally coded for efficient information transfer. However, word frequency is not the only reliable predictor of word length: Piantadosi, Tily, and Gibson (2011) show that a word's predictability in context is in fact more strongly correlated with word length than word frequency. Here, we present an artificial language learning study aimed at investigating the mechanisms that could give rise to such a distribution at the level of the lexicon. We find that participants are more likely to use an ambiguous short form in predictive contexts, and distinct long forms in surprising contexts, only when they are subject to the competing pressures to communicate accurately and efficiently. These results support the hypothesis that language-users are driven by a least-effort principle to restructure their input in order to align word length with information content, and this mechanism could therefore explain the global pattern observed at the level of the lexicon.

## Introduction

Zipf (1935) observed that word length tends to be inversely proportional to word frequency in the lexicon. He hypothesised that this widespread cross-linguistic pattern was due to the Principle of Least Effort: language-users align formmeaning mappings in such a way that effort is minimised while expressivity is still maintained. However, word frequency is not the only reliable predictor of word length. Using corpora from 11 different languages, Piantadosi et al. (2011) show that a word's predictability in context (where they define context as the two words preceding the target word) is even more strongly correlated with word length than frequency is: words that are, on average, more predictable in context tend to be shorter.

Measuring how predictable or unpredictable a word is in a particular context gives us a way of defining the information content of a word. For example, consider the two sentences:
(1) The early bird catches the worm.
(2) Our early bird special today is a baked-apple worm.

In sentence (1), a well-known proverb, the word worm is entirely predicted by the preceding words. The word itself thus gives us practically no new information, and so it has low information content. In sentence (2), the same word is highly unlikely given the preceding words, and thus we find it surprising. This element of surprise is associated with high information content.

Using these concepts, we can apply Zipf's Principle of Least Effort to hypothesise that a speaker's drive to reduce effort will be directed towards words that are already highly predictable given the context, i.e. have low information content. Words that are more surprising in a particular context will be less likely to be reduced, or more likely to be lengthened. The resulting state in which low-information words are shorter than high-information words, and thus the length of a word is roughly proportional to the amount of information associated with the word, is consistent with the Uniform Information Density (UID) principle (Jaeger, 2010) or the Smooth Signal Redundancy (SSR) hypothesis (Aylett \& Turk, 2004), which state that information is distributed roughly evenly across words in an utterance.

There are many ways to operationalise the information content of a word. One way is to use the N -gram probability of a word, i.e. its probability conditioned on a window of N preceding or following words. This is the method used by Piantadosi et al. (2011). Zipf's word frequency measure is in fact just a limiting case of this N -gram probability, where $\mathrm{N}=0$. Other measures include syntactic probability, a word's probability of appearing in a particular syntactic structure (Jaeger, 2010, e.g.), and givenness, a word's predictability given the semantic context (Aylett \& Turk, 2004).

Both corpus studies and controlled behavioural experiments have linked low information content, operationalised in these different ways, to various types of linguistic reduction. Lieberman (1963); Aylett and Turk (2004); Gahl and Garnsey (2004); Tily et al. (2009); Kuperman and Bresnan (2012), and Seyfarth (2014) show that words with low information content are more likely to undergo various types of phonetic reduction. Bell, Brenier, Gregory, Girand, and Jurafsky (2009) show that each of the four different measures of information content mentioned above may in fact contribute separately to the phonetic duration of a word. Fedzechkina, Jaeger, and Newport (2012) show that case markers are more likely to be omitted on nouns in more probable syntactic roles. Jaeger (2010) shows that that-complementisers are more often dropped when the following word is less surprising in context.

If predictability in context can lead to phonetic reduction, as well as deletion of morphemes and entire words, then these effects might make their way to the overall distribution of form-meaning mappings in the lexicon. However, there is relatively little work directed at understanding how predictability affects this widely observed pattern at the level of the lex-
icon.
One way of investigating the issue is by tracking languageusers' online choices when producing words that are part of a 'clipped pair', i.e. when both a long form and an abbreviated or 'clipped' form exist that have the same or very similar meanings (Mahowald, Fedorenko, Piantadosi, \& Gibson, 2013). E.g. in English, info/information is a clipped pair. Mahowald et al. presented participants with sentences containing a blank and asked them to complete the sentence with either the long or the clipped form corresponding to the relevant meaning. They found that participants were more likely to choose the short form in predictive contexts, which is consistent with the hypothesis that the lexicon-level patterns observed by Piantadosi et al. (2011) may be due in part to a least-effort mechanism, in which speakers balance communicative efficacy with efficiency.

However, because this study uses English sentence frames and target words, we cannot rule out potentially confounding contributions from register, prosody, and participants' learned preferences to their word choice in particular instances. Moreover, we cannot assess whether the effect is really driven by the competing pressures for communicative accuracy and efficiency without manipulating the presence or absence of these different communicative pressures. For instance, in Mahowald et al.'s task, it seems participants clicked on a word rather than typing it in, and thus there was no difference in effort between choosing the long or short form. In addition, participants were told to choose a word based on "which sounded more natural", rather than being directly engaged in a task requiring successful communication.

Here, we present a new artificial language learning study investigating the question of whether language-users align word length with information content when communicating. Our results are consistent with previous findings that language-users tend to use shorter forms in more predictive contexts. Furthermore, the behaviour we observe across different experimental conditions supports the hypothesis that this effect is driven at least in part by a least-effort principle, in which language-users balance the competing pressures for communicative accuracy and efficiency to reshape the lexicon into one where word length is roughly proportional to average information content.

## Method

Artificial language learning studies have previously been used to shed light on the cognitive mechanisms and environmental pressures that shape large-scale linguistic structure. In this paradigm, participants learn an artificial language, and then we observe how they reshape their input as they use the language, in this case to communicate with a partner (e.g., Winters, Kirby, \& Smith, 2015; Kirby, Tamariz, Cornish, \& Smith, 2015; Fehér, Wonnacott, \& Smith, 2016).

## Participants

120 participants ( 53 females, 66 males; one did not report their gender) were recruited and remunerated via Amazon

Mechanical Turk. 108 of these reported themselves as native English speakers, of which 96 were monolingual. A range of other languages were represented across the remaining participants. Ages ranged from 18 to 70 (mean=32.9, $\mathrm{SD}=9.5$ ).

## The Training Language

The study was run online. Participants were trained on two names for each of two plant-like alien objects, by repeatedly being shown pictures of the objects labeled with a simple sentence. The sentence consisted of a framing word followed by the object's name. There were two possible frames, bix and gat. Overall there were 64 training trials, with each object appearing 32 times and each frame appearing 32 times. Crucially, one object appeared seven times more frequently with the frame bix than gat (28 and 4 times, respectively), while the other object appeared seven times more frequently with the frame gat than bix (again, 28 and 4 times, respectively). This meant that each object appeared in both a predictive context and a surprising context; which frame signified which of these contexts was flipped between the two objects.

Furthermore, the object name appeared half the time in its full form, a 7-letter word, and half the time in shortened form, a 3-letter word derived by clipping the last two syllables off the long name. These short and long forms were evenly distributed across both predictive and surprising contexts, ensuring that the input language contained no inbuilt bias towards using one form in any particular context. ${ }^{1}$ A schematic diagram of the object frequencies and labels is provided in Fig. 1 A .

In natural languages, shorter words are subject to greater confusability for a number of reasons: shorter forms have less space for signal redundacy and thus are more likely to be completely lost in noisy signal transmission; and because languages have a finite phoneme inventory, there are more unique possible long strings than short strings, and thus word shortening often results in ambiguity. Indeed, shorter words are more likely to be polysemous and homophonous (Piantadosi, Tily, \& Gibson, 2012). To model this fact in our miniature lexicon, we designed the names such that the short name for both objects was identical (zop), while the long names were unique (zopekil and zopudon).

## Procedure

Participants were assigned to one of four conditions, where we manipulated the presence of pressures to communicate accurately and quickly in a between-subjects $2 \times 2$ design (Kanwal, Smith, Culbertson, \& Kirby, 2017). Each experiment consisted of two phases: training and testing. The training phase was uniform across conditions, while the testing phase varied by condition.

[^117]

Figure 1: (A) The input frequencies of the objects and framing sentences presented during training trials in all four experimental conditions. (B) A sample training trial. (C) A sample director trial in the Combined condition (top) and a matcher trial followed by feedback (bottom).

Training phase On each training trial, an object was presented on screen alone for 700 ms . The appropriate sentence then appeared beneath the object for a further 3000 ms , yielding a total trial duration of 3700 ms . A blank screen showed for 500 ms between trials. The 64 training trials were presented in a different randomised order for each participant.

Testing phase After the training phase, testing procedures varied depending on the experimental condition. In the Combined condition, participants were under a pressure to communicate accurately and efficiently, as according to the Principle of Least Effort, it is balancing these competing pressures that leads language-users to distribute word length inversely to word predictability. The remaining three conditions removed one or both of these accuracy and time pressures.

Condition 1: Combined In the testing phase of this condition, participants were paired with a partner to play a communication game, using the method developed for running two-player online experiments in Kanwal et al. (2017). On
each trial, the 'director' was shown an object on the screen with a framing word followed by a blank. The director was instructed to choose a name for the object to complete the sentence, and once the name was entered, the sentence would be transmitted to the 'matcher'. The director could choose one of two options to complete the sentence: the unique long name for the object or the (ambiguous) short name. Once the chosen name was selected by clicking on the appropriately labeled button, it had to be entered into the blank space by pressing and holding the mouse as each letter appeared one after the other at 1200 ms intervals. Only after all the letters in the name had appeared in the box was the completed sentence transmitted to the matcher. This belaboured method of production, in which the long name was significantly slower to produce than the short name, was introduced to model the difference in effort and speed associated with producing long versus short utterances.

Once the director completed their description, it was transmitted to the matcher, who was asked to choose which of the two objects they thought the director was referring to. Both players were then given feedback as to whether the matcher's choice was correct.
The players alternated roles after every trial, with the matcher becoming the director and the director becoming the matcher, until both completed 32 director trials and 32 matcher trials. The proportion of times each object appeared with each frame in each player's director trials matched those of the training proportions: one object appeared seven times more frequently with the frame gat than bix, and the other appeared seven times more frequently with bix than gat. The order of each participant's 32 director trials was randomly shuffled.

To model the pressures in spoken communication to be both efficient and accurate, pairs were told at the beginning that they would be rewarded a bonus payment of $\$ 1$ if they were the pair to complete the game in the quickest time with the highest number of correct match trials. Time was only counted when the director was entering a name into the blank, and the total time count was displayed next to the blank during this process, to emphasise the time pressure. Screenshots of sample director and matcher trials are shown in Fig. 1C.

In this condition, with pressures to be speedy yet accurate, we expected participants to converge on an optimal strategy in which the short name is used for an object when it appears in its predictive context, and the long name otherwise. In predictive contexts, the framing word already provides a lot of information to the matcher about which object is likely under discussion, and thus participants can minimise effort by using the short form. Conversely, in surprising contexts, the full object name is required to ensure disambiguation.

In order to establish a causal link between these purported mechanisms and the behaviour we observe, we included three further experimental conditions, described below, for a full $2 \times 2$ manipulation of the pressures for accuracy and efficiency.

Condition 2: Accuracy In this condition, participants were paired to play a communication game as described above, but in the director trials, there was no intermediate step between the director choosing a name to complete the sentence and the matcher receiving the sentence; the names were entered instantaneously, thus removing any difference in effort between producing long or short names. Pairs were told that the goal of the game was simply to have their partner make as many correct guesses as possible. No bonus prize was offered in this condition, as we expected many pairs to hit ceiling as they did in Kanwal et al. (2017)-however, fewer than expected actually did so here.

In this condition, we predicted that participants would be more likely to use the long names for both objects across all contexts, as the long names are less confusable, and without a pressure to be efficient, there is little reason to shorten.
Condition 3: Time In this condition, communication was taken out of the game entirely; participants played a oneplayer game consisting of 64 director trials. In each trial, participants completed the sentence with either the long or short name for the object shown, but there was no subsequent communicative task. The name was simply entered as in the Combined condition, by pressing and holding the mouse in the blank space, with each letter appearing at 1200 ms intervals, while a timer displayed the total time count. The next trial began once all the letters had appeared in the box. Participants were told at the beginning of the game that they would be rewarded a bonus payment of $\$ 1$ if they were the player with the shortest total time count.

Here, we expected participants to use the short name for both objects across all contexts: with no communicative purpose attached to the transmissions, and an incentive to be as quick as possible, using the short name in every trial is the best strategy.
Condition 4: Neither The fourth and last condition contained neither a pressure for efficiency nor a pressure for accuracy. As in the Time condition, participants played a oneplayer game with no explicit communicative element. Additionally, there was no time difference associated with transmission; once a label was chosen to complete a sentence, it was instantaneously recorded and the player advanced to the next trial. We included this condition to provide a baseline for participants' behaviour from which to assess the effects of the accuracy and time pressures in the other three conditions.

In this condition we expected that participants would either probability-match-i.e. use the long and short forms for both objects with equal frequency, as in the training trials (Hudson Kam \& Newport, 2005)—or their behaviour would reveal prior biases language users bring to the task, such as a preference against using ambiguous forms, as observed in Kanwal et al. (2017).

## Results

Fig. 2 shows the proportion of trials in which the short name was produced by each participant or pair of participants in

Figure 2: The proportion of trials in which the short name was used in predictive contexts versus the proportion of trials in which it was used in surprising contexts. For the Combined and Accuracy condition, each data point combines a pair of communicating players, representing the sum of their director trial productions. For the Time and Neither condition, each data point corresponds to an individual player's productions. The size of the circles is perceptually scaled (Tanimura et al., 2006) to reflect the number of data points coinciding at each value. Data from only the second half of testing trials is shown here, as participants were more likely to have converged on a stable mapping by this time. These results demonstrate that behaviour consistent with the principles of UID or SSR-using short forms in predictive contexts and long forms in surprising contexts, generating systems that fall in the bottom right corner of each graph-only reliably arises in the Combined condition.
predictive versus surprising contexts. Our predictions were borne out by the results in all four conditions. In the critical Combined condition, in which participants were subject to the combined pressures for accuracy and efficiency, pairs of communicating participants produced systems in which the short name was used in predictive contexts and the long name in surprising contexts. Crucially, only when both pressures were present did participants reliably produce systems where word length was conditioned on context in this way. In the Accuracy condition, participants tended to use the long name for both objects regardless of context, and in the Time condition, they used the short name for both objects regardless of context. In the Neither condition, some participants stuck with the long name or the short name throughout the trials regardless of context, as in the Accuracy or Time conditions; however, most participants probability-matched.

A logistic regression model was fit to the full dataset in R using the lme4 package, with short name use (as contrasted with long name use) as the binary dependent variable; context (predictive or not), experimental condition, and their interaction as fixed effects; and by-participant random slopes

Figure 3: This figure shows the extent to which participants' name choices are conditioned on context (lefthand graph) and object (righthand graph). The dotted line in the lefthand graph represents the mutual information $\left(\mathrm{MI}_{\mathrm{C}}\right)$ associated with the 'optimal' language in least-effort terms-the language in which the short form is used only in predictive contexts, and the long form only in surprising contexts. $\mathrm{MI}_{\mathrm{C}}=0$ for the input language. In the righthand graph, mutual information $\left(\mathrm{MI}_{\mathrm{o}}\right)$ can range from 0 (same name fixed for both objects) to 1 (distinct names fixed for each object). $\mathrm{MI}_{\mathrm{O}}=0.5$ for the input language, marked by the dotted line. Data from only the second half of testing trials is shown in this figure, as participants were more likely to have converged on a stable mapping by this time.
and intercepts for context. The model was sum coded, setting the grand mean as the intercept, to which each level was then compared. The results yielded a significant positive interaction of context in the critical Combined condition ( $\beta=0.619, S E=0.158, p<0.001$ ), indicating that in this condition, participants were significantly more likely to use the short name in predictive contexts. The only other significant effects found were as follows: a positive overall effect in the Time condition ( $\beta=2.187, S E=0.292, p<0.001$ ), indicating that participants were more likely to use the short form in this condition regardless of context; a negative overall effect in the Accuracy condition ( $\beta=-1.470, S E=0.233, p<$ 0.001 ), indicating that participants were less likely to use the short form in this condition regardless of context; and finally a negative interaction effect of context in the Accuracy condition ( $\beta=-0.490, S E=0.161, p=0.002$ ), indicating that in fact participants were even less likely to use the short form in the predictive context in this condition.

An analysis of how participants conditioned the variation in their name usage sheds further light on the differing patterns of behaviour seen across conditions. We calculated the average mutual information between name produced and context (predictive or not) in each participant's output language $\left(\mathrm{MI}_{\mathrm{C}}\right)$. The more reliably participants are conditioning their use of the long and short names on context, the higher we would expect the value of $\mathrm{MI}_{\mathrm{C}}$ to be. The distributions for all four conditions are plotted on the lefthand graph of Fig. 3.

We also calculated the average mutual information between name produced and object (the blue fruit or the red stalk) in each participant's output language ( $\mathrm{MI}_{\mathrm{O}}$ ). This measure allows us to determine whether some participants are us-
ing fixed names for each object, regardless of context. The results are plotted by condition in the righthand graph of Fig. 3. If participants are using a distinct name for each object, $\mathrm{MI}_{0}$ will be close to 1 ; if they are using the same name for both objects, $\mathrm{MI}_{\mathrm{O}}$ will be close to 0 . The former pattern is what we see in the Accuracy condition: most participants use the unique long name for each object, regardless of context. The latter pattern is what we see in the Time condition: most participants use the ambiguous short form for both objects, regardless of context.

In the Combined and Neither conditions, $\mathrm{MI}_{\mathrm{O}}$ hovers around that of the input language. Based on this graph alone, participants may be probability matching in both these conditions, or perhaps reliably conditioning their output on other factors. Looking back at $\mathrm{MI}_{\mathrm{C}}$ disambiguates: it is significantly higher in the Combined condition than in any other condition. A linear regression on $\mathrm{MI}_{\mathrm{c}}$ with condition as predictor variable (fit to the second half of testing trials, as in Fig. 3) yielded a significant negative effect of the Accuracy ( $\beta=$ $-0.081, S E=0.033, p=0.016)$, Time $(\beta=-0.184, S E=$ $0.041, p<0.001$ ), and Neither ( $\beta=-0.128, S E=0.041, p=$ 0.002 ) conditions, with the Combined condition set as the intercept. This result is consistent with what we saw in Fig. 2: in the Combined condition, many participants are optimally conditioning their responses on context, generating systems that fall in the bottom right corner of the graph; in the other conditions, almost no data points fall in this region.

## Discussion

There is mounting evidence that utterance length is linked to information content (Lieberman, 1963; Aylett \& Turk, 2004; Gahl \& Garnsey, 2004; Tily et al., 2009; Bell et al., 2009; Jaeger, 2010; Piantadosi et al., 2011; Kuperman \& Bresnan, 2012; Fedzechkina et al., 2012; Seyfarth, 2014). The explanation put forth in much of this previous work is that speakers are driven by pressures much like those outlined in Zipf's Principle of Least Effort: the competing demands for accurate and efficient communication lead speakers to converge on an optimal system in which information content is spread roughly uniformly across the utterance, resulting in low-information units being shorter than high-information units. This resultant effect appears to have made its way into the structure of the lexicon as a whole: shorter words appear on average in more predictive contexts than longer words (Piantadosi et al., 2011). But is this effect really due to the proposed mechanism? Can speaker choice lead to the reshaping of a lexicon to align it with the principles of Uniform Information Density and Smooth Signal Redundancy?

Here, we presented the first study that concretely addresses these questions. Previous studies either lacked a manipulation of the communicative pressures operating in the task, or lacked a communicative element entirely. In our study, by observing participants' online behaviour in a task in which the pressures to communicate accurately and efficiently were manipulated across four experimental conditions, we have
shown that participants use shorter words in more predictive contexts only when both competing pressures were acting on them. When these pressures were isolated or removed entirely, participants failed to reliably condition their word choices on context.

Furthermore, because our study employed an artificial language learning paradigm, our findings avoid potential confounds from factors such as register, prosody, and participants' learned preferences in their native or second languages. Our results are nevertheless consistent with previous findings that language-users tend to use shorter forms in more predictive contexts when using their native language.

Our results serve as a proof of concept that the lexiconlevel effect observed by Piantadosi et al. (2011) could be driven at least in part by a least-effort principle in which language-users balance the competing pressures for communicative accuracy and efficiency to reshape the lexicon into one where word length is roughly proportional to information content. However, there is a crucial step between what we have observed here-language-users alternating between long and short variants for a single meaning depending on context-and what Piantadosi et al. (2011) observed in the lexicon of different languages, where most meanings don't correspond to both a long and a clipped variant, but rather map to a single fixed form. For these cases, which make up the majority of the lexicon, the length of the form is strongly correlated with the average predictability-in-context of the meaning, across all its different occurrences. We can hypothesise a link between these two phenomena: as a word appears in increasingly more predictive contexts, a reduced variant may come into use. If speakers use the reduced variant in predictive contexts, then this reduced form will consequently become much more frequent than the long form, leading to the long form eventually dying out altogether. This would end in a scenario where a short word, with no alternative variants currently in use, appears on average in a high number of predictive contexts, and thus has a low average information content. Though this story sounds reasonable, a precise mechanistic explanation of how this preference for short forms in more predictive contexts leads to permanent shifts in formmeaning mappings has yet to be thoroughly investigated. We hope this topic is given more attention in future work.

# Preparatory Effects of Problem Posing on Learning from Instruction 

Manu Kapur<br>ETH Zurich, Switzerland

#### Abstract

A randomized-controlled study compared the preparatory effects of problem-posing on learning from subsequent instruction. Students engaged in problem-posing either with solution generation (where they generated problems and solutions to a novel situation) or problem-posing without solution generation (where they generated only problems) prior to learning a novel math concept. Problem-posing with solution generation prior to instruction resulted in significantly better conceptual knowledge, without any significant difference in procedural knowledge and transfer. These findings suggest that although solution generation prior to instruction plays a critical role in the development of conceptual understanding, and generating problems can further enhance transfer.

# Comparing Individual and Collaborative Problem Solving in Environmental Search

#### Abstract

Collaborative spatial problem solving is an important yet not thoroughly examined task. Participants navigated individually and in dyads through virtual cities of varying complexity. They only saw the environment part visible from their current location from a bird's eye view map perspective. We recorded missed target locations, overall trajectory length and search time per person until self-indicating whole coverage. Our results show a general increase in missed locations, trajectory length, and search time with the complexity of the environment. These increases differed due to individual and collaborative search. For complex, but not for simple environments individual participants navigated shorter distances, finished earlier, but also missed more target locations than when searching the same environments in collaboration. These results indicate that in complex environments collaborative search is less error prone than individual search, but takes longer. Such initial findings will constrain future theorizing about collaborative spatial problem solving.

# Iterated Teaching Can Optimise Language Functionality

#### Abstract

Experimental studies of the cultural evolution of language have focused on how constraints on learning and communication drive emergence of linguistic structure. Yet language is typically transmitted by experts who adjust the input in ways that facilitates learning by novices, e.g. through child-directed speech. Using iterated language learning of binary auditory sequences, we explored how language change is affected by experts' intention to teach the language to novices. Comparison between teaching chains and simple transmission chains revealed that teaching was associated with a greater rate of innovation which led to emergence of more expressive languages consisting of shorter signals. This is the first study to show that during cultural transmission, teaching can modify, and potentially optimise, functional characteristics of language.

Keywords: Teaching; iterated language learning; cultural transmission; algorithmic complexity; compositional structure; combinatorial structure

## Introduction

Cultural transmission of knowledge proceeds via the social learning mechanisms of imitation, emulation and teaching Boyd \& Richerson, 1985; Richerson \& Boyd, 2005). Of these, the adaptive value of teaching has recently received increased attention (Cavalli-Sforza \& Feldman, 1981; Kline et al. 2013; Kline, 2015; Csibra \& Gergely, 2009), highlighting in particular the ostensive use of language in the transmission of technological knowledge required for production of tools and other cultural artifacts (Caldwell \& Millen, 2009; Morgan, Uomini, Rendell, Chouinard-Thuly et al., 2015). In its most general sense, teaching can be defined as any kind of behaviour, intentional or not, that promotes learning by narrowing the range of inferences or behavioural options that another individual can pursue (Kline, 2015). Teaching is especially important for transmission of cognitively opaque cultural traits and traditions, i.e. those whose function is not immediately obvious, thereby contributing to cumulative culture (Mesoudi 2011). While transmission of simpler cultural traits may not benefit from additional teaching (Caldwell \& Millen, 2009), once culture becomes more complex, teaching delivers additional benefits for the transmission process (Morgan et al., 2015).

In contrast, studies of the cultural transmission of language have mainly researched how constraints that
operate on observational learning drive the emergence of structural features like learnability, expressivity (i.e. lack of ambiguity), combinatorial and compositional structure, that support effective communication (Kirby, Cornish and Smith, 2008; Kirby, Tamariz, Cornish \& Smith; 2015; Verhoef, Kirby \& de Boer, 2014). These studies use the iterated language learning method whereby the result of learning in one generation of learners serves as input for the next generation. The picture that emerges from these studies is that cognitive capacity constraints in human learners promote compressibility of individual signals and entire languages, and that the requirements of efficient communication drive languages to be expressive. In tandem, these constraints - the need for transmission efficiency and for referential efficiency - lead to emergence of combinatorial linguistic structure, i.e. systematic associations of components of the signal with dimension of meaning (Kirby et al., 2015).

However, research on language development in children has presented substantial evidence that child language learners receive input that is specifically tailored to support learning, in the form of child-directed speech (e.g. Burnham, Kitamura, \& Vollmer-Conna, 2002; Kempe \& Brooks, 2005; Soderstrom, 2007). While there is considerable debate about whether child-directed speech is universal (e.g. Broesch \& Bryant, 2013; Falk, 2004; Schieffelin, 1985), whether it constitutes intentional teaching or whether it predominantly supports affective bonding and emotion regulation (e.g. Singh, Morgan \& Best, 2002; Uther, Knoll \& Burnham, 2007), functionally it qualifies as a behaviour that not only provides local enhancement by directing the learner's attention to relevant information (Kline, 2015) but also pre-samples the input in a way that can support correct learner inferences about language (Eaves, Feldman, Griffiths \& Shafto, 2016). For learning to occur, no ostensive cues or direct feedback are required as long as the statistical properties of the modified input ensure improved learning. In this study, we explore how tailoring the input in such a way for the learner shapes language structure over the course of language transmission.

If teaching leads to modification of the input that promote correct inferences about language then we can make predictions about the directions in which iterated teaching will change the structure of the emerging system, compared to simple transmission that is only constrained by cognitive
limitations of the learner. Previous iterated language learning studies have highlighted a number of structural features that emerge because languages need to be both learnable and communicatively efficient. We predict that emergence of these features should be facilitated under conditions of teaching: First, if teaching accommodates learnability constraints one would expect transmission fidelity to improve even faster in chains where teaching takes place, compared to simple transmission. Second, as languages evolve to be efficient signalling systems individual signals acquire combinatorial structure by which smaller meaningless subcomponents are recombined to improve signal discriminability, a feature that improves transmission across noisy channels (Verhoef, 2012; Verhoef et al., 2014; Roberts, Lewandowski \& Galantucci, 2015) and should be enhanced through teaching. Third, in order to be communicatively efficient, languages also need to maintain expressivity by avoiding under-specification and ambiguity, another feature we expect to emerge faster under conditions of teaching. Fourth, languages become more systematic and self-similar, a property that, akin to phonotactic rules, supports learnability by reducing combinatorial freedom. This feature should also be enhanced by teaching. Finally, emerging compositional structure serves to systematically link meaningless components of signals to underlying dimensions of their meanings. Although compositional structure requires communicative pressure in addition to language transmission (Kirby et al., 2015; Nowak \& Baggio, 2016), to isolate the effect of teaching, and in the interest of feasibility, we decided to start our exploration with a simple transmission study that did not impose communicative pressure on learners. Despite the lack of communicative pressure, it is still conceivable that teachers modify the input so as to enhance compositional structure in order to highlight this functional aspect of language.

## Method

The present experiment compares transmission of an 'alien' language along chains of learners where each learner's output generated during testing is faithfully represented as input to the learner in the next generation (Simple Transmission condition) with transmission of the language through chains of learners who, after training, are asked to teach the language to the learner in the next generation (Teaching condition). Teaching in this set-up constitutes demonstration of the language to the next learner without any verbal explanation or instruction. The crucial question is whether teachers modify the input when presenting the language to the next learner in a way that goes beyond those modifications that are due to constraints on learning and reproduction.

Participants: Sixty undergraduate students were recruited at the University library for participation in a transmission chain study. Participants were assigned numbers corresponding to their slot in one of six chains, and
were called into the test area when the previous participant had finished the training phase. Performance of these participants was compared to that of sixty other participants who had been tested in a different simple transmission study conducted earlier (Kempe, Gauvrit, Gibson \& Jamieson, submitted). The 'alien' language used in this experiment consisted of high and low tones assembled into 6 or 8 -tone sequences. This signalling system was developed to eliminate any familiarity with signals that could bias learners towards preferences for specific aspects of combinatorial structure.

Materials: Two 500 ms sine-wave tones (high: $440 \mathrm{~Hz}=$ musical note $a$; low: $293.7 \mathrm{~Hz}=$ musical note $d$ ) were synthesised and recorded onto differently coloured answer buzzer of 9 cm diameter each. The fixed tone duration made it impossible to modify the length of the tones if pressing the buzzers for longer periods of time thus eliminating duration as a property of the signals. Seed languages consisted of random sequences of high vs. low tones, which were either six or eight tones long. These binary sequences instantiating the 'words' in the 'alien language' were paired with eight coloured objects differing in shape (spiky 'kiki'type vs. fluffy 'bouba'-type), size ( $2 \times 2 \mathrm{~cm}$ vs. $4 \times 4 \mathrm{~cm}$ ) and brightness ( $25 \%$ vs $75 \%$ saturation) (see Figure 1), which were printed on laminated cards sized $5 \times 8 \mathrm{~cm}$. All objects also had unique properties due to differences in specific shapes and hues.

Figure 1: Meanings associated with the signals (binary sequences) in the 'alien buzzer language'.

Procedure: After signing a consent form, participants in both conditions were told they would learn an 'alien' language used by a species of aliens that had no mouth and therefore used buzzers for communication. Participants were then shown six of the eight cards one at a time to familiarise them with the 'alien' objects. Training proceeded in an incremental fashion: In the Simple Transmission condition, participants were given a demonstration of the binary buzzer sequence for each card, and were asked to repeat it. Demonstration and practice were then immediately repeated resulting in incremental training consisting of two consecutive trials per card, before proceeding to the next card. Order of cards was randomised for each participant by shuffling the cards. After training, participants were shown the cards one at a time, and asked to produce the 'alien buzzer words' to the best of their abilities. Their responses were videotaped, coded and then presented unaltered to the next participant. To prevent the languages from degenerating, a 'homonymy filter' (Kirby et al., 2008) was applied by which up to two identical sequences (i.e. homonyms) were withheld and only six items were
presented during training. In case of no homonyms, two cards were withheld at random; in case of just one pair of homonyms, the card corresponding to one of the homonyms was withheld at random along with one other randomly chosen card. This manipulation was used to encourage productivity and to prevent languages from degenerating into ambiguous systems.

In the Teaching condition, chains were also seeded with six out of eight cards, to maintain compatibility with the Simple Transmission condition. In Generation 1, training proceeded in exactly the same way as in the simple transmission condition. However, from Generation 1 onwards, after training, participants were asked to 'teach' the language to the next participant in the chain who was called into the testing area at that time. When teaching, participants were instructed not to provide any verbal comments or instructions but to simply demonstrate the buzzer sequences twice to the next participant, allowing them to repeat the sequence after each demonstration.

## Results

Participant buzzer responses were videotaped and coded for further analyses. Inter-coder reliability, determined for $17 \%$ of trials, was $94 \%$. All dependent variables were analyzed using Growth Curve Analyses (GCA). To see whether trends were linear or tended to level off we included a quadratic term of Generation following Beckner, Pierrehumbert \& Hay (2017). Thus, our model contained fixed effects of Condition (Simple Transmission vs. Teaching) and linear and quadratic effects of Generation, and random intercepts of Chains as well as random slopes of Generation (Winter \& Wieling, 2016), resulting in a model of the structure Condition + Generation + Generation ${ }^{2}$ + Condition*Generation + Condition*Generation ${ }^{2} \quad+$ (l|Chain) $+\quad$ (0+Generation $\mid$ Chain $) \quad+$ ( $0+$ Generation ${ }^{2} \mid$ Chain). In all cases, the quadratic model provided a better or the same fit to the data compared to the linear model as determined by likelihood-ratio tests.

Expressivity: Languages in the teaching condition contained fewer homonyms than languages in the simple transmission condition. The outputs in the transmission condition were more prone to degenerate into underspecified, more ambiguous languages, as indicated by an interaction of Condition with the linear, $\beta=-0.44, \mathrm{t}=$ 2.50, $\mathrm{p}<.05$, and the quadratic effect of Generation, $\beta=$ $0.05, \mathrm{t}=2.78, \mathrm{p}<.01$. These findings are depicted in Figure 2. Note that in this and all subsequent figures error bars correspond to one S.E.M.

Figure 2: Number of unique sequences (out of 8 ) in Simple Transmission and Teaching chains.

Transmission Accuracy: We used length-normalised Levenshtein edit distance (LED) as an inverse measure of transmission accuracy. LED decreased faster in the Simple Transmission condition (Figure 3), as evidenced by a significant interaction between Condition and the linear effect of Generation, $\beta=-0.03, \mathrm{t}=-2.13, \mathrm{p}<.05$. In other words, when participants were asked to teach they introduced more innovations than when they simply tried to reproduce the binary sequences.

Figure 3: Mean length-normalised Levenshtein edit distance in Simple Transmission and Teaching chains.

Self-similarity: Average pairwise length-normalised LED between all pairs of sequences in a language served as an inverse measure of within-language similarity. This selfsimilarity increased (i.e. LED decreased) overall as indicated by a main effect of Generation, $\beta=-0.06, t=-$ $3.80, \mathrm{p}<.001$. The significant quadratic term suggests that increase of self-similarity was mainly due to the drop from the seed language and levelled off in subsequent generations (Figure 4).

Figure 4: Mean inverse self-similarity (within-language LED) in Simple Transmission and Teaching chains.

Length: Sequences had started out with an average length of 7 tones in the seed language at Generation 0 . In the Teaching condition, sequences remained of roughly the same length, which was significantly shorter than in the Simple Transmission condition, $\beta=-0.81, t=-2.60, p<.05$. The interaction between Condition and the linear effect of Generation, $\beta=0.66, \mathrm{t}=2.46, \mathrm{p}<.05$, confirmed that sequence length increased only during simple transmission (Figure 5).

Figure 5: Mean sequence length in Simple Transmission and Teaching chains.

Combinatorial structure: Structure of individual signals was operationalised as algorithmic complexity, using an estimate developed for short binary strings based on the coding theorem method (Gauvrit, Soler-Toscano, Zenil \& Delahaye, 2014; Zenil, Soler-Toscano, Delahaye \& Gauvrit, 2015). This measure provides an inverse estimate for the amount of structure of a given sequence relative to the variation in structure possible for all sequences of the same length (Figure 6). It captures the intuition that sequences like adadadad or aaaadddd, where $a$ represents the high and
$d$ represents the low note, are more structured than sequences like aadaddda. GCA did not yield any significant effects although the interaction between Condition and the linear effect of Generation, $\beta=-0.13, \mathrm{t}=-1.82, \mathrm{p}=.08$, fell short of significance, suggesting that there may have been a trend for algorithmic complexity to decrease somewhat during simple transmission.

Figure 6: Mean length-normalised algorithmic complexity in Simple Transmission and Teaching chains.

Compositional Structure: To determine compositional structure for each language, we calculated the Pearson product-moment correlations between differences in the three meaning dimensions of all meaning pairs and differences between associated signals pairs within each language, using 10,000 iterations of a Monte Carlo process to obtain a standardised score. This measure remained below the value associated with $\mathrm{p}=.05$, and did not differ between conditions and generations indicating that no compositional structure had emerged (Figure 7).

Figure 7: Mean compositional structure in Simple Transmission and Teaching chains. The horizontal line indicates $z=1.96, p=.05$.

## Discussion

We compared six teaching chains with six simple transmission chains to explore the effect of teaching during cultural transmission of language. As this was an exploratory study, we did not include a requirement to engage in referential communication. Thus, it was not unexpected that compositional structure did not emerge (Kirby et al., 2015), and we found no evidence that teachers would introduce it spontaneously.

What we found was that although transmission accuracy increased overall, it was significantly lower in the Teaching condition, counter to our expectations. Thus, considerably more innovations were introduced into the signals when participants were asked to teach rather than just to reproduce what they had learned. We suggest that these innovations served to stabilise certain features of the languages that the teachers considered crucial. The most notable change from Simple Transmission performance achieved through innovation in the Teaching condition was to maintain expressivity of the language: The number of different sequences within the taught languages remained high thus preventing these languages from degenerating by accumulating homonyms. This is an interesting result because previous research had demonstrated that without a strong incentive to communicate, capacity constraints of the learners drive languages towards under-specification and ambiguity (Kirby et al., 2015). What our findings suggest is that teaching can override this tendency, presumably due to strong biases about the functional destination of language, which is to be expressive, i.e. referentially efficient. It is noteworthy that the expressivity advantage in the Teaching condition arose even though we applied a homonymy-filter in the Simple Transmission condition to prevent the languages from degenerating. Without this filter, languages in the Simple Transmission condition would have accumulated even more homonyms (Kirby et al., 2008), presumably further deviating from the Teaching condition.

Another feature that remained stable in the Teaching condition was sequence length: Teachers managed to maintain sequence length at around the original 7 tones while in the Simple Transmission condition, sequence length increased dramatically. Stabilising or even reducing length is a strategy that can ensure learnability and transmission accuracy by keeping the form of signals within the limits imposed by working memory constraints. As this brevity constraint operated only in the Teaching condition it may reflect a cooperative adjustment on the part of the teacher designed to aid the learner.

We observed little further increase of self-similarity of languages beyond an initial gain following exposure to the initial random binary sequences. Self-similarity can be thought of as a measure of systematicity that is somewhat akin to phonotactic rules. If teachers attempted to resolve the trade-off between expressivity of the language and brevity of the signals, they would be more likely to use the full space of distinct binary sequences of shorter lengths, which restricts opportunity to achieve self-similarity. In line
with this conjecture, the trend towards self-similarity was less pronounced in the Teaching condition, although the difference between conditions did not reach statistical significance.

We also had hypothesised that teaching would lead to a faster increase in combinatorial structure to improve transmission efficiency. For the binary sequences used as signals in this study, introducing combinatorial structure would entail establishing subcomponents (e.g. ad or aad) that can be recombined using operations like repetition or mirroring, as in strings like adadad ( -0.75 [numbers in parentheses are the associated values of length-normalised algorithmic complexity) or aadaadaad (-1.43). In contrast, complex strings like ddaaad (1.43) or ddaaaadda (2.02) do not contain combinations of discernible subcomponents. According to our hypothesis, the Teaching condition should have given rise to more sequences of the former than the latter type. However, our data showed exactly the opposite trend: Although not significantly so, length-normalised algorithmic complexity tended to be higher in the Teaching condition, indicating less combinatorial structure than in the Simple Transmission condition. One possible explanation for this finding is that when trying to produce as many different sequences as possible while maintaining brevity of the signals, teachers sample more densely from the distribution of shorter sequences thereby inevitably utilising more sequences of higher complexity. On the other hand, when the brevity constraint is relaxed, learners in the Simple Transmission condition may produce longer sequences yet processing capacity limitations will force them to settle for more structured ones, which are made up of a limited repertoire of subcomponents.

This pattern of results shows that when teaching, which in this study entailed knowingly serving as input-generating models, participants changed their behaviour to adjust the input so as to constrain learner hypotheses in accordance with their own tacit knowledge about how languages function. Specifically, they were negotiating a trade-off between referential efficiency and transmission efficiency by introducing innovations that allowed them to generate unique sequences for each meaning, to prevent languages from degenerating into under-specified systems, while at the same time facilitating transmission fidelity by stabilizing the length of these sequences. It can be argued that the biases that shaped this teaching behaviour reflect participants' knowledge about the functionality of language as it was acquired through their native language use and, thus, these biases may not be informative about of the role teaching may have played in language evolution. However, learners in the simple transmission condition had access to exactly the same knowledge yet without the motivation to teach those biases were overridden by the drive towards compressibility. Thus, whatever the origins of the knowledge about the functionality of language are, our findings suggest that this knowledge affects teaching.

To summarise, the results of this study support the idea that teachers modify the input to learners in ways that reflect
their biases about the functional utility of a cultural trait. Applying this idea to the study of the cultural evolution of language means that theories of language transmission need to include teaching into the suite of transmission mechanisms under consideration. We hope that our findings will inspire more detailed explorations of the role of teaching in the cultural evolution of language in the future.

# Dynamic Effects of Conceptual Combination on Semantic Network Structure 

Yoed N. Kenett (yoedk@sas.upenn.edu)<br>Sharon L. Thompson-Schill (sschill @ psych.upenn.edu)<br>Department of Psychology<br>University of Pennsylvania, Philadelphia, PA 19104 USA

#### Abstract

The generative capacity of language entails an ability to flexibly combine concepts with each other. Conceptual combination can occur either by using an attribute of one concept to describe another (attributive combination) or by forming some relation between two concepts to create a new one (relational combination). Prior research has addressed whether common or distinct processes support these two putatively different types of combinations. We turn the question around and ask whether the consequences of these combination types on our conceptual system might differ, by comparing semantic memory networks before and after participants perform either attributive or relational conceptual combinations. We find a general effect on the semantic networks: the structure of network decreases after participants conceptually combine some of the concepts in the network. However, the relational combination manipulation has a greater effect. Furthermore, only the relational combination manipulation leads to an increase in the network's connectivity.

Keywords: Conceptual combinations; Semantic Networks

## Introduction

Language generation involves the ability to combine concepts into novel combinations (Boylan, Trueswell, \& Thompson-Schill, 2017). Investigating how individuals combine concepts can shed unique light on different aspects of conceptual knowledge, including the cognitive mechanisms that enable the generative and flexible use of language. For example, consider the noun-noun combination robin hawk: while some interpret this combination as "a red-breasted hawk", applying the attribute "red-breast" of the robin to the hawk; others interpret this combination as "a hawk that preys on robins", applying a thematic, relational role between robins and hawks (Wisniewski, 1996). While these two types of conceptual combination mechanisms-attributive and relational-are studied via behavioral and neurocognitive means (Boylan et al., 2017; Estes, 2003), whether these two mechanisms are similar or distinct remain an open question. Furthermore, the effect of these mechanisms on semantic memory structure has not yet been studied. In this paper, we apply a computational network science methodology to examine the effects of attributive and relational mechanisms on semantic memory structure. Specifically, we will focus on conceptual combinations in noun-noun compounds.

Noun-noun compounds contain a modifier noun followed by a head noun. The modifier noun can be either "attributive" (as in zebra clam, where zebra denotes the attribute "striped") or "relational" (as in mountain lake,
where "mountain" is an object bearing a spatial relation with "lake"). An attributive based conceptual combination involves applying an attribute from the modifier noun to describe the head noun, such as zebra clam ("a clam that has stripes") A relational based conceptual combination, however, cannot be paraphrased this way - tennis ball is not "a ball that is tennis", but rather "a ball for playing tennis" (Downing, 1977; Gagné \& Shoben, 1997).

An open theoretical issue is whether attributive and relational mechanisms are similar or distinct; and if distinct, how these mechanisms are applied (Estes, 2003; Gagné, 2000; Gagné \& Shoben, 1997; Rogers \& McClelland, 2004). We address this issue from a novel perspective: we apply a network science methodology to represent and compare semantic memory networks before and after participants conceptually combine some of the concepts in the network with other concepts in either an attributive or a relational manner. Such an approach allows us to examine, for the first time, in what way conceptual combinations affect semantic memory structure, and how it differs based on attributive or relational mechanisms. We posit that such a conceptual combination manipulation will have restructuring effects on the semantic network, by changing or creating new connections between concepts in the network.

Recent studies have used computational network science to represent the structure of semantic memory (memory for knowledge and facts, Jones, Willits, \& Dennis, 2015), using network science tools, as a semantic network and analyze its properties (for a review, see Borge-Holthoefer \& Arenas, 2010). A semantic network comprises a set of nodes and edges, where nodes correspond to words or concepts and edges connect pairs of nodes and signify some sense of relations between the connected nodes. Of the various network models developed in network science theory, the network model that has been widely used to examine complex systems is the Small World Network (SWN) model. A SWN is a network that is characterized by both high local connectivity and short global distances between nodes, allowing for efficient transfer of information. This network type is known as a small world network because every node is relatively close to other nodes. Analyses of different languages have consistently shown how different linguistic systems exhibit such SWN characteristics, characteristics which are now considered fundamental in facilitating efficient and quick retrieval of linguistic information (Borge-Holthoefer \& Arenas, 2010). Common parameters of network structure include - the networks
clustering coefficient (CC), the average shortest path length (ASPL), and the modularity index (Q).

The CC measures the network's connectivity. It refers to the probability that two neighbors of a node will themselves be neighbors (i.e., a neighbor is a node $i$ that is connected through an edge to node $j$ ). The ASPL and Q index measure the global structure of the network. The ASPL measure refers to the average shortest number of steps needed to be taken between any two pair of nodes. The $Q$ measure examines how a network breaks apart (or partitions) into smaller sub-networks. The larger the modularity measure, the more the network comprised of sub-networks (Newman, 2006). A SWN is characterized by having a high CC and a short ASPL. To examine whether a specific network is a SWN, the statistical properties of empirical data are compared to those of a random null network with the same number of nodes and edges.

Previous work has conducted such analysis to examine cognitive phenomena such as language development, bilingualism, memory search and retrieval, and creative ability (Borge-Holthoefer \& Arenas, 2010). For example, Kenett et al. (2014) found that low and high creative individuals show different semantic network structure. The semantic network of high creative individuals exhibited lower ASPL and Q values, and higher CC values compared to that of the low creative individuals. This was the case despite both networks having an equal number of nodes, edges and average number of edges per node. Thus, semantic networks analysis can be applied to examine differences in semantic memory structure related to different conditions such as attributive or relational combinations.

Some current theories of semantic memory posit that conceptual representations are not invariable across people or across time, but rather dynamically change contingent on context (e.g., task demand, stimulus modality) and individual differences (e.g., processing preferences), with short- and long-term effects on the structure of semantic memory (Yee \& Thompson-Schill, 2016). Such a dynamic perspective describes an experienced-based, distributed, semantic memory system that allows for flexible, generative language. We apply semantic network analysis to examine how the process of combining concepts changes the semantic network and whether such effects depend on the different mechanisms (attributive or relational) applied in such combinations (see also Schilling, 2005).

Here, we present preliminary results of an on-going study where we examine and compare the structure of semantic memory networks before and after an attributive or relational conceptual combinations task. We operationalize the effects of the different conceptual combination mechanisms on semantic memory structure as differences in quantitative measures of the semantic network before and after the conceptual combination task. Specifically, we focus on global measures of the network's structure (ASPL and Q ) and connectivity (CC). We predict that any possible differences between these two mechanisms will be manifested in the post-manipulation networks.

## Materials \& Methods

## Participants

Participants ( $\mathrm{N}=26$ ) were recruited from the University of Pennsylvania as part of a larger on-going research study on conceptual combinations and semantic memory structure. Participants were $55 \%$ female, average age of 22.6 years ( $\mathrm{SD}=3.9$ ) and with an average 16.4 years of education (SD $=3$ ). Participants were randomly assigned to the attributive combinations (AC) or relational combinations (RC) conditions ( $\mathrm{N}=13$ in each group). This study was approved by the University of Pennsylvania Institutional Review Board.

## Design Overview

We characterized the semantic network of participants using their free association responses obtained twice, before and after completing a conceptual combination task that was biased (using both detailed instructions and a priming manipulation) to elicit either attributive or relational interpretations. With this procedure, we were able to assess the main effect, within subjects, of conceptual combination (by comparing the structure of the semantic networks at both time points) as well as the interaction, between subjects, of the type of conceptual combination on network change. We also collected a number of measures of cognitive ability that will be used in planned analyses of individual differences in these effects. We will first describe the conceptual combination task we used to manipulate the type of combination process (attributive or relational). We will then describe the method we applied to represent the semantic networks (before and after the conceptual combination task).

## Conceptual Combination Task

Participants were presented with 25 noun-noun combinations and were required to come up with an interpretation for each combination (Wisniewski \& Love, 1998). They were also asked to indicate how familiar they were with each combination and how hard it was for them to retrieve the interpretation they gave. In order to examine the effect of attributional and relational combination mechanisms on semantic memory, we used ambiguous noun-noun combinations-combinations that can either have an attributive or relational interpretation-and we primed the participants to generate either attributional or relational interpretations. This was achieved both by an instruction manipulation and by an initial noun-noun combination priming phase (Wisniewski, 1996). Our task comprised the following parts: instruction manipulation, priming phase, and ambiguous conceptual combination task. Participants performed this task between two sessions of semantic network estimation (a week apart; see Semantic Network Estimation). This allowed us to examine the effect of the different conceptual combination mechanisms on semantic memory structure.

Figure 1: 2D visualization of the pre- and post- AC and RC semantic networks

During the instructions stage, both participant groups received the same general description of the task. They were then told that there are different strategies that people use to combine concepts together and were given either attributional or relational instructions. In the attributional instructions, participants were told that one such strategy entails applying one dominant attribute of one word to explain the other. In the relational instructions, participants were told that one such strategy entails relating both words in some way. Participants read three ambiguous noun-noun combinations in which the specific required interpretation was emphasized. For example, participants read ant apple. In the attributive instructions participants were told that this could mean 'a small apple' but not 'apple with ants on it'. In the relational instructions participants were told that this could mean 'apple with ants on it' but not 'a small apple'.

In order to increase the difference between the two experimental conditions, we followed these instructions with an attributive or relational priming phase in the conceptual combination task, following from Wisniewski (1996), which showed that noun-noun combinations can be primed to generate either attributive or relational interpretations. We presented participants with ten modifierhead noun-noun combinations, where the head noun
remained constant but the modifier noun either primed an attributive combination or a relational combination (e.g. razor insult for the attributive combination condition vs. girlfriend insult for the relational combination condition).

Finally, participants completed the ambiguous nounnoun conceptual combination task for 25 word-pairs. In order to select stimuli not only that were ambiguous (in that they elicited attributive and relational interpretations across subjects) but also that were flexible (in that the percentage of attributive and relational interpretations could be affected by an instructional manipulation), we conducted a norming study via Amazon's Mechanical Turk (AMT). The AMT surveys were conducted on a larger pool of 50 noun-noun pairs, divided into two surveys of 25 noun-noun pairs each. We conducted three different variations of these surveys with 20 AMT participants in each survey. In the first variation (baseline condition), participants were presented with the noun-noun pairs and asked to generate an interpretation to it. These interpretations were then classified as either attributive or relational by two independent judges (inter-rater agreement > .8). This variation allowed identifying ambiguous noun-noun pairs, classified as pairs that ranged from $30 \% / 70 \%$ to $50 \% / 50 \%$ interpretations. The second and third AMT variations
(biased conditions) manipulated task instruction, as described above, to examine how much these noun-noun pairs could be "pushed" into one type of interpretation. These interpretations were similarly rated as attributive or relational by two independent judges (inter rater agreement $>.8)$. Finally, we examined the effect of the instruction manipulation on biasing the interpretations. We calculated a percent signal change, which quantified the percentage change in interpretations of an ambiguous word-pair from the baseline condition to the biased interpretation condition. This was calculated for both types of interpretations for all noun-noun combinations.

Based on the AMT surveys, 25 noun-noun combinations were chosen. These combinations were chosen so that the modifier-nouns were comprised from five different semantic categories (animals, fruits and vegetables, nature, food, and home). All of the modifier nouns, and none of the head nouns, were included in the semantic network analysis as described below. The average ambiguity of these word pairs was $54 \% / 46 \%$ attributive/relational interpretations. Percent signal change from baseline to biased attributive interpretations was $28 \%$ and biased relational interpretations was $42 \%$. No significant differences were found between the percent signal change for attributive vs. relational interpretations ( $p<.4$ ).

## Semantic Network Estimation

The semantic networks of the AC and RC groups were computed using the computational approach developed by Kenett et al. (2011). Participants in both groups performed a continuous free association task twice, once before and once after the conceptual combination task. Participants were presented with a cue word and had one minute to generate as many associative responses they could for that cue word. Participants generated free associations to a list of 50 cue words. These 50 cue words consisted of five categories used in the conceptual combination task, including the five modifier nouns for each category and five other category members. Thus, the a priori structure of the semantic network consists of five (category) communities.

The semantic network of these 50 cue words was computed and compared between the pre- and post- AC and RC conditions: First, the data were preprocessed to standardize responses and fix any spelling mistakes. Second, the associative correlation between any pair of cue words was calculated using Pearson's correlation. This resulted in a $50 \times 50$ matrix where each cell denotes the association correlation between node $i$ and node $j$. Finally, the planar maximally filtered graph filter was used to remove spurious correlations (Kenett et al., 2014). This produced an adjacency (connectivity) matrix that represents the associative correlations between any pair of nodes. As our focus is on the structure of the networks, the association correlations were binarized to equal one. Thus, the resulting semantic networks are unweighted (all weights equal one) and undirected (symmetrical relations). Constructing semantic networks for different groups (pre- and post- AC
and RC) that are comprised from the same nodes (50 cue words) and with an equal number of edges ( 288 edges) allows comparing between them. Furthermore, the average degree, the average amount of edges per node in all networks was equal (average of 5.76 edges per node).

Analyses were performed with the Brain Connectivity Toolbox for Matlab (Rubinov \& Sporns, 2010). The clustering coefficient (CC; measuring network connectivity) and the average shortest path length (ASPL; measuring global distances) were calculated (Boccaletti, Latora, Moreno, Chavez, \& Hwang, 2006). The network's CC and ASPL were evaluated qualitatively against the equivalent parameters in a random network with the same number of nodes and edges ( $\mathrm{CC}_{\text {rand }}$ and ASPL ${ }_{\text {rand, }}$, respectively). Lastly, the modularity (Q) index was calculated (Newman, 2006). In order to assess the reliability (i.e., statistical significance) of observed differences across time points and across subject groups, we used a bootstrap method (Efron, 1979) to simulate and then compare partial networks for each of the conditions. We reasoned that if the networks differed from each other, then any partial network consisting of the same nodes in the networks should also be different. Furthermore, the bootstrap method makes it possible to generate many simulated partial semantic networks, allowing for statistical examination of the difference between them. The bootstrapping procedure involves random selection of half of the nodes comprising the networks. Partial networks were constructed for each condition (pre- and post- AC and RC) separately for these selected nodes. This method is known as the without-replacement bootstrap method (Bertail, 1997). Finally, for each partial network, the CC, ASPL, and the Q index were computed. This procedure was simulated with 10,000 realizations. The difference between the bootstrapped partial networks on each network parameter was then tested using a mixed model analysis of variance (group [AC, RC] x time [pre, post]).

## Procedure

Participants completed all tasks using the Qualtrics software on two different sessions a week apart. In the first session, participants completed the free-association task. In the second session, participants first completed the conceptual combination task and then the free association task. In the free association task, participants were instructed to generate, in one minute, as many different responses they could think of to a cue word. In each trial, the cue word was presented in the center of the screen with a response box below it, where participants typed their responses. Below the response box appeared a timer, counting down from 60 seconds. After 60 seconds elapsed, a new trial immediately began. Cue words were presented randomly and after 25 cue words participants had a short break. In the conceptual combination task, participants were first instructed on the task with the task manipulation instruction (attributive or relational). Next, a short practice was conducted with the experimenter, who gave feedback on the participant's interpretations. Stimuli used in the practice were not used in
the task itself. In each trial the noun-noun combination appeared in the center of the screen with a response box below it. Participants were instructed to write their interpretations in the response box. Underneath the response box the participant had to choose how familiar s/he was with the noun-noun compound on a five point Likert scale (ranging from extremely familiar to not familiar at all) and how easy it was for them to generate the interpretation on a seven point Likert scale (ranging from extremely easy to extremely difficult). Participants were randomly assigned to the attributive and relational conditions. The stimuli were randomly presented.

## Results

We computed the semantic networks for the pre- and postAC and RC conditions based on the procedure outlined above. Next, we computed and compared the different network measures for all four networks (Table 1). To visualize the networks, we used the force-directed layout of the Cytoscape software (Shannon et al., 2003) to plot the graphs (Figure 1). In these 2D visualizations, nodes (cue words) are represented as circles and links between them are represented by lines. Since these networks are unweighted and undirected, the links merely convey symmetrical relations between two nodes. The grayscale of the nodes relate to the five semantic categories used in our study.

The network analysis revealed both general and specific differences between the pre- and post- AC and RC networks. In regard to structural properties of the networks, ASPL and Q, the post session led to lower ASPL and Q values, which was stronger for the RC network. In regard to connectivity property of the network, CC , the post session led to different effects in the AC and RC networks: while the AC network had a lower CC value, the RC network had a higher CC value, compared to the first session (Table 1).

Table 1: Network measures for the pre- and post- AC and RC networks

|  | AC-Pre | AC-Post | RC-Pre | RC-Post |
| :---: | :---: | :---: | :---: | :---: |
| CC | .702 | .699 | .697 | .701 |
| ASPL | 2.930 | 2.814 | 3.223 | 3.034 |
| $\mathbf{Q}$ | .578 | .565 | .583 | .560 |
| CC $_{\text {rand }}$ | .103 | .125 | .131 | .176 |
| ASPL $_{\text {rand }}$ | 2.331 | 2.341 | 2.339 | 2.338 |

The bootstrapping analysis revealed a significant main effect of time (pre, post) for ASPL and Q, due to decreased values for the post-session (all $p$ 's $<.001$ ). This analysis also revealed for all measures a significant interaction between group and time (all $p$ 's $<.001$ ). For ASPL and Q, this effect resulted from a stronger effect for the RC group (all p's < .001) and for the CC resulted from an increase in CC for the RC group and a decrease in CC for the AC group in the post-session (all $p$ 's $<.001$ ).

## Discussion

In this work, we applied a computational network science approach to examine the dynamic effects of conceptual combination mechanisms on the structure of semantic memory. We found general and specific effects on the network: In both groups, the post manipulation network exhibited lower structural properties of global distances and modularity, which was more pronounced in the RC group. Furthermore, while the AC post-manipulation network exhibited lower connectivity, the RC post-manipulation network exhibited higher connectivity. Thus, our results indicate that the relational combination manipulation has a greater effect on semantic memory structure than an attributive combination manipulation.

Notably, both networks have the same nodes, amount of edges, and average degree (number of edges per node). Thus, these differences reflect both a global task-induced effect on semantic networks and a local effect of relational combination manipulation on semantic memory structure. Both lower ASPL and Q have been related to higher creative ability (Kenett et al., 2014), thus indicating the creative effect of conceptual combinations on semantic memory. This stronger effect, combined with higher CC, in the RC group, suggests that relational combinations may demand the generation of novel contexts in which both nouns relate to each other, thus leading to higher restructuring of the network. More fine grained examination is needed in order to test specific effects on these networks.

Our findings are in line with current theories of semantic memory, which view it as a dynamic system (Schilling, 2005; Yee \& Thompson-Schill, 2016). Such theories argue that both context (task demands) and individual differences (processing style) lead to short- and long-term changes in semantic memory structure. Our current study applies semantic network analysis to examine how a conceptual combination task affects the structure of semantic memory and whether it is affected differently based on a specific conceptual combination mechanism. We show how manipulating concepts in the semantic network (through a conceptual combination manipulation) changes the structure of the network. We will also examine how individual differences affect the structure of semantic memory, based on the behavioral measures we are collecting in our ongoing study. Our findings are also related to recent studies investigating how relational versus attributive based categories differentially effect cognitive processing, such as typicality effects and learning (Asmuth \& Gentner, 2017; Gentner \& Kurtz, 2005; Rein, Goldwater, \& Markman, 2010). For example, Asmuth and Gentner (2017) show how relational nouns are more "mutable" (affected by context) in memory than entity nouns. Thus, our approach offers a quantitative method to examine such behavioral findings.

Finally, there are a few limitations to this study. First, our study currently has a small sample size, which can affect the reliability of our results. We are currently continuing to collect data to conduct these analyses with a larger sample size in each group to strengthen our results. Furthermore,
our research computed semantic networks aggregated at the group-level. It is possible that within these aggregated group-based networks there are further individual differences that relate to semantic memory structure and conceptual combinations. Future research needs to examine the effects of conceptual combinations on semantic memory structure at the individual-level (Benedek et al., 2017).

In conclusion, the work reported here is a first step at harnessing computational network science to investigate the effects of different conceptual combination mechanisms on semantic memory structure. We plan to continue and increase sample size and examine how our findings relate to various behavioral measures we are also collecting, such as creative ability, intelligence and personality traits. Overall, our results demonstrate that semantic networks can be applied to study group-level effects of different conceptual combination mechanisms and contribute to the growing body of literature demonstrating their efficacy in understanding high-level cognition.

#### Abstract

People reason about possibilities routinely, and reasoners can infer "modal" conclusions, i.e., conclusions that concern what is possible or necessary, from premises that make no mention of modality. For instance, given that Cullen was born in New York or Kentucky, it is intuitive to infer that it's possible that Cullen was born in New York, and a recent set of studies on modal reasoning bear out these intuitions (Hinterecker, Knauff, \& Johnson-Laird, 2016). What explains the tendency to make modal inferences? Conventional logic does not apply to modal reasoning, and so logicians invented many alternative systems of modal logic to capture valid modal inferences. But, none of those systems can explain the inference above. We posit a novel theory based on the idea that reasoners build mental models, i.e., iconic simulations of possibilities, when they reason about sentential connectives such as and, if, and or (Johnson-Laird, 2006). The theory posits that reasoners represent a set of conjunctive possibilities to capture the meanings of compound assertions. It is implemented in a new computational process model of sentential reasoning that can draw modal conclusions from non-modal premises. We describe the theory and computational model, and show how its performance matches reasoners' inferences in two studies by Hinterecker et al. (2016). We conclude by discussing the model-based theory in light of alternative accounts of reasoning.

Keywords: mental models, modal reasoning, possibilities, reasoning, probability logic

## Introduction

The word "possibility" is fraught with ambiguity, because philosophers distinguish between different sorts of possibility. An "alethic" possibility is any description that is not self-contradictory. "Deontic" possibilities are those that are permissible (e.g., instances of drinking alcohol when over the legal age restriction), and impossibilities are those that are prohibited (e.g., drinking while under the age restriction). Deontic possibilities can be violated, whereas alethic possibilities cannot (cf., Bucciarelli \& JohnsonLaird, 2005; Bucciarelli, Khemlani, \& Johnson-Laird, 2008). The present paper focuses on a different notion of possibility: "epistemic" possibilities concern possibilities that are consistent with a reasoner's personal knowledge. Reasoning based on possibilities is referred to as "modal" reasoning, because when you assert that something is "possible", you qualify its occurrence. Conventional systems of logic cannot take into account the logical properties of modals to draw conclusions, because they
concern unqualified propositions that are either true or else false. Consider these two assertions:

1a. Sarah is Egyptian.
b. Possibly, Sarah is Egyptian.

Assertion (1a) is unqualified: it asserts a fact about Sarah. If it is true then Sarah is indeed an Egyptian, and if it is false, she is not an Egyptian. Assertion (1b) is subtler. In addition to facts and their negations, it introduces possibilities. Logicians have historically analyzed modal assertions as referring to a set of "possible words" (see Kneale \& Kneale, 1962; Portner, 2009). To say that something is possibly the case is to say that it is true in at least one possible world, and to say that something is necessarily the case is to say that it is true in all possible worlds.

Many different systems of modal logic exist (Kaufmann, Condoravi, \& Harizanov, 2006). Each adopts a different set of axioms that affect which inferences can be proved. Different axiom systems affect which modal inferences are valid and which are not (see, e.g., Kripke, 1963). An inference is valid if it yields a conclusion that is true in every case in which the premises are true (Jeffrey, 1981, p. 1). In principle, an infinite number of modal logics exists, but logicians tend to focus on the axioms themselves, which run in parallel with semantic assumptions about the accessibility of one possibile world from another (Kripke, 1963). For instance, the axiom:

$$
\square \mathrm{A} \rightarrow \mathrm{~A}
$$

where ' $\square$ ' is a symbol that stands for the logical notion of necessity, $A$ is any proposition whatsoever, and ' $\rightarrow$ ' denotes material implication. The axiom asserts that the necessity of $A$ material implies $A$. The axiom does not hold in the modal logic "system K" (for "Kripke"), but it does hold another logic, "system T", and it corresponds to the assumption that accessibility is reflexive, i.e., if a proposition is necessary in a world then it holds in that world.

Here is a set of inferences that are invalid in all systems of modal logic:

2a. A or B or both.
b. Therefore, possibly A.
c. Therefore, possibly B.
d. Therefore, possibly A and B.

These inferences seem intuitively reasonable, but the conclusions ( $2 \mathrm{~b}-\mathrm{d}$ ) are invalid in any modal logic. Suppose that $A$ is impossible but $B$ is true. In logic, the premise is true, but (2b) is false. So, the inference is invalid. Similar suppositions show that all the inferences are invalid, and so, no modal logic permits them. Why, then, are the inferences compelling - almost "obvious" - for humans?

Despite some investigations into reasoning about possibilities (e.g., Bell \& Johnson-Laird, 1998; Byrnes \& Beilin, 1991; Goldvarg \& Johnson-Laird, 2000; Inhelder \& Piaget, 1958; Piéraut-Le Bonniec, 1980; Osherson, 1976; Sophian \& Somerville, 1988), no comprehensive theory of human reasoning exists that explains how humans integrate reasoning about facts with reasoning about possibilities. The fundamental mystery is: where do the possibilities come from? Anecdotally, some researchers find that when participants are allowed to write or type out their own responses to a set of reasoning problems, they spontaneously qualify their inferences, e.g., by noting that a conclusion "is possible" or "could be true" or "might follow." These responses are, of course, different ways of expressing modal conclusions. Other research finds that reasoners are capable of carrying out various modal reasoning tasks systematically, e.g., given a set of premises, they are able to determine whether a conclusion is necessary or possible (e.g., Bell \& Johnson-Laird, 1998; Khemlani, Lotstein, Trafton, \& Johnson-Laird, 2015; Newstead \& Griggs, 1983). But only recently have researchers examined reasoners' tendency to endorse modal conclusions from non-modal premises. Hinterecker and colleagues (2016) gave participants a battery of problems in which participants had to endorse or reject different conclusions from modal premises. Contrast this inference:

## 3. A or B or both. <br> Therefore, possibly A and B.

with this one:

## 4. A or B, but not both.

Therefore, possibly A and B.
Reasoners responded sensibly: they accepted (3) most of the time ( $82 \%$ of trials) but they accepted (4) on only a small minority of trials ( $10 \%$; see Hinterecker et al., 2016, Experiment 1). But, both (3) and (4) are invalid in logic.

## Probabilistic logic

Can Hinterecker and colleagues' findings be explained by an alternative theory? The two inferences above may be treated more sensibly in probabilistic logic, hereafter, "plogic", which is a formal system devised by Adams (1975; 1988). P-logic reinterprets validity on probabilistic terms: a conclusion is probabilistically valid (p-valid) only if in any consistent assignment of probabilities its conclusion is at least as probable as its premises. Hence, in (3), the conclusion, possibly ( $A$ and $B$ ), does not rule out any cases,
i.e., it can be true independent of whether $A$ or $B$ are true. The premise, $A$ or $B$ or both, in contrast, rules out the situation in which both $A$ and $B$ are false. And so, the conclusion has a probability greater than that of the premise in (3), and it is p -valid. In a similar vein, (4) is p-invalid because the probability of the conclusion, possibly( $A$ and $B$ ), is 0 given the premise. And so, no matter what probability is assigned to the premise, the inference is p invalid. P-logic is central to recent probabilistic accounts of human reasoning known colloquially as the "new paradigm" (see, e.g., Evans, 2012; Oaksford \& Chater, 2007; Over, 2009; Johnson-Laird, Khemlani, \& Goodwin, 2015).

But, p-logic does not always make sensible predictions. For instance, it predicts that the following inference is p valid:

## 5. A or B, but not both. <br> Therefore, A or B, or both.

The probability of the conclusion in (5) is greater than or equal to that of the premise, and so p-logic predicts that reasoners should make it. (The inference is always valid in logic.) Yet, participants rejected it on $97 \%$ of trials in the aforementioned study by Hinterecker and colleagues. Perhaps a deeper problem with probabilistic accounts is that they do not explain the provenance of modal conclusions, e.g., "possibly A", from non-modal premises. Hence, an alternative account of reasoning is needed to explain modal inferences.

## A model-based theory of modal inference

The mental model theory of reasoning - hereafter, the "model theory" - posits that reasoners draw conclusions by building and scanning iconic representations of possibilities, i.e., mental models (Johnson-Laird, 2006; Johnson-Laird \& Byrne, 1991). The theory assumes that interpreting compound assertions such as those linked by the connectives and, or, and if, yields a set of discrete possibilities. Models mimic the structure of what they represent, i.e., they are iconic (Peirce, 1931-1958, Vol. 4). But, they can also contain abstract tokens, such as symbols denoting negations (Khemlani, Orenes, \& Johnson-Laird, 2012). They can represent temporal sequences of events as multiple models unfold in time the way events do (Bucciarelli, Mackiewicz, Khemlani, \& Johnson-Laird, under review; Khemlani, Mackiewicz, Bucciarelli, \& Johnson-Laird, 2013).

The theory posits two primary systems for reasoning (see, e.g., Johnson-Laird \& Steedman, 1978): a fast system builds mental models and scans them without the use of working memory. A slower system revises models and fleshes them out to yield a set of fully-explicit models. It also searches for alternative models consistent with the premises. It can correct the errors and biases that the fast system yields, but it is subject to the limitations of working memory. The difference between mental models and fully-explicit models is clear when reasoning about disjunctions, e.g., He has the
soup or the salad or both. Mental models abide by a "principle of truth", i.e., they represent what is true in a compound clause, and not what is false. They can flesh out the initial mental models to yield a set of fully-explicit models, i.e., possibilities that specify both what is true and what is false. The mental models of the disjunction above can be depicted in the following schematic diagram:

| soup | salad |
| :--- | :--- |
| soup | salad |

Each row in the diagram denotes a different possibility. Hence, the first row denotes the possibility in which he has the soup. In contrast, a fully-explicit model represents both what is true in each possibility, as well as what is false:

$$
\begin{array}{lr}
\text { soup } & \neg \text { salad } \\
\neg \text { soup } & \text { salad } \\
\text { soup } & \text { salad }
\end{array}
$$

Three primary findings support the model theory. First, inferences from one model are easier than inferences from multiple models (e.g., Johnson-Laird, Byrne, \& Schaeken, 1992). Second, because reasoners tend to build mental models instead of fully-explicit models, they are prone to systematic errors (see Khemlani \& Johnson-Laird, 2017, for a review). Third, reasoners rely on counterexamples to correct erroneous inferences (e.g., Johnson-Laird \& Hasson, 2003).

But, the theory has at least two serious shortcomings. First, it does not integrate facts and possibilities. As a result, it cannot explain the "obvious" inferences in example (2) above. Indeed, no theory of reasoning adequately integrates facts and modal reasoning, but the problem is particularly acute for the model theory, as the theory is based on the representation of possibilities, and so modal reasoning is within its purview. And second, its various computer implementations do not make quantitative predictions (Johnson-Laird \& Yang, 2008). To rectify these shortcomings, we describe a novel assumption about the representation of mental models below, and then we present a new computational model capable of delivering quantitative predictions by varying how models are built and revised.

## The principle of conjunctive possibilities

We amend the model theory to explain where possibilities come from in inferences that make no mention of them with the following principle:

The principle of conjunctive possibilities: By default, compound assertions between clauses refer to conjunctions of possibilities. A clause can be evaluated as possible if it is affirmed in at least one possibility of the conjunctive set. It can be evaluated as necessary if it can be affirmed in all possibilities. And it is deemed factual if it is affirmed in a set of only one possibility.

The principle posits that a disjunction, He has the soup or the salad or both, refers to a set of possibilities, i.e.:

```
possible( soup & \negsalad ) &
possible(-soup & salad ) &
possible( soup & salad )
```

The addition of the principle solves two mysteries of modal reasoning: first, it explains why reasoners are apt to make modal inferences from non-modal assertions. If compound assertions refer to possibilities, then reasoning about possibilities is the default instead of an extension to more basic reasoning patterns (cf. Inhelder \& Piaget, 1958). Second, because the principle is that possibilities are related through conjunction, it allows reasoners to conclude that any of the separate possibilities can be concluded as possible. An immediate consequence of the assumption is that modal inferences are the default, and reasoning about facts is a special case of reasoning about possibilities.

The principle is presaged by recent ideas due to Zimmerman (2000), who proposed that disjunctions refer to lists of alternatives in a "possible worlds" semantics, and Geurts (2005) who extended the idea to disjunctions that concern facts. The principle we propose, however, applies to all sorts of sentential connectives, including disjunctions, conjunctions, conditionals, and even causal relations, e.g., causes, enables, and prevents (Johnson-Laird \& Khemlani, in press; Khemlani, Barbey, \& Johnson-Laird, 2014).

The principle maintains the separation between mental models and fully-explicit models. Hence, it makes all of the same predictions as previous versions of the model theory. It also predicts that reasoners should deem (5) invalid, which we repeat here:

## 5. A or B, but not both. Therefore, A or B, or both.

Both a truth-functional analysis in logic and the notion of pvalidity in p-logic treats (5) as valid. But, if reasoners represent the exclusive disjunction as a conjunction of possibilities, i.e.:

```
possible( soup & \negsalad ) &
possible(\negsoup & salad )
```

then the conclusion does not follow from the representation, because nothing yields the possibility in which both cases hold.

Nevertheless, the previous predictions are qualitative, not quantitative. A veridical simulation of human reasoning needs to provide a quantitative simulation of the extant data. To do so, we developed a novel computational implementation of the model theory, and we tested it against two experiments by Hinterecker et al. (2016). We now describe the computational model and its simulation of data.

## A computational implementation of the model theory

We developed a computational theory of sentential reasoning that integrates reasoning about facts and reas-

Figure 1. A schematic diagram of the computational model of reasoning. The system operates by parsing premises in natural language, constructing mental models and scanning them to formulate initial conclusions (system 1), and then searching for counterexamples and building fully-explicit models to interrogate initial inferences (system 2).
oning about possibilities. It implements the principles of the mental model theory of reasoning (see, e.g., Khemlani \& Johnson-Laird, 2013) and the principle of conjunctive possibilities introduced here. Figure 1 provides a schematic of the program. The computational model is structured around three general systems:
a) A linguistic system uses a grammar and lexicon to parse verbal assertions.
b) An intuitive system (System 1) uses the parse to construct an initial mental model, i.e., a conjunction of possibilities. It also scans the model to formulate initial inferences.
c) A deliberative system (System 2) can flesh out the mental model and search for alternative models. This system can manipulate and update the representations created in System 1, and it can modify conclusions, but it too can fail when a problem calls for more working memory than it has (Khemlani \& Johnson-Laird, 2017).
In the computational model, system 1 does not have access to working memory, and so it can construct only one mental model at a time. It can flesh out the mental model to make it explicit. The probability of doing so is governed by a parameter, $\varphi$. System 2, however, has access to working memory. As a result, the operations of system 1 are faster and more prone to err than system 2. System 2 can operate on multiple models at a time, search for counterexamples, and construct a set of fully explicit models. The probability of calling system 2 is governed by a separate parameter, $\sigma$. In principle, the size of working memory could also be governed by a parameter in order to model individual differences in reasoning.

The system is capable of carrying out a number of inferential tasks, but for brevity, we consider just two:
assessing that a given conclusion is possible, and assessing that it is necessary. In order to assess an inference, the computer model checks that each possibility in the conjunction corresponding to the conclusion is supported by the premises. If they all are, then the conclusion follows of necessity, and if at least one is, then the conclusion is a possibility. The concept of necessity may vary from participant to participant and from problem to problem: some problems may encourage reasoners to check that the models of the premises hold in all models of the conclusion (a strong notion of validity), and some problems may encourage reasoners to check only that all the possibilities to which the conclusions refer hold in the premises (a weaker notion of validity). Consider how you might respond to problems such as this one:
6. Suppose that: A or B, or both.

Does it follow that: A or B, but not both?
The conjunctive possibilities to which the first premise refers are:

```
possible( A & -B ) &
possible(\negA & B ) &
possible( A & B )
```

And the possibilities to which the second premise refers are:

```
possible( A & -B ) &
possible(\negA & B )
```

Reasoners with a strong notion of validity should judge that (6) is invalid, because the models of the premise do not all hold in the models of the conclusion. Reasoners with a weaker notion of validity should assess that (6) is valid, since the models of the conclusion hold in all the models of the premises. To simulate this non-determinism of human reasoning, we built a third and final parameter into the system, $\gamma$, that denotes the probability of the system adopting a weak version of validity.

We applied the computational model to simulate recent data on modal reasoning. The simulations show a close fit between the predictions of the system and humans' inferential behavior after conservative parameter searching.

## Simulations of Hinterecker et al. (2016)

We sought to use the computational implementation of the model theory to simulate participants' performance in Experiments 1 and 3 in Hinterecker et al. (2016), as those two studies are directly pertinent to how reasoners draw modal conclusions from non-modal premises. In Experiment 1, Hinterecker and colleagues gave participants a battery of diagnostic problems that involve disjunctions. Two of those problems tested the tendency to draw modal conclusions from disjunctions that make no mention of possibilities, and two tested the ability to infer an inclusive disjunction from an exclusive one, and an exclusive

Figure 2. Observed (histograms) data and predicted (circles) proportions of accepting the conclusion for different inferences. Top panel: inferences from Hinterecker et al. (2016, Experiment 1). Bottom panel: inferences from Hinterecker et al. (2016, Experiment 2). For each of the problems, the assertion on top denotes the premise and the assertion on the bottom denotes the conclusion.
disjunction from an inclusive one. Figure 2 summarizes the proportion of participants to accept the varying conclusions given the single premise.

The only parameter that could have affected the system's simulations on the problems in Experiment 1 was the $\gamma$ parameter, which dictates how probable it is for participants to make use of a weak notion of validity. An exhaustive exploration of the parameter space yielded an optimal $\gamma$ value of .75 , i.e., the system optimally modeled the data when it stochastically applied weak validity to $75 \%$ of simulated problems. We generated synthetic data by running 1000 simulations of the four inferences in Experiment 1. Figure 2 (top panel) shows the proportion of correct responses in the observations (histograms) and predictions (circles) in the study as a function of the inference. The
computer model matched the participants' performance in the experiment well ( $\mathrm{r}=.99, \mathrm{RMSE}=.10$ ). The predictions of the computer model were in the $99^{\text {th }}$ percentile relative to hypothetical datasets (Khemlani \& Trafton, 2013).

Hinterecker's et al. (2016) Experiment 3 was a more stringent test of reasoners' ability to infer modal conclusions from an inclusive disjunction, $A$ or $B$ or both. For each problem in the experiment, participants assessed the disjunction and then accepted or rejected the one of the following four conclusions: possibly $A$ and $B$, possibly $A$, possibly $B$, possibly not- $A$ and not- $B$. None of these inferences is valid in any known logic, but as Figure 2 (bottom panel) shows, reasoners endorsed three of the four conclusions. We disabled all of the parameters to see how the computer model matched the participants' performance; it did so extremely well ( $\mathrm{r}=.99$, RMSE $=.12$ ), and additional parameter manipulations would have resulted in only nominal changes to the fit.

In sum, the computational model implementing the model theory and the principle of conjunctive possibilities yielded a close fit to the data from Hinterecker et al. (2016).

## General discussion

Reasoners have no difficulty drawing modal conclusions from compound assertions that make no mention of modality. The ability to do so often seems "obvious"; only experts are likely to realize that this inference is invalid in logic:
7. A or B or both.
Therefore, possibly A.

No known logical system designed to deal with modalities, i.e., a modal logic concerning what is possible or necessary, permits the inference above. Reasoners naive to logic may also be surprised to find that both orthodox logic and probabilistic logic render the following inference valid:

## 8. A or B, but not both. <br> Therefore, A or B, or both.

On our account, reasoners are justified in feeling that the invalidity of (7) and the validity of (8) are counterintuitive and incorrect. The model theory of reasoning, which is based on possibilities (Johnson-Laird, 2006), treats compound assertions, such as conjunctions, conditionals, and the disjunctions in (7) and (8), as conjunctions of possibilities. Hence, reasoning about possibilities is fundamental. Reasoners represent possibilities directly, and so modal reasoning is a natural consequence of the way people represent assertions.

The principle of conjunctive possibilities characterizes the inferences in (6) and (7) more intuitively: it predicts that (6) should be deemed valid and (7) should be deemed invalid. And a computational implementation of the principle makes identical predictions, which are validated by recent experiments on modal reasoning by Hinterecker et al. (2016).

At present, no alternative theory of reasoning, whether based on mental logic (e.g., Rips, 1994) or on the probability calculus (e.g., Oaksford \& Chater, 2007), can explain these phenomena of modal reasoning. Moreover, no computational model of reasoning, whether in psychology, artificial intelligence, or logic, characterizes the inferences in the same manner as the system we outlined above. The reason, as we argue, is that everyday reasoning is based on possibilities, not probabilities or truth-functions.

# Numerical and Non-numerical Magnitude Estimation 

Dan Kim<br>The Ohio State University<br>John Opfer<br>The Ohio State University

#### Abstract

Despite a heated debate regarding a cognitive mechanism of magnitude representation, little has been done to directly compare numerical and non-numerical estimation and provide a unified account of the two processes. In the current study, we examined estimation of numerical and non-numerical quantities on a continuum using various psychophysical functions. Inconsistent with the proportion reasoning and measurement skills accounts, estimates of both numerical and non-numerical quantities were better predicted by the logarithmic-linear model than by cyclic power models. Furthermore, individual differences in the degree of logarithmic compression was highly correlated over tasks, whereas bias measures from competing models did not show such associations. These findings suggest that estimation of both numerical and non-numerical magnitude is processed via shared representation systems that are logarithmically or linearly constructed.

#### Abstract

Selective sustained attention (SSA) is an important cognitive process that enables everyday functioning and task performance by allowing us to: 1) choose components of our environment to process at the exclusion of others and 2) maintain focus on those components over time. Although SSA is known to undergo rapid and marked changes during the preschool and early primary school children years, there has been a paucity of behavioral data on these years of development due to a lack of child-appropriate testing paradigms. TrackIt is a paradigm that was recently developed to fill the previously existing measurement gap for SSA in these years. In this study, we analyzed errors that children (aged 3-7) make when performing TrackIt, to better understand what factors drive improvement in their performance over age. In addition, we manipulated parameters within TrackIt to place varying levels of demand on children's SSA, and measured behavioral performance over age, with the goal of measuring and characterizing developmental trends during these years. Since TrackIt is still a recent paradigm, our results also help suggest appropriate parameter settings for calibrating the task to different age groups.

Keywords: selective sustained attention; TrackIt

## Introduction

Selective sustained attention (SSA) is an important cognitive process that enables everyday functioning and task performance by allowing us to: 1) choose components of our environment to process at the exclusion of others and 2) maintain focus on those components over time. SSA is known to rely on both endogenous factors (e.g., internal goals) as well as exogenous factors (e.g., stimulus salience) (O’Connor \& Manley, 2004) -- studying specifically how these factors interact and work together in guiding attention contributes to a growing understanding of SSA's
mechanisms. Task paradigms that allow simultaneous investigation of both exogenous and endogenous factors of SSA have been available for adults and infants but not for preschool and early primary school children ( $\sim 3-7$ years) until recently (for review, see Fisher \& Kloos, 2016). These years are particularly important from a research standpoint because data from infants and adults suggests that SSA develops significantly during these intermediate years (Oakes, Kannass, \& Shaddy, 2002). TrackIt, a paradigm developed specifically to fill this measurement gap, is designed to be appropriately challenging for a range of developmental years including the preschool years, with varying parameters for adjustment of difficulty across ages (Fisher et al., 2013).

Prior studies with TrackIt demonstrated that children improve on the task between 3 and 5 years of age (Fisher et al., 2013, Erickson et al., 2015), consistent with the overall developmental pattern of improvement in SSA with age. In order to investigate this improvement more closely, the current study looked at 1) what factors tend to drive the failures (errors), and what, of those, consequently improve to drive the overall performance improvement (see "Factors driving improvement" below), and 2) what the behavioral trajectories representing this improvement look like across an expanded age range. To delve into this issue, we manipulated parameters of TrackIt to place varying levels of demand on children's selective sustained attention to achieve a coarse mapping of behavioral performance in several parameter combinations over ages 3 to 7. In contrast to prior studies using TrackIt that focused on the analysis of correct responses (Fisher et al., 2013; Erickson et al., 2015), this study also examined the patterns of errors as a function of task difficulty and age.

## Factors Driving Improvement

This study introduces a new addition to the TrackIt program: error analysis. This functionality (a software update that is now part of the TrackIt program that is freely available to interested researchers) adds, to the behavioral output, information on the types of errors that participants make. Analyzing the types of errors that children make over development may provide greater insight into what factors constitute the overall improvements that we see in children's SSA performance. For example, some error types help to distinguish between behavioral errors due to failure of SSA and those due to insufficient visuo-spatial resolution. Also, finding that a significant proportion of errors can be related to failure of SSA would help validate TrackIt as a task assessing attention. Thus, the first goal of this study was to present preliminary analyses of error type breakdown over age and difficulty.

## Behavioral Trajectories

Mapping out age-related changes in performance within the multi-dimensional parametric space of variables (i.e., number of distractors, grid size, speed of objects, type of distractors) involved in visual attention serves two important purposes: 1) it begins to fill in the empirical gap in characterizing children's visual SSA development within a single consistent measurement framework, and 2) it suggests initial parameter selection ranges for age groups, to guide researchers using TrackIt (Doebel et al., 2015). Hence, the second goal of this study is to present preliminary findings on parameter space mappings.

## Method

## Participants

Participants were 144 typically developing children (71 female, $M_{\text {age }}=5.08$ years) recruited from local preschools, day care centers, and elementary schools in Pittsburgh, PA. See Table 2 below for a breakdown of participant age statistics.

## Materials and Apparatus

Stimuli were presented on a Lenovo touchscreen laptop with physical screen dimensions $19.1 \mathrm{~cm} \times 34.2 \mathrm{~cm}$ and pixel dimensions 1920x1080 pixels. Participants were seated at a desk facing the screen with their heads about 2 feet away from the screen.

## TrackIt Task

In this task (freely available for download at http://www.psy.cmu.edu/~trackit/), participants were asked to visually track a single target object as it moved on a grid among moving distractor objects. For each trial, the target and distractor objects were randomly picked without replacement from a set of unique objects spanning 9
different shapes with 9 different color possibilities (81 objects in total). ${ }^{1}$ See Figure 1 for examples.

At the beginning of each trial, the objects appeared on the grid, centered in distinct grid cells, and the target object was indicated by a red circle around it. The initial positions of the objects were randomized. The experimenter started each trial with a button press after ensuring the participant was ready to begin.

Upon starting the trial, the red circle disappeared, and the objects began to move in linear trajectories from grid cell to grid cell at a constant speed. At the end of each trial, all objects disappeared from the screen, and the participants were asked to indicate with their finger (on the touch screen) which grid cell the target object was last in before it disappeared.

The sequence of positions in the path of each objects was randomized, with one restriction for just the target: the target had to be in the center of a grid cell at the end of a trial, to reduce ambiguity for the participant in determining its final location. Due to this restriction, the length of trials was not fixed, but varied slightly from trial to trial (to allow the target to reach the center of a grid cell. The minimum trial length was set to 10 seconds. The parameters -- grid size, number of distractors, and speed of objects in pixels per second -- were determined from prior testing in TrackIt with a separate group of 3- to 5-year old children (Fisher et al., 2013), and organized according to participant age and difficulty level as seen in Table 1. Object motion display was set to 30 frames per second.

Table 1: TrackIt parameter combination used in each difficulty level.

|  | Age <br> Group <br> (years) | Grid <br> Size | \# of <br> Distractors | Object <br> Speed <br> (pix/s) |
| :--- | :---: | :---: | :---: | :---: |
| Difficulty | $3-5$ | $4 \times 4$ | 4 | 500 |
| Level 1 | $4-6$ | $6 \times 6$ | 6 | 500 |
| Level 2 | 7 | $6 \times 6$ | 8 | 800 |
| Level 3 |  |  |  |  |

Note: pix/s = pixels/second.

We assessed three different difficulty levels, administered to different age groups, as shown in Table 1. Separate groups of participants were tested in each difficulty level. The sample size per age and difficulty level is presented in Table 2. It should be noted that, ultimately, we aim to obtain a large-scale representative sample of

[^118]Table 2: Sample sizes and age statistics of each age group, for each difficulty level

| Age Group (years) | Difficulty Level 1 |  | Difficulty Level 2 |  | Difficulty Level 3 |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  | $\mathrm{n} / \mathrm{m} / \mathrm{f}$ | $\begin{gathered} \text { Age } \\ \text { Mean (Std) } \end{gathered}$ | $\mathrm{n} / \mathrm{m} / \mathrm{f}$ | $\begin{gathered} \text { Age } \\ \text { Mean (Std) } \end{gathered}$ | n/m/f | $\begin{gathered} \text { Age } \\ \text { Mean (Std) } \end{gathered}$ |
| 3 | 25/13/12 | 3.64 (0.21) | - | - | - | - |
| 4 | 17/9/8 | 4.64 (0.27) | 19/6/13 | 4.69 (0.22) | - | - |
| 5 | 26/14/12 | 5.38 (0.23) | 41/19/22 | 5.43 (0.27) | - | - |
| 6 | - | - | 6/4/2 | 6.34 (0.25) | - | - |
| 7 | - | - | - | - | 10/8/2 | 7.27 (0.16) |

Note: $n / m / \mathrm{f}=$ sample size/\# male/\# female.
participants at each age and difficulty level; the present paper reports the initial findings from this study.

Memory Check At the conclusion of each trial, children were presented with 4 shapes that could have served as target objects in this task (one of which was actually the target) and asked to point to the shape they had been tracking (see Figure 1). The responses to memory check questions were recorded by the children's touch screen responses. The memory checks were introduced to help discriminate between two possible reasons why a participant may fail to correctly report the location where the target object disappears. The first possibility is that encoding of the identity of the target object may be insufficiently strong to persist through an entire trial - this would indicate an encoding failure. The second possibility is that a child may track distractors for a part of the trial despite remembering which object was supposed to be watched - this would indicate the failure of selective sustained attention. The target was colored as in the trial, while the remaining 3 shapes and their colors were sampled without replacement from the remaining 8 shapes and colors.

## Design and Procedure

The experimenter administered the TrackIt task to participants in a quiet room or hallway. At the beginning of the task, participants were told that: 1) the objects will start moving around the grid when the experimenter presses a button; 2) the goal is to follow the target object with their eyes; 3) at some point the objects will suddenly disappear, and their job is to point to where the target object was when it disappeared. Each trial was followed by a baseline screen displaying a smiley face, a memory check screen, and a second smiley face baseline (in that order). Participants were told that the smile did not indicate a correct answer and rather meant we were happy they were playing our game. See Figure 1 for a diagram of the task sequence.

Participants completed 11 trials of the task. The first trial was a practice trial and was completed with assistance from the experimenter who traced the moving target with their index finger. The first trial was accordingly omitted from analysis. Participants were then told that they would need to complete the rest of the task by themselves, tracking the target with their eyes only.

Figure 1. The TrackIt task pipeline. A single trial, followed by smiley face, memory check, and smiley face.

Error Analysis Next, we were interested in better understanding what types of tracking errors participants were making. Tracking errors were any answers in the main TrackIt task that weren't the correct cell that the target ended in. Tracking errors were thus further classified based on the incorrect grid cell response indicated by the participant, in relation to the final positions of the target and distractors on the grid. Specifically, in addition to a correct response, we considered 5 types of errors:

Spatial Resolution: The response was a cell adjacent to the correct grid cell, but was not also adjacent to a distractor.

Distractor: The response was a cell that contained a distractor.

Distractor Spatial Resolution: The response was a cell that did not contain a distractor, was adjacent to a cell that contained a distractor, and was not also adjacent to the correct grid cell.

Uncategorizable: The response was a cell that did not contain a distractor, and was adjacent to both the correct grid cell and a cell that contained a distractor.

Other: None of the above. That is, the response was a cell that did not contain a distractor, and was adjacent to neither the correct grid cell, nor a cell that contained a distractor.

In the above, "adjacent" cells are defined as those within one horizontal, vertical, or diagonal step of a given cell. (Cells are not considered adjacent to themselves.) For example, corner cells have 3 adjacent cells, edge cells have 5 adjacent cells, and other cells have 8 adjacent cells.

Note that finding that a significant proportion of errors are distractor-related errors (distractor, distractor spatial resolution, or uncategorizable) would help to validate TrackIt as a task assessing attention; if we find that kids make many spatial resolution errors, it may indicate that the performance is limited by kids' visuo-spatial acuity. In contrast, if we find that kids make predominantly "other" errors, it could suggest that they lose interest in the task entirely or do not understand the task and respond randomly.

## Results

## Memory Check

Responses to individual memory check questions (i.e., which object were you supposed to watch?) were averaged over the 10 experimental trials to yield a Memory Accuracy score for each participant. Memory Accuracy data are presented in Figure 2.

Figure 2. Tracking accuracies for each age and difficulty level, both with and without memory-incorrect trials.

In all conditions and age groups Memory Accuracy was above chance ( $25 \%$ given four response options, all one-sample $t \mathrm{~s}>6.2, p \mathrm{~s}<0.0001$ ). To investigate possible effects of age and difficulty, memory accuracy scores were submitted to a 2-way ANOVA with both age as difficulty level as between-subject factors. This analysis indicated a
main effect of age $(F(2,128)=32.2, p<0.0001) .{ }^{2}$ There was no effect of difficulty and no age-by-difficulty interaction (both $F \mathrm{~s}<1.34$, $p s>0.24$ ). Therefore, any differences in object tracking accuracy between difficulty levels were unlikely to stem from differences in the strength of encoding of the target objects.

## Error Analysis

For this analysis, we excluded trials in which the participant failed the memory check, as encoding errors were a separate type of error that we analyzed separately. We compared the rate of each error type to chance, assuming that the participant response was randomly distributed over the incorrect squares of the grid. Chance was estimated by simulating final states of 10,000 TrackIt trials for each level. Chance levels are given in Table 3.

Table 3: Chance probability of each error type assuming the participant response is uniformly distributed over the grid.

| Error Type | Level 1 | Level 2 | Level 3 |
| :---: | :---: | :---: | :---: |
| Correct | 0.0625 | 0.0278 | 0.0278 |
| Spatial Resolution | 0.0434 | 0.0426 | 0.0277 |
| DSR | 0.3606 | 0.1514 | 0.4814 |
| Distractor | 0.2131 | 0.4449 | 0.1962 |
| Uncategorizable | 0.2114 | 0.1004 | 0.1084 |
| Other | 0.109 | 0.2329 | 0.1585 |

Note: DSR = Distractor Spatial Resolution.
Given that the participant made a tracking error, the average portions of error that were distractor errors was consistently significantly above chance in Level 1 (3-year olds: one-sample $t=3.352, \quad p<0.005 ; 4$-year olds: $t=4.117$, $p<0.001$; 5-year olds: $t=4.756, p<0.0001$ ), Level 2 (4-year olds: $t=4.831, p<0.0001$; 5-year olds: $t=3.805, p<0.001$; 6 -year olds: $t=9.869, p<0.0001$ ), and Level 3 (7-year olds: $t=14.065, p<0.0001$.

In order to understand how error types change with increasing age, we regressed each error type proportion over age. The $\beta$ coefficients and $F$ - and $p$-values for each error type and difficulty level are given in Table 4. In particular, note that only the Distractor, Distractor Spatial Resolution, and Uncategorizable errors in Level 1 show significant decreases with age.

## Tracking Accuracy

[^119]For analyzing tracking accuracy, we included all trials (even those for which the memory check was failed), because we are interested in the true performance of subjects in order to calibrate TrackIt. Furthermore, as shown by a plot of tracking accuracy both including and excluding incorrect

Table 4: Linear regression results from regressing error type proportions over age

| Difficulty Level 1 |  |  |  |
| :---: | :---: | :---: | :---: |
| Error Type | $\beta$ | $F(1,66)$ | $p$ |
| Spatial Resolution | -0.0203 | 1.33 | 0.253 |
| DSR | -0.0706 | 6.96 | $0.010^{*}$ |
| Distractor | -0.0653 | 7.54 | $0.0078^{* *}$ |
| Uncategorizable | -0.0444 | 4.81 | $0.0318^{*}$ |
| Other | -0.0101 | 0.977 | 0.327 |
| Difficulty Level 2 |  |  |  |
| Error Type | $\beta$ | $\mathrm{F}(1,65)$ | p |
| Spatial Resolution | -0.00915 | 1.07 | 0.304 |
| DSR | 0.0125 | 0.185 | 0.669 |
| Distractor | -0.0229 | 0.644 | 0.425 |
| Uncategorizable | -0.0320 | 1.63 | 0.206 |
| Other | -0.0142 | 0.540 | 0.465 |

Note: DSR = Distractor Spatial Resolution.

* $\mathrm{p}<0.05$. ** $\mathrm{p}<0.01$
memory response trials (see Figure 3), filtering by memory check had little effect on the tracking accuracy scores. For all difficulty levels in all age groups, tracking accuracy was significantly above chance (chance is $1 / 16$ for Level 1 and $1 / 36$ for Levels 2 and 3, $t s>3.9, p s<0.0005$ ).

For each of the first two difficulty levels, we saw a significant upward trend effect by an F-test on linear regression ( $\beta=0.2302, F=38.33, p<0.0001$ for Level 1 and $\beta=0.1427, F=7.605, p<0.01$ for Level 2). We could not assess a trend for difficulty Level 3 because we only had one age group for that level.

Figure 3. Tracking accuracies for each age and difficulty level, both with and without memory-incorrect trials.

For difficulty Level 1, tracking accuracy of 3-year olds was significantly below that of 4 -year olds (two-sample $t=-5.05, p<0.0001$ ), but tracking accuracy of 4-year olds was not significantly below that of 5 -year olds (two-sample $t=-1.02, p=0.315$ ). Similarly, for difficulty Level 2 , tracking accuracy of 4 -year olds was significantly below that of 5-year olds (two-sample $t=-2.18, p<0.033$ ), but tracking accuracy of 5-year olds was not significantly below that of 6 -year olds (two-sample $t=-0.88, p=0.382$ ).

In the two age groups that performed two difficulty levels (4-5 year olds), two-sample t-tests revealed that performance differences between difficulty levels were not significant ( $t s<1.11, p s>0.11$ ).

## Discussion

The first purpose of this study was to gain insight into the factors driving improvement by investigating the types of errors made by children. A second purpose was to explore the multidimensional parameter space available within TrackIt, with the goal of identifying both developmental milestones in terms of TrackIt performance as well as appropriate settings for use with children.

## Memory Accuracy

Memory accuracy results indicate that encoding error is more prominent in younger children and improves significantly over age. On the other hand, memory accuracy did not differ significantly across difficulty levels, nor was there an age-difficulty interaction effect. Both of these results are encouraging because they suggest that encoding error does not become a confound when using TrackIt with different difficulties across age groups.

## Error Analysis

As discussed above, the proportion of distractor errors was consistently significantly above chance in every age group and difficulty. In Level 1 difficulty, distractor, distractor spatial resolution, and uncategorizable errors (all distractor-related errors) significantly decreased over age. Noting that uncategorizable errors indicate a combination of spatial and distractor spatial resolution errors, these together suggest that distractors' effect on performance decreases with increasing age.

On the other hand, the reduction in both spatial and distractor spatial resolution errors may also stem from a reduction in errors due to visuospatial resolution. While this was a known confound when analyzing the improvement in tracking accuracy over age, our analysis enables us to partially isolate these two sources of improvement by showing more specifically that distractor errors decrease over time. Since distractor errors are associated only with SSA, and not spatial resolution, this provides a stronger
suggestion (as compared to previous results showing only improvement in TrackIt performance) that the improvement in TrackIt performance over age indeed reflects SSA development.

As with previous analyses, we found greatest improvements in performance between 3- and 4-year olds (see Figure 3), which may explain why the significant change in distractor, spatial resolution, and distractor spatial resolution errors was observed only in difficulty Level 1, the only difficulty level at which we tested 3-year olds. We hypothesize that one possible cause of these results, given that changes in the proportion of distractor-related errors occur primarily between ages 3 and 4, is that these ages may be an especially critical period of rapid SSA development.

## Tracking Accuracy

In our tracking accuracy results, we observed significant developmental upward trends with age in difficulty Levels 1 and 2, as shown in Figure 3. However, more specific analyses of each difficulty level revealed ceiling effects. These suggest that the parameter combinations for Level 1 and Level 2 may be appropriate settings for assessing 3- and 4-year olds, respectively, insofar as they avoid ceiling effects, but more difficult parameter combinations may be necessary for sensitive measurement with older children.

Since performance of 4- and 5-year olds did not drop significantly from Level 1 to Level 2, a linear increase in number of distractors and grid size with age does not seem to be enough to preserve difficulty across age groups.

## Limitations and future directions

Our study did not include 2 year-olds and had limited samples of 6- and 7-year olds. Since significant improvement was observed between 3 and 4 years of age, it may be important to look at 2-year olds also.

The behavioral output of TrackIt is limited in that it records only the participant's response at the end of the trial. In particular, we do not know if participants are continuously attentive to the target throughout the trial (on correct trials) or when participants cease to attend to the target (on incorrect trials). Currently, studies are being run in the lab which combine eye-tracking technology with TrackIt and make this information accessible, potentially giving us a more complete picture of how participants behave during the TrackIt task.

## Conclusion

The findings of this study lay the foundation for further work using TrackIt to study SSA development over a range of ages by a) identifying parameter combinations appropriate for certain age groups, b) discounting reduction in encoding errors as a confounding source of performance improvement over age, and c) enriching the behavioral output of TrackIt with information about the types of errors children make, and hence the sources of their performance
improvements over time. Because of its parametric flexibility, TrackIt can assess SSA across a wide range of ages in the same basic task, lowering the risk that changes measured across age are due to different tasks. Additionally, TrackIt has good psychometric properties in general (test-retest reliability, predictive validity, and now a moderate degree of mapping of parametric space). TrackIt thus provides a practical and novel way of measuring attention in an age-range where we know rapid changes occur, but which we haven't had a task to assess with any degree of sensitivity.

#### Abstract

Successful and repeated cooperation requires fairly sharing the spoils of joint endeavors. Fair distribution is often done according to preferences for equitable outcomes even though strictly equitable outcomes can lead to inefficient waste. In addition to preferences about the outcome itself, decision makers are also sensitive to the attributions others might make about them as a result of their choice. We develop a novel mathematical model where decision makers turn their capacity to infer latent desires and beliefs from the behavior of others (theory-of-mind) towards themselves, anticipating the judgments others will make about them. Using this model we can construct a preference to be seen as impartial and integrate it with preferences for equitable and efficient outcomes. We test this model in two studies where the anticipated attribution of impartiality is ambiguous: when one agent is more deserving than the other and when unbiased procedures for distribution are made available. This model explains both participants' judgments about the partiality of others and their hypothetical decisions. Our model argues that people avoid inequity not only because they find it inherently undesirable, they also want to avoid being judged as partial.

Keywords: fairness, social cognition, theory-of-mind, decision making, Bayesian models

## Introduction

From the distribution of wealth across society to the distribution of dessert at the end of a dinner party, humans seem uniquely capable of enlarging the size of the pie and sharing it fairly (Tomasello, 2014). We make these decisions guided by normative principles such as efficiency, which says to maximize the total utility of the group and fairness, which says in part that distributions should be both equitable and impartial. We also use these principles intuitively when judging whether others' decisions are fair when considered from an impartial or objective perspective (Rawls, 1971; Nagel, 1986).

In the real world where resources aren't perfectly divisible, these principles can often come into conflict. It is well known that efficient allocations of resources are often inequitable and equitable allocations of resources are often inefficient - they leave some of the pie on the table. For example, if Alice has one apple and Bob has none and we take Alice's apple and throw it out, Alice and Bob are in a more equitable state but the total welfare (efficiency) is reduced. This is called inefficient equity. Even young children prefer inefficient equity: they prefer to destroy a resource rather than distribute it inequitably (Blake \& McAuliffe, 2011; Shaw \& Olson, 2012). Preferences for equity and efficiency are often captured quantitatively by directly deriving them from the outcomes. For instance, efficiency might correspond to the total or average outcome among a group of agents and inequity might correspond to the differences between the outcomes of different agents (Adams, 1965; Fehr \& Schmidt, 1999).

While early work focused on whether a given outcome is perceived as fair (Adams, 1965; Fehr \& Schmidt, 1999), there is now growing evidence that decision makers are sensitive to what their choice signals about themselves. Specifically, inequity created without showing partiality can be fair. If both Alice and Bob are equally deserving but there is only one apple, a decision maker might avoid giving it to either one in order to avoid an outcome that is neither equitable nor impartial. For instance, if the decision maker decided to give the apple to Alice an observer would infer that the decision maker is partial to Alice. However, if the decision maker can flip a coin or access another source of randomness and use the chance outcome to determine who should get the apple, the decision maker can create inequity but without worrying about others attributing partiality (Shaw \& Olson, 2014; Choshen-Hillel, Shaw, \& Caruso, 2015).

Both adults and children adjust their distributional preferences depending on whether they are the ones choosing or not. For instance, people are usually dissatisfied with receiving less than an equally worthy counterpart, but when they created the inequity themselves they were more likely to find this acceptable (Choshen-Hillel \& Yaniv, 2011). Adults and children are willing to create inequity that disadvantages themselves but are less willing to create inequity that could be interpreted as favoritism or nepotistic preferences (ChoshenHillel et al., 2015). These results are incompatible with explanations of social preferences that only consider an aversion to inequitable outcomes or other preferences that are directly derived from outcomes. Understanding how to combine these conflicting perspectives (efficiency vs. equity and equity vs. impartiality) is a challenge that we can address with computational modeling. Specifically, how might a flexible preference for these normative values be integrated together and flexibly applied?

Computationally, preferences like impartiality are significantly more sophisticated than just evaluating expected outcomes. We propose that an aversion to partiality is an aversion to having ones actions appear partial to others. Thus to evaluate whether an action will appear partial requires anticipating how one's actions will be interpreted by others. This requires a mentalistic theory-of-mind: the capacity to interpret behavior as being driven by beliefs, desires and intentions (Dennett, 1989). The same choice made in a different context or from a different set of alternatives might be evaluated differently as it will carry different information about the underlying goals and desires that drove the choice. For instance, if a decision maker can choose to give his colleague

Figure 1: An influence diagram (ID) is a directed acyclic graph over three types of nodes: state nodes (circles), decision nodes (rectangles), and utility nodes (diamonds). Directed edges between nodes determine causal dependencies. State and utility nodes take values that depend on the values of their parent nodes. The total utility to the decision maker is the sum over the utility nodes. Green and red utility nodes correspond to rewards and costs respectively. The value of decision nodes is freely chosen by the decision making agent according to equation (4). (a) ID of the Base Decision Maker. Merit corresponds to $\boldsymbol{\gamma}$ and the Inequity and Efficiency nodes corresponds to the first and second components of equation (3) (b) ID of the Judge which infers whether a base decision maker was partial given an observation of her action, $P($ partial $\mid a)$. (c) The Constructed Social Preference recursively builds on the Base Decision Maker adding an aversion to appearing partial $\left(U_{P}\right)$. (d) Simulated results when the decision maker can allocate $\$ 1,000$ to one agent and $\$ 100$ to another or the value on the x -axis to both agents when both agents are equally meritorious. The Constructed Social Preference is more likely to select the wasteful equal option to avoid an attribution of partiality.
either $\$ 100$ or $\$ 1,000$ and chooses to give him $\$ 1,000$ we might infer that he likes his colleague. However if his choices were to give either $\$ 1,000$ or $\$ 2,000$, giving $\$ 1,000$ signals a dislikes for his colleague. Thus the same action requires a different interpretation depending on the unchosen option. Furthermore, the capacity for theory-of-mind can affect distributional preferences: previous work found that children with a more developed theory-of-mind were more likely to give fair offers in the ultimatum game (Takagishi, Kameshima, Schug, Koizumi, \& Yamagishi, 2010).

In this work, we propose that preferences over the beliefs others will form are constructed by turning theory-of-mind inward, anticipating the evaluations others will make about the actions one might take. With the knowledge of how one's actions will be judged before deciding, a decision maker can calibrate her actions to send the right signals (Baumeister, 1982; Bénabou \& Tirole, 2011). We note that we do not believe agents to be necessarily intentionally signaling impartiality to others. Instead agents may strive to maintain a desired image of themselves from an objective viewpoint or "self-signal" (Nagel, 1986; Bodner \& Prelec, 2003; Bénabou \& Tirole, 2011).

In this paper we develop a computational framework for capturing the above intuitions. We use influence diagrams as a structural representation of a rational actor and Bayesian inference over influence diagrams to enable theory-of-mind inferences about whether an action will be perceived as partial. While the framework we will present is a general way of constructing preferences from the anticipated judgments of others, we focus specifically on constructing distributional preferences with the desire to be perceived as impartial (Shaw, 2013; Shaw \& Olson, 2014; Dungan, Waytz, \& Young, 2014;

DeScioli, 2016). We first present a mathematical model that integrates preferences for efficient and equitable outcomes with an aversion to appear partial. We then test our model empirically in two parameterized allocation games with many conditions that allow us to test some of the fine-grained predictions of the model. Finally, we conclude by sketching how our model can be extended to capture other social desires constructed from a decision maker's preference to appear positively in the minds of others.

## Computational Analysis

In this work we aim to model both the way participants act in resource allocation games as well the judgments they make about the resource allocations of others. We start from the simpler preferences for efficiency and equity which are based on outcomes and build towards constructing a social preferences for impartiality which are implicitly intentional.

We define a resource allocation game as follows. Let $\mathcal{A}$ be the set of actions available to the decision maker. For each action $a \in \mathcal{A}$ there is a probabilistic transition function $P(R \mid a)$ which maps an action to a vector of rewards $R$ where each $r_{i} \in R$ is the amount of reward given to agent $i$. In a resource allocation game, the decision maker picks an action (a) such that the expected reward to the other agents $(R)$ achieves the desires of the decision maker.

We now define the desires of the Base Decision Maker as components of a utility function. These desires will determine how Base Decision Maker distributes resources. We consider two base desires. The first is a relative preference over the rewards received by specific agents. To realize this preference, we include the reward received by each of the other agents as weighted components of the decision maker's
own utility. Depending on the value of these weights, an agent might impartially value others or might be partial towards certain individuals. Formally, let $\alpha_{i} \in \boldsymbol{\alpha}$ be the weight that the decision maker places on the reward given to agent $i$. When $\alpha_{i}>0$, the decision maker gains utility proportional to the reward received by $i$, when $\alpha_{i}<0$ the decision maker loses utility proportional to the reward received by $i$ and when $\alpha=0$ the decision maker is indifferent to the reward received by $i$. By expressing different $\alpha$ over different agents the decision maker can express partiality (or aversion) towards specific agents. Including the rewards received by all others as positive elements $(\alpha>0)$ in the decision maker's own utility creates a preference for Pareto efficient allocations, a form of efficiency where the reward distributed cannot be increased by taking other actions without making one of the receiving agents worse off.

The second base desire implements a form of proportional equity, the idea that those who contribute more to a joint endeavor should reap a larger share of the rewards or "justdesserts". A well studied way to capture proportional equity quantitatively is to constrain the relative reward $\left(r_{i}\right)$ given to each agent to be proportional to their relative effort or merit ( $\gamma_{i}$ ) (Adams, 1965):

$$
\begin{equation*}
\frac{r_{1}}{\gamma_{1}}=\frac{r_{2}}{\gamma_{2}}=\ldots=\frac{r_{N}}{\gamma_{N}} \tag{1}
\end{equation*}
$$

We transform these constraints into a measurement of inequity:

$$
\begin{equation*}
I(R, \boldsymbol{\gamma})=\sum_{i \in N} \sum_{\substack{j \in N \\ j>i}}\left|\gamma_{j} r_{i}-\gamma_{i} r_{j}\right| \tag{2}
\end{equation*}
$$

With a notion of efficiency and equity in place, we can define the allocation preferences for the Base Decision Maker. The expected utility (EU) to the decision maker of choosing $a$ is:

$$
\begin{equation*}
\mathrm{EU}_{\mathrm{base}}[a]=-\alpha_{I A} \mathrm{E}_{a}[I(R, \boldsymbol{\gamma})]+\sum_{i \in N} \alpha_{i} \mathrm{E}_{a}\left[r_{i}\right] \tag{3}
\end{equation*}
$$

where $\mathrm{E}_{a}[I(R, \boldsymbol{\gamma})]$ is the expected amount of inequity created by action $a$ and $\alpha_{I A} \in \boldsymbol{\alpha}$ is the weight the decision maker places on inequity aversion. $\mathrm{E}_{a}\left[r_{i}\right]=\sum_{r_{i}} r_{i} P\left(r_{i} \mid a\right)$ is the expected reward for $i$ when the decision maker takes action $a$. Decision making follows probabilistically by sampling from the soft-max of expected utility:

$$
\begin{equation*}
P(a \mid \boldsymbol{\alpha}) \propto \exp (\beta * \mathrm{EU}[a]) \tag{4}
\end{equation*}
$$

with higher values of $\beta$ leading to a higher probability of selecting the action with the highest expected utility.

Influence diagrams are a natural choice for structurally representing this model since they can flexibly capture decision problems with multiple factors and recursive sources of value. Furthermore, they can be used to reason about the latent mental states of a decision maker from just a sparse and noisy observation of behavior (Jern \& Kemp, 2015; Kleiman-Weiner, Gerstenberg, Levine, \& Tenenbaum, 2015). The utility of the

Base Decision Maker which is defined in equation (3) can be expressed graphically as the influence diagram shown in Figure 1a. The first term of equation (3) corresponds to the $U_{I}$ node and the second term corresponds to the $U_{E}$ node.

We now consider a Judge who makes inferences and judgments about the underlying preferences of the Base Decision Maker following an observation of behavior. Specifically, in the Base Decision Maker the $\boldsymbol{\alpha}$ encode the preferences of the agent and so for the Judge these $\boldsymbol{\alpha}$ become the target of inference. For our purposes, the Judge is interested in the extent that the Base Decision Maker is partial to one or more agents. The Judge's prior is that the Base Decision Maker is partial (a binary variable) with probability 0.5 . If partial, one of the $\alpha_{i}=\alpha_{\text {partial }}$ ( $i$ chosen uniformly at random) and the other $\alpha_{-i}=-\alpha_{\text {partial }}$. Otherwise, if the agent is not partial, all $\alpha_{1 \ldots N}=1$. The Judge also has some prior uncertainty on the degree that the Base Decision Maker cares about inequity so $\alpha_{I A} \sim \operatorname{Exponential}(\boldsymbol{\lambda})$. With these priors over the types of preferences a Base Decision Maker might have, a Judge can use Bayesian inference to compute the extent that an agent was partial based on just a single observed allocation:

$$
\begin{equation*}
P(\text { partial }, \boldsymbol{\alpha} \mid a) \propto P(a \mid \boldsymbol{\alpha}) P(\boldsymbol{\alpha} \mid \text { partial }) P(\text { partial }) \tag{5}
\end{equation*}
$$

where $P(a \mid \boldsymbol{\alpha})$ is the model of action shown in equation (4) and the $\boldsymbol{\alpha}$ are then marginalized out to obtain a posterior on $P$ (partial $\mid a$ ). Figure 1 b shows how the judge does inference over the parameters of the influence diagram representing the Base Decision Maker.

A Constructed Social Preference inherits from and recursively builds upon both the Base Decision Maker and the Judge. In particular, the Constructed Social Preference has an additional preference to appear impartial. Since this is a preference over the beliefs others will form as a result of her decision, the preference to appear impartial is a preference over the posterior $P($ partial $\mid a)$. The Constructed Social Preference integrates these belief based preferences with the preferences for equity and efficiency of the Base Decision Maker:

$$
\begin{equation*}
\mathrm{EU}_{\text {constructed }}[a]=\mathrm{EU}_{\mathrm{base}}[a]-\alpha_{P A} P(\text { partial } \mid a) \tag{6}
\end{equation*}
$$

where $\alpha_{P A}$ is the extent that the Constructed Social Preference cares about whether other agents view her as impartial or not. This equation and the influence diagram in Figure 1c show how the Constructed Social Preference is built on top of the Judge and Base Decision Maker.

The Constructed Social Preference goes beyond preferences over outcomes like those in the Base Decision Maker. Instead, it anticipates the inferences other agents will make about its actions and optimizes its actions so that others have desirable beliefs. Figure 1d shows a simulated example where a decision maker had to choose between allocating either $\$ 1,000$ to one agent and $\$ 100$ to another equally meritorious agent or giving a smaller but equal value to both. The Constructed Social Preference is more likely to select the equal

Figure 2: Empirical results and model predictions of (a) choices and (b) judgments of partiality for the trials in experiment 1 where both of the agents were equally meritorious. Trials with no gray bar indicate the model predicted near 0 . Error bars are the standard error of the mean.
option since it implies lower partiality even though both the Base Decision Maker and the Constructed Social Preference care equally about avoiding inequity.

In order to compare the model with human participants, we used maximum-likelihood estimation to optimize the free parameters to human judgments. The five parameters used for all simulations were: $\beta=0.003, \alpha_{\text {partial }}=6, \lambda=0.7$, $\alpha_{P A}=1350$. If agent $i$ was more meritorious than agent $j$ then $\frac{\gamma_{i}}{\gamma_{j}}=4$. Importantly, the parameters used to model the partiality data were constrained to be the same as those used to model participants' decisions.

## Experiments and Results

We test the predictions of this model in two parametric behavioral experiments that measure participants' decisions in a hypothetical resource allocation game as well as judgments about the partiality of another agent who made an allocation. Both experiments were run on Amazon Mechanical Turk. For each condition we compare the average responses with the predictions of the model.

## Experiment 1: Proportionality and Impartiality

In experiment 1 we investigate how equity and merit affect choices in an allocation game. We presented two groups of participants with the following vignette which describes an allocation game that took place in an everyday office setting:

[^120]bonus and Alex the $\$ 100$ bonus / Give them both a bonus of [\$0 / \$100 / \$500 / \$1000 / \$1,100])
Participant group 2: Max decides to [give Alex the \$1,000
bonus and Josh the $\$ 100$ bonus / give Josh the $\$ 1,000$ bonus and Alex the $\$ 100$ bonus / give them both a bonus of (\$0 / \$100 / \$500 / \$1000 / \$1,100)]. Who do you think Max likes better? (Definitely Alex $=-1$, Equal $=0$, Definitely Josh $=1$ )

The bold text shows the different variants of the vignettes. On different trials the value of the equal option varied between $\$ 0$ and $\$ 1,100$. On some trials both employees received equal work evaluations and on some trials one employee received a better work evaluation. The names of the employees changed on each trial but were always a high frequency male name.

We first report the results for when both employees were equally meritorious (Figure 2). We found high rates of inequity aversion that led to highly wasteful bonus allocations (Choices: $\mathrm{N}=89$; Judgments: $\mathrm{N}=104$ ). When the equal sized bonus was $\$ 0$, almost $50 \%$ of participants chose to allocate nothing, wasting a total of $\$ 1,100(\$ 1,000+\$ 100)$ rather than allocating unequal bonuses. When the bonus was $\$ 100$, over $75 \%$ of participants wasted the $\$ 1,000$ bonus in favor of two equal $\$ 100$ bonuses. These allocations were highly wasteful and were Pareto dominated since the unequal allocation would have made at least one of the employees better off without making the other employee worse off.

The partiality judgments made by a second set of participants is consistent with the idea that the aversion to creating unequal outcomes stems in part from a desire to appear impartial. We transformed judgments of liking into a partiality index by measuring absolute difference from 0 . Even when the alternative equal allocation required wasting the entire bonus, a person who allocated the large but unequal bonus was judged as highly partial (towards the person who received the higher bonus). Our computational model corroborates this interpretation and captures both participants' judgments of partiality and then uses those judgments to explain the strong aversion to an unequal outcome. The full model closely follows the pattern of decision making.

We now turn to the trials where one of the two employees received a better evaluation at work than the other and was thus more meritorious (Choices: $\mathrm{N}=89$; Judgments: N $=104)$. Figure 3 shows that this difference was sufficient to drive participant choices away from the wasteful equal bonus towards giving the large but unequal bonus to the employee who was more meritorious. This shift is consistent with equity (the more deserving employee got a greater share of the rewards). However, this also resulted in a novel type of wasteful decision making: the option to allocate $\$ 1,000$ or more to both employees was forgone over $70 \%$ of the time by the Pareto dominated unequal option that maintains equity based on merit.

Surprisingly, participants attributed the lowest partiality to employees who selected the equal bonus even though one of the receiving employees was more deserving than the other. This points to a possible difficulty in achieving equitable dis-

Figure 3: Empirical results and model predictions of (a) choices and (b) judgments of partiality for the trials in experiment 1 where one of the agents was more meritorious than the other. Trials with no gray bar indicate the model predicted near 0 . A "fair bonus" was when the decision maker gave the large bonus to the agent with more merit. An "unfair bonus" was when the decision maker gave the large bonus to the agent with less merit. Error bars are the standard error of the mean.
tributions. Even when some agents might be more deserving than others, inferences of partiality are still readily made when observing an unequal distribution. Here equity and impartiality work against each other. Since the equal bonus led to a lower attribution of partially, as the size of the equal bonus grows, the model slowly shifts to the efficient equal bonus.

## Experiment 2: Procedural Fairness and Impartiality

In a second experiment we repeated the equal merit condition of experiment 1 but also included the possibility that the employee making the decision could flip a fair coin to decide who gets $\$ 1,000$ and who gets $\$ 100$ (Choices: $\mathrm{N}=54$; Judgments: $\mathrm{N}=158$ ). Besides the addition of this coin the vignette was identical to the vignette in experiment 1 . This is a key test of the impartiality hypothesis since when the size of the equal bonus is low, an inequitable but efficient allocation can be given without signaling partiality towards either of the employees by flipping a coin (Shaw \& Olson, 2014; Choshen-Hillel et al., 2015).

Consistent with the model predictions shown in Figure 4, participants did not judge employees who flipped the coin to be partial towards either of the employees. When the value of the equal bonus was low ( $\leq \$ 100$ ) participants no longer wasted resources like they did in experiment 1 . Instead they flipped the coin in order to allocate the full bonus without signaling partiality.

Combining the two experiments, we quantify the overall model performance across all of the conditions in the two experiments. Figure 5 shows the quantitative correlation of the model predictions with the average judgments of participants. Overall, participant judgments and decisions were highly correlated $\left(R^{2}=0.94\right)$ with the model predictions. This suggests that the model is capturing some of the fine grained structure of how people attribute both partiality and use it to make allocations of welfare.

Finally, we compare the full model presented here against a lesioned model that includes inequity aversion but does not reason about partiality and hence corresponds to the Base Decision Maker (i.e., $\alpha_{P A}=0$ ). The parameters in the lesioned model were directly fit to the choice data and were not constrained to fit the judgments. This model fit the data less well than the full model $\left(R^{2}=0.82\right)$. However, this lesioned model has less parameters than the full model. To test
for the possibility that the full model is overfitting the data we performed cross-validation using randomly chosen subsets of half the data to fit the free parameters and then tested against the held-out half. The held-out cross-validation correlation between the model and participants was $R^{2}=0.93$ which suggests that the full model is robust and is not overfitting. In contrast, the lesioned model performed much worse ( $R^{2}=0.74$ ) under cross-validation. When the full model was applied only to the choice data it captured nearly all of the variance ( $R^{2}=0.97$ ) and was still robust when evaluated on only held-out trials $\left(R^{2}=0.96\right)$.

## Discussion

We introduced a new computational model for constructing preferences by modeling rational agents which care about what others will infer about them from their actions. In this model, the machinery of theory-of-mind is turned inward to simulate how an action will likely be perceived or judged by others. Agents then use the perceptions and judgments they anticipate others will form to construct rich preferences over socially desirable traits such as impartiality. We tested key components of the model in two behavioral experiments that were designed to contain conflict between efficiency, equity and partiality and measured both participants' hypothetical resource allocations and the judgments they made about the partiality of others who had acted. The predictions of the model were closely correlated with both allocation decisions as well as partiality judgments. Finally, we note the best fit parameters had a high value for $\alpha_{P A}$ which suggests that partiality aversion was playing an important role in the model fit for predicting choices. A lesioned model that did not contain this parameter failed to predict participants' judgments in both experiments.

We now briefly describe qualitatively some of the other predictions this model can make without any structural extension. Our model predicts that when the decision maker and one of the agents have a previous relationship (such as old friends or a reciprocal relationship in a different context) there will be a greater probability of inferring partiality since this previous relationships will manifest itself on the prior over partial. With a greater probability of others inferring partiality a decision maker will be even less likely to give their friend a larger reward than another person. This reasoning might explain why nepotism and cronyism is judged as unfair

Figure 4: Empirical results and model predictions of (a) choices and (b) judgments of partiality for experiment 2 which introduced the option to flip a fair coin to decide the allocation of the unequal bonuses. Trials with no gray bar indicate the model predicted near 0 . Error bars are the standard error of the mean.

Figure 5: Quantification of model performance. Each point represents the model prediction and participant judgment for a single condition. For better fitting models the points will lie close to the $y=x$ diagonal. (left) The full model compared including both decision and judgment data. (middle) The full model compared only on the decision data. (right) Lesioned model that did not include partiality compared only on the decision data.
and avoided (Dungan et al., 2014). Other procedural tools such as the delegation of the decision to a third party may also be important to avoid the attribution of partiality. Under the model we have presented, if an attribution of partiality can be made less likely, the decision maker might be more likely to participate in nepotism and favoritism.

In future work we would like to investigate how other forms of social preferences can be constructed by placing preferences over anticipated judgments. For instance, people might desire to appear as trustworthy and generous or avoid appearing selfish or envious. Ultimately we suspect that an agent who carefully manipulates their image so that all others think she is a great person - will end up behaving quite similar to a person who is truly good. However, her behavior will be less robust - when she suspects her actions are unobserved or can only be interpreted ambiguously, the constructed social preferences disappears along with the altruistic or fair behavior (Dana, Weber, \& Kuang, 2007). By constructing social preferences such as impartiality, a key component of fairness, from the anticipated judgments of others, we quantitatively predict the fine-grained structure of both participants' decisions concerning the allocation of resources and participants' judgments about those who make distribution decisions. Our model makes clear that the power of theory-of-mind is not necessarily limited to understanding the beliefs and desires of other intentional agents. It can also be pointed inward to strategically shape beliefs and desires in others.

# Explaining Guides Learners Towards Perfect Patterns, Not Perfect Prediction 

Elizabeth Kon (ellie.kon@berkeley.edu), Tania Lombrozo (lombrozo@berkeley.edu)<br>Department of Psychology, University of California, Berkeley, 3210 Tolman Hall,<br>Berkeley, CA 94720 USA

#### Abstract

When learners explain to themselves as they encounter new information, they recruit a suite of processes that influence subsequent learning. One consequence is that learners are more likely to discover exceptionless rules that underlie what they are trying to explain. Here we investigate what it is about exceptionless rules that satisfies the demands of explanation. Are exceptions unwelcome because they lower predictive accuracy, or because they challenge some other explanatory ideal, such as simplicity and breadth? To compare these alternatives, we introduce a causally rich property explanation task in which exceptions to a general rule are either arbitrary or predictable (i.e., exceptions share a common feature that supports a "rule plus exception" structure). If predictive accuracy is sufficient to satisfy the demands of explanation, the introduction of a rule plus exception that supports perfect prediction should block the discovery of a more subtle but exceptionless rule. Across two experiments, we find that effects of explanation go beyond attaining perfect prediction.

Keywords: explanation; learning; causal reasoning

## Introduction

"The great tragedy of science - the slaying of a beautiful hypothesis by an ugly fact." T. H. Huxley (1870)

The best explanations account for all the data we invoke them to explain. But in science and in life, explanations often have exceptions. Even when exceptions fail to "slay" our explanatory hypotheses, they certainly diminish them. What is it about exceptions that threatens the quality of explanations?

One possibility is that exceptions are threatening because they offer evidence against the truth of the explanation in question. To the extent our explanation fails to predict an anomalous observation, we might hold out for a better alternative - one that predicts the observation with greater probability, such that the observation provides greater evidential support for that alternative explanation.

A second possibility is that exceptions diminish the quality of explanations not because they reveal predictive failures, but because they reveal that an explanation is deficient with respect to some other explanatory ideal. Across philosophy and science, we praise explanations for their simplicity, breadth, generality, and ability to unify a diverse range of phenomena. Exceptions may diminish the quality of explanations because they threaten these ideals.

In the current experiments, we test these alternatives by investigating how the process of explaining affects learning (for reviews, see Fonseca \& Chi, 2011; Lombrozo, 2012). Prior work has found that when learners are prompted to explain, they're more likely to discover regularities that support "good" explanations (Lombrozo, 2016). In particular, Williams and Lombrozo (2010) found that when learning to classify robots from novel categories, those participants who
were prompted to explain why each exemplar might belong to its respective category were significantly more likely to discover a subtle classification rule that accounted for all eight items (the $100 \%$ rule), as opposed to settling for a more salient classification rule that only accounted for six ("the $75 \%$ rule"), leaving two exceptions.

The results of Williams and Lombrozo (2010) support the idea that explaining encourages learners to find an exceptionless pattern, but do not reveal what it is about exceptions that makes the $75 \%$ rule less good than the $100 \%$ rule. If explaining drives learners away from exceptions because they decrease predictive accuracy, then a rule with non-arbitrary exception - that is, with exceptions that can be reliably identified a priori, such that predictive accuracy can reach $100 \%$ - should rival an exceptionless rule. In contrast, if exceptions are undesirable because they threaten some other explanatory virtue, such as simplicity or breadth, then even a rule with non-arbitrary exceptions should be dominated by a $100 \%$ rule that classifies all items in a unified way.

To test these predictions, we had participants learn novel relationships while prompted to explain or write down their thoughts, and where the exceptions to the $75 \%$ rule were either arbitrary (as in prior work) or meaningful (in the sense that they supported perfect prediction by representing a "rule plus exception" on the basis of two features). If prompting learners to explain pushes them to find a simple, exceptionless pattern, then the two conditions should yield similar results, whether or not the exceptions are meaningful. On the other hand, if explainers are satisfied by a rule that supports perfect prediction, then discovery of the relatively salient $75 \%$ rule with meaningful exceptions should block discovery of the more subtle $100 \%$ rule. We test these competing predictions in Experiment 1 using a sequential training procedure, and in Experiment 2 using a prediction task.

Our task and stimuli go beyond prior work in a second way, as well. Instead of using a classification task in which participants explain category membership by appeal to arbitrary features, we use a causally-rich property explanation task. Prior work suggests a preference for exceptionless, single-feature rules in classification (e.g., Norenzayan et al., 2002; but see Murphy, Bosch, \& Kim, 2016); explanation could simply heighten this classification-based preference. In the current studies, rather than explaining category membership, participants explain why novel creatures eat flies or eat crabs, where both the $75 \%$ and $100 \%$ rules reflect plausible causal explanations. If prompting learners to explain still promotes discovery of a $100 \%$ rule with these modified stimuli, it would suggest that previously-documented effects of explanation on learning are not restricted to classification tasks (see

| Arbitrary <br> Exception | Meaningful <br> Exception | Both sets | Both sets | Both sets |
| :---: | :---: | :---: | :---: | :---: |
|  |  |  |  |  |

Figure 1: All Stimuli. The top row creatures all eat flies, and the bottom row eat crabs. For the arbitrary exception exceptiontype, participants saw the creatures in the first column, and for the meaningful exception exception-type, they saw the creatures in the second column. Both stimulus sets included creatures in columns three through five.
also Walker et al., 2017). This finding would also help bridge the gap between laboratory studies involving artificial materials and educational materials such as biology texts, where effects of explanation have been documented and inform curricula (Fonseca \& Chi, 2011).

## Experiment 1

Experiment 1 investigates whether engaging in explanation encourages learners to seek simple, exceptionless rules, or to instead find rules that allow for perfect predictive accuracy. To test this, we created two stimulus sets: one with a "meaningful exception rule" (a $75 \%$ rule with exceptions identifiable by the presence of a second feature), and another with an "arbitrary exception rule" (a $75 \%$ rule with exceptions that do not share a common feature). The meaningful exception rule was relatively easy to discover and supported perfect prediction, but not on the basis of a single feature. If prompting learners to explain makes them persist in seeking an exceptionless single-feature rule, we would predict comparable results for the meaningful exception stimuli and the arbitrary exception stimuli, with learners prompted to explain significantly more likely than those in a control condition to discover the more subtle $100 \%$ rule. On the other hand, if perfect predictive accuracy satisfies the demands of explanation, we would expect discovery of the more salient meaningful exception rule to block discovery of the $100 \%$ rule, yielding an attenuated effect of explanation on $100 \%$ rule discovery, and a boost in discovery of the meaningful exception rule.

## Method

Participants Participants were 443 adults recruited from the Amazon Mechanical Turk marketplace. Of these, 124 failed attention or memory checks (described below) or left questions blank and were therefore excluded from analyses. The statistical significance of results are unchanged when these participants are included.

Materials The stimuli consisted of two sets of eight "creatures" each, four of which ate flies and four of which ate crabs (see Figure 1). For each set, participants could use two possible rules to determine whether a creature ate flies or crabs. The first accounted perfectly for all eight creatures (the " $100 \%$ rule"): all four creatures that ate flies had snouts pointing up; all four creatures that ate crabs had snouts pointing down. The second rule accounted for six of the eight creatures (the " $75 \%$ rule"): three of four creatures that ate flies were on land; three of four creatures that ate crabs were underwater. Importantly, both features of interest (snout direction and habitat) supported plausible causal explanations for why a creature eats flies versus crabs, e.g., "It eats flies because its snout is pointed up, so it can reach flies" or "It eats flies because it lives on land, where flies are found."

The two stimulus sets differed in the nature of the exceptions to the $75 \%$ rule. For participants in the arbitrary exceptions condition, the exceptions to the $75 \%$ rule did not share a meaningful, plausible characteristic on the basis of which they could be identified as exceptions. For participants in the meaningful exceptions condition, the exceptions to the $75 \%$ rule were "newborns"- they were green and shown with eggs in a nest. We refer to this manipulation as "exception-type."
Procedure The task consisted of a study phase followed by a reporting phase and a rule rating phase.

At the start of the study phase, participants were randomly assigned to one of four conditions, which were created by crossing two prompt-types, Explain or Write Thoughts, with two exception-types, arbitrary or meaningful.

In the study phase, all participants were told to study the creatures, and that after the study phase they would be asked questions about how to determine which food a creature eats. To provide context and help participants interpret the images, they were told that the creatures were: "from the planet ZARN: the adults of all of these creatures eat either flies or crabs. Newborn creatures look exactly like their adult forms except that they are green because they photosynthe-
size. There are different subspecies of this animal with different properties. However, they all have a mouth on an inflexible snout, and an ear that sticks up. They are all tailless, born from eggs and have a 4-chambered heart." Participants were presented with a randomized array of the eight creatures corresponding to their condition's exception-type (arbitrary or meaningful). They were then prompted to focus their attention on each creature, individually, in a random order, with a prompt determined by the experimental condition to which they were randomly assigned. Participants in the explain conditions were told to "try to explain why creature X eats flies/crabs." Participants in the write thoughts conditions were told to "Write out your thoughts as you learn that creature X eats flies/crabs." Participants were given 50 seconds to respond to each prompt, at which time their responses were recorded and the prompt for the next item appeared.

In the reporting phase, participants were told that "we're interested in any patterns that you noticed that might help differentiate creatures that eat flies and creatures that eat crabs. For example, did most or all of the fly-eaters you studied tend to have one property, and most or all of the crab-eaters you studied have another property? We're going to ask you to list all of the patterns (differences between fly-eaters and crabeaters) that you noticed, one at a time. PLEASE REPORT ANY PATTERNS THAT YOU NOTICED, EVEN IF THEY WEREN'T PERFECT AND EVEN IF YOU DON'T THINK THEY'RE IMPORTANT." This language, adapted from Edwards, Williams, and Lombrozo (2013), was employed to encourage participants to report the $75 \%$ rule even if they thought it was incidental or superseded by the $100 \%$ rule. In addition to describing the rule they discovered in a freeresponse box, participants were asked how many of the eight items followed the rule.

After finishing the reporting phase, participants were again presented with all eight creatures as well as four candidate explanations (presented in a random order) for "why creatures A-D eat flies (as opposed to crabs)." They were forced to stay on the page for at least 15 seconds to ensure that they read the explanations (there was no upper time limit). Along with an inaccurate explanation included as a control, the explanations provided for rating were:

- $100 \%$ rule: "Because creatures A-D have snouts that point up, and creatures E-H have snouts that point down."
- $75 \%$ rule: "Because creatures A-D live on land, and creatures E-H live in the water."
- $75 \%$ rule + exception associated with their exception-type:
- with arbitrary exceptions: "Because creatures A-D live on land, and creatures E-H live in the water (with some exceptions)."
- with meaningful exceptions: "Because creatures A-D live on land, and creatures E-H live in the water (with the exception of newly-hatched creatures, who are born in the opposite environment)."

Ratings were collected on a 7-point scale with anchors at 1 ("Very Poor Explanation") and 7 ("Excellent Explanation").

Before concluding the experiment, participants completed an attention and memory check question that served as the basis for participant exclusion. They were asked to "look at the following images and select the one that you have studied in previous questions. In the text box next to that image, please also type in whether you think that it eats flies or crabs. It is important for us to know whether our participants are paying attention and are reading all of the instructions, so if you are reading this, what we actually want you to do is to select "None of these objects look familiar," and in the corresponding text box to write in whether the image you recognize from the other options eats flies or crabs." By selecting the instructed button, participants indicated they had been reading instructions, and by correctly reporting the diet of the creature they recognized, participants indicated that they attended to the stimuli in the primary task.

## Results

Overall, participants reported finding an average of 1.25 patterns $(S D=0.96, \min =0, \max =4)$ that they reported accounted for an average of 5.94 exemplars $(S D=1.8, \mathrm{~min}=0$, $\max =8$ ). Reported patterns were coded for mention of the $100 \%$ rule and/or the $75 \%$ rule.
$\mathbf{1 0 0 \%}$ rule reporting: To test whether explanation prompts affected $100 \%$ rule discovery, and whether effects differed across exception-type, we conducted a logistic regression predicting whether participants discovered $100 \%$ rule (yes vs. no) by prompt-type (explain vs. write thoughts) $\times$ exception-type (arbitrary vs meaningful). This revealed a significant effect of prompt-type on reporting the $100 \%$ rule, collapsed over exception-types $\left(\chi^{2}=6.64, p=0.01\right.$; see Figure 2). The interaction term between prompt-type and exception-type was not significant $\left(\chi^{2}=0.28, p=0.6\right)$.

Figure 2: Proportion of Participants Reporting the $100 \%$ Rule in Experiment 1

The results of this analysis are consistent with the hypothesis that what people seek when explaining are rules high in explanatory virtues such as simplicity and breadth: the opportunity to employ a rule + meaningful exception (which was both easy to discover and afforded perfect prediction) did not block participants in the explain condition from seeking an alternative that accounted for all items with a single feature. However, this conclusion should be accepted with some caution: when analyzed alone, there was not a significant effect of prompt-type within the meaningful exceptions conditions ( $\chi^{2}=1.93, p=0.16$ ), but there was in the arbitrary exceptions condition ( $\chi^{2}=5, p=0.03$ ).
$\mathbf{7 5 \%}$ rule reporting: Previous studies have found that prompting participants to explain can decrease $75 \%$ rule reporting relative to a control condition (e.g., Edwards et al., 2013; Williams \& Lombrozo, 2010, 2013). In this study, the proportions of participants reporting the $75 \%$ rule were: $51 \%$ for explain/arbitrary; $46 \%$ for write thoughts/arbitrary; $69 \%$ for explain/meaningful; and $63 \%$ for write thoughts/meaningful.

To analyze these data we ran another logistic regression: discovered $75 \%$ rule (yes vs. no) by prompt-type (explain vs. write thoughts) $\times$ exception-type (arbitrary vs. meaningful). The effect of prompt-type was not significant ( $\chi^{2}=1.15, p$ $=0.28$ ). The effect of exception-type was significant $\left(\chi^{2}=\right.$ $10.08, p<0.01)$. However, the interaction between prompttype and exception-type was not significant $\left(\chi^{2}=0.02, p=\right.$ $0.9)$. So while people were more likely to report the $75 \%$ rule when the exceptions were meaningful, this effect was not moderated by prompt-type. Few participants reported both the $100 \%$ and $75 \%$ rules: $16 \%$ for explain/arbitrary; $9 \%$ for write thoughts/arbitrary; $23 \%$ for explain/meaningful; and $17 \%$ for write thoughts/meaningful.

Rule Rating: To confirm that the manipulation of exception-type had some effect on perceived explanation quality, we compared explanation ratings for the $75 \%$ rule + exception as a function of exception type. Indeed, a t-test revealed higher ratings when the exception was meaningful $t(309)=-4.3, p<0.01$ (see Table 1 for all mean ratings).

Table 1: Average Rule Rating by Exception-type

| Condition | $100 \%$ rule | $75 \%$ rule | $75 \%$ rule + <br> exception | Bad Rule |
| :--- | :---: | :---: | :---: | :---: |
| Arbitrary <br> Exceptions | $5.50(2.23)$ | $3.11(1.95)$ | $4.87(2.05)$ | $1.81(1.54)$ |

## Discussion

On balance, the results from Experiment 1 support the idea that when it comes to the effects of explanation on learning,
an explanation that supports perfect prediction can still be deficient if it fails to account for all observations in a unified way. The experiment also suggests that the original effects reported in Williams and Lombrozo (2010) are not restricted to explicit classification tasks with arbitrary features: we successfully reproduced effects of explanation in a property explanation task where explanations were causally meaningful.

Introducing a rule with meaningful exceptions did have significant effects: participants were more likely to report discovering the $75 \%$ rule when the exceptions were meaningful (regardless of prompt), and they evaluated the explanation containing a $75 \%$ rule to be more satisfactory when the exceptions were meaningful. However, introducing the 75\% rule with meaningful exceptions did not block participants prompted to explain from discovering the $100 \%$ rule: they seemed to persevere in looking for an exceptionless, singlefeature rule rather than settling for a rule that supported perfect prediction on the basis of multiple features. This conclusion is supported by the significant effect of prompt-type on $100 \%$ rule discovery, which was not qualified by a further interaction with exception-type. At the same time, we note that when restricting analysis to the meaningful exceptions condition, the effect of explanation was not significant. The results of Experiment 1 are therefore somewhat inconclusive, and we revisit the contrast between arbitrary and meaningful exceptions in Experiment 2.

## Experiment 2

Because the results from Experiment 1 were somewhat inconclusive, we ran a new variant of the task. The task used in Experiment 2 was designed to heighten the value of perfect prediction: rather than receiving labelled exemplars at each step, participants attempt to predict the food that each creature eats, receiving feedback as they proceeded. If explanatory judgments track perfect prediction, then participants prompted to explain in this task should be satisfied with a $75 \%$ rule when it involves meaningful exceptions, thereby supporting perfect prediction and blocking or attenuating the effect of explanation on $100 \%$ rule discovery.

## Method

Participants For this study, 164 adults were recruited from the Amazon Mechanical Turk marketplace. Of these, 61 failed the attention and memory checks described above. We note any cases in which relaxing these exclusion criteria affected conclusions regarding statistical significance.
Materials Stimuli were the same as in Experiment 1.
Procedure This task consisted of a study phase and a reporting phase. As in Experiment 1, participants were randomly assigned to one of four conditions, which were created by crossing two prompt-types, Explain or Write Thoughts, with two exception-types, arbitrary or meaningful.

In the study phase, participants were presented with the same introductory text as in Experiment 1. They were then
given 5 seconds to look over all eight creatures together before being shown the creatures individually in a random order.

When presented with each of the eight creatures individually, participants were asked to determine whether the creature eats crabs or flies. Based on the accuracy of their response, they were then taken to a screen that said either "CORRECT This item does eat flies/crabs" or "INCORRECT This item eats flies/crabs." They were then given 45 seconds to respond to their condition-specific prompt; either "This creature eats flies/crabs. Try to explain why this creature eats flies/crabs." or "This creature eats flies/crabs. Write down whatever you are thinking." After cycling through all eight creatures, participants went through them a second time, again in a random order, with 30 seconds to respond.

The reporting phase was identical to that of Experiment 1.

## Results

Overall, participants reported finding an average of 0.95 patterns $(S D=0.96, \min =0, \max =6)$ which they reported accounted for an average of 6.35 exemplars ( $S D=1.53$, min $=0$, $\max =8$ ). Reported patterns were coded for mention of the $100 \%$ rule and/or the $75 \%$ rule.
$\mathbf{1 0 0 \%}$ rule reporting: To analyze $100 \%$ rule discovery (see Figure 3), we ran a logistic regression of discovered $100 \%$ rule (yes vs. no) by prompt-type (explain vs. write thoughts) $\times$ exception-type (with arbitrary exceptions vs. with meaningful exceptions). The interaction between prompt-type and exception-type was not significant ( $\chi^{2}=$ $0.23, p=0.63$ ).

However, there was a significant effect of explanation (collapsed across the two stimulus sets) $\left(\chi^{2}=4.15, p=0.04\right)^{1}$. These findings suggest that the presence of a salient rule that supported perfect prediction in the meaningful exceptions condition was insufficient to block discovery of the $100 \%$ rule, and therefore support the proposal that explainers preferentially seek simple, exceptionless patterns, not merely perfect predictability.

Again, to see whether the effect of explanation held within the meaningful exceptions condition, we ran a logistic regression predicting discovered $100 \%$ rule (yes vs. no) by prompttype (explain vs. write thoughts) using only the results from the meaningful exceptions condition. We found that there was again no significant effect of explanation when restricting analysis in this way, $\left(\chi^{2}=2.94, p=0.09\right)$.
$\mathbf{7 5 \%}$ rule reporting: The proportions of participants reporting the $75 \%$ rule were: $36 \%$ for explain/arbitrary; $32 \%$ for write thoughts/arbitrary; $61 \%$ for explain/meaningful; and $59 \%$ for write thoughts/meaningful.

To analyze these data we ran a logistic regression predicting discovered $75 \%$ rule (yes vs. no) by prompt-type (explain vs. write thoughts) $\times$ exception-type (arbitrary vs. meaningful). Again, the effect of prompt-type was not significant $\left(\chi^{2}=0.06, p=0.8\right)$, the effect of exception-type was

[^121]

Figure 3: Proportion of Participants Reporting the $100 \%$ rule in Experiment 2
significant: $\left(\chi^{2}=7.11, p=0.01\right)$, and the interaction between prompt-type and exception-type was not significant $\left(\chi^{2}=0.02, p=0.9\right)$. Few participants reported both the $100 \%$ and $75 \%$ rules: $4 \%$ for explain/arbitrary; $0 \%$ for write thoughts/arbitrary; $4 \%$ for explain/meaningful; and $4 \%$ for write thoughts/meaningful.

Prediction Performance: As a check to ensure that the $75 \%$ rule with a meaningful exception indeed improved predictability, we additionally analyzed prediction performance in the second block of the task. Specifically, we compared the proportion of exception items that were correctly classified (of 2) as a function of exception-type (arbitrary vs. meaningful) for the 45 participants who reported discovering the $75 \%$ rule, but not the $100 \%$ rule. A t-test revealed that prediction accuracy was indeed higher when exceptions were meaningful ( $M=1.39, S D=0.83$ ) than when they were not ( $M=0.53$, $S D=0.72), t(38)=-3.68, p<0.01$.

## Discussion

The results of Experiment 2 support the proposal that explainers strive for simple, exceptionless patterns rather than settling for perfect predictability. Even though the presence of meaningful exceptions did improve performance on the prediction task, it did not decrease discovery of the $100 \%$ rule differently for participants who explained and for participants who wrote their thoughts.

## Discussion

Across two experiments, we find support for the proposal that when explaining, people prefer rules that are high in explanatory virtues (such as simplicity and breadth) over alternative rules that allow for perfect prediction, but that are deficient in these virtues. The threat posed by exceptions therefore appears to be rooted in their disruption of explanatory ideals and not only predictive accuracy. This result is consistent with the
observation from science and philosophy that the most predictive models are often not the most explanatory. Additionally, by using a causally-rich property explanation task rather than an arbitrary categorization task, we find support for the claim that effects of explanation on the discovery of exceptionless patterns are not restricted to classification contexts.

Despite these promising results, many questions remain open. First, we found a weaker effect of explanation on $100 \%$ rule discovery in the meaningful exceptions conditions than in the arbitrary exceptions condition. This suggests that the presence of a $75 \%$ rule that afforded perfect prediction attenuated $100 \%$ rule discovery. However, the three-way interaction between $100 \%$ rule discovery, prompt type, and exception type did not reach significance, even when pooling results across studies. It thus remains a possibility that introducing meaningful exceptions has a small but real effect on $100 \%$ rule discovery; this is worth revisiting with a larger sample and more varied stimuli and learning tasks. Second, our results speak to the consequences of engaging in explanation, but not to the mechanisms by which explaining generates these consequences. The possibility we have advanced is that by virtue of explaining, participants are more likely to reject working hypotheses as they encounter exceptions, and therefore persevere in looking for a pattern that supports a good explanation, where a "good" explanation goes beyond predictive accuracy. Given that participants approach these problems with a host of prior beliefs, future studies should investigate this process more directly, including how learners go about generating hypothesis, seeking information, and updating their beliefs in light of new information.

The fact that explaining can be beneficial in learning is influencing educational systems from online learning environments (e.g. Williams et al., 2014) to college chemistry courses (Teichert \& Stacy, 2002). However, as demonstrated here, explanation privileges rules that are simple and exceptionless, and not all learning contexts involve this kind of structure. In fact, previous work has found that prompting learners to explain is sometimes detrimental (e.g. Berthold et. al., 2011; Kuhn \& Katz, 2009; Rittle-Johnson \& Loehr, 2016; Williams \& Lombrozo, 2013; see also Nokes et al., 2011). This underscores the importance of understanding when and why engaging in explanation will and will not promote particular learning outcomes; our current findings provide an additional step towards achieving this understanding.

#### Abstract

People often perceive their in-groups as more heterogeneous than their out-groups. We propose an information sampling explanation for this in-group heterogeneity effect. We analyze a model in which an agent forms beliefs and attitudes about social groups from her experience. Consistent with robust evidence from the social sciences, we assume that people are more likely to interact again with in-group members than with outgroup members. This implies that people obtain larger samples of information about in-groups than about out-groups. Because estimators of variability tend to be right-skewed, but less so when sample size is large, sampled in-group variability will tend to be higher than sampled out-group variability. This implies that even agents that process information correctly - even if they are naive intuitive statisticians - will be subject to the in-group heterogeneity effect. Our sampling mechanism complements existing explanations that rely on how information about in-group and out-group members is processed.

Keywords: Information Sampling, Judgment Bias, Perception of Variability.

## Introduction

A large amount of research has shown that people frequently perceive their groups as more heterogeneous than groups to which they do not belong (Boldry, Gaertner, \& Quinn, 2007; Rubin \& Badea, 2012; Ostrom \& Sedikides, 1992). For example, Park and Judd (1990) found that students majoring in one subject judged students with other major as less variable on such characteristics as extroversion, impulsiveness, and how analytical and reserved they are. This "in-group heterogeneity effect" has received several classes of explanations. One class of existing explanations rely on differences in how information about in-groups and out-groups is processed (Ostrom \& Sedikides, 1992; Ostrom, Carpenter, Sedikides, \& Li, 1993; Park \& Rothbart, 1982) or encoded (Linville, Fischer, \& Salovey, 1989; Linville \& Fischer, 1998; Judd \& Park, 1988; Park \& Judd, 1990). Another explanation takes as a premise that heterogeneity is seen as a positive feature of social groups and that people want to have a positive view of their in-groups (this is the much studied "in-group outgroup bias", see Hewstone, Rubin, and Willis (2002)). People would thus be motivated to see in-groups as more heterogeneous than out-groups (Ostrom \& Sedikides, 1992; Rubin \& Badea, 2012).

Here, we propose a distinct, sampling-based, explanation for the in-group heterogeneity effect. We note that people tend to obtain larger samples of information about in-groups than about out-groups. For example, people can avoid interacting again with an out-group if they had a bad experience
with members of this group. By contrast, people have to keep interacting frequently with members of the in-group even if they had negative experiences with those. Avoidance of the in-group is thus less likely (there is a large literature on this differential 'adaptive sampling' behavior, see Denrell, 2005; Fazio, Eiser, \& Shook, 2004; Fiedler \& Juslin, 2006).

The second premise of our explanation is that the variability of samples of information tends to increase with the size of the sample. Consider for example the variance of a sample of $k$ independent standard normal variables (with mean $\mu=0$ and variance $\sigma=1$ both unknown). This is a random variable that can be written $\hat{\sigma}_{k}=Q /(k-1)$ where $Q$ is a distributed according to a chi-squared distribution with $k-1$ degrees of freedom $\chi_{k-1}^{2}$. The mean of $Q$ is $k-1$. Two features of chisquared distribution are noteworthy: $Q$ is right-skewed (the probability that the sample variance is lower than the mean is higher than $50 \%$ ) and the skewness is decreasing in $k$ (the skewness is equal to $\sqrt{8 /(k-1)}$ ). Overall this means that the sample variance tends to underestimate the true variance ( $\sigma=1$ ) and that the extent of the underestimation decreases as the sample size increases.

These two premises jointly imply that the experienced variability of in-groups will tend to be higher than the experienced variability of out-groups. Under the assumption that people's subjective perception of group variability is closely related to the variance of the sample of information they obtained about this group (Kareev, Arnon, \& Horwitz-Zeliger, 2002; Weber, Shafir, \& Blais, 2004; see Boldry et al., 2007 for a review), this implies that people will tend to perceive in-groups as more variable than out-groups.

This explanation for the in-group heterogeneity effect operates at a different level than existing explanations. Whereas existing explanations focus on how the mind processes information, our explanation focuses on the properties of the samples of information to which the mind has access. We emphasize how the structure of the environment can lead to systematic sampling asymmetries, which in turn imply systematic judgment asymmetries. As such, our explanation fits in the 'sampling approach' to human judgment (Denrell, 2005; Fazio et al., 2004; Fiedler \& Juslin, 2006; Le Mens \& Denrell, 2011).

## Model

Consider a setting where one agent forms attitudes and beliefs about two groups ( $g=i n$, out ). The agent belongs to one
of the two groups - the in-group. In this simple model, we assume that the agent observes two dimensions of the groups: an attitudinal dimension, $A$ and another dimension $X$. Here we assume that the dimension $X$ is not stereotypical in the sense that it does not serve as the basis for categorization. In each period, the agent samples the group or not. When the agent samples a group she observes both dimensions $A$ and $X$ of one of its members.

Belief Updating Let $A_{t, g}$ denote attitude of the agent toward group $g$ at the end of period $t$. If she samples the group in period $t$, two things happen.

- She updates are attitude toward the group. Her new attitude is a weighted average of her previous attitude and the new observation $a_{t, g}$ :

$$
\begin{equation*}
A_{t, g}=(1-b) A_{t-1, g}+b a_{t, g}, \tag{1}
\end{equation*}
$$

where $b \in[0,1]$. We assume that $a_{t, g}$ is normally distributed (with mean 0 and variance 1 ). This attitude updating rule has been found to provide good fit to experimental data on sequential choice under uncertainty (see Denrell, 2005 for a review).

- She obtains an observation $x_{t, g}$ of the non-attitudinal dimension. We assume that $x_{t, g}$ is normally distributed (with mean 0 and variance 1)

If the agent does not sample the group, her attitude does not change ( $A_{t, g}=A_{t-1, g}$ ) and she does not obtain any additional observation of the $X$ dimension.

Perception of Variability Consistent with the sampling approach tradition, we assume that the agent processes sampled information correctly. Let $V_{t, g}$ denote the perceived variability on dimension $X$ at the end of period $t$. Here, we assume that this is given by the standard unbiased sample variance estimator. (In the next section, we consider other estimators of variability.)

$$
\begin{equation*}
V_{t, g}=\frac{1}{n_{t, g}-1} \sum_{k=1}^{t}\left(x_{k, g}-\bar{x}_{t, g}\right)^{2} I_{k, g} \tag{2}
\end{equation*}
$$

where $I_{k, g}$ is an indicator variable equal 1 if group $g$ is sampled in period $k$ (and equal to 0 otherwise), $n_{t, g}$ is the number of samples $\left(n_{t, g}=\sum_{k} I_{k, g}\right), \bar{x}_{t, g}$ is the mean of the sampled observations on the $X$ dimension at the end of period $t$, and $x_{k, g}$ is the observation in period $k$.

Sampling Rule To ensure that variability estimates exist for both groups, we assume that the agent has sampled 2 observations from each group before the first period. In the subsequent periods, the sampling rule follows that used in Denrell (2005). In each period the agent samples the in-group or the out-group based on the current attitude towards that group. Note that sampling rule does not depend on observations on

Figure 1: Model with unbiased variance estimator: Likelihood that the estimate of in-group variability is higher than the estimate of out-group variability $\left(P\left(V_{t, i n}>V_{t, \text { out }}\right)\right)$ as a function of time. Each point is based on $10^{5}$ simulations with $b=0.5, r=0.5, s=3$.
dimension $X$. The probability that the agent samples the ingroup is given by the exponential version of the Luce choice rule (Denrell, 2005):

$$
\begin{equation*}
P_{t+1, \text { in }}=r+(1-r) \frac{e^{s A_{t, \text { in }}}}{e^{s A_{t, \text { in }}}+e^{s A_{t, o u t}}}, \tag{3}
\end{equation*}
$$

Here $s$ is a parameter that regulates the sensitivity of the sampling probability to the current attitude, and $r \in[0,1]$ is a parameter that corresponds to the sampling 'bias' in favor of the in-group. The higher $r$ is, the higher is the baseline probability that the agent will sample the in-group. When $r$ is high, the agent is likely to frequently sample the in-group even if she has a negative attitude toward it ( $A_{t, i n}$ is low). This sampling 'bias' in favor of the in-group implies that the agent will gather larger samples of information about the in-group than about the out-group.

## Analysis

We ran computer simulations of the above model. The parameter values that were used in all simulations are $b=0.5, r=$ $0.5, s=3$. These values are similar to estimated parameter values in sequential choice experiments (Denrell, 2005).

Figure 1 displays the likelihood that the estimate of the ingroup variability is higher than the estimate of the out-group variability, $P\left(V_{t, \text { in }}>V_{t, \text { out }}\right)$, as a function of the number of periods. It is higher than 0.5 for all periods after period 1. In other words, the in-group tends to be perceived as more variable than the out-group. The likelihood that the in-group is perceived as more variable than the out-group first increases quickly and then decreases very slowly with the number of periods. It is equal to 0.54 after 50 periods and 0.53 after 100 periods. This suggests that this asymmetry persists even after many periods.

Figure 2: Model with unbiased variance estimator. Distribution of the sample sizes of the two groups after 15 periods. Based on $10^{5}$ simulations with $b=0.5, r=0.5, s=3$.

To develop an intuition for this result, we focus on the end of period 15. First note that the in-group is sampled more times than the out-group (Figure 2). This is because of the assumed sampling advantage of the in-group (eq. 3). Second, note that the distributions of sampled variabilities for the two groups are right skewed but to a different extent (see Figure 3). The distribution of the sampled variability for the in-group $V_{15, \text { in }}$ is less skewed than the distribution of the sampled variability for the out-group, $V_{15, \text { out }}$. By contrast, the mean sample variabilities are the same: ${ }^{1}$ $E\left(V_{15, \text { in }}\right)=E\left(V_{15, \text { out }}\right)=\sigma^{2}=1$. Overall, this implies that $V_{15, \text { in }}$ tends to be larger than $V_{15, \text { out }}$.

More generally, the distribution of variability estimates for a group is skewed, but the skewness decreases with sample size. If $V_{t, g}$ is based on $n$ observations, it is a random variable with a $\chi^{2}$ distribution with $n-1$ degrees of freedom (the mean is assumed to be unknown to the agent). The $\chi^{2}$ distribution is skewed to the right, therefore the probability that the variance estimate is lower than the true variance $\left(\sigma^{2}=1\right)$ is higher than 0.5 . Consider the probability mass below 1 for sample sizes $5,10,15,20$ and 50 . The probability masses are $0.59,0.56,0.55,0.54$, and 0.53 , respectively. In all cases, it is higher than $50 \%$, but it goes down as sample size increases and converges to 0.50 as the sample size becomes large. Because our assumptions about the sampling process imply that the sample collected about the in-group tends to be larger than the sample collected about the out-group, the distribution of $V_{t, i n}$ is likely less skewed than the distribution of $V_{t, o u t}$. This implies that $V_{t, \text { in }}$ is likely larger than $V_{t, o u t}$. In other words, an in-group heterogeneity effect emerges.

[^122]

Figure 3: Model with unbiased variance estimator. Distributions of the variability estimates (according to eq. 2) $V_{15, \text { in }}$ and $V_{15, \text { out }}$ after 15 periods. Black vertical line denotes the true variance on the $X$ dimension $(\sigma=1)$. Based on $10^{5}$ simulations with $b=0.5, r=0.5, s=3$.

## Other Estimators of Variability

A Bayesian Estimator of Variability An alternative implementation of our assumption that information is processed 'correctly' is to assume that the agent is a Bayesian processor of information, with correct priors about the true variance. For simplicity, we assume that the mean on the $X$ dimension is known and equal to $0 .{ }^{2}$ The true variance is drawn from an inverse gamma distribution with parameters $\alpha$ and $\beta$. The inverse gamma distribution is a conjugate distribution: the posterior also follows an inverse gamma distribution.

$$
\begin{equation*}
f\left(\hat{\sigma}_{t, g}^{2}\right) \sim I G\left(\alpha+\frac{\sum_{k=1}^{t} I_{k, g}}{2}, \beta+\frac{\sum_{k=1}^{t}\left(x_{k, g}-\bar{x}_{t, g}\right)^{2} I_{k, g}}{2}\right) \tag{4}
\end{equation*}
$$

We simulated the model by assuming the same attitude updating rule and sampling rule as before, but with the Bayesian estimator of variability in equation 4 . We assumed $\alpha=15 / 2$ and $\beta=\alpha$. ${ }^{3}$

Figure 4 displays the evolution of $P\left(V_{t, \text { in }}>V_{t, \text { out }}\right)$. In this Bayesian setting as well, the in-group tends to be perceived as more variable than the out-group. This result is important, because it demonstrates that even a rational processor of information will tend to perceive the in-group as more variable than the out-group in settings where the in-group is more likely to be sampled again (i.e. $r>0$ ). A similar pattern would emerge if the agent were also updating her attitudes $\left(A_{t, g}\right)$ using Bayes' rule, provided that the sampling rule implies that larger samples are obtained about the in-group than about the out-group.

[^123]

Figure 4: Model with Bayesian estimator of variability. Likelihood that the posterior estimate of in-group variability is higher than the posterior estimate of out-group variability $\left(P\left(V_{t, \text { in }}>V_{t, \text { out }}\right)\right.$ ) as a function of time. Based on $10^{5}$ simulations with $b=0.5, r=0.5, s=3, \alpha=15 / 2, \beta=\alpha$.

Sample Variance In the main analysis, we assumed that the agent estimated the group variabilities using a statistically unbiased estimator (eq. 2). We did so because we wanted to demonstrate that an asymmetry in the perception of variability could emerge even in this case. Several papers have assumed that people use the standard sample variance estimator (e.g. Juslin, Winman, \& Hansson, 2007; Kareev et al., 2002):

$$
\begin{equation*}
V_{t, g}=\frac{1}{n_{t, g}} \sum_{k=1}^{t}\left(x_{k, g}-\bar{x}_{t, g}\right)^{2} I_{k, g}, \tag{5}
\end{equation*}
$$

This estimator is biased for small samples, and the size of the bias is stronger for smaller samples. Unsurprisingly, simulations based on this estimator lead to a stronger asymmetry than in the above analyses. For example, after 15 periods, the likelihood that the estimate of in-group variability is higher than the estimate of out-group variability is $P\left(V_{15, \text { in }}>V_{15, \text { out }}\right)=0.62$. This number was 0.56 when the unbiased variance estimator was used.

We did not find empirical evidence that suggests that people's intuitive variability estimates are closer to the unbiased or the biased estimators. Qualitatively, this is not an issue for our argument, because the asymmetry in perception of groupvariability emerges in both cases. Further work should investigate this issue. This would allow for quantitative predictions about the size of the in-group heterogeneity effect.

## Relation to Existing Literature on In-group Heterogeneity

Most prior explanations of the in-group heterogeneity effect have invoked differences in how information about in-group and out-group is processed. Here we discuss how our ex-

[^124]planation differs from this prior work (we use a taxonomy similar to Ostrom and Sedikides (1992)).

Several explanations rely on motivated cognition (Kunda, 1990). The first mechanism invokes people's desires for positive identities. Those who want a positive social identity are motivated to view their in-groups more positively than other groups (Tajfel, 1982). At the same time, heterogeneity is frequently perceived as a positive feature of social groups (Ostrom \& Sedikides, 1992). Therefore, people are motivated to perceive the in-group as more heterogeneous than out-groups. A related mechanism invokes people's desire for distinct identities. A more heterogeneous in-group allows people to see themselves as unique within the in-group. Thus, people are motivated to see their in-groups as heterogeneous (Pickett \& Brewer, 2001). Yet another explanation based on motivated cognition notes that it is easier to dehumanize more homogeneous groups (Haslam, 2006; Brewer, 1999). Therefore, if the out-group is perceived as less variable than the ingroup, it is easier to justify negative attitudes and even cruel actions towards out-group members.
Another explanation notes that people tend to have prior beliefs that the out-group is more homogeneous. Park and Hastie (1987) showed that if participants first observed exemplars from a group followed by a description of its general characteristics, they perceived this group as more variable compared to when they observed that information in reversed order. This suggests that the prior about homogeneity affects how information is encoded. This finding implies an in-group heterogeneity effect under a (reasonable) assumption that people often learn descriptions of out-groups before interacting with some of their members (e.g. through stereotypes communicated by others in their environment) whereas they learn about natural in-groups by direct observations.

A third class of explanations notes that the self is part of the in-group (Park \& Judd, 1990). Since the self is often perceived as particularly differentiated and unique, this would contribute to an impression that the in-group is more heterogenous than the out-group.
A fourth class of explanations suggests that information about different groups is encoded and retrieved in different fashions. For example, Ostrom et al. (1993) found that information about in-group members is stored in categories related to individual information whereas the information about the out-group members is stored in categories related to stereotypical attributes. Therefore, when the information is recalled, the in-group tends to be associated with more individuating information compared to stereotype based homogeneous information about the out-group. In terms of recall, Park and Judd (1990) suggested that participants recall more extreme exemplars about in-groups than about outgroups. This suggests that memory search processes might differ across in-group and out-group.

These four classes of explanations emphasize features of information processing. By contrast, our explanation focuses properties of the sample of information on which the mind
operates. Because our explanation focuses on a different level than explanations that focus on information processing, it does not contradict these. Rather, it complements them. Our analyses and the experimental findings discussed above suggest that both types of mechanisms likely play a role in explaining why people see their in-groups as more heterogeneous than their out-groups.

The most closely related paper to ours is a paper by Linville et al. (1989). It analyzes an exemplar model that describes how information about groups is encoded, stored and recalled. The authors argue that higher familiarity with the in-group than with the out-group is the cause of the bias. Familiarity in this case is the number of exemplars of each group a person has encountered. They model the encoding, storage and recall of the information using a set of parameters and show that the strength of the bias depends on the information processing. They also consider the case of perfect memory (perfect encoding, no forgetting, and perfect recall). They find an asymmetry in expected variability estimates $\left(E\left(V_{\text {in }}\right)>E\left(V_{\text {out }}\right)\right)$. Their argument is similar to the logic of our model, but their analysis focuses on the asymmetry produced by reliance on the biased variance estimator we discussed above (see eq. 5). Our results differ, because they demonstrate that a systematic tendency to perceive the ingroup as more heterogeneous can emerge even when people use an unbiased estimator of variability. In some sense, our result is stronger because the asymmetry in expected variability implied by the biased variance estimator goes down very quickly with sample size. The asymmetry based on the skewness of the distribution of estimators of variability persists even as sample size becomes somewhat large (although it disappears for very large samples). Another difference is that our model focuses on sampling from the environment whereas this prior paper focused on sampling within the mind.

## Discussion

## Sensitivity Analysis

The magnitude of the in-group heterogeneity effect produced by our model depends on the model parameters.

The baseline probability of sampling the in-group ( $r$ in eq. 3) has a large effect on the magnitude of the bias. For $r$ values close to zero, the likelihood that the in-group is perceived as more variable becomes close to 0.5 (e.g., 0.51 for $r=0.05$ ), but when the advantage of the in-group is high ( $r=0.9$ ), the likelihood that the in-group is perceived as more variable can be as high as 0.64 (see Figure 5). The baseline probability of sampling from the in-group reflects the difficulty of obtaining information about the members of the outgroup. Its value depends on the empirical setting. For example, depending on the social group and socioeconomic structure of a country, the probability can range from small values (for fairly international and integrates societies) to very high values (in isolated homogeneous societies).

The other parameters, $b$ (the weight of the new attitude, see eq. 1) and $s$ (the slope parameter in the sampling rule, see

Figure 5: Model with unbiased variance estimator: Likelihood that the estimate of in-group variability is higher than the estimate of out-group variability $\left(P\left(V_{t, \text { in }}>V_{t, o u t}\right)\right.$ ) after 15 periods, as a function of the baseline probability of sampling the in-group $(r)$. Based on $10^{5}$ simulations with $b=0.5, s=3$.
eq. 3) have a positive effect on the strength of the in-group heterogeneity effect, but the effect is not strong.

A different but related model to ours would not assume an inherent sampling advantage for the in-group (take $r=0$ ). In this case, our model does not predict any in-group heterogeneity effect if the groups are equally attractive (i.e., $a_{t, i n}$ and $a_{t, \text { out }}$ are drawn from the same distribution). But suppose that the in-group is more attractive. It is possible to model this by assuming that the mean of the distribution of $a_{t, i n}$ is higher than the mean of the distribution of $a_{t, \text { out }}$ (for simplicity, we assume the variances are equal). In this case, the agent will obtain larger samples about the in-group than about the out-group and an in-group heterogeneity effect will emerge if $s$ and $b$ are high enough.

## In-Group Homogeneity

Several papers have documented instances of an in-group homogeneity effect that seems to contradict the dominant finding of an in-group heterogeneity effect (Simon \& Pettigrew, 1990; Rubin \& Badea, 2007). Our sampling mechanism can acomodate some of these findings.

An in-group homogeneity effect has been found when the feature under consideration is used as a basis for categorization. That is, the value of that feature defines whether the person is categorized into the in- or out-group (Rubin \& Badea, 2007). In this case, the true variability of the in-group might be smaller than the variability of the out-group on the focal feature. Our model can be adapted to this setting by relaxing the assumption that the true variances are the same for the two groups. We can assume instead $\sigma_{i n}^{2}<\sigma_{o u t}^{2}$. Our model implies that the variabilities of both groups will tend to be underestimated, but that the in-group variability will be un-
derestimated to a lower extent than the out-group variability. If the difference in the extent of underestimation is smaller than the difference in true variabilities, our model implies the emergence of an in-group homogeneity effect, in line with the true difference in variabilities. But if the difference in true variabilities is small, our model can lead to the emergence of an in-group heterogeneity effect.

Although most prior research conceptualized the 'ingroup' and the 'out-group' as specific groups, some papers have conceptualized the out-group as 'everyone but the ingroup' (e.g. Alves, Koch, \& Unkelbach, 2016). In this case, the true variability of the out-group is likely much larger than the true variability of the in-group. This setting is a special case of the setting discussed in the previous paragraph.

Finally, there is some evidence that when the in-group is a minority it tends to be judged as more homogeneous than the out-group (Simon \& Pettigrew, 1990). Our model can be adapted to this setting as well. Consider a situation where the in-group is smaller than the out-group and, furthermore, the number of in-group members is smaller than the number of periods. The agent will sample all the in-group members but the sample size will remain small (bounded by the number of members). To illustrate this, let us return to our example where the number of periods is $t=15$ and let us also assume that the sizes of the in-group and out-group are 5 and at least 10 , respectively. Then the sample size for the in-group will not exceed 5 whereas the size of the out-group members sample will be at least 10. This sample size asymmetry in favor of the out-group implies an in-group homogeneity effect.

## Conclusion

People frequently obtain larger samples of information about in-groups than about out-groups. Because estimators of variability tend to be more strongly right-skewed when samples are smaller, this implies that people will be likely to perceive in-groups as more variable than out-groups. In this paper, we showed that this in-group heterogeneity effect emerges even when people process information correctly - even if they are naive intuitive statisticians. Our theory complements existing explanations that proposed that information about in-group and out-group members was processed in different fashions.

#### Abstract

Previous research on the effects of probability and delay on decision-making has focused on examining each dimension separately, and hence little is known about when these dimensions are combined into a single choice option. Importantly, we know little about the psychological processes underlying choice behavior with rewards that are both delayed and probabilistic. Using a process-tracing experimental design, we monitored information acquisition patterns and processing strategies. We found that probability and delay are processed sequentially and evaluations of risky delayed prospects are dependent on the sequence of information acquisition. Among choice strategies, directly comparing the values of each dimension (i.e., dimension-wise processing) appears to be most favored by participants. Our results provide insights into the psychological plausibility of existing computational models and make suggestions for the development of a process model for risky intertemporal choice.

Keywords: Risky Intertemporal Choice; Process Tracing; Path Dependency; Sequential Processing; Decision Strategies

## Introduction

While research on risky choice and intertemporal choice have separately provided significant insights into the effects of probability and delay, decisions which involve both elements have received less scrutiny. Two unresolved questions are whether probability and delay are processed sequentially (and if yes, which dimension is considered first), and whether evaluation of risky delayed prospects is path dependent. Öncüler and Onay (2009) found that the order in which participants processed risky delayed prospects affected the final evaluations of these prospects. Using a process-tracing design, they found that amount-related (i.e., money) information was acquired first most often, followed by information about delay and then probability. Interestingly, when participants were required to process delay first, they provided higher evaluations of the same prospect compared to when they processed probability first, supporting the view of path dependency in risky intertemporal choice.

Despite being central to the characterization of choice behavior, no other studies have utilized process-tracing methods in the domain of risky intertemporal choice. Processtracing methods can provide insightful observations about the processes that take place before the actual decision, such as search, integration, and processing of available information (e.g., Reisen, Hoffrage, \& Mast, 2008). In risky intertemporal choice they can provide information about the order in which participants integrate amount, delay, and probability information as well as choice strategies adopted. Accordingly, process data can set the foundations for the development of com-
putational models and offer testable predictions regarding the choice process.

The experimental results relating to path dependency and sequential evaluation are not readily explained by traditional expected discounted utility models. These models focus on predicting choice outcomes (descriptive as-if models), hence arguably not accounting for the underlying psychological processes that are responsible for choice behavior, or simplifying strategies (e.g., heuristics) that people may employ in their decision-making. For instance, some expected utility models assume that people integrate probability and delay information into a common metric of psychological distance (e.g., Baucells \& Heukamp, 2012; Vanderveldt, Green, \& Myerson, 2015). However, Öncüler and Onay (2009) observed in their process data that this strategy was not favored (i.e., transitions between probability and delay information were the least frequent), thus rendering the "common psychological distance" account less likely among competing explanations.

The main purpose of the current work is to extend Öncüler and Onay's (2009) investigation from a pricing task, in which participants had to indicate the present certainty equivalent or pCE of a risky delayed prospect (the minimum amount of money that one is willing to accept instead of a delayed gamble) to a choice task in which participants choose between two risky delayed prospects. We then examine the predictions for path dependency and sequential evaluation in both tasks. This comparison allows us to ask whether choice is also characterized by path dependency and whether the characteristics of this dependency are similar between choice and pricing. The identification of such characteristics and processing strategies can also inform the development of models that rely on psychologically plausible accounts of choice behavior (i.e., psychological process models). Such models have become increasingly popular in many areas of decisionmaking (e.g., Koop \& Johnson, 2013), and often assume that decision-making follows simple rules of information processing, such as dimension-wise evaluation, sequential processing, and partial integration of available information (see e.g., Brandstätter, Gigerenzer, \& Hertwig, 2006).

## Method

## Participants

We tested a total of 63 undergraduate students ( 42 female; Age: $M=19.02, S D=1.56$ ) at the University of New South Wales who participated in return for course credit.

Figure 1: Schematic representation of the experimental design in the pricing (A) and choice (B) tasks. In the pricing task, participants could open as many boxes as they wanted before they gave the pCE of the delayed lottery. There was no limit about the time inspecting a box. The position of each dimension on the screen (Amount, Probability, and Delay) was randomized across trials. The association between colored boxes and dimensions remained invariant throughout each experimental session but was randomized across participants. The design was identical in the choice task and participants had to choose between two delayed lotteries. In this screenshot, the mouse opens an Amount box in the pricing task (i.e., \$120) and a Delay box of Option 1 in the choice task (i.e., 13 months).

## Task and design

We used a process-tracing design (i.e., similar to a MouseLab information board; see Payne, Bettman, \& Johnson, 1993) to monitor information acquisition strategies and processing steps. The experiment consisted of two parts: the first part was a pricing task, where participants had to indicate the pCE of 68 delayed lotteries (presented sequentially and in random order). For each delayed lottery, there were 3 colored boxes in the center of the screen, each containing the numerical value of each lottery's dimensions: Amount of money (in \$), Probability (in \%), and Delay (in months; see Figure 1A). However, this information was hidden and revealed only upon clicking on each corresponding box. When participants clicked on a box, it stayed active (i.e., showing its value) as long as the mouse cursor was within the borders of the box. When they moved the mouse out of the box, it returned to its default state (i.e., hidden). There was no limit in the amount of clicks or the time inspecting a box. In addition, participants could return to an already seen box if they wanted to. The position of each box was randomized across trials.

The second part was a choice task (Figure 1B), which always followed the pricing task and involved a choice between two delayed lotteries. Unbeknownst to the participants, the choice dyads were formed using pairs of prospects from the pricing task ( 34 choice pairs from 68 delayed lotteries). The procedure of acquiring information about each delayed lottery was identical to the pricing task.

## Procedure

Participants sat in front of a computer screen and were given instructions about the task (e.g., details about the information acquisition in the pricing task and what pCE represents). There was also a practice stage prior to the main task where
participants could familiarize themselves with the processtracing character of the task. For the pricing task, there was a box where they could type in their evaluation (Figure 1A). For the choice task, they were told that the task is exactly the same as before, with the only differences being that there was an extra option on the screen and they had to choose between the two, by clicking on the corresponding option label (Figure 1B).

## Results

## Pricing Task

All participants completed the experiment. We excluded one participant because they never acquired probability and delay-related information. Our initial objective was to explore the basic properties of information acquisition in the pricing task (see Figure 2): the frequency that each dimension was inspected, the frequency that each dimension was inspected first (i.e., at the beginning of each trial), last (i.e., before participants provided the pCE value), and intermediate (i.e., excluding first and last inspection items), and the mean inspection time for each dimension. For the analysis of frequency data, we used a linear multilevel model with dimension as fixed-effect and random intercepts for each participant. We applied a square root transformation for the frequency data. ${ }^{1}$ As Figure 2A suggests, participants acquired more amount-related information, followed by probability and delay, and this pattern was present in all categories of interest (All: $\chi^{2}(2)=269.07, p<.001$; First: $\chi^{2}(2)=$ 60.67, $p<.001$; Intermediate: $\chi^{2}(2)=77.69, p<.001$; Last:

[^125]$\left.\chi^{2}(2)=96.18, p<.001\right) .{ }^{2}$ The same pattern is observed in the mean inspection time (Figure 2B): participants spent more time looking at amount information, followed by probability and delay $\left(\chi^{2}(2)=67.20, p<.001\right.$; significant differences between each dimension). Also, the relative preference for inspecting each dimension does not seem to change over time as can be seen in Figure 2C: block $\times$ dimension interaction, $\chi^{2}(6)=1.19, p=0.98$.

Figure 2: Graphical representation of information acquisition in the pricing task: A) Relative frequencies of opened boxes of each dimension (All: Overall; First \& Last: First and Last boxes opened in a trial; Intermediate: Excluding First and Last boxes). B) Mean inspection time for each dimension. C) Pattern of acquisition items across blocks of trials (17 trials/lotteries each).

The next step in our analysis was to inspect transitions between consecutive ( $n \leftrightarrow n+1$ ) information items. This analysis can provide us with information about the sequential nature of risky intertemporal choice. For example, based on the adjacency principle ("information used in temporal proximity should be acquired in close proximity"; see Johnson, Schulte-Mecklenbeck, \& Willemsen, 2008, p. 264), if the Amount $\leftrightarrow$ Probability transition occurs more often and temporally precedes the Amount $\leftrightarrow$ Delay transition, it means that participants pay more attention to the amount and probability aspects of the prospect and probability discounting (or processing of probability) occurs prior to delay discounting (or processing of delay). Table 1 suggests that the Amount $\leftrightarrow$ Probability transition not only occurs more often than any other transition (All column), but it seems to precede any other transition (First column), and be considered more often before the final evaluation of the lottery (Last column). The relatively low proportion of Delay $\leftrightarrow$ Probability transitions

[^126]suggests that participants are not attempting to create a common metric of psychological distance by integrating these two dimensions (cf. Öncüler \& Onay, 2009).

Table 1: Transitions between dimensions in Experiment 1. The $\leftrightarrow$ symbol indicates all transitions from one dimension to the other.

| Transition | All: $N$ | All: \% | First: \% | Last: \% |
| :--- | :---: | :---: | :---: | :---: |
| Amount $\leftrightarrow$ Probability | 8,834 | 0.46 | 0.47 | 0.50 |
| Delay $\leftrightarrow$ Amount | 5,117 | 0.27 | 0.28 | 0.27 |
| Delay $\leftrightarrow$ Probability | 4,335 | 0.23 | 0.22 | 0.19 |

Note: Relative frequencies do not add up to 1 because transitions between the same dimension (e.g., Amount $\leftrightarrow$ Amount) are not included in the table.

We then explored the concept of path dependency as suggested by Öncüler and Onay (2009) by comparing the final evaluations of lotteries when Amount $\leftrightarrow$ Probability or Amount $\leftrightarrow$ Delay was the first occurring transition. Öncüler and Onay found that when participants followed the Amount $\leftrightarrow$ Delay path they gave higher evaluations of the same prospect compared to the Amount $\leftrightarrow$ Probability path. Our results replicate this effect: when examination of delay preceded that of probability, participants gave higher evaluations for the majority of trials ( $70 \%$ ). However, it is not clear how subsequent transitions in our experiment might have affected the final evaluation of the prospect. We try to address this issue along with the issue of imbalance in transitions (which emerges due to the higher frequency of Amount $\leftrightarrow$ Probability transitions) in a following experiment.

## Choice Task

Figure 3 presents information acquisition for each dimension in the choice task, aggregated across the two choice options. The pattern of results looks similar to the pricing task with a few exceptions: First, looking at the overall trend of dimension inspection, there is no difference between amount and probability (Figure 3A; $b=-0.01, t=-0.84, p=.40$ ), but both differ with respect to delay (pairwise contrasts, $p<$ .001). A similar pattern is observed in the intermediate inspection items (no difference between amount and probability, $b=0.07, t=0.34, p=.73$, but they both differ from delay, $p<.001$ ). This presents a difference between the two methods of preference elicitation, indicating that in a choice setting amount and probability may have the same degree of influence on choice. As in the pricing task, the first dimension considered followed the amount $>$ probability $>$ delay scheme, $\chi^{2}(2)=37.23, p<.001$, but there was no difference between dimensions regarding the last information item, $\chi^{2}(2)=2.68, p=.26$. The mean time spent at each dimension (Figure 3B) was not different between amount and probability ( $p=.95$ ), but both were higher than delay ( $p<.001$ ). Regarding selection of each dimension across time, Figure 3C suggests that it does not change between the two halves of the choice task, $\chi^{2}(2)=2.67, p<.001$.

Figure 3: Graphical representation of information acquisition in the choice task, aggregated across the two options: A) Relative frequencies of opened boxes of each dimension (All: Overall; First \& Last: First and Last boxes opened in a trial; Intermediate: Excluding first and last). B) Mean inspection time for each dimension. C) Pattern of acquisition items across blocks of trials ( 17 trials/choices each).

Next, we examined transitions between consecutive information items ( $n \leftrightarrow n+1$ ) which are informative of the strategies that participants use. Assuming a $2 \times 3$ information board/grid where rows represent choice alternatives and columns dimensions (as in Figure 1B), transitions between items can be categorized as dimension-wise (or intradimensional: when the transition examines the same dimension between the two choice options, e.g., Amount in Option $1 \leftrightarrow$ Amount in Option 2), alternative-wise (or interdimensional: when the transition moves between different dimensions of the same option, e.g., Amount in Option $1 \leftrightarrow$ Delay in Option 1), diagonal (i.e., when the transition moves from one dimension of one option to a different dimension of the other option, e.g., Probability in Option $2 \leftrightarrow$ Delay in Option 1), and same (i.e., two consecutive inspections of the same dimension in the same option, e.g., Probability in Option $1 \leftrightarrow$ Probability in Option 1). Table 2 presents the frequency of each of the categories of transitions in the choice task: a first inspection of all transitions (All column) suggests that participants equally combined dimension and alternative-wise strategies. One of the most commonly used strategy indices (SI; Payne, 1976) suggests that participants equally used both strategies to make decisions. The SI is a ratio of the difference between alternative and dimension-wise transitions and it is defined as $\mathrm{SI}=\left(r_{a}-r_{d}\right) /\left(r_{a}+r_{d}\right)$, where $r_{a}$ is the total number of alternative-wise transitions and $r_{d}$ is the total number of dimension-wise transitions. It ranges between -1 to +1 , with negative numbers suggesting more dimension-wise processing and positive numbers suggesting more alternativewise processing. For our data, the $S I$ equaled 0.06 , indicating
roughly equal use of both strategies.
Table 2: Categories of transitions in the choice task. Arrows indicate the direction of the transition within the information board (see Figure 1B).

| Transition |  | All: $N$ | All: $\%$ | First: $\%$ | Last: $\%$ |
| :--- | :---: | :---: | :---: | :---: | :---: |
| Dimension | $\uparrow \downarrow$ | 7,115 | 0.39 | 0.58 | 0.54 |
| Alternative | $\rightleftarrows$ | 8,072 | 0.44 | 0.39 | 0.39 |
| Diagonal | $\nearrow$ | 3,117 | 0.17 | 0 | 0.07 |
| Same | - | 146 | 0.01 | 0.02 | 0.01 |

However, Böckenholt and Hynan (1994) argued that the SI is a biased measure of strategy use when there is a different number of alternatives and dimensions. Specifically, if the number of dimensions is larger than the number of the alternatives ${ }^{3}$, then a positive SI is to be expected, indicating more alternative-wise processing. Böckenholt and Hynan developed an index (strategy measure; SM) which takes into account all possible transitions (e.g., including Diagonal and Same in Table 2):

$$
\begin{equation*}
S M=\frac{\sqrt{N}\left[\left(\frac{A D}{N}\right)\left(r_{a}-r_{d}\right)-(D-A)\right]}{\sqrt{A^{2}(D-1)+D^{2}(A-1)}} \tag{1}
\end{equation*}
$$

where $N$ is the total number of all types of transitions, $A$ is the number of alternatives, $D$ is the number of dimensions, and $r_{a}$ and $r_{d}$ denote frequency for alternative-wise and dimensionwise transitions, respectively. As with the SI, negative values of the SM indicate more dimension-wise processing, as can be seen in Figure 4. Specifically, dimension-wise processing becomes more prevalent as time progresses, as indicated by the linear decrease of the $S M$ value.

Figure 4: Strategy measure ( $S M$ ) averaged across participants for each trial/choice of the task.

## Experiment 1B: Constrained sequential search

Method The purpose of this experiment was to examine in detail the effect of path dependency observed in the pricing task. Participants $\left(N=40, M_{\text {age }}=19.08\right)$ provided the pCE of risky delayed prospects sequentially (i.e., in two stages;

[^127]see also upper panel in Figure 6): in the first stage, they could see either probability or delay (amount was always visible on the screen), and give the present value of the prospect (if delay was presented first), or the certainty equivalent value (if probability was presented first). The value they provided in the first stage appeared in the second stage along with the numerical value of the unseen dimension, and participants had to provide a second and final value for the prospect. We manipulated (three experimental parts) the way that participants acquired probability and delay-related information: a) a free search part where participants could select to see either probability or delay in the first stage, and b) two constrained search parts where either probability or delay was presented to participants first. Hence, participants were presented with the same risky delayed prospect three times.
Results We first examined search patterns in the free search part of the experiment: we found that in $68.50 \%$ of all trials, participants chose to see probability first, replicating the effect we observed in the pricing and choice tasks, that is a preference for inspecting and integrating probability information before delay information. We also examined search patterns as a function of the amount offered (amount was always visible on the screen). Figure 5 presents an interesting pattern: participants' tendency to inspect the probability dimension first increases as amount increases. Despite the overall preference for acquiring probability first (even in the lowest amount category, [ 50,175 ), it is $64.38 \%$ ) the difference between the lowest and highest amount categories is about $10 \%$ ( $74.16 \%$ in the last category).

Figure 5: Proportion of trials in which participants chose to see probability first as a function of Amount (in \$; binned in five equal categories).

Regarding path dependency, we examined the final pCEs in the constrained search parts of the task. Figure 6 shows the proportion of participants that gave a higher final evaluation when they were constrained to inspect probability first (as compared to delay first) as a function of the numerical values of each gamble's probability (lower panel A) and delay (lower panel B). For example, the leftmost data-point in Figure 6A indicates that for the same risky delayed prospect (which has a probability of $2 \%$ ) about $40 \%$ of all participants gave a higher final pCE when they were presented with probability information first than when they were presented
with delay information first (see also the table in the upper panel). Even though Figure 6 essentially ignores interactions between each dimension and collapses across all amount, probability, and delay values, it shows some interesting patterns. First, as the probability in a prospect increases, the proportion of participants who gave a higher evaluation when they were presented with probability first increases, as shown by a multilevel logit regression with probability as fixed effect and participant-specific random intercepts (standardized $b=0.40, z=4.44, p<.001)$. Second, there is a similar trend in the delay panel (as temporal distance increases, the proportion of participants that gave a higher evaluation of the same gamble when they were presented with probability first increases) but it is not as pronounced as in the probability panel (standardized $b=0.24, z=2.70, p=.007$ ). Interestingly, this pattern seems to apply to small values of probability and delay, as when we constrain our analysis in the upper half of both scales (i.e., $50 \%$ to $90 \%$ for probability; 16 to 24 months for delay) the effect disappears (both multilevel logit regressions, $p>.05$ ). Overall, our results replicate the path dependency patterns in Öncüler and Onay (2009) and suggest that path dependency is not stable, but is moderated by the numerical values of each dimension.

|  | Probability First |  |  |  | Delay First |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| Stage 1 | \$450 | $2 \% \rightarrow$ | $X_{P F}$ |  | \$450 | $21 \mathrm{M} \rightarrow$ | $X_{D F}$ |
| Stage 2 | $X_{P F}$ | $21 \mathrm{M} \rightarrow$ | $Y_{P F}$ | > | $X_{D F}$ | $2 \% \rightarrow$ | $Y_{D F}$ |

Figure 6: Upper panel: Representation of the task (M: Months). Lower panel: Proportion of participants who gave a higher final pCE (i.e., $Y_{P F}>Y_{D F}$ ) for the same gamble when they were presented with information about probability first across Probability (A) and Delay levels (B).

## Discussion

We set out to uncover the strategies and information acquisition patterns that people use when they evaluate and make decisions about risky delayed prospects. Using three differ-
ent process-tracing tasks to elicit preferences, we observed systematic patterns relating to search, integration, processing, and strategy-use. First, participants acquired more amountrelated information, followed by probability and delay in the pricing task, whereas in the choice task amount and probability appeared to have the same degree of influence on determining choice. Our results are in accordance with recent studies in intertemporal risky choice which found that probability might play a more important role than delay (e.g., Konstantinidis, van Ravenzwaaij, Güney, \& Newell, 2017; Vanderveldt et al., 2015), but are at odds with Öncüler and Onay (2009) who found that participants preferred to acquire delay information before and more frequently than probability information.

Second, Amount $\leftrightarrow$ Probability transitions were more frequent and preceded any other transition in the pricing task. This pattern of results suggests that evaluation of risky delayed prospects is subject to sequential processing. Also, the integration of probability and delay into a common psychological distance measure seems less likely as the Probability $\leftrightarrow$ Delay transition occurs less frequently and temporally follows other types of transitions.

Third, regarding path dependency and sequential processing, our constrained search experiment revealed that the final evaluation of risky delayed prospects is not only dependent on the path taken (i.e., integrating probability information before delay information, and vice-versa), but on the numerical values of each dimension. For example, when participants were first presented with low probability values, they largely discounted the final value of the same prospect as compared to when they saw delay-related information first about the same prospect. We found that the effect of path dependency observed in Öncüler and Onay (2009), that is, the Delay $\rightarrow$ Probability path generating higher values than the Probability $\rightarrow$ Delay path, is only observed with small probabilities.

Fourth, examination of transitions in the choice task reveals that participants employ dimension-wise strategies more frequently than alternative-wise strategies to make decisions in risky intertemporal choice settings. Even though there was no reliable difference between dimension and alternative-wise processing regarding the total number of transitions, taking into account different measures of strategy use (e.g., search indices, overall, first and last inspection items, and transitions between items), we found that dimension-wise processing may be more prevalent among participants, supporting recent studies which found that dimension-wise models in the domains of risky choice and intertemporal choice outperform their alternative-wise counterparts (e.g., Dai \& Busemeyer, 2014).

Lastly, even though individual information acquisition patterns might reflect noisy and idiosyncratic use of strategies, we identified systematic processing strategies and information acquisition patterns that a process model (or any other type of model) in the field of risky intertemporal choice should take into account. Our results also provide testable
grounds for psychological assumptions in models of risky intertemporal choice: we found little evidence that participants treat probability and delay as representing a common factor of psychological distance, or that probability can be translated into delay, and vice-versa.

## Acknowledgments

This research was supported by an Australian Research Council Discovery Project Grant (DP140101145). We thank Emma Williams and Dominic Tran for their help in collecting the data, and Ashley Luckman for helpful discussions.

#### Abstract

A growing body of evidence supports the hypothesis that humans infer future states of perceived physical situations by propagating noisy representations forward in time using rational (approximate) physics. In the present study, we examine whether humans are able to predict (1) the resting geometry of sand pouring from a funnel and (2) the dynamics of three substances-liquid, sand, and rigid balls-flowing past obstacles into two basins. Participants' judgments in each experiment are consistent with simulation results from the intuitive substance engine (ISE) model, which employs a Material Point Method (MPM) simulator with noisy inputs. The ISE outperforms ground-truth physical models in each situation, as well as two data-driven models. The results reported herein expand on previous work proposing human use of mental simulation in physical reasoning and demonstrate human proficiency in predicting the dynamics of sand, a substance that is less common in daily life than liquid or rigid objects.

Keywords: Intuitive physics; mental simulation; substance representation; prediction

## Introduction

Consider KerPlunk, a children's game in which marbles are suspended in the air by a lattice of straws within a cylindrical tube. The goal of the game is for each player to take turns removing straws while minimizing the number of marbles that fall through the lattice. The task requires players to reason about the interaction between rigid bodies and obstacles in 3D space. But what if the marbles were replaced by balls of liquid or sand? Could humans predict how those substances would move? Would those predictions agree with a generative model based on ground-truth, Newtonian physics?

Recent computational evidence has demonstrated that human predictions do agree with Newtonian physics, given noisy perception and prior beliefs about spatially represented variables: i.e., the noisy Newton hypothesis (Bates, Yildirim, Tenenbaum, \& Battaglia, 2015; Battaglia, Hamrick, \& Tenenbaum, 2013; Gerstenberg, Goodman, Lagnado, \& Tenenbaum, 2015; Hamrick, Battaglia, Griffiths, \& Tenenbaum, 2016; Kubricht et al., 2016; Sanborn, 2014; Sanborn, Mansinghka, \& Griffiths, 2013; K. Smith, Battaglia, \& Vul, 2013). The hypothesis suggests that humans rationally infer the values of physical variables and utilize normative conservation principles (approximately) to make predictions about future scene states. Computationally, this is achieved by sampling the initial locations, motions from noisy sensory input, and sampling physical attributes in a physical scene, propagating these variables forward in time according to approximated physical principles, and aggregating queries on the final scene states to form predicted response distributions.

Bates et al. (2015) extended the noisy Newton framework from block tower judgments (Battaglia et al., 2013) to liquid dynamics using an intuitive fluid engine (IFE). In their IFE, ground-truth physics was approximated using smoothed particle hydrodynamics (SPH (Monaghan, 1992), a particlebased computational method for simulating non-solid dynamics. Their model predictions matched human judgments about future fluid states and outperformed alternative models that did not employ probabilistic simulation or account for physical uncertainty. Furthermore, the authors found that their participants' predictions were sensitive to latent fluid attributes (stickiness and viscosity), suggesting that humans have rich knowledge about the intrinsic properties of liquid.

The present study argues for the same general class of model as Bates et al.'s (2015) IFE and extends their work by examining (1) whether human predictions about future states of multiple substances (i.e., rigid balls, liquid, and sand) differ, and (2) whether those differences can be consistently modeled using approximate, probabilistic simulation based on a hybrid particle/grid simulator adapted from previous work (Kubricht et al., 2016). Although granular materials (e.g., sand) are encountered in everyday life, they are far less common than liquid; can humans accurately predict how sand will interact with obstacles and support surfaces? We present two experiments exploring the human capacity to predict the dynamics of substances varying in familiarity and physical properties, examining how human judgments and model predictions vary for different substances. Experiment 1 examines human predictions about the resting composition of sand after pouring from a funnel. In Experiment 2, participants make predictions about the flow of liquid, sand, and rigid balls past obstacles using a design similar to Bates et al.'s (2015) study.

## Computational Models

## MPM Physical Simulator

The Material Point Method (MPM) (Sulsky, Zhou, \& Schreyer, 1995) is commonly used in computer graphics to simulate the behavior of solids and fluids. The MPM has produced physically accurate and visually realistic simulations of the dynamics of liquid (Jiang, Schroeder, Selle, Teran, \& Stomakhin, 2015) and sand (Klár et al., 2016), in addition to general continuum materials such as stiff elastic objects (Jiang, Schroeder, Teran, Stomakhin, \& Selle, 2016).

The Appendix presents a mathematical overview of our MPM simulator, which provides a unified, particle-based simulation framework that handles rigid balls, liquid, and
sand with essentially the same numerical algorithm, albeit with appropriately differing material parameters. The MPM method is physically accurate, numerically stable, and computationally efficient, enabling us to synthesize a large set of stimuli in a short amount of time by simply varying material parameters and the locations of the initial objects and colliding geometries. Running all the simulations in the same framework for the purposes of the present study also enables fair comparisons among the three types of substances, since we avoid potential inconsistencies in the numerical accuracies of multiple simulators specialized to particular materials.

## Intuitive Substance Engine

Although the MPM simulator provides accurate and stable kinematics and dynamics for liquid, sand, and rigid balls using a unified framework, this high-precision, deterministic process does not account for the variability of human judgments in various intuitive physics tasks. Inspired by previous implementations of the noisy Newton framework (e.g., Bates et al., 2015; Battaglia et al., 2013), we combined our MPM simulator with noisy inputs, yielding an Intuitive Substance Engine (ISE) that accounts for uncertainty in human perception and reasoning in physical situations involving the three substances examined in this study. Details on how noisy perceptual inputs are defined and sampled are provided in the Model Results section of each experiment.

It is important to note that our ISE (employing MPM simulation) is roughly equivalent to Bates et al.'s (2015) IFE (employing SPH simulation) in that both models apply the noisy Newton framework to substance dynamics. Indeed, SPH is a viable method for simulating the dynamics of both granular materials and liquids, although MPM provides a more efficient and accurate means of doing so. We do not envision that the predictions of the two methods would differ substantially from one another when applied to a given set of stimuli.

## Data-Driven Models

Two data-driven models based on statistical learning methods were constructed as competing models-the generalized linear model (GLM) (McCullagh, 1984) and Extreme Gradient Boosting (XGBoost) (Chen \& Guestrin, 2016). GLM is a classic machine learning method, commonly expressed by $\mathbf{Y}=\mathbf{X B}+\mathbf{U}$, where $\mathbf{X}$ is the feature input matrix, $\mathbf{B}$ is the parameter matrix (learned using a training dataset), and $\mathbf{U}$ is the error between the ground truth matrix $\mathbf{Y}$ and prediction $\mathbf{X B}$.

XGBoost is a recently-published machine learning method which has been utilized by multiple research teams to achieve outstanding performance in several Kaggle competitions. Essentially, it is a type of tree ensemble model: i.e., a set of classification and regression trees (CART). Formally, $\hat{y}_{i}=$ $\sum_{k=1}^{K} f_{k}\left(x_{i}\right)$, where $K$ is the number of trees, $f_{k}$ is a function in the functional space $\mathbf{F}$ comprising the set of all possible CARTS. The objective function is defined as $R(\theta)=$ $\sum_{i=1}^{n} l\left(y_{i}, \hat{y}_{i}\right)+\sum_{k=1}^{K} \Omega\left(f_{k}\right)$, where $\theta$ includes the model parameters to be learned during training, $l$ is the loss function, which measures the cost between ground truth $y_{i}$ and prediction $\hat{y}_{i}$, and $\sum_{k=1}^{K} \Omega\left(f_{k}\right)$ is a regularization term that prevents the model from over-fitting the training data.

Figure 1: Intermediate frames from the demonstration video in Experiment 1 from the (A) zoomed-out and (B) zoomed-in perspective. (C) Sand pile choices in Experiment 1's judgment task.

## Experiment 1

The first experiment was designed to determine whether humans are able to predict the resting geometry of sand after it is poured from a funnel onto a surface, and whether dynamic visualizations of the pouring behavior facilitate mental simulation of sand-surface interactions.

## Participants

A total of 108 undergraduate students ( 81 females), of mean age $=20.2$ years, were recruited from the University of California, Los Angeles (UCLA), Department of Psychology subject pool and were compensated with course credit.

## Materials and Procedure

Participants first viewed a demonstration video of sand falling from a funnel suspended 10 cm above a level surface. The pouring event was viewed three times from a zoomed-out perspective (Fig. 1A) and then a zoomed-in perspective (Fig. 1B). The duration of the video was 29 sec. After viewing the demonstration video, participants were presented with a sand-filled funnel suspended $1 / 2,1,2$, and 4 cm above the surface in a randomized order.

Forty-three participants were assigned to the Static Condition and viewed a static image (zoomed-out) in which the funnel was positioned at a particular height. Sixty-five were assigned to the Dynamic Condition and viewed a video (zoomed in and out; looped three times; 35 sec duration) of sand pouring from a funnel that was positioned at different heights above the surface. In the Dynamic Condition, the region of the surface where the sand fell was occluded by a gray rectangle.

After viewing each situation, participants were asked to indicate which of four sand piles would result from the sand pouring from the funnel at the indicated height (Fig. 1C). For each trial, the stimulus images (for the Static Condition) and final video frames (Dynamic Condition) remained on the screen until a response was made. The pile choices were shown from the zoomed-in perspective and represented the

Figure 2: Model prediction results compared to human judgments. (Upper) Static Condition. (Lower) Dynamic Condition. Each bar, 1, 2, 3, and 4, corresponds to testing trials with funnel height $1 / 2,1,2$, and 4 cm , respectively.
ground-truth resting geometries resulting from each situation: i.e., Piles $1,2,3$, and 4 correspond with the pile resulting from funnels suspended $1 / 2,1,2$, and 4 cm above the surface, respectively. The experiment consisted of 4 trials. The stimulus videos can be viewed at https://vimeo.com/216585992.

## Human Results

At each funnel height, the proportion of participants choosing each sand pile did not differ between the Dynamic and Static Conditions: $\chi^{2}(3)=2.21,2.34,2.41$, and 1.13 for funnel heights of $1 / 2,1,2$, and 4 cm , respectively. These results suggest that dynamic visualizations of sand pouring from the funnel in each situation did not alter participants' judgments about the sand's resting geometry. However, the participants' pile choices did vary across different heights $\left(\chi^{2}(9)\right.$ $=176.54$ ), indicating that funnel height influenced their predictions on the resting geometry of falling sand.

As shown in Fig. 2, participants' pile choices shifted toward higher-numbered, flatter piles as funnel height increased. These results indicate that participants' predictions were sensitive to funnel height, but inconsistent with groundtruth resting states. In the next section, predictions from the three computational models (ISE, GLM, and XGBoost) are compared to human performance to determine whether the noisy Newton framework can account for participants' deviations from ground-truth judgments.

## Model Results

ISE Predictions: The input variables for our ISE in Experiment 1 were funnel height (i.e., initial sand height) with perceptual uncertainty and sand friction angle with mental simulation uncertainty. Given the ground-truth values of initial funnel height and friction angle $\left(H_{i T}, \theta_{i T}\right), N=10,000$ noisy samples $\left\{\left(H_{i}, \theta_{i}\right), \quad i=1, \ldots, N\right\}$ were generated and passed to our MPM simulator, which returned the final height of the
sand pile for each sample. Instead of choosing from 4 piles (i.e., the task presented to the participants), the MPM simulator compares the estimated height of the final sand pile, formally $D\left(H_{i}, \theta_{i}\right)=H_{p} \in \mathbb{R}>0$, with the heights of the 4 pile options given to human participants. The pile option with the minimum height difference was chosen as the predicted judgment for each sample. Finally, by aggregating predictions across the 10,000 samples, our ISE outputs a predicted response distribution for each trial.

To model physical uncertainty in participants' mental simulations, our ISE sampled funnel heights and friction angles from noisy distributions. Gaussian noise ( 0 mean, $\sigma_{H}^{2}$ variance) was added to the ground-truth funnel height in each situation. Gaussian noise was also added to the ground-truth friction angle $\theta_{i T}$, but in logarithmic space (see Sanborn et al., 2013): $\theta_{i}=f^{-1}\left(f\left(\theta_{i T}\right)+\varepsilon\right)$, where $\theta_{i T}$ is the ground truth value of the initial sand height, $f\left(\theta_{i T}\right)=\log \left(\omega \cdot \theta_{i T}+k\right)$, and $\varepsilon$ represents Gaussian noise with 0 mean and $\sigma_{\varepsilon}^{2}$ variance. The results reported herein used the following model parameters: $\sigma_{H}=0.12 H_{i T}, \sigma_{\varepsilon}=0.6, \omega=0.8$ and $k=1.5$.
Data-Driven Predictions: To predict human judgments, both GLM and XGBoost were tested on the $i$ th pile ( $i=$ $1,2,3,4)$ and trained on the remaining three piles. During training, 10,000 samples were drawn for each remaining pile ( 30,000 samples) and passed to our MPM simulator. Samples were generated using the sampling method described in the previous section. After training on the 30,000 samples, both data-driven models were tested on another 10,000 samples generated from noisy input based on the configuration of pile $i$. The final distribution was formed by aggregating the predictions across the 10,000 samples.

Table 1: Root-mean-square deviation (RMSD) values for the ground-truth (GT), ISE, GLM, and XGBoost models for Experiments 1 and 2. Lower values of RMSD indicate better model fits.

|  | GT | ISE | XGBoost | GLM |
| :--- | :---: | :---: | :---: | :---: |
| Experiment 1 (Static) | 0.458 | 0.101 | 0.267 | 0.171 |
| Experiment 1 (Dynamic) | 0.445 | 0.104 | 0.237 | 0.148 |
| Experiment 2 (Liquid) | 0.145 | 0.081 | 1.382 | 0.077 |
| Experiment 2 (Sand) | 0.170 | 0.080 | 1.422 | 0.120 |
| Experiment 2 (Balls) | 0.186 | 0.102 | 2.067 | 0.191 |

Model Comparisons: Fig. 2 depicts the predictions of the ISE, XGBoost, and GLM models compared to human judgments. All four models achieved high correlations with human performance (Static: $r(12)=0.91,0.84$, and 0.27 ; Dynamic: $r(12)=0.88,0.88$, and 0.30 for ISE, XGBoost, and GLM, respectively). Human performance was much less correlated with ground-truth predictions (Static: $r(12)=0.17$; Dynamic: $r(12)=0.19$ ). The ISE model predictions were more correlated with the human data than the competing datadriven model predictions in the Static condition but were only slightly more correlated than XGBoost predictions in the Dynamic condition. Hence, this paper uses The root-mean-square deviation (RMSD) between human responses and model results to compare the model fits. We found that RMSD between human responses and ISE predictions for the 4 judgment trials was less than that between ground-truth pre-
dictions in both Static and Dynamic Conditions (see Table 1). We also examined modeling performance using the Bayesian information criterion (BIC) to account for the different number of free parameters in each model. We found that the ISE provides a better fit to the human data than the groundtruth and data-driven models in both conditions. For groundtruth, ISE, XGBoost, and GLM models, Static BIC $=-25.0$, $-62.3,-31.2,-45.4$, and Dynamic BIC $=-25.9,-61.3$, $-35.0,-50.0$, respectively. The model with the lowest BIC value is preferred.

Although XGBoost captures most of the trends in the human judgments, it appears to over-fit the data in some cases. In the Static Condition, XGBoost's predicted response proportion for Pile 1 in the Trial $1(1 / 2 \mathrm{~cm}$ funnel height) is greater than the proportion in Trial $2(1 \mathrm{~cm}$ funnel height), which is consistent with human judgments. In the Dynamic Condition, however, XGBoost's predicted response proportion for Pile 1 is greater in Trial 1 than in Trial 2, which is inconsistent with trends in human performance. Alternatively, GLM showed very poor performance, predicting an increasing probability of Pile 1 choices for larger funnel heights. This trend is in the opposite direction of that observed in the human data, most likely due to the small number of training trials used to make each prediction.

## Experiment 2

Our results from the first experiment indicate that humans are able to predict the resting geometry of sand piles, even though they may not have very rich experience interacting with sand in daily-life. The second experiment was conducted to determine 1) whether humans can reason about complex interactions between sand and rigid obstacles and 2) whether their predictions about the resting state of sand in novel situations differ from predictions about other substances, such as liquid and rigid balls.

## Participants

A total of 90 undergraduate students ( 66 females), mean age 20.9, were recruited from the UCLA Department of Psychology subject pool, and were compensated with course credit.

## Materials and Procedure

The procedure in Experiment 2 was similar to the design in Bates et al.'s (2015) experiment: i.e., participants viewed a volume of a substance suspended in the air above obstacles and were asked to predict the proportion that would fall into two basins separated by a vertical divider below (Fig. 3). The present experiment differed from previous work in that participants reasoned about the resting state of one of three different substances: liquid, sand, or sets of rigid balls. Also, whereas the previous study used polygonal obstacles, those in the present study were circles varying in size. Depth information was also not present in the rendered situations. The stimulus videos can be viewed at https://vimeo.com/216585992.

Situations were generated by sampling between 2 and 5 obstacle locations from a uniform distribution bounded by the width and height of the chamber. The diameter, $d$, of each obstacle was sampled from a uniform distribution bounded by [ $0.15,0.85]$ relative to the randomly-generated center points.

Figure 3: Initial (top) and final (bottom) state of liquid (left), sand (middle), and a set of rigid balls (right) for a testing trial in Experiment 2 with 5 obstacles. The percentages indicate the amount of each substance that fell into the left and right basins. Only the initial state of each substance was shown in the testing trials.

The center points were generated by uniformly sampling the entire space. If the generated obstacles were placed outside the boundary, the configuration was rejected and re-sampled. Our MPM simulator was used to determine the ground-truth proportion of each substance in the left and right basins for each of the generated situations. For each substance, forty testing trials ( 10 trials with $2,3,4$, and 5 obstacles) were chosen from the generated set such that the ground-truth proportion of substance in the left basin was approximately uniform across trials. The testing trials were the same for each substance.

Participants were randomly assigned to either the liquid, sand, or rigid balls condition. Thirty participants were assigned to each condition in a between-subjects experimental design. Prior to the testing trials, participants completed five practice trials with two obstacles in each situation in a randomized order. After answering 1) which basin the majority of the substance would fall into and 2) the expected proportion that would fall into the indicated basin, participants viewed a video (13 second duration) of the situation unfolding and were told the resulting proportion in the ground-truth simulation. After completing the practice trials, participants completed 40 testing trials in a randomized order by answering the same two questions in each trial. No feedback was given following the completion of each testing trial.

## Human Results

Participants' predicted proportions in the testing trials were strongly correlated with ground-truth predictions in the liquid, sand, and rigid balls conditions $(r(38)=0.86,0.82$, and $0.88 ;$ RMSD $=0.145,0.170,0.186$, respectively). The deviation for each trial was calculated by subtracting the groundtruth proportion from each participant's proportion response. The deviation differed significantly between the three substance conditions ( $F(2)=3.64, p=0.03$ ), indicating that the difference between human predictions and the groundtruth status varied according to the substance type. To determine whether participants' response proportions differed between substances, a random factor ANOVA was conducted for a chosen set of trials. The chosen set excluded those trials where the majority of each substance fell into the same basin

Figure 4: Model prediction results compared to human predictions. From left to right: Ground-truth (GT), ISE, GLM, and XGBoost.
(left or right) according to the ground-truth simulation. We found that the response proportions showed significant differences depending on substance type $(F(2)=8.43, p<0.01$ ). The next section examines whether an ISE and two datadriven models can capture differences in human performance between the three substances.

## Model Results

ISE Predictions: In Experiment 2, the observable input variables for our ISE for each substance were 1) the initial, horizontal position of the substance, and 2 ) the positions of the circular obstacles in each situation. The latent substance attributes accepted by the engine were viscosity, friction angle, and restitution coefficient for liquid, sand, and the rigid balls, respectively. Gaussian noise was added to the substance's (ground-truth) horizontal position ( 0 mean, 0.35 variance) and the obstacles' (ground-truth) positions in 2D space ( 0 mean, 0.4 variance). Logarithmic Gaussian noise was added to each substance's ground-truth attribute value via the logarithmic transformation specified in Experiment 1. The results reported here utilized the following model parameters for all three substances: $\sigma_{\varepsilon}=0.5, \omega=0.8, k=1.2$. Two thousand samples ( 40 situations $\times 50$ noisy samples) were used for each substance.
Data-Driven Predictions: Similar to Experiment 1, both GLM and XGBoost were tested. The training data were randomly generated situations with basin proportions calculated using resting state output from our MPM simulator. Input features were the collection of both the observable input variables and latent substance attributes used in the ISE prediction. In total, 6000 samples were used for training.
Model Comparisons: Fig. 4 depicts the comparison between human and model basin predictions from the groundtruth (GT), ISE, GLM, and XGBoost models, and Table 1 depicts the root-mean-square deviation (RMSD) of each model's predictions from human ones. The human data were highly consistent with ISE predictions $(r(38)=0.93,0.93$, 0.93 ; $\mathrm{RMSD}=0.081,0.080,0.102$ for liquid, sand, and rigid balls, respectively). The ISE model predictions deviated from the human data to a lesser degree than the GT model predictions $(r(38)=0.87,0.85,0.88 ;$ RMSD $=0.145,0.170,0.186$ for liquid, sand, and rigid balls, respectively), indicating a superior account of human predictions across a range of substances. In comparison, GLM and XGBoost predictions were
less consistent with human predictions (GLM: $r(38)=0.77$, $0.78,0.65$, RMSD $=0.077,0.120,0.191$; XGBoost: $r(38)=$ $0.67,0.74,0.71, \operatorname{RMSD}=1.382,1.422,2.067$ for liquid, sand and rigid balls, respectively). As in the previous experiment, we compared each model's BIC measure in each condition to account for the number of free parameters in each model. We found that the BIC values for the ground-truth, GLM, and XGBoost models (GT: BIC $=-154.5,-141.8$, -134.6 ; GLM: BIC $=-194.0,-158.6,-121.4$; XGBoost: BIC $=36.9,39.2$, 69.2 for liquid, sand, and rigid balls, respectively) were consistently greater than the values for the ISE model (BIC $=-190.0,-191.0,-171.6$ for liquid, sand, and rigid balls, respectively), further reinforcing the superior performance of our simulation-based model.

It is worth noting that our ISE achieved consistent performance across all three substances, whereas GLM and XGBoost were less capable of predicting human judgments about rigid balls and liquid. In addition, our ISE used only one third of the training samples that XGBoost and GLM needed, demonstrating that a generative physical model with noisy perceptual inputs is capable of learning with a smaller number of samples than data-driven methods.

## Discussion

Results from Experiments 1 and 2 provide converging evidence that humans can predict outcomes of novel physical situations by propagating approximate spatial representations forward in time using mental simulation. This stands in contrast to early research in rigid-body collisions suggesting that human physical predictions do not obey ground-truth physics, instead relying on heuristics (e.g., Gilden \& Proffitt, 1994; Runeson, Juslin, \& Olsson, 2000). ISE predictions entailing the noisy Newton framework outperformed both ground-truth and data-driven models in both experiments, further confirming the role of perceptual noise and physical dynamics in human intuitive physical predictions.

Previous work has demonstrated that humans spontaneously employ mental simulation strategies when reasoning about novel physical situations (Clement, 1994; Hegarty, 2004; Schwartz \& Black, 1996). Recent fMRI results suggest that intuitive physical inferences are made using an internal physics engine encoded in the brain's "multiple demand" network (Fischer, Mikhael, Tenenbaum, \& Kanwisher, 2016). Although our ISE employed herein accounted for perceptual uncertainty in each situation, the simulations themselves closely approximated normative physical principles. Adding "stochastic noise" to physical dynamics, however, has been shown to increase model performance when predicting human responses in simple physical situations (K. A. Smith \& Vul, 2013). While dynamic uncertainty can easily be built into rigid-body collisions, employing this strategy in the present physical simulations would preclude stable numerical evaluation. Thus, future computational work should explore methods for adding dynamic uncertainty into complex physical simulations while preserving their accuracy and stability.

Results from the present study demonstrate that human predictions about substance dynamics can be accurately predicted by a unified simulation method with uncertainty im-
plemented into underlying physical variables. It is unlikely, however, that the human brain numerically evaluates partial differential equations to discern whether physical quantities (e.g., mass and momentum) are conserved, nor is it likely that the brain stores the locations of vast numbers of particles to form physical predictions and judgments. Instead, our results provide evidence that humans approximate the dynamics of substances in a manner consistent with ground-truth physics but succumb to biases invoked by perceptual noise when inferring future environmental states. It remains unclear, however, whether the dynamics of rigid objects, liquids, and granular materials are approximated using separable mechanisms or a single cognitive architecture with different assumptions and constraints. The success of our unified simulation model across different substance-types supports the latter perspective.

## Appendix: Details of Our MPM Simulator

The governing partial differential equations utilize the principles of conservation of mass and momentum:

$$
\begin{equation*}
\frac{D \rho}{D t}+\rho \nabla \cdot \mathbf{v}=0, \quad \frac{D \mathbf{v}}{D t}=\nabla \cdot \sigma+\rho \mathbf{g}, \tag{1}
\end{equation*}
$$

where $\sigma$ is the stress imparted on a particle, $\mathbf{g}$ is the gravitational acceleration, and $\frac{D}{D t}$ is the material derivative with respect to time. The equations are discretized spatially and temporally with a collection of Lagrangian particles (or material points) and a background Eulerian grid. The material type of the simulated substances is naturally specified from the constitutive model, which defines how a material exerts internal stress (or forces) as a result of deformation.

Rigid balls are simulated as highly stiff elastic objects with the neo-Hookean hyperelasticity model, described through the elastic energy density function

$$
\begin{equation*}
\Psi(\mathbf{F})=\frac{\mu}{2}\left(\operatorname{tr}\left(\mathbf{F}^{T} \mathbf{F}\right)-d\right)-\mu \log (J)+\frac{\lambda}{2} \log ^{2}(J), \tag{2}
\end{equation*}
$$

where $d$ is the dimension ( 2 or 3 ), $\mathbf{F}$ is the deformation gradient (i.e., the gradient of the deformation from undeformed space to deformed space), $J$ is the determinant of $\mathbf{F}$, and $\mu$ and $\lambda$ are Lamé parameters that describe the material's stiffness.

Liquid is modeled as a nearly incompressible fluid, with its state governed by the Tait equation (Batchelor, 2000):

$$
\begin{equation*}
p=k\left[\left(\frac{\rho_{0}}{\rho}\right)^{\gamma}-1\right] \tag{3}
\end{equation*}
$$

where $p$ is the pressure, $\rho$ and $\rho_{0}$ are the current and original densities of the particles, $\gamma=7$ for water, and $k$ is the bulk modulus (i.e., how incompressible the fluid is). Through this Equation-of-State (EOS), the stress inside a non-viscous fluid is given by $\sigma=-p \mathbf{I}$, where $\mathbf{I}$ is the identity matrix. We further adopt the Affine Particle-In-Cell method (APIC) (Jiang et al., 2015) to greatly reduce numerical error and artificial damping. This enables us to simulate fluids with better accuracy compared to alternative computer graphics methods.

The motion of dry sand is largely determined by the frictional contact between grains. In the theory of elastoplasticity, the modeling of large deformation (e.g., frictional contact) can be based on a constitutive law that follows the Mohr-Coulomb friction theory. Following (Klár et al., 2016), we simulate dry sand based on the Saint Venant Kirchhoff (StVK) elasticity model combined with a Drucker-Prager non-associated flow rule. Plasticity models the material response as a constraint projection problem, where the feasible
region (or yield surface) of the final material stress is restricted to be inside

$$
\begin{equation*}
\operatorname{tr}(\sigma) c_{F}+\left\|\sigma-\frac{\operatorname{tr}(\sigma)}{d}\right\|_{F} \leq 0 \tag{4}
\end{equation*}
$$

where $d$ is the dimension and $c_{F}$ is the coefficient of internal friction between sand grains. The stress (and thus deformation gradient) of each sand particle is projected onto the yield surface so as to satisfy the second law of thermodynamics.

#### Abstract

Team cognition can be defined as the ability that humans have to coordinate with others through a complex environment. Sports offer exquisite examples of this dynamic interplay requiring decision making and other perceptual-cognitive skills to adjust individual decisions to the team selforganization and vice-versa. Considering players of a team as periodic phase oscillators, synchrony analyses can be used to model the coordination of a team. Nonetheless, a main limitation of current models is that collective behavior is context independent. In other words, players of a team can be highly synchronized without this corresponding to a meaningful coordination dynamics relevant to the context of the game. Considering these issues, the aim of this study was to develop a method of analysis sensitive to the context for evidence-based measures of team cognition.

Keywords: Team Cognition; Synchronization; Ecological Dynamics;

## Introduction

Central to the definition of a team are the interactions amongst its components (McNeese, Cooke, Fedel \& Gray, 2016). When players cooperate together as a team, the resulting collective behaviors rarely are expressed in terms of the simple summation of the individuals' activities. That is, the team's activity emerges from the coordination of actions and often nonlinear interactions of its players. For example, to be successful in European football (soccer), players must coordinate their actions with others across many different spatial and temporal scales. While recent research has focused on elucidating the mechanisms that facilitate such large-scale coordination, the identification of the fundamental, self-organizing principles that underlie team dynamics remains an unresolved matter (see e.g., Memmert, Lemmink \& Sampaio, 2016; Folgado, Duarte, Fernandes \& Sampaio, 2014). Indeed, techniques to measure collective
emergent behavior are still in an early stage of development (Araujo, Silva \& Ramos, 2014), while many attempts to measure team work have typically focused on measuring outcome performance rather than team dynamics. However, recent attempts to study the dynamics of multi-agent activity have benefitted from concepts and tools from Dynamical Systems Theory (DST) (e.g., Duarte, Araújo, Correia, Davids, Marques, \& Richardson, 2013). While DST provides suitable techniques for modeling living systems, it makes no direct claims about their status nor provides a theoretical basis for understanding goal directed behavior. Amongst the broad range of DST tools, one of the most common approaches used by students of perception, action and cognition is the study of synchronization.

## Measuring Synchronization

Measures of synchrony are used for describing phenomena that obey recurrent, dynamical laws; and have been applied for a wide range of phenomena coming from substantially different fields of study as natural sciences, engineering or even social life (Pikovsky, Rosenblum \& Kurths, 2001).

Whereas in physical, nonliving systems synchrony is often mediated via mechanical coupling (e.g., Huygens famous observations regarding the synchronization of two clock pendulums, (1673/1986), psychological and social systems often synchronize via informational (e.g., visual) coupling (Schmidt, Carello \& Turvey, 1990). Although most research on the synchrony and coupling between actors has focused on dyads, a recently developed method, cluster phase analysis (CPA, Frank \& Richardson, 2010), has been used to extend synchrony measures to groups larger than two people. CPA has been used, for example, to assess the degree to which a group of people successfully synchronized their intentional, oscillatory rhythmic movements with rocking chairs; with synchrony measured using an adaptation of the Kuramoto
order parameter ( $a k a$ cluster amplitude, $\dot{r}$ where high synchronization $=1$ ). Similar methods have been used to characterize teams' phase synchrony in football (see e.g., Duarte et al., 2013; Duarte, Travassos, Araujo \& Richardson, 2014). Here, separate measures of team synchrony are derived using players' displacements along either the latitudinal or longitudinal axis, where a common result is that synchrony is higher in longitudinal displacements than in lateral displacements (Duarte, et al., 2013). Using this method, researchers have also noted that the observed degree of synchrony was not subject to possession of the ball (see e.g., Pinto, 2014; Duarte, et al. 2013), presumably one of the key factors of team organization during the match. However, it may be argued that the technical aspects of this methodological approach do not consider relevant contextual features of the game that are key to self-organizing principles in team sports. This lack of situational context is a consequence of 1) the behavioral variable submitted to the model and 2) the constraints that presents the mathematical model. Behavior is measured in a time-series of displacements along one dimension; however, the Kuramoto model requires phase angles as its input. To overcome this incompatibility, the displacement time-series are transformed to instantaneous phase angles by using the Hilbert Transform (see Pikovsky, et al. 2001 for details). However, this method is limited in that high synchrony can be a consequence of the players simply being very close to each other within that onedimensional space (e.g., $x$-dimension), whereas, conversely if players are far apart within that dimension, synchrony would be low.

Considering these issues (technical and contextual) we aimed to further extend the use of CPA by using insights from a recently developed framework that applies the ecologicaldynamics approach to perception and action in football (López-Felip, 2014). Our model parameters were defined by two situational variables of the game: such as players' orientation-to and distance-from the goal of interest (i.e. the goal being actively attacked by the offense and defended by the defense). Our main hypothesis was that when accounting for these two contextual variables, team synchrony would be dependent on ball possession. This result would suggest the need for further exploring context dependent analyses for evidence-based measures of team cognition.

## Method

## Participants

Twenty-two male elite football players from two European clubs played a friendly game during the pre-season 20162017. Participants ranged in age from 17 years to 34 years (average $26.5 \pm 0.4$ years). At the time of data collection, neither of the teams had initiated their regular competitions, however, the away team was a member of what is typically considered to be a superior league. The entire first half of the match was registered with no injuries or substitutions.

## Instruments

Player position data were collected via GPS (sampling rate of 15 Hz ) for an entire half of forty-five minutes plus extra time. These GPS monitors could reliably capture positional raw data (2D) based on the latitude and longitude positions of all players throughout the match.

## Procedures

The positional raw data were subsequently matched to corresponding events throughout the competition (captured via video). This allowed us to asses when during each timeseries a team was in possession of the ball (i.e. attacking role), as well as identify any prolonged periods of stoppage
(e.g., from injury assistance, goals, etc.) to remove from analysis. The criteria for determining ball possession was based on Reis, Duarte, Araújo, Folgado, \& Frias (2013).

## Data Analysis

Starting with the positional raw data, exocentric coordinates were used to define the state space in which trajectories of players were captured. Then, the goals were represented as specific variables of this state space to create a new variable, angle of the direction to the goal $\left(\theta_{\mathrm{g}}\right)$ :

$$
\begin{equation*}
\theta_{\mathrm{g}}=\tan ^{-1}\left(\frac{\mathrm{x}_{\text {goal }}-\mathrm{x}_{\text {player }} \mathrm{i}}{\mathrm{y}_{\text {goal }}-\mathrm{y}_{\text {player }}}\right) \tag{Eq.1}
\end{equation*}
$$

This measure provided a metric of each player's orientation with respect to the goal. Relative angles were submitted to CPA, creating a time-series of Kuramoto parameter values describing each team's synchrony at every time step.
(Eq. 2)

$$
\dot{r}^{\prime}\left(t_{i}\right)=\left|\frac{1}{n} \sum_{k=1}^{n} \exp \left(i \theta_{k}\left(t_{i}\right)\right)\right|
$$

To account for the distance of a team to the goal of interest, each team's center of mass was assessed at each time step. Distance of the center of mass ( $d_{C O M}$ ) was measured as the mean longitudinal position of all team members over time.
(Eq. 3)

$$
C O M=\frac{1}{N} \sum_{\text {player }=1}^{n} x_{\text {player }}
$$

To simplify our analysis, $d_{\text {COM }}$ values were categorized into four quadrants each spanning 25 m ; where Q1 contained distances closest to the goal of interest and Q4 contained distances furthest away (see Figure 1).

Figure 1: Black disc represents the attacking team and black triangles represent the defending team. Dashed lines represent each player's goal angle. Vertical black lines divide the field in 4 equidistant quadrants. Q1 is the quadrant closest to the active goal and Q 4 the furthest. Then, $x-y$ axes represent the longitude and latitude coordinates from where positional raw data were collected.

Then, provided our research question, we assessed changes in each team's synchrony as 1 ) a function of ball possession (whether teams were attacking or defending) and 2) the distance between the team's center of mass to the goal of interest, $d_{\text {Сом }}$. To do so, each point in the time series of Kuramoto parameter values was independently evaluated as a function of the corresponding $d_{\text {СОМ }}$ quadrant. The resulting mean values for each quadrant were submitted to further analysis, resulting in values reported in Figure 2.

## Results

As determined using the cluster amplitude analysis the overall degree of synchronization of teams were between 0.55 and 0.99 . When phase synchrony was assessed for each team as a function of the playing role in the game (i.e., attacking or defending) and the $d_{C O M}$ to the goal of interest, synchronization differed. Figure 2 shows how the mean tendency of synchrony varies as a context of where and when a team is attacking or defending. That is, mean synchrony decays as teams' $d_{\text {Сом }}$ approaches Q 1 .

Table 1: Mean synchrony of each team as a function of playing role and $d_{\text {COM }}$.

| Team | Quadrants | $\dot{r}=$ Attacking | $\dot{r}=$ Defending |
| :---: | :---: | :---: | :---: |
| Home | Q1 | $N A$ | 0.86 |
| Away | Q1 | 0.84 | 0.89 |
| Home | Q2 | 0.92 | 0.95 |
| Away | Q2 | 0.93 | 0.97 |
| Home | Q3 | 0.97 | 0.98 |
| Away | Q3 | 0.97 | 0.98 |
| Home | Q4 | 0.99 | $N A$ |
| Away | Q4 | 0.99 | 0.99 |

Overall, synchrony increased as the teams moved farther from the goal of interest. At the same time differences in synchrony depending on the team's role became more pronounced as the teams moved closer to the goal of interest. A similar pattern of effects [role: $F(1,15488)=31, p<.001$; quadrant: $F(3,15488)=6484, p<.001$; role $\times$ quadrant: $F(3$, $15488)=622, p<.001$ ] was observed for the home team (note that the $d_{\text {СОм }}$ of the home team never entered Q1 when attacking or Q4 when defending; likely due to the away teams dominance of the match).

Figure 2: Mean synchrony of each team based on field location and role.

## Discussion

The purpose of this study was to develop a method of analyzing team coordination that is sensitive to the context in which team actions unfold over the course of a game. It was hypothesized that by using a measure of phase synchrony sensitive to the contextual circumstances of ball possession, synchrony of a team would change. To test this, two variables that were relevant to the context of the game such as footballer's angle relative to the direction of the active goal and COM of each team on the field were used.

With respect to the experimental hypothesis, a linear effects mixed model showed that team synchrony is dependent on team role and distance from the active goal. Significant effects were found for role and quadrant, qualified by a role $\times$ quadrant interaction in both teams.

Measures of team synchrony showed higher mean values when a team was in defense. These data suggest that individuals tend to coordinate their movements together relative to the goal more in those instances in which they are defending, than the ones in which they are attacking. At the same time, lower synchrony values were found in those instances in which a team was closer to the opponent's goal. This is not surprising for the attacking team, because behavior of a football team when attacking is to spread out and create as many open spaces as possible to the opponent team. Interestingly, the team in defense showed also low values of synchronization in Q 1 . One possibility is that this
may be due to the driving-driver effect (Step \& Turvey, 2010). According to this, the team in defense would try to anticipate the actions of the team in possession of the ball, reflected in the drop of mean synchrony of the defense team in Q1. This conjecture remains an open question.

Although these data showed differences of synchrony in terms of ball possession, the levels of whole team synchrony were, overall, high. All the mean values of cluster amplitude for the angle to the direction of the active goal ranged between 0.84 and 0.99 . These values are similar to those found in football (Duarte et al., 2013) or in intentional oscillatory rhythmic movements of rocking chairs (Frank \& Richardson, 2010).

## Implications for Measuring Synchronization

Based on the approach of previous studies, the present work assessed synchrony by means of an adaptation of the Kuramoto Order Parameter. As explained in the introduction section, when using time-series of displacements in the $x, y$ or $z$ axes to assess synchronization, there is the need to calculate the instantaneous phase angle of the time-series (usually done by the Hilbert Transform). By following these steps, synchrony may remain high and unchanged due to the limitations of the methodology as explained earlier in the introduction.

Hence, the present work, approaches the assessment of synchrony via an alternative methodology. First, we considered that we could explore the possibility of using an angle that was not limited to a one-dimensional plane. Simply because representing dynamics of collective behavior at one dimension did not seem to lead us to our purposes (i.e., provide contextual meaning to assessments of collective behavior). Second, based on previous research, displacements from a time-series have not been able to discriminate between synchrony levels and ball possession during the game. Thus, our approach attempted to link a behavioral variable to the final target that a team aims (i.e., scoring a goal). For example, in models of steering and obstacle avoidance (see e.g., Fajen \& Warren, 2003; Warren, 2006), one of the variables taken in their assessments is the relative angle of the performer's position relative to the goal or obstacle. Here, using a similar variable and clustering the angle of each player relative to the active goal, allowed us to model team dynamics at a 2-dimensional plane and do it relative to the final purpose of the game.

Taking this approach to using the Kuramoto, is not a final model. This is just a preliminary step towards developing a more robust model of synchronization in collective behavior that aims to be sensitive to the context in which team activity occurs.

## Conclusions

This study investigated the degree to which ball possession impacts team synchrony as a function of the team's $d_{\text {COM }}$. López-Felip and Porter (2015) argued that both variables were proposed as proper parameters to include when
modeling football team behavior as a dynamical system. Our finding suggest that appropriately modeling team behavior must take into account variables that capture the meaningful current state of affairs of the game-such as players' orientation and location relative to key points of interest. Future research in this domain should seek to identify and incorporate additional, meaningful aspects (e.g., tactics) to addressing team coordination.

More broadly, these findings may be understood in the claim that efforts to model living systems and their actions should account for context. Understanding the functional, context dependent relationship that exists between organismenvironment and situation could serve to guide and constrain future dynamical analyses and mathematical modeling of team systems (Turvey, 1992; Turvey \& Shaw, 1995).

# More Siblings Means Lower Input Quality in Early Language Development 

Catherine Laing<br>Duke University<br>Elika Bergelson<br>Duke University

#### Abstract

Previous research has suggested that first-born infants acquire words faster than their later-born peers (Berglund et al., 2005), but may have some disadvantages in other aspects of syntactic and socio-communicative development (e.g. Hoff, 2006). Here we analyzed infants' early lexical development alongside their caregiver input from 6-18 months, in relation to how many siblings they have. We find that having more siblings (rather than being first- or later-born) has a gradient and negative relationship with infants' language development. This affect appears to be manifested in caregiver input: across three different measures of input quality/quantity, disadvantages were found for infants with more siblings. Having a larger number of siblings diminished the quality of the input and led to slower overall lexical development. Implications for language development and learning within dyadic and multi-member contexts are discussed.

# Uncovering visual priors in spatial memory using serial reproduction

#### Abstract

Visual memory can be understood as an inferential process that combines noisy information about the world with knowledge drawn from experience. Biases can arise during encoding of information from the outside world into internal representations, or during retrieval. In this work, we use the method of serial reproduction, in which information is passed along a chain of participants who try to recreate what they observed. We apply this method to the study of visual perception in the context of spatial memory biases for the remembered position of dots inside different geometric shapes. We present the results of non-parametric kernel density estimation of the end result of serial reproduction to model visual biases. We confirm previous findings, and show that memory biases revealed with our method are often more intricate and complex than what had previously been reported, suggesting that serial reproduction can be effective for studying perceptual priors.

Keywords: Vision; spatial memory; inductive biases; serial reproduction; iterated learning;

## Introduction

Retrieving detailed visual information from memory requires efficient representations of often complex and noisy visual scenes. In Bayesian accounts of reconstruction from visual memory, the memory system integrates sensory information with knowledge acquired from previous experience ("priors"). Effective use of this information may reduce variability in visual memory and improve overall reconstruction accuracy (Weiss et al., 2002). Using priors is usually advantageous because they capture regularities in the structure of the world that are innate or observed over our lifetimes. However, this can lead to substantial biases during reconstruction. This is because prior information may deviate significantly from our observations, especially when a visual scene is unexpected given previous experience.

In many cases, visual priors are categorical (or prototypical), represented in memory as schematic or simplified objects (Huttenlocher et al., 1991). In one experimental paradigm that reveals categorical effects, participants are asked to remember the location of a dot presented within a circle or other bounding shape. After a brief presentation and a delay, participants reproduce the dot's location by placing
it in the recalled position (see Figure 1). Huttenlocher et al. (1991) found that participants tend to misplace dots toward a central (prototypical) location in each of the quadrants of a circle. Following these results, Wedell et al. (2007) tried to predict prototypical positions in spatial memory for dots presented inside a variety of geometric shapes (circle, square, triangle, vertical oval, horizontal oval, and pentagon). In the study, participants were shown thirty-two dots aligned along two concentric circles within each shape. A parametric model with four components (prototypes) was fitted to the remembered positions of the dots, confirming that visual memory of these shapes shows substantial categorical effects.

The approach to characterizing categorical biases used in Huttenlocher et al. (1991) has a number of limitationsspecifically, a relatively small number of to-be-remembered locations (32) and a weak measurement of the biases, resulting in limited resolution for capturing the locations of the categories. In addition, Wedell et al. (2007) used a parametric model with a fixed number of categories. The choice of the model, and the number of categories that were used were not fully justified, requiring certain a priori assumptions. Here, we propose to use a paradigm based on serial reproduction to characterize visual memory biases without needing to rely on parametric modeling and with substantially better resolution and accuracy.

## The method of serial reproduction

Serial reproduction has a long history in experimental psychology, where it has been used to study how various biases distort information when it is transmitted from person to person (Bartlett, 1932). Figure 2 shows a schematic illustration of the experimental paradigm: a participant views a stimulus, such as a dot presented within a bounding shape, and is then asked to reproduce the stimulus as accurately as possible from memory. Critically, the reproduction created by the first participant is used as the stimulus for the second participant, who is then asked to do the same. At each iteration, the reconstruction produced by the previous participant becomes

Figure 1: Illustration of prototype effects in memory for points in a circle. The red crosses represent prototypes, and the small points are typically misremembered as being closer to those prototypes.
the stimulus for the next participant to reproduce. Famous early results include the transformation of an owl-like Egyptian hieroglyph into a small cat after ten iterations of a serialreproduction drawing task (Bartlett, 1932). This result was interpreted in terms of inductive biases in memory: as veridical information from the input becomes degraded following successive iterations, the reconstruction of the ambiguous image is pulled towards a prototypical object with similar visual properties.

Serial-reproduction experiments have long been used to simulate phenomena in cultural transmission, evolutionary biology, anthropology, and cognitive science (Kirby et al., 2008; Claidière et al., 2014), but it wasn't until recently that a rational analysis of serial reproduction considered how information should change as it is transmitted along a chain of rational agents (Xu \& Griffiths, 2010). Under a rational analysis, reconstruction from memory is defined as the problem of inferring the most accurate state of the world from noisy data, such as an imperfect memory trace and perceptual noise during encoding of the image. This problem is modeled using the framework of Bayesian statistics. Previous experience is captured by a prior distribution over possible states (a hypothesis space of world states). A posterior is computed, based on the likelihood, which indicates the probability of observing that information, given some hypothesis about the true state of the world. Xu \& Griffiths (2010) examined the predictions of this Bayesian account of reconstruction from memory for serial reproduction. They found that serial reproduction by Bayesian agents defines a Markov chain with the following transition probabilities:

$$
p\left(x_{n+1} \mid x_{n}\right)=\int p\left(x_{n+1} \mid \mu\right) p\left(\mu \mid x_{n}\right) d \mu
$$

where $x$ is a noisy stimulus (such as an imperfect memory trace) and $\mu$ is the true state of the world that generated that stimulus (in this case, the veridical image that impinged on the visual system). This Markov chain captures the probability of a new stimulus $x_{n+1}$ being created as a reconstruction of a previously seen stimulus $x_{n}$ in each iteration in the serial reproduction chain, and has a stationary distribution, called the
prior predictive distribution, which defines the probability of observing a stimulus $x$ when $\mu$ is sampled from the prior:

$$
p(x)=\int p(x \mid \mu) p(\mu) d \mu
$$

This process approximates a Gibbs sampler for the joint distribution on $x$ and $\mu$ defined by multiplying $p(x \mid \mu)$ and $p(\mu)$. This finding is significant because it provides a mathematical formalism for describing the consequences of serial reproduction: assuming that participants share common inductive biases, the transmission chain will converge to a sample from their shared prior.

In this paper, we explore spatial memory priors in a task where participants were asked to remember the position of a small black dot inside a variety of geometric shapes. Operating under the assumption that people share the same inductive biases, or spatial memory priors, we show that serial reproduction appears to converge on these priors remarkably quickly, revealing patterns that are consistent with some established findings, although in many cases revealing new and intricate patterns that were previously unknown. Finally, we demonstrate the advantages of using a non-parametric kernel density estimation procedure to characterize the prior.

## Methods

## Participants

Participants were recruited online using Amazon Mechanical Turk. All gave informed consent. The experimental protocol was approved by The Committee for the Protection of Human Subjects (CPHS) at the University of California, Berkeley. Each experiment required approximately 70-100 participants. A total of 570 participants took part in Experiment 1 and an additional 590 took part in Experiment 2.

## Stimuli

All images were approximately $400 \times 400$ pixels in size. Each shape was a 6 -pixel-wide black outline over a white background. The sizes and colors of the backgrounds for the images were intended to ensure that the images would be clearly visible in any standard browser window (unlikely to become occluded), and such that the boundaries of the images would be invisible.

## Procedure

We carried out a series of serial reproduction experiments. Participants were presented with timed displays (a shape outline with a dot initialized somewhere within the boundaries of the shape), and were instructed to reproduce the exact location of the dot inside of the shape. Once complete, their response was sent to another worker (again, as a timed display), who was instructed to reconstruct this display from memory, and so on. A total of ten iterations were completed for each chain. See Figure 2 for a schematic diagram of the serial reproduction procedure.

Practice trials. Participants completed ten practice trials in order to become familiar with the user interface. During these practice trials, they were presented with a circle (a black outline of a circle over a white screen), with a dot initialized somewhere within its boundaries. This display was presented for 4000 ms , followed by a blank screen lasting 1000 ms . Next, the circle was presented without the dot and remained on the screen until the participant positioned the dot in the location that they remembered. As soon as the participant clicked, the dot appeared under the mouse cursor. Participants could reposition the dot as many times as they needed. Once done, they pressed a button to proceed to the next trial.

Experimental trials. Following the ten practice trials with the circle, there were ninety-five experimental trials with exactly one of the shapes. In Experiment 1, the shape could be a circle, triangle, square, vertical oval, horizontal oval, or a pentagon. In Experiment 2, the shape could be a regular polygon with more than five vertices. For each of the 95 experimental trials, the presentation time was reduced to 1000 ms . As with the practice trials, the position of the shape on the screen was randomized somewhere inside a larger canvas in order to control for participants resorting to tracking the position of the dot by trivially marking its absolute position on their computer screens. In addition, participants were given trial-by-trial feedback regarding their accuracy. If their responses were within eight percent of the width and height subtended by the shape on the screen, they were told that their response was accurate (a message in green font: "This was accurate"), and received a small monetary bonus. If not, they received no bonus beyond the basic payment for the HIT, in addition to any bonuses accrued from the previous trials, and were presented with a red message ("this was not accurate"). These trials were discarded from the experiment. Participants could not provide multiple responses within a chain.

Experiment 1: We used the same six shapes as Wedell et al. (2007): A circle, equilateral triangle, square, vertical and horizontal ovals, and a regular pentagon. For each shape, we initialized the position of five hundred dots within its boundaries (for the circle, we initialized four hundred dots).

Experiment 2: Because our method revealed a variable number of peaks (prototypes) in the prior for the angular shapes in Experiment 1, and that these appeared to be due in large part to the number of vertices in the polygons (all were regular polygons-an equilateral triangle, square, and pentagon), we wanted to determine the point at which the prototypes begin to merge into the four prototypes in the prior for the circle. We did this by conducting the same experiment with polygons containing increasingly more vertices (approximating a circle more closely as vertices were added).

## Results

Our results are presented in two parts. First, we present all our results for Experiment 1, in which we used the same shapes as Wedell et al. (2007). We demonstrate that using a serial reproduction paradigm, as well as non-parametric kernel density

Figure 2: Serial reproduction chain for one trial in the memory task, illustrating the iterative process for a single dot being remembered. The trial in black represents a standard memory paradigm. In red are additional iterations of the task using the result from the previous iteration as the new stimulus, which form the nodes in the serial reproduction process.
estimation, replicates some (but not all) of their key findings. In particular, we find four prototypes arranged in the centers of the four quadrants of the circle, as well as the horizontal and vertical oval shapes, as they did. However, we also show new and intricate patterns in the priors for the angular shapes (triangle, square, and pentagon). We evaluate the predictions of the model by Wedell et al. (2007) on the data we obtained following one iteration, for all the shapes, and compare them to predictions that we obtain from our estimates of the prior following all ten iterations. In addition, we show quantitative evaluations of the change in copying accuracy for the equilateral triangle. Second, we show the results for Experiment 2, where we illustrate the effect of adding vertices to regular polygons on the prior, revealing hitherto unknown grouping effects of the prototypes in spatial memory that occur as regular polygons begin to approximate a circle.

## Measuring spatial memory priors

Serial reproduction results. Figure 3 shows visualizations of the estimates that we obtained following ten iterations of the serial reproduction experiment using four hundred initial seeds for the circle. Each panel shows the results for each of the ten iterations, including the initial seeds. Notice that the prototypes begin to emerge in as early as the fourth iteration. For the panel showing the results of the tenth iteration, we show an estimate of the prior using our non-parametric kernel density estimate in lieu of plotting the points. Figure 4 shows the results that we obtained for the equilateral triangle. Notice the emergence of bimodal peaks near each of the vertices. This finding suggests that for this shape, there are a total of six prototypes in the prior, grouped in pairs at each corner.

Figure 3: Serial reproduction of 400 dots presented in a circle, for ten generations (iterations) of the process. The top left scatterplot shows the positions of the original seeds (sampled from a uniform distribution) inside the circle shape. The remaining subplots show scatterplots of the results of the serial reproduction chain for iterations 1-10. The subplot of the tenth iteration, in the bottom right, also shows the kernel density estimate. Note that from one iteration to the next, points that were originally scattered uniformally within the circle boundary begin to converge on each of the nearest prototypes at the center of each of the four quadrants in the circle. By the tenth iteration of the process, four clusters are clearly discernable.

Simple shapes. In Figure 5 (panels B and D), we show the kernel density estimates that we obtained for all the shapes. In the case of the circle, vertical oval, and horizontal oval, our results are consistent with past findings (shown in panels A and C). However, we discover bimodal peaks in the vertices of the angular shapes (prototype pairs clustered at each of the corners). This result is particularly striking for the triangle and the square shapes. The same result is present for the pentagon shape, although unlike the peaks in the prior for the triangle and square, those in the pentagon are not quite rotationally invariant, although all three geometric shapes are, suggesting that the shapes and orientations of the modes in the priors are not a simple function of the presence of edges, or the angles at these edges.

Convergence analysis. For the triangle results, we completed a convergence analysis (See Figure 4, panels B and C), using the Jensen-Shannon divergence (JSD). To estimate the variability of these JSDs, we generated 100 bootstrapped data sets sampled from the original data (with replacement). For each one, we computed the JSDs of consecutive iterations (see panel B). The JSD between the initial distribution and iteration 1 was significantly larger than that between the two final iterations ( $p=0.02$ ) and there were no significant differences between the distance between iterations 9 and 10 compared with iterations 8 and $9(p=0.43)$.

Figure 4: Results we obtained for each iteration in the chain for the triangle shape. A. Kernel Density Estimate (KDE) for the initial distribution and the 10 iterations. B. Convergence analysis using the Jensen-Shannon divergence (JSD) between consecutive iterations. C. JSD between all iterations and the last iteration. Note that both measures decrease with the number of iterations, and suggest that convergence occurs at or near the tenth iteration in the serial reproduction chain.

As another measure of convergence, we also computed the JSD between all iterations and the last iteration (Jacoby \& McDermott, 2017) (see panel C). The distance between the last two iterations was significantly smaller than the distances between iteration 10 and each of the remaining iterations ( 0 through 8). The distance between iteration 10 and 9 was marginally larger than the distance between iteration 10 and 8 ( $p=0.041$ ). These analyses suggest that convergence occurs at or near the tenth iteration. To test if the responses of participants became more "prototypical" over the course of the experiment (as they progressed through their trials), we used the estimate of the prior from the final iteration to measure the average log-likelihood of their responses. We used data from the $83 \%$ of the participants who performed more than $80 \%$ of the trials within the accepted criteria (responses within $8 \%$ of the height and width of the shape on the screen). We found that the log-likelihood significantly improved when comparing the first and second half of their responses $(\mathrm{t}(49)=-2.47$,
$p=0.008$ ), and when comparing the first 10 trials to the last 10 trials of each of the subjects $(\mathrm{t}(49)=-2.04, p=0.046)$.

Figure 5: Kernel density estimates for the priors were estimated for all six shapes using the tenth iteration of the serial reproduction chain. A. \& C. Original result by Wedell et al. (2007). B \& D. Kernel density estimates with serial reproduction. E. Boxplots showing model comparisons. We computed the log likelihood difference for the two models as explained in the main text. In all cases the serial reproduction model was significantly better ( $p<0.01$ for all shapes except vertical oval ( $p=0.03$ ) resulting in positive log-likelihood ratios.

Model comparisons. Using a combination of nonparametric kernel density estimation and serial reproduction lets us uncover intricacies in the prior for angular shapes (including bimodal peaks at the vertices) that paint a nuanced picture of human spatial memory priors. In addition, our approach enables us to obtain more than just point estimates of the locations of prototypes in spatial memory. Nevertheless, we provide a comparison between point estimates obtained from our method to those obtained from the model by Wedell et al. (2007), for each shape, using the same number of pa-
rameters. The model describes the remembered position for a dot $i$ (a response vector $\vec{R}_{i}$ ) as a weighted average of the actual location at which the dot was presented, which they refer to as the "fine-grain memory representation", and the weighted sum of the prototype locations, using the following equations:

$$
\begin{gather*}
\vec{R}_{i}=w \vec{S}_{i}+(1-w) \sum_{j=1}^{4} v_{i j} \vec{P}_{j}  \tag{1}\\
v_{i j}=\frac{e^{-c\left\|\vec{S}_{i}-\vec{P}_{j}\right\|}}{\sum_{k=1}^{4} e^{-c\left\|\vec{S}_{i}-\vec{P}_{k}\right\|}} \tag{2}
\end{gather*}
$$

where $\vec{S}_{i}$ and $\vec{R}_{i}$ are vectors in $\mathbb{R}^{2}$ containing the $x$ and $y$ coordinates for each point $i$ in the stimulus phase (iteration 0 ), and in the first response phase (iteration 1), respectively. The $\vec{P}_{j}$ terms correspond to the four prototype vector coordinates being estimated by the model, in addition to weights $w$ that correspond to the relative strength of the veridical memory (as opposed to the strength of a prototype in the prior).The $v_{i j}$ capture the relevance weight of each of the four $j$ prototypes for each point $i$. In other words, the strength of the influence of prototype $j$ for each point $i$. The parameter $c$ corresponds to a "sensitivity" parameter that models the sharpness of the prototype boundaries.

We generated 100 split-half samples of the points for iteration 0 (inital seeds), iteration 1 , and iteration 10 . Next, for each sample, we obtained estimates of the prototype locations for four prototypes (the same number used by Wedell et al.) by running their model using the training half of iteration 0 and the same points in iteration 1. In order to ensure a fair comparison, we sampled four points under local maxima from the Kernel Density Estimate (KDE) fit to the same points in iteration 10. This gave us four prototype estimates from the Wedell et al. (2007) model, and four points corresponding to local maxima in the KDE we fit to the points in the training half of iteration 10 (which can only be obtained from our paradigm), for each training split half. We evaluated the accuracy of these two sets of four prototype estimates by computing the sum of the negative-log-likelihood values from a KDE that we fit to the remaining points in the testing half of iteration 10. Next, we computed the log likelihood difference for the two models, for each of the shapes. In all cases, the serial reproduction model performed significantly better ( $p<$ 0.01 for all shapes except the vertical oval $(p=0.03)$ resulting in positive log-likelihood differences. Boxplots showing all the results are displayed in Figure 5E.

Grouping of prototypes. The apparent increase in peaks in the prior for more complex regular shapes afforded the opportunity to consider changes to the prior in the limit, as the shapes begin to approximate a circle. We computed the entropy of the obtained KDEs to quantify their complexity. Complexity increased with the number of vertices (going from a triangle to a heptadecagon, or seventeen-sided regular polygon). However, the prior for a icosihenagon (twenty-one sided regular polygon) begins to reveal the transformation of
the corner peaks into one of the quadrant peaks. Entropy further decreases for the icosipentagon ( $p<0.001$ ), revealing a prior that appears nearly identical to the prior for a circle, and with similar entropy ( $p=0.68$ ) (see Figure 6).

Figure 6: Grouping, and complexity of prior estimates. A. KDEs for regular polygons of increasing complexity. B. Entropy of the last iteration computed for all shapes. Entropy increases steadily with shape complexity ( 3 to 17 vertices). After the number of vertices exceeds 21, entropy stabilizes, and peaks start grouping toward the nearest quadrant center (as with the circle). We used the Bonferroni correction for multiple comparisons.

## Discussion

In this paper, we made a preliminary foray into exploring spatial memory priors using serial reproduction: a process in which information being transmitted through successive participants leaves behind only a signature of the transformation process itself: the perceptual and reconstructive biases of those participants. This iterative process provides an effective tool for greatly amplifying biases in perception and memory.

We used a serial reproduction paradigm in the context of a spatial memory task. KDEs of the dots' final positions revealed detailed structure in priors over location. We found that the priors for circles and ovals show peaks at the center of each of their four quadrants, but also discovered that angular shapes show bi-modal peaks at the vertices in the prior. The modes appear on either side of each vertex, and do not seem to be a simple function of the angle at each vertex, since they are not rotationally invariant in all cases. We provided quantitative comparisons between the performance of a parametric model, and point estimates derived from the KDEs we obtained following ten iterations of the chain. These comparisons demonstrated that our estimates were significantly better than those obtained from the parametric model (we used the same number of parameters-four prototype estimates, even though our method yields kernel density estimates that clearly reveal more than four in some cases). In future work, we intend to determine if priors differ across individuals, by repeating the experiments so that each participant completes a subset of chains in their entirety
(within-subject design). While some studies show differences between within and between-subject designs (Claidière et al., 2014), most studies showed high agreement between these versions (Xu \& Griffiths, 2010; Jacoby \& McDermott, 2017).

Our results suggest that our approach may provide an opportunity to uncover complex priors for a wide range of perceptual phenomena that would otherwise elude traditional experimental approaches, and parametric models. We plan to use it to measure memory biases when there is more than one point to be remembered (Lew \& Vul, 2015), and to probe for structured priors in memory for local orientation (Wei \& Stocker, 2016). Finally, we intend to uncover perceptual biases in spatial memory using natural complex images, and maps, to explore the effect of higher-order visual features and semantic content on spatial memory biases, and to probe for the emergence of geographic landmarks.

## Acknowledgments

This work was funded in part by NSF grant 1456709 to T.L.G., and DARPA Cooperative Agreement D17AC00004 to T.L.G and J.W.S. We would like to thank Thomas Morgan for his help with online experiments.

#### Abstract

When it comes to decision making, the dominant view suggests that engaging in a detailed analytical thought process is more beneficial than deciding based on one's feelings. However, there seems to be a tradeoff, as the complexity and amount of elements on which to base the decision increases, decisions based on affect seem to be more accurate than decisions based on a thorough analytical process in specific contexts. In those last cases, an affective modulation of memory may help to make better decisions in complex tasks that exceed human's limited cognitive capacities. Some dual process accounts, "deliberation-without-attention" hypothesis (Dijksterhuis et al., 2006), oppose a cognitive (i.e., conscious) route to an affective (i.e., unconscious) route. Since most dual process accounts suggest one type of process is better than the other, the interaction and integration of affective and more conscious analytical processes in decision making have been understudied. To address this issue, we propose an explanation of the dynamics and interaction of cognitive (i.e., explicit) and affective (i.e., implicit) encoding and retrieval of elements in memory, using a unified theory based on core affect (Russell, 2003), in the shape of a cognitive model in the ACT-R cognitive architecture.

Keywords: Core affect; ACT-R; decision making; dual process theory; memory modulation; implicit strategy

## Introduction

In a set of experiments, Dijksterhuis et al. (2006) and Mikels et al. (2011) show how being focused on the details of provided information, rather than feelings, affects accuracy in a decision making task. According to these results, being feeling focused in a more complex, memoryoverloading task proves to lead to better performance.

Until recently, the influence of emotion has been neglected in the judgment and decision making literature, with the focus initially being put on the biases emotions enable (Kahneman \& Tversky 1979). Gradually, the focus has shifted toward the positive role of emotions in decision making, as suggested by neurological evidence (Damasio, 1994; Bechara, Damasio, \& Damasio, 2000). In parallel, core affect theory (Russell, 2003) in emotion research, and the somatic marker hypothesis (Damasio, 1994) in decision making research, have emerged to explain how emotion can guide behavior towards a positive outcome.

In this paper we suggest that the results from Dijksterhuis et al. (2006) and Mikels et al. (2011) (i.e., being feelingfocused in a more complex task leads to better performance) can be explained with a core-affect model. Core affect (Russell, 2009) is a neurophysiological state accessible to consciousness as a simple non-reflective feeling and can be
described through the valence (i.e., negative or positive) and arousal (i.e., intensity) values. Our hypothesis here is that core affect modulates memory. The modulation would place emphasis on the objective value of an attribute (i.e., good or bad) rather than details (e.g., higher than average gas mileage), simplifying the information and allowing for more efficient use of cognitive resources. The core affect experienced by participants while implicitly considering options cumulates and later leads to a decision illustrating the emotion-cognition interaction. This, we think, proves to be a better strategy when the limit of memory capacity is reached (e.g., complex task). This hypothesis was tested using a cognitive architecture based on a unified theory of cognition, ACT-R. We previously used this core affect model to explain the impact of affective valence and arousal on memory and memory decay using participant's memory of negative and positive emotion words after different time periods (Juvina \& Larue, 2016). However, here the focus is on the role of affect in decision making. This allows for an explanation of how core affect and cognitive mechanisms are meshed.

## Background

The concept of emotion has been a subject of interest for quite some time. However, theories have only recently attempted to explain their role in cognitive processes using empirical research. Appraisal theories (Lazarus \& Folkman, 1984; Ortony, Clore and Collins, 1990) have emerged as the dominant approach to emotions in the last few decades. Appraisal has been defined as the personal meaning and significance to well-being that is constructed from evaluations of situational factors and knowledge. While this trend of theories clarifies the route by which humans evaluate their environments (e.g., in a bottom-up way), they do not clarify how ongoing affect influences the encoding and retrieval of information in an implicit manner.

In response to this incompleteness, core affect theory (Russell, 2003), "feeling is for doing" (Zeelenberg \& Pieters, 2006), and the somatic marker hypothesis (Damasio, 1994) have attempted to bridge the gap between emotion and behavior. The latter particularly addresses the domain of decision making.
Russell (2009) believes that most phenomena attributed to emotions can be explained in more simple terms (e.g., core affect) without the need for emotion. Core affect is a visceral state that happens before the emotion is consciously identified: feeling good or bad, lethargic or energized (Russell, 2009). Russell's core affect theory suggests
underlying values for valence and arousal are more important than emotion, which he believes is socially constructed. The core affect is the central notion of this theory. Previous events change the core affect, which can occur before the event is actually consciously perceived by the subject and persists during the episode. It also influences the other elements of the emotional episode.
In the domain of decision making, some researchers (Gigerenzer \& Selton, 2002) view heuristics, not only
affective ones, as strategies that lead to sufficient decisions. Implicit strategies for decision making have previously been studied in ACT-R with Instance Based Learning (Gonzalez, Lerch \& Lebiere, 2003). In this paper, another type of implicit strategy involved in decision making - an affective strategy - is investigated.

Existing computational models of affect and emotion are based on appraisal theories and tend to be pre-programmed and hardwired based on the specifications of a particular theory (e.g., Marsella \& Gratch, 2009; Marinier, Laird, \& Lewis, 2009). Previous attempts have been made in ACT-R to add biological roots of emotions (Dancy et al., 2015) effect of emotion on learning and decision making (Belavkin, 2003) and stress (Ritter, Reifers, Klein, \& Schoelles, 2007) by overlaying the architecture.

Since core affect is implicit, more primitive, and more general than the construct of emotion (Russell \& Feldmann Barrett, 1999; Russell, 2009), it could be particularly adapted to be included in a cognitive architecture. When meshed with existing cognitive mechanisms, it could add to existing unified theories of cognition. The resulting model would increase the explanatory power of the core affect theory by clarifying different aspects of the emotioncognition interaction.

## Core affect and memory: theory and implementation

## ACT-R and memory

To capture the core affect modulation of memory and its impact on decision making, we support our model with ACT-R (Adaptive Control of Thought - Rational; Anderson, 2007), a unified theory of human cognition. ACT-R is also a cognitive architecture that is used to develop computational models of various cognitive tasks. ACT-R is composed of various modules: goal, imaginal, visual, aural, manual, vocal, and two memory modules: declarative memory (i.e., facts) and procedural memory (i.e., how to do things). The declarative memory module, which stores facts (i.e., know-what), is the one the core affect directly modulates. Declarative memory includes both symbolic structures (i.e., memory chunks) and sub-symbolic quantities that control the operation of the symbolic structures in the equations. The valuation and arousal values, which help to define the core affect, are subsymbolic quantities added to the current sub-symbolic equations of ACT-R.

## Core affect and memory

We present a summarized version of the core affect mechanism to facilitate the understanding of our model. An extended version of the core affect mechanism can be found in Juvina and Larue (2016). The original equation (Anderson, 2007) that computes the activation of a declarative memory chunk is:

$$
\begin{equation*}
A_{i}=B_{i}+S_{i}+P_{i}+\varepsilon_{i} \tag{1}
\end{equation*}
$$

- $\quad A_{i}$ is the activation of the chunk $i$.
- $\quad B_{i}$ is the base-level term and reflects the recency and frequency of use of chunk $i$.
- $\quad S_{i}$ is the spreading term and reflects the effect of the context on the retrieval of chunk $i$.
- $\quad P_{i}$ is the partial matching term and reflects the degree to which the chunk $i$ matches the specification of the retrieval request.
- $\varepsilon_{i}$ is a noise or variability component.

Activation of a chunk reflects its use, and decays over time if the chunk is not used. Retrieval time and the retrieval probability of a chunk are determined by activation (e.g., chunks under a certain retrieval threshold cannot be retrieved). However, the selection process is impacted by noise. The chunk with the highest activation has the highest probability of being selected, but other chunks get the opportunity as well allowing some exploration behavior in ACT-R.
In the current ACT-R architecture, reward based learning affects procedural memory. However, subjective values (e.g., pleasant or unpleasant) might actually be carried by declarative memory as affectively charged representations, which are easier/harder to retrieve according to these values (Smith, Most, Newsome, \& Zald, 2006). A new ACT-R module called "Valuation" was developed to add valuation and core affect capabilities into ACT-R. In theory, core affect is a diffuse affective state that is not necessarily linked to any specific event and is characterized as a point in a two-dimensional space, where the two underlying dimensions are valence (i.e., pleasure-displeasure) and arousal (Russell, 2009). In our implementation, core affect is defined as two accumulators called core-affect-valuation (Valuation) and core-affect-arousal (Arousal), which are sub-symbolic quantities computed by the "Valuation" module. It also maintains the parameters and history information that are needed for these computations. Both values affect the probability that a chunk can be retrieved from declarative memory. Valuation is an indicator of the affective valence of a particular stimulus or fact learned through interaction with the environment. Arousal is an indicator of the importance or priority that is given to a particular stimulus or fact; it is the absolute value of valuation. Relying on the existing memory mechanisms from the ACT-R theory, valuation and arousal are just two separate terms added to the general activation equation previously introduced:

$$
\begin{equation*}
A_{i}=B_{i}+S_{i}+P_{i}+V_{i}+A r_{i}+\varepsilon_{i} \tag{2}
\end{equation*}
$$

- $\quad V_{i}$ is the valuation term and reflects the rewards received by the model after referencing chunk $i$.
- $A r_{i}$ is the arousal term which reflects the importance of chunk $i$ and is computed as the absolute magnitude of the valuation term.

The learning of valuations occurs when a reward is triggered: the valuations of all chunks that been referenced within a time window are updated. This is compatible with findings of overlapping neural substrates between the attribution of subjective value to stimuli and reward-based learning (Paton, Belova, Morrison, \& Salzman, 2006). The effective reward of a chunk $i$ is the reward value received at time $n$ minus the time since the last reference of chunk $i$.

The learning of valuations for a chunk $i$ is controlled by the following equation:

$$
\begin{equation*}
V_{i}(\mathrm{n})=V_{i}(\mathrm{n}-1)+\alpha v\left[R_{i}(\mathrm{n})-V_{i}(\mathrm{n}-1)\right] \tag{3}
\end{equation*}
$$

- $\quad V_{i}(\mathrm{n})$ is the valuation of chunk i after its nth update.
- $V_{i}(\mathrm{n}-1)$ is the valuation of chunk i prior to its nth update.
- $\alpha v$ is the learning rate for valuations.
- $\quad R_{i}(\mathrm{n})$ is the effective reward value received by chunk i before its nth valuation update.
- $V_{i}(0)$ is determined based on initial parameter settings.

Reward signals allow the model to learn valuation and arousal values for elements according to what is presented in the environment.
Additional parameters make it possible to weight valuation and arousal independently in the equation. Values used in this paper can be seen in Table 1:

- Valuation weight (:vw) is a scale parameter for the valuation term in the general activation equation.
- Arousal weight (:aw) is a scale parameter for the arousal term in the general activation equation.
- Valuation time window (:vtw) is a time window over which to update the valuations. It determines how many chunks are updated.

In the architecture, core affect is the weighted accumulation of valuation and arousal values for all retrievable chunks, and weights are probabilities of retrieval reflecting chunk activations. This value is implicitly maintained by the architecture.

In this implementation, affect phenomena are not hardwired in the cognitive architecture but learned from the interaction among various architectural components and between architecture and environment. Only primitive affective mechanisms: valuation (i.e., valence obtained through interactions) and arousal, were included in the cognitive architecture. Valuation and arousal are added as terms in the general activation equation and influence the probability of a chunk to be retrieved. This is consistent
with the core affect theory (Russell \& Feldmann Barrett, 1999; Russell, 2009).

Our hypothesis is that this is all that is necessary to include at the architectural level to model the interaction between cognition and affect.

## Model

## Conditions

The procedure used here was derived from an experiment by Dijksterhuis et al. (2006) and replicated by Mikels et al. (2011). During these experiments, participants were given information about four different car options (i.e., Car A, Car B, Car C, and Car D) and were instructed to choose which car they believed to be the best choice. Simple attributes, framed as either positive or negative (e.g., this car gets good/bad gas mileage), were provided one at a time for each car option. The best choice was defined as the car with the most positive attributes. The best choice had $75 \%$ positive attributes, two cars had $50 \%$ positive attributes, and one car had $25 \%$ positive attributes. The design consisted of one dependent variable (i.e., car choice) and two independent

Figure 1. Experiment procedure and memory representations across task in detail-focus vs feeling-focus conditions
Participants were split into four conditions based on the two independent variables (i.e., feeling-focus simple, feeling-focus complex, detail-focus simple, and detail-focus complex). Those in the feeling-focus conditions were instructed to rate how they felt about each attribute and make their choice while focusing on their feelings. In the detail-focus conditions, participants were instructed to rate how well they were remembering the attributes and make their decision based on the details of the attributes. Simple conditions had four attributes for each car option, whereas complex conditions had 12 attributes per car option.

All conditions completed a memory recall task at the end of the trial. Results from a chi-square analysis indicated that participants in the detail-focus simple condition performed better than participants in the feeling-focus simple condition, although this difference did not reach significance. However, participants in the feeling-focus complex condition significantly outperformed those in the detail-focus complex condition. There was no difference between focus conditions for memory recall, but there was a difference between simple and complex conditions. Both Dijksterhuis et al. (2006) and Mikels et al. (2011) concluded
that focusing on your feelings leads to better complex decisions compared to more deliberate thinking.

Table 1. Model parameters

| :rt | -2.4 |
| :--- | :--- |
| :vw | 1.0 |
| :aw | 2.0 |
| :av | 0.2 |
| :vtw | 0.5 |

## Encoding across conditions

Encoding mechanisms used are the same, but:

- In the detail-focus, the strategy used makes you consider all features and ratings associated to those features.
- In the feeling-focus condition, the strategy used gives more value to the ratings (i.e., good/bad) than their features..

Table 2. Model strategy in the detail-focus condition

| Step | Strategy in the detail-focus condition |
| :--- | :--- |
| Presentation phase |  |
| 1 | "Car-feature-value" triplet is displayed |
| 2 | See car |
| 3 | Encode car |
| 4 | See feature |
| 5 | Encode feature |
| 6 | See value |
| 7 | Encode value |
| 8 | Clear imaginal (enter chunk in declarative <br> memory) |
| 9 | Go back to step 1 until all cars have been <br> displayed |
| Evaluation phase |  |
| 10 | Pick a car that has not been evaluated yet |
| 11 | Retrieve triplet (car-feature-value) with a "good" <br> judgment |
| 12 | Count the positive values for this car |
| 13 | Go back to step 10 until there are no cars left |
| 14 | Decide the car with the highest count |

Detail-focus condition (Table 2). Stimuli consisting of three elements (car - feature - rating) are presented one at a time to the model The model looks at each element separately and encodes them as a memory chunk of the following association: car - feature - rating. Car is also a memory chunk (Presentation phase in "Detail-focus" in Figure 1).

When all stimuli have been presented to the model, it proceeds to the evaluation through a tallying heuristic (Gigerenzer, 2016): by interrogating its memory on features for each car, counting all chunks for which it can retrieve an association with a "good" rating for a feature. The car with the highest overall number of "good" rating-feature-car associations that could be retrieved is the one that is named
by the model as the best car choice (Evaluation phase in "Detail-focus" in Figure 1). The significantly higher number of reasoning steps in the detail-focus condition (Table 2) results from the thorough analytical process that participants were assumed to engage in during this condition.

Table 3. Strategy in the feeling-focus condition

| Step | Strategy in the feeling-focus condition |
| :--- | :--- |
| Presentation phase |  |
| 1 | "Car-feature-value" triplet is displayed |
| 2 | See car |
| 3 | Retrieve chunk car |
| 4 | See value |
| 5 | Trigger reward depending on value |
| 6 | Update valuations |
| 7 | Go back to step 1 until all cars have been displayed |
| Evaluation phase |  |
| 8 | Retrieve car with highest activation |
| 9 | Decide (highest valuation car is the one with the <br> most "good" features) |

Feeling-focus condition (Table 3). The same stimuli are presented to the model randomly; but the model is going to follow a different strategy. It only looks at the car and rating, as shown in Table 3 (Presentation phase in "Feelingfocus" in Figure 1). The model retrieves the car chunk associated with the presented car, and according to the rating "good" or "bad", sends a reward signal. This reward affects the valuation of this specific car without it being necessary to encode all the features of the car. When the reward signal is sent, all the valuations of chunks that were retrieved in this time window are updated. Recall the explanation in the previous section (detail-focus condition) that the memory representation includes the car chunks. Thus, if the car to which this rating was attached is in the time window, it gets a valuation update.

When all stimuli have been presented to the model, it proceeds to the evaluation by retrieving one of the previously presented cars (Evaluation phase in "Feelingfocus" in Figure 1). The retrieved car is the one with the highest activation, which likely has the highest rating because valuation was updated positively during the first stage of car presentations.

## Results and Discussion

Results in Figure 2 are shown for 50 runs of the model (stable performance, based on cumulative standard deviation, was reached after 43 runs).
There was a significant difference in accuracy between the two feeling focus conditions (i.e., simple and complex), $t(97.89)=2.67, p<0.01$. A significant difference in accuracy was also found between the detail-focus complex condition and feeling-focus complex condition, $t(83.1)=$ $6.001, p<.001$. These same differences were observed in the original experiments.

The model also captured participant's better performance in the detail-focus simple condition compared to the feelingfocus simple condition (difference is not significant like in the original results). However, while still within the standard error range, the detail-focus complex condition appears lower than in the original experiments. This could be explained by something that is not captured in the strategy of our model. When uncertain, human participants could have guessed more accurately (compared to random guesses by the model) based on prior knowledge. For instance, a participant may have eliminated options based on memory that certain options had fewer positive attributes.

Figure 2. Accuracy in feeling-focus vs. detail-focus in complex and simple conditions for the original experiments and our model

## Model dynamics in detail-focus condition

In the simple condition, the model has a performance close to the feeling-focus condition. However, in the complex condition more features are memorized for each car. In this condition, more words are forgotten as the experiment is longer and there are more words to remember. Activation of those unused chunks decay over time. Therefore, when going through all the cars and remembering the features, there are more chances of memory retrieval failures.

The forgetting time is also amplified by the length of the recall strategy, contributing to future retrieval failures. The model may be forgetting features of the next car while listing the elements of the current car. This explains the poorer performance of the model in the complex condition. It is important to note that the model does not account for possible confusions in the car and feature-rating associations.

## Model dynamics in feeling-focus condition

The model performs better in the complex condition than in the simple condition. In the complex condition, while the proportion of good features is the same, the overall number of features per cars is higher. This gives the model more opportunity for rewards. In the simple condition, there are
fewer features and less reward opportunities. The activation equation has a noise parameter. Due to this noise the chunk with the highest valuation might not be the one with the highest activation (thus, not the one retrieved). Therefore, when retrieval from memory is initiated, decay and noise might make the activation number obtained through the activation equation close but higher for another car than the one who received the highest rating. This happens more often in the simple condition where you will have chunks of very close valuations. Figure 3 illustrates the differences in valuation between the chunk representations of the car options. The gap in valuation between options is more visible in the complex condition.

In contrast to the detail-focus condition, retrieving the highest rated car in the Feeling-condition is a very simple and fast process. It only requires one retrieval of the car with the highest activation (no features retrieval involved), therefore there is less decay of activation for the chunks and therefore less ground for retrieval mistakes.

Figure 3. Evolution of the chunk valuation of each cars in feeling-focus condition across rounds, simple vs complex conditions

## General Discussion and Conclusion

In this paper we presented a mechanism for core affect in ACT-R. This mechanism specifies how affect modulates memory (e.g., reducing information or emphasizing the positive or negative value) compared to attempting to remember the entire set of attributes in the detail-focus condition (i.e., high memory load). It also shows that implicit decisions might lead to better decisions than explicit decisions in certain contexts.

We model affect in a cognitive architecture as a phenomenon, which emerges from the dimensions of the core affect theory (i.e., valence and arousal) and is learned through the interaction with the environment. We interpret valence as valuation. Valuation is a sub-symbolic quantity for chunks learned through interactions with the world. Arousal is the absolute value of valuation. Core affect is the weighted accumulation of valuation and arousal values for all retrievable chunks, and weights are probabilities of retrieval reflecting chunk activations. Parameters given to the ACT-R architecture, existing reward mechanism of the architecture, and usage information about the chunks are used to compute valuation and arousal values. The core affect values are implicitly maintained by the architecture. Valuation and arousal are added as terms in the general activation equation and influence the probability of a chunk
to be retrieved. We rely on the existing general activation equation of ACT-R to integrate our model in a unified theory of cognition.

While the core affect theory has been present in theories of emotion, and the role of emotions has been considered in the domain of decision making, very little has been done to connect the work on core affect theory to decision making.

We hypothesized and demonstrated that those mechanisms that allow for an affect phenomenon to emerge, were sufficient to account for the behavior encountered in Mikels et al. (2011)'s experiment. Engaging in a detailed analytical thought process might be as beneficial as deciding based on your feelings in a simple environment (i.e., low cognitive load). However, there is a tradeoff. As the amount of elements on which to base your decision increases, exerting a high load on your declarative memory, decisions based on affect seem to be more accurate than decisions based on a thorough analytical process in those complex environments. We demonstrated that an affective modulation of memory by core affect, which simplifies the amount and complexity of information, could explain this phenomenon. Therefore, core affect may help individuals make better decisions in complex tasks, which exceed limited cognitive capacities by reducing the need to memorize each element included in the decision. Instead, the interaction with the elements a decision is supposed to be based on, can be implicitly processed in conjunction with affect, and the resulting decision can be based on those affects. Furthermore, we showed that an implicit mechanism (core affect) allows us to make an efficient decision.

#### Abstract

In this study, we focused on the Generic Overgeneralisation (GOG) effect (Leslie, Khemlani, and Glucksberg 2011) and tested the relevance of context and an explanation based on quantifier domain restriction for the pattern of judgement data observed. Participants judged generic majority characteristic statements like tigers have stripes or statements with universal quantifiers that have different sensitivity to context ('all', 'all the', 'each') preceded by one of three levels of context: a) neutral, where the information in the context does not interact with the truth value of the critical statement, b) contradictory, where it presents an exception which should rule out a universally quantified statement, and c) supportive. Our results suggest that proponents of the generics-as-default view ruled out context prematurely and that in fact context is a viable alternative explanation for much of the so-called GOG effect.

Keywords: context; generalisation; genericity; quantification; quantifier domain restriction

## Introduction

Quantificational generalisations, as in (1), are expressed in quantitative, statistical terms, while generic generalisations, as in (2)-(3), make general claims about kinds of entities and refer to a property that is characteristic of the kind in question, but not necessarily statistically prevalent, as in (3):
(1) Some lions live in cages.
(2) Lions roar.
(3) Lions have manes.

Generic generalisations have long been studied in formal semantics, within which genericity is frequently viewed as a species of quantification. Even though generics have been studied since the seventies (see Dahl 1975; Carlson 1977), how to characterise their semantic interpretation and how to model their truth conditions remains a controversial topic (see discussion in Mari, Beyssade, and del Prete 2013). Within formal semantics, modal logic and probabilistic approaches are most prominent, both of which treat genericity as akin to quantification. According to the modal approach, which is the most widely adopted formal analysis
of genericity, generic meaning is obtained as the effect of an underlying operator or quantifier dubbed 'GEN', which is not phonologically realised but which is active in the composition of the sentence meaning and is an unselective variable binding operator similar to adverbs of quantification like usually, typically, always, as analysed in Lewis (1975). This operator is sentential and is represented by a tripartite structure as in (4) (Krifka et al. 1995). Thus, the logical form of (2) may be given as follows in (5):
(4) GEN [restrictor] [matrix]
(5) $\operatorname{GEN}_{\mathrm{x}}[$ Lions (x)] [Roar (x)]

Generic generalisations can be made using a wide range of different grammatical means, including definite and indefinite singulars and bare plurals in English, but no language has a unique, unambiguous marker of genericity equivalent to a quantifier or determiner. It is important to note that none of the analyses that posit a 'GEN' operator offer an explanation for this, a point that a recent psychological approach to generics, capitalises upon.

This growing body of experimental and developmental psychological work on the topic proposes that genericity is categorically different from (and significantly simpler than) quantification (Leslie 2007, 2008, Gelman 2010). This latter hypothesis, called the Generics-as-Default view (GaD view henceforth), treats generics as an innate and default mode of thinking. This idea is linked to the 2 -system view of cognition argued for by Kahneman and Frederick (2002) among others, which includes a distinction between System 1, a fast, automatic, effortless lower-level system, and System 2, a slower, more effortful higher-level rulegoverned system. According to this view, the fact that no language has a dedicated overt 'GEN' operator does not come as a surprise: given that generics are the most primitive default generalisations, children do not need to learn anything in order to acquire them.

The GaD approach argues that the fact that there is no overt generic operator in any known language is because generics are the unmarked, System 1, case. On this view, only effortful, non-default quantificational generalisations
require overt linguistic exponence. However, while assigning generics to a more basic, unmarked System 1, mode of thinking may sound intuitive at some level, it rests on a vague and undefined notion of markedness. Leslie refers to Chomsky (2000), but she gives no definition of markedness. Intuitively, it seems that what is at stake is surface level overt realisation (third notion of markedness of Haspelmath 2006).

A challenge for both types of approach is to determine which properties can be used in generic statements. Generic generalisations range from definitional statements that do not tolerate any exceptions (triangles have three sides) to statements that involve characteristic properties and are true of the majority of the kind with only a few exceptions (tigers have stripes) - which are called 'majority characteristic' by Leslie et al. (2011) - through statements that are true of a minority of the kind yet are characteristic (ducks lay eggs) - which are called 'minority characteristic'to statements that have low prevalence but involve a property that is noteworthy in some way (sharks attack people) - which are called 'striking'. A further complication is that statistical prevalence is neither a necessary nor a sufficient condition to license generic generalisations, as statements like books are paperbacks may be true of the majority of the kind, but are typically judged as false and thus fail as generic generalisations ('false generalisations').

In Lazaridou-Chatzigoga, Katsos and Stockall (2015) we juxtaposed the linguistic approach to genericity and the experimental research investigating the GaD hypothesis and we highlighted the significant challenges for each approach. We concluded that interdisciplinary work, integrating the tools and perspectives of both strands of investigation, is needed in order to advance our understanding of genericity.

In Lazaridou-Chatzigoga, Stockall and Katsos (2017) we focused on the effect called 'Generic Overgeneralisation' (GOG) (Leslie et al. 2011), which has been used to support the GaD view on generics. The Generic Overgeneralisation (henceforth 'GOG') effect is "the tendency to overgeneralise the truth of a generic to the truth of the corresponding universal statement" (Leslie et al. 2011:17). In that paper, we discuss a set of four non-mutually exclusive explanations for the GOG effect: a) ignorance of the relevant facts, $b$ ) subkind (taxonomic) interpretation, c) the atypical behaviour of all and d) Quantifier Domain Restriction (QDR), which will be explained in more detail in the next section. We proposed that all these factors play a role in explaining the attested behaviour by adults. These factors are independently attested and known to interact with the interpretation of generic and quantified statements. We suggested that even the name of the GOG effect might be misleading. The effect mainly tries to capture the behaviour observed with the quantifier all, which supposedly gets a generic interpretation as a result of an overgeneralisation bias. Thus, perhaps a better name for that effect would be 'Quantifier Reanalysis' effect, because this term would direct the focus where we believe it belongs: on the interpretation of all, or more generally of quantifiers,
rather than the interpretation of generic statements. The overall aim in that paper was to showcase the role of linguistic factors (both semantic and pragmatic) in the interpretation of generic and quantified statements, and to underscore the relevance of linguistically motivated explanations.

In this paper, we address the effect of context on generic and universally quantified generalisations empirically.

## The GOG effect

The first detailed investigation of the GOG effect is found in Leslie et al. (2011). In their experiment 1, participants performed a truth-value judgement task on sentences that were presented in one of three forms: generic, universal (all), or existential (some). The statements involved different kinds of properties: quasi-definitional (triangles have three sides), majority characteristic (tigers have stripes), minority characteristic (ducks lay eggs), majority non-characteristic (cars have radios), striking (pit bulls maul children), and false generalisations (Canadians are right-handed). The authors report that adults sometimes judge universal statements as true, despite knowing that they are truth-conditionally false. For example, participants judged a quantified statement like all tigers have stripes as true, even though they know it is false given that there are albino tigers. The authors claim that the participants made this 'error' because they relied on the corresponding generic statement, which is true. They find that the GOG effect is restricted to characteristic properties and that it occurs in more than half the trials: 78\% for majority characteristic and $51 \%$ for minority characteristic statements.
The authors argue that these elevated acceptance rates are due to participants interpreting the 'false' universally quantified statements as if they were their 'true' generic counterparts, and are thus a clear case of GOG. Before reaching that conclusion, the authors acknowledge three alternative explanations, which they argue are ruled out with subsequent experiments: a) ignorance of the relevant facts, namely, that participants do not know that male ducks do not lay eggs, which they ruled out by administering a knowledge test that confirmed knowledge of the relevant facts (their experiment 3), b) subkind interpretation, namely, that participants interpret all ducks lay eggs as 'all kinds/types of ducks lay eggs', which is a true statement, which they discarded through a paraphrase task (their experiment 2 b ), where only $1 \%$ of the paraphrases explicitly mentioned subkinds, and c) Quantifier Domain Restriction (henceforth QDR), to which we turn in the next paragraph.
Under an explanation based on $Q D R$ participants might interpret a statement like all ducks lay eggs as applying only to a relevant subset of ducks, namely the mature fertile female ducks. Quantified statements are interpreted within a context, which may restrict the scope of the quantifier (see Stanley and Szabó 2000). Thus, the reason why people accept the all statement is because (they believe) it is true once the quantifier has been restricted to the relevant subset of ducks. The authors addressed this alternative explanation
in their experiment 2 a , where they provided the participants with a background context, which was presented before each statement. These contexts included artificial population estimates of the following form:
(6) 'Suppose the following is true: there are 431 million ducks in the world. Do you agree with the following: all ducks lay eggs."

This information was supposed to prime quantification over every individual duck in the world, and thereby make it difficult/impossible to interpret all as restricted to only the ducks that are presupposed by lay eggs. If acceptance of all ducks lay eggs in the first experiment was driven by QDR the authors predicted that it would disappear in the context of population information of the kind above. However, the GOG effect still occurred on a substantial portion of trials for statements with all, with a $60 \%$ acceptance rate for majority characteristic statements and $30 \%$ for minority characteristic statements - less than when the statements appeared with no preceding context ( $78 \%$ and $51 \%$ respectively), but still a high percentage. The authors thus concluded that domain restriction could not be the sole explanation for the GOG effect.

On the above grounds, Leslie et al. (2011) rejected all three alternative explanations and argued they had found evidence for a strong generic bias, according to which people sometimes treat universally quantified statements as if they were generic.

## Overview of the present study

In the present study, we addressed QDR as an explanation for the GOG effect building on a design used by LazaridouChatzigoga and Stockall (2013). We chose to focus on the relevance of context and QDR given that the latter is a pervasive phenomenon affecting quantifiers and their interpretation within a context, and is routinely invoked in quantification (Heim 1991). According to QDR, the domain of a universal quantifier can be restricted in the following sense: in a discourse like 'There was rhubarb pie for dessert, Everyone developed a rash' (example modified from von Fintel 1994) a quantifier like everyone does not quantify over all the individuals in the world, but rather over the contextually restricted set of individuals. Furthermore, listeners are known to be charitable (Grice 1975). Thus, in a conversation one assumes that speakers take the most sensible positions and make the most plausible assertions. Under this view, interpreting everyone as quantifying over all the individuals in the world seems a rather unlikely intended interpretation and moreover one that is not charitable to the speaker because it renders her utterance false, whereas interpreting everyone with respect to the available set of individuals is not only plausible but also charitable to the speaker.

We hypothesised that if we could show that the amount of GOG behaviour can be altered by carefully manipulating different levels of contextual information preceding the
critical utterance, we would have evidence that the observed tendency to accept universally quantified statements as true can be explained through independently motivated mechanisms and that there is no need to appeal to GOG.
Rather than the population statistics contexts used by Leslie et al. (2011), which only had a moderate effect on participant behaviour, we decided to use three different types of contexts. Furthermore, because of the design we adopted, we decided to focus only on majority characteristic statements ('tigers have stripes') leaving minority characteristic statements ('ducks lay eggs') for future investigation. We varied the context preceding the critical utterance as follows: a) neutral, where the information in the context does not interact with the truth value of the critical statement; b) contradictory, where exceptions which should rule out a universally quantified statement are made salient, and c) supportive, where a paraphrase of the critical property is given, which makes its generality salient. Two of the three context types (contradictory and supportive) made the relevant domain for QDR salient, while the neutral context served as a baseline measure. The contradictory and supportive contexts turned the implicit restriction to 'all normal' individuals to an explicit one by either highlighting some abnormal individuals (contradictory) or by stating that the relevant individuals had the relevant property, i.e. they were normal individuals (supportive).
In addition to manipulating context, however, a compelling test of the QDR view also requires testing whether the GOG effect is observed only with all or whether different universal quantifiers would show such an effect. There are reasons to believe that all should not be treated as a representative universal quantifier. It has been argued to a) participate in fallacious reasoning (Jönsson and Hampton 2006), b) be prone to hyperbolic/loose use similar to 'almost all' (Claridge 2011), and c) be ambiguous between distributive and collective interpretation (Beghelli and Stowell 1997). Thus, using different types of universal quantifiers is essential to test the scope of the GOG effect. Furthermore, a study that specifically addresses the relevance of QDR should include universal quantifiers with different sensitivity to QDR. More specifically, QDR is less likely if the universal quantifier used does not require linking with a set under discussion, as is the case with all, compared to each and all the, which have to be interpreted as D(iscourse)-linked (Partee 1995, Pesetsky 1987).
To recapitulate, (a) the contextual manipulations used were expected to make the implicit domain restriction explicit and salient to the participants and (b) this manipulation was expected to influence truth-value judgements by showing a decrease in acceptance rates in the contradictory condition and an increase in acceptance rates in the supportive condition.

## Method

## Participants and procedure

120 volunteers ( 49 male, 70 female, 1 other; aged 19-67; mean age 37.28; SD 13.06) participated in the experiment
over the Internet. Participants were recruited through Amazon's Mechanical Turk system for human interface tasks. All spoke English as their first language and lived in the United States. The study was presented in the online platform Qualtrics. Each trial consisted of three displays. In the first display participants read a background context, in the second display they read a statement and in the third display they were asked to judge whether they agreed with the statement they just read. Their response was recorded by selecting keyboard keys (' A ' for yes and ' K ' for no).

## Materials and design

Participants were presented with 84 statements, including 48 fillers presented in a randomised order. The 12 test items consisted of majority characteristic statements like tigers have stripes and horses have four legs. We included 26 control items, 12 definitional statements like ants are insects and 12 false generalisations like books are paperbacks to get baseline measures and to (semi)counterbalance the percentage of expected True/False responses. All the contexts and items were normed beforehand by English native speakers, who did not take part in the experiment. This was done to make sure that the context manipulations worked as intended. Most of the experimental items used are a subset of the items used by Leslie et al. (2011). The two conditions we manipulated for the majority characteristic items were: a) determiner type: bare plural generic/all/all the/each, and b) context type: neutral/contradictory/supportive. The statements were presented in one of the determiner forms and were preceded by one of three types of context: a) neutral, b) contradictory, or c) supportive, examples of which are given below:
(7)
a. neutral context: Linton $Z o o$ is home to three tigers, Tibor, Baginda and Kaytlin, whose playful games visitors love to watch and photograph.
b. contradictory context: Linton Zoo is home to three tigers, Tibor, Baginda and Kaytlin, whose fur is all white due to a recessive gene that controls coat colour.
c. supportive context: Linton Zoo is home to three tigers, Tibor, Baginda and Kaytlin, whose black and orange coats visitors love to photograph.

Given the 4 determiners (generic/all/all the/each) we created 4 lists with 3 sublists each that varied with respect to the pairing of the items with context type, which gave us 12 lists in total. There were 10 participants in each sublist, who were assigned randomly. Here is a sample of a trial of a statement with all after a neutral context:
(8)

DISPLAY 1:
Background:
Linton Zoo is home to three tigers, Tibor, Baginda and Kaytlin, whose playful games visitors love to watch and photograph.

DISPLAY 2:
Statement: All tigers have stripes. DISPLAY 3:
Do you agree with the statement?
o Yes (A) o No (K)
The definitional and false generalisations were in the generic form in all lists. Fillers served to ensure the percentage of expected True/False responses was similar. The definitional and false generalisations, as well as the fillers, were preceded by a context that did not vary across conditions. The materials can be viewed at http://www.dimitra-lazaridou-chatzigoga.com/cogsci-paper/

## Results and discussion

The final model used included 116 out of the 120 participants. 4 participants were excluded based on their responses to definitional statements; we excluded subjects that responded correctly at fewer than 10 out of 12 items.

## Acceptance rates

Table 1 summarises the proportion of 'TRUE' responses to the TVJ question for the test items (majority characteristic statements) in each condition. We report proportion of 'TRUE' responses rather than the actual number of responses to facilitate comparison with Leslie et al.'s (2011) results.

Table 1: Mean Proportion (SE) of 'TRUE' responses as a function of context and determiner type.

|  | Context |  |  |
| :--- | :--- | :--- | :--- |
| determiner | neutral | contradictory | supportive |
| GEN (ø) | $99.14(3.12)$ | $87.07(0.86)$ | $100(0)$ |
| all | $80.56(3.82)$ | $48.15(4.83)$ | $87.96(3.14)$ |
| all the | $78.33(3.78)$ | $37.50(4.43)$ | $90(2.76)$ |
| each | $79.17(3.72)$ | $30.83(4.23)$ | $85.83(3.2)$ |

As we see above, generics were accepted at higher rates overall than universals, as expected, given that we had chosen items that were true in generic form. Both in the neutral and the supportive condition acceptance rates for generics were at ceiling ( $99 \%$ and $100 \%$ respectively) and were only lower in the contradictory condition (87\%). With universals, the picture is more complicated. All three universals (all, all the, each) were accepted at similar rates in both the neutral and the supportive condition, showing only a small increase in the supportive condition. In the neutral condition, all-statements were accepted $81 \%$ of the time, all the-statements $78 \%$ of the time and eachstatements $79 \%$ of the time. In the supportive condition, allstatements were accepted $88 \%$ of the time, all thestatements $90 \%$ of the time and each-statements $86 \%$ of the time. Universals after a contradictory context yielded fewer acceptances overall, as expected: all-statements were accepted $48 \%$ of the time, all the-statements $38 \%$ of the time and each-statements $31 \%$ of the time. Acceptance rates
for both generics and universals differed significantly between the neutral and the contradictory condition.

On the surface, we do get many 'TRUE' responses to universal quantifiers, as in the GaD literature, which might look like a GOG effect. We predicted that contradictory context should decrease acceptances across the board, while supportive context should increase them. We expected a smaller effect for generics because the generic statements were constructed so as to be true and because of their resistance to contextual restriction (i.e. we expected ceiling effects) and we predicted differences between the universal Qs depending on their sensitivity to QDR/D-linking. Nevertheless, we had specific predictions about the relative rates depending on the level of context, which according to Leslie et al. should not differ. In order to appreciate the relative effect of context on acceptance rates, we subtracted the average means of the contradictory condition from the average means of the neutral condition, as well as the average means of the supportive condition from the average means of the neutral. We took acceptance rates in the neutral condition as our baseline plotted at 0 . Negative values mean fewer acceptances and positive values mean more acceptances. We interpreted the rates obtained as the relative effect of context on acceptance rates plotted in figure 1 below.

Figure 1: The relative effect of context.
We get the effect for the contradictory context exactly as predicted for the universal Qs. The relative effect is bigger for those quantifiers that require QDR because of their semantics (all the, each) than for the one that allows but does not require QDR to the relevant subset (all). We also find that context does affect GEN in the contradictory context.
The prediction about the supportive context was not borne out because of ceiling effects in the neutral condition. Adding explicit information supporting the statement hardly mattered, as acceptance rates did not rise significantly. The ceiling effect might be due to participants being charitable and/or exceptions not being immediately salient.

We used R (R Core Team, 2012) and the lme4 package (Bates et al. 2015) to perform a generalised mixed-effects linear analysis of the relationship between determiner and context, specifying a binomial family. Responses were treated as a dummy coded categorical variable and were modelled with glmer. First, we fitted a full model with det.type and context.type as fixed effects (with an interaction term) and with random intercepts for subjects and items. We performed a likelihood ratio test of the full model with an interaction term against a model without the interaction term and the comparison proved non-significant $\left(\chi^{2}(6)=8.3455, p=0.2139\right)$. Thus, including an interaction term did not improve model fit, so we used the model without the interaction term for all subsequent analyses/comparisons.
We then fitted versions of the full model, in which a single effect was removed and we compared the reduced model to the model without interaction. To test the main effect of context, we removed context. A likelihood ratio test of the model without interaction against the model without context proved highly significant $\left(\chi^{2}(2)=311.81, \mathrm{p}<2.2 \mathrm{e}-16\right)$. Thus, we concluded that there was a main effect of context. To test the main effect of determiner, we removed determiner. A likelihood ratio test of the model without interaction against the model without determiner proved highly significant $\left(\chi^{2}(3)=58.183, \mathrm{p}=1.436 \mathrm{e}-12\right)$. Thus, we concluded that there was a main effect of determiner.

## General Discussion

We set out to explore one of the alternative explanations for the judgement data that concern universally quantified statements, which have been used as evidence of a GOG effect. The study presented here provides experimental evidence for the relevance of a QDR-based explanation of the purported GOG effect. In our study, context did not only affect acceptance rates for all and other universal quantifiers (all the, each), but it further predicted the levels of QDR depending on the level of context. The effect of context was greater for all the and each, two quantifiers that require QDR, while it was smaller for all, whose domain is only optionally restricted. Leslie et al. had ruled out the relevance of context and hence predicted no differences in acceptances across contexts for all. Furthermore, even though they only discuss all they make general claims about (universal) quantification being prone to the GOG effect. We argue that drawing conclusions about universal quantification (and by extension about genericity) requires more subtle manipulations. The differences we found between the different universal quantifiers are predicted according to the QDR view advanced here, but ought to be inconsistent with the GaD view, were they to discuss them.
We also find that context matters for generics too, a fact that bears further investigation, but is in line with recent work that claims that generics display some context sensitivity (Sterken 2015). This might be more consistent with an analysis in which GEN also involves (some form of) quantification rather than one that treats GEN as
categorically/ontologically different from universal quantifiers.
Overall, we argue that there exist alternative explanations for big portions of the supposed GOG effect. The study discussed here did not address all the alternatives, but so far in the literature it has been shown that at least pure error, ignorance and now context all significantly affect acceptance rates. In work in progress, we address crosslinguistic variation in the realisation of generic and universal generalisations. The general thrust of this work is that, rather than being under the influence of a default bias, adults are simply sensitive to the subtle interplay of quantifier semantics and pragmatics on the one hand, and context on the other. This approach has the advantage of accounting for data without postulating ad-hoc mechanisms such as GOG just for generics.

## Acknowledgments

This work was supported by a British Academy/Leverhulme Trust Small Research Grant (SG-132271). We are grateful to Faidra Faitaki and Valentina Hu for their help with experimental materials and data entering, to Anne Beshears, Patrick Elliott, Shivonne Gates, David Hall, Jessica Soltys, Tom Stanton, Nikola Vukovic and Elspeth Wilson for their help with norming and the experimental software, and to Stephen Politzer-Ahles for advice on the statistics.

#### Abstract

Using real-time eye-movement measures, we asked how a fantastical discourse context competes with stored representations of semantic and world knowledge to influence children's and adults' moment-by-moment interpretation of a story. Seven-yearolds were less effective at bypassing stored semantic and world knowledge during real-time interpretation than adults. Nevertheless, an effect of discourse context on comprehension was still apparent.

Keywords: discourse; children; sentence comprehension; eyetracking; semantics; cognition; fantastical fiction

## Real-time interpretation of fantastic fiction

Linguistic processing requires listeners to identify relevant thematic relationships between the entities and events evoked in a sentence. Studies of visually-situated language processing have shown that comprehenders use such relations to predict upcoming linguistic input, and in turn direct their attention to compatible referents in the visual world (e.g., Altmann \& Kamide, 1999; Kamide, Altmann, \& Haywood, 2003). For example, when hearing the sentence 'The boy eats the big cake' while looking at a scene containing a cake and a bird, adults and children as young as 2 years of age look to the cake while 'eats' is unfolding (Mani \& Huettig, 2012). Children as young as 3 years of age can also use their prior knowledge of the relationships between actions and agents to generate more sophisticated predictions, e.g. anticipating 'bone' upon hearing "The dog hides" (Borovsky, Elman, \& Fernald, 2012).

In adults, comprehension is also rapidly influenced by higher-order meaning created by physical, functional and situational relations between entities and events (Chambers \& San Juan, 2008; Sedivy, 2003; Tanenhaus, SpiveyKnowlton, Eberhard, \& Sedivy, 1995). Situation-specific factors, including a fictional context, can in fact override lexical and semantic relationships based on stored knowledge (Cook \& O’Brien, 2014; Filik, 2008; Nieuwland \& Van Berkum, 2006). However, prior research with grade school children has shown that they tend to privilege lexical
information over situation-specific knowledge (Snedeker \& Trueswell, 2004; Trueswell, Sekerina, Hill, \& Logrip, 1999). Children may therefore find it difficult to rely on a fictional context to inform real-time language processing, particularly in fantastical fiction where described events (e.g., a person flying) strongly depend on information in the narrative, and are at odds with the nature of the real world. Conversely, it is possible that the incongruent actions and salient contrast between the real and narrative worlds involved in a fantastical narrative may strengthen children's mental simulation of story information, and thus support their ability to rely upon contextual information to anticipate upcoming language input. Preschool children are already becoming competent comprehenders of discourse; they become sensitive to its causal structure (Lynch et al., 2008) and begin to make inferences connecting the events evoked in narrative with world knowledge (Barnes, Dennis, \& Haefele-Kalvaitis, 1996). Preschool children also understand that events in fiction can contradict their knowledge of the real world, and involve systematic rules governing what can and cannot happen within the context of that world (Sharon \& Woolley, 2004; Van de Vondervoort \& Friedman, 2014).

Thus, is not clear how effectively young children can use fantastical facts introduced in a narrative to interpret the story as it unfolds. Notably little work has investigated the real-time processes and underlying mechanisms involved in children's interpretation of fictional discourse. Most investigations of children's narrative comprehension have instead relied on offline measures, such as the verbal production of story elements (e.g. Paris \& Paris, 2003). By using implicit measures such as eye movements we can gain additional insights into children's moment-by-moment and automatic consideration of possible referents as language unfolds in real time.

In the current study, we investigate children's real-time language processing in discourse contexts that present fantastical protagonists and improbable events, using a spoken language eye tracking methodology. The goal of the study is to compare children's and adults' use of fictional
information that contradicts lexical and world knowledge to constrain predictions about upcoming language input. Can young children rely upon fantastical facts introduced in the prior discourse to predict upcoming referents, and what is the time course of this process? In other words, how does a fantastical discourse context compete with information in children's stored representations of semantic and world knowledge to constrain their understanding of the situations being described? The competition between semantic and real-world knowledge and discourse information that violates that knowledge can be explored by presenting children with a discourse-final sentence in which the protagonist acts on an object in an unusual way (e.g., wearing boxes on her feet). By examining eye movements in the window of time between the onset of a verb that semantically constrains the referent (e.g., 'putting on') and the onset of the following noun, we can gain insights into children's interpretation of the unfolding sentence. If children rely upon the fantastical discourse to interpret the sentence, we would expect them to demonstrate more anticipatory eye movement to objects that are congruent with the discourse than to objects that are congruent with stored event semantics and world knowledge, but incongruent with the discourse.

We also explore the relationship of predictive language processing in fantastical contexts with other mental functions. Anticipation of events consistent with a fantastical fictional world is likely to require the suppression of stored knowledge based on the stable semantic relationships of the real world. We might therefore expect it to be positively predicted by inhibitory control and negatively predicted by receptive vocabulary and semantic fluency, which reflect strong, well-defined networks of semantic relationships. Constraints on working memory may also limit children's performance by limiting the ability to maintain concurrent interpretations. Studies measuring event-related potentials (ERPs) have shown working memory to predict adults' ability to use rich contextual information to build a message-level representation of linguistic input (Huettig \& Janse, 2016; Wlotko \& Federmeier, 2012), perhaps because it binds knowledge to linguistic and semantic knowledge in space and time.

## Method

## Participants

Sixty-four 7-year-old children (range: 7;0-7;11, Mage: $7 ; 4$ ) and 68 adults (range: 18-35 years; Mage: 25) participated in the current experiment. Seven-year-olds were chosen because they are highly experienced with narratives; because younger (3-5-year-old) children are more often willing to attribute unconventional behaviour to humans (Boerger, 2011); and because pilot testing revealed that they could attend through 16 consecutive eye-tracking trials, and complete the full one-hour procedure without signs of fatigue. Inclusionary criteria were normal or corrected-tonormal vision and no history of diagnosis or treatment of
cognitive, speech, language, hearing, or attentional issues. Children heard English spoken at home more than 75\% of the time. Adults were native speakers of English. Data from 27 additional participants were collected, but not used due to: unsuccessful calibration ( 3 adults, 1 child), no trials that captured eye movements more than $50 \%$ of the time ( 7 adults, 5 children), failed pre-test ( 3 children), lack of attention ( 2 adults, 3 children), and misunderstanding the task ( 1 adult, 2 children).

## Materials

Cartoon images were taken from open-source resources, and the displays accompanying each narrative depicted agents and objects against a white background. Sentences were prerecorded by a female, native Canadian-English speaker.

## Norming of stimuli

Offline tasks with a separate group of 4- and 5-year-old participants were conducted to establish that even younger children could recognize the objects and used the verbs to identify referents in the expected manner. Children were tested at the Ontario Science Centre. The experimenter showed the child a four-object display, provided a label, and asked her to identify the relevant object. $100 \%$ of children recognized all the images presented during the critical sentences ( $\mathrm{N}=8$ per target image). Children were then introduced to pictures of agents (e.g. 'This is Chloe the fairy'), following which they were presented with a fourobject display, and asked (e.g.) 'What will Chloe eat?' Fourand 5-year-olds selected the only referent that was semantically plausible following the verb over $90 \%$ of the time across trials ( $\mathrm{N}=16$ per target image).

Figure 1. Example of stimuli used for the sentence comprehension task.

## Procedure

Sentence comprehension task Participants sat in a stationary chair in front of a computer with a 1920x1200 LCD display. Eye movements were recorded using a Tobii X120 eye-tracker. A nine-point calibration procedure was used to set up tracking of both eyes. In the description phase of the experimental condition ( $\mathrm{N}=327$-year-olds and $\mathrm{N}=34$
adults), participants saw a centrally presented picture of a fantastical agent (e.g., a superhero or monster), and simultaneously heard a story. Story sentences contained referents that were semantically congruent with a preceding verb, and referents that were unusual patients of the preceding verb. For instance: 'Chloe the fairy doesn't have cake for her snack. She has snow for her snack! And Chloe doesn't wear shoes on her feet. She wears boxes on her feet! What is Chloe going to do?' Participants then saw a central fixation cross. In a subsequent test phase, participants saw a display comprising the four mentioned items (e.g. cake, snow, shoes, and box), one placed in each corner of the screen, and heard the critical sentence. In 4 of the 8 experimental trials, the verb in the critical sentence was semantically constraining (e.g., 'Chloe is eating up the snow'). Thus, the verb narrowed to 1 the number of referents in the display that were coherent with children's stored semantic knowledge (henceforth, semantically congruent referent, or SCR: e.g., cake) as well as the number of referents that were coherent with the story information (discourse-congruent referent, or DCR: e.g., snow). In the other 4 experimental trials, the verb did not constrain the referent: e.g. 'Chloe is looking at the snow'. Half of the participants heard a critical sentence based on the first part of the story (e.g., Chloe eating up the snow), and half heard a story based on the second part of the story (e.g., Chloe putting on the box). In 8 filler trials, participants heard that agents 'sometimes' performed expected actions and 'sometimes' performed actions that violated world knowledge, breaking up the pattern in the content and outcomes of the stories and reducing the risk of strategic adjustments. Counterbalancing was in place for the portion of the story that was referenced during the critical sentence, the order in which typical and atypical verb patients were mentioned, the pairing of stories with constraining and neutral verbs, and the location of the DCR on the screen. The location of other objects was randomized.

To confirm that children could recall simple discourse of the type used in the experiment, the sentence comprehension task was preceded by two offline pre-trials in which children were asked a comprehension question in place of the critical sentence. For instance, children heard 'Gordon the gnome doesn't bang on a drum. He bangs on a pillow! And Gordon doesn't dig with a shovel. He digs with a toothbrush!' Once the array of possible referents was displayed, children were asked 'What does Gordon bang on?' Only three children failed to identify the target during one or both of the two comprehension trials, and were excluded from the analysis.

A separate set of 327 -year-olds and 34 adults participated in a control condition in which no story discourse preceded the critical sentence. In this condition, during the description phrase participants saw the picture of the agent, but in place of the story they only heard (e.g.) 'This is Chloe the fairy', followed by the critical sentence.

Following the sentence comprehension task participants completed several individual difference measures. These were drawn largely from the National Institutes of Health

Toolbox (NIH TB) Cognition Battery (McDonald, 2014), which is administered in a computerized adaptive format. Each of the tasks in the Toolbox has been normed and validated for ages 3-85.

Inhibitory control The inhibitory control measure was the NIH TB Flanker Inhibitory Control and Attention Test. The test requires participants to focus on a specific stimulus while inhibiting attention to other stimuli flanking it. Sometimes the middle stimulus is congruent (pointing in the same direction as the flankers) and sometimes incongruent (pointing in the opposite direction). Scores reflect both accuracy and reaction time.

Working memory Working memory was measured using the NIH TB List Sorting Working Memory Test, which involves both storage and manipulation of items in memory. Images of animals and foods are displayed with accompanying audio and written text (e.g., "horse"). The participant is asked to repeat back the items in size order from smallest to largest, within a single dimension (either animals or foods: 1-List) and then on 2 dimensions (foods, then animals: 2-List). The score is equal to the number of items that are both recalled and sequenced correctly.

Receptive vocabulary The receptive vocabulary measure was the NIH TB Picture Vocabulary Test. Participants hear a word and simultaneously see four photographic images on the computer screen. Participants were asked to point to the picture that most closely matches the meaning of the word.

Semantic fluency Semantic fluency was measured using two components of the NEPSY word generation task (Korkman, Kirk, \& Kemp, 2007). Participants were given one minute to produce as many members of a semantic category as they were able. Categories were 'animals' and 'foods and drinks'. Participants received one point for every correct item. Incorrect words and repetitions were excluded.

## Data scoring and analysis

The proportion of time that participants spent looking to each referent was calculated separately for three timewindows corresponding to different speech landmarks, namely the pre-naming window ( 1000 ms prior to verb onset to verb onset), verb window ( 1280 ms prior to noun onset to noun onset) and noun window ( 233 ms after noun onset to 2000 ms after noun onset). Average looking time within these windows was calculated separately for constraining and neutral verb trials, based on gaze position measures assessed every 50 ms .

Raw scores for receptive vocabulary, inhibitory control and attention, and working memory were downloaded from the NIH Toolbox Assessment Center. Two coders viewed video recordings of the semantic fluency (word generation) task. There was excellent agreement between coders' judgments, $r(126)=1, p=<.001$. Disagreements were resolved by a third coder.

Looking time data failed to fit a normal distribution following log and empirical logit transformations (Barr, 2008.) Therefore, all analyses were bootstrapped in SPSS 21 , using 1000 case resamples with replacement from the original dataset and a $95 \%$ percentile confidence interval.

## Results

Control condition In the control condition with no story, both children and adults looked at chance to the DCR ( $p$ $>.05$ ), and above chance to the SCR (children: $t(27)=5.61, p$ $=.001$, adults: $t(29)=4.64, p=.001)$, as expected (Figure 2).

Constraining verb trials Recall that the displays contained two distractor objects in addition to the DCR and SCR. We first ascertained whether participants looked preferentially to the DCR and SCR. Both adults and children did so at a rate significantly above chance (children: $t(31)=8.1, p=.001$; adults: $t(33)=7.82, p=.001$ ). A one-way ANOVA demonstrated that adults' and children's looking behaviour was similar $(F(1,65)=.00, p$ $>.05$.) Thus, both children and adults discounted distractors from their interpretation of the unfolding sentence following verb onset, as seen in Figure 3.

In order to discover how hearing a constraining verb influenced children's and adults' anticipatory processing, we then examined the proportion of time that participants spent looking to the DCR and SCR before and after verb onset. Since constraining and neutral verb trials were identically structured prior to verb onset, we collapsed looking time in the pre-verb window across trial types (constraining and neutral) for this analysis. Paired t-tests demonstrated that upon hearing a constraining verb, the proportion of both children's and adults' looking time to the semantically congruent referent rose relative to its pre-verb baseline (children: $t(31)=-3.54, p=.005$ ); adults: $t(32)=-$ $2.16, p=.04)$. The proportion of adults' looking time to the discourse-congruent referent also rose following the onset of the constraining verb $(t(32)=-3.32, p=002)$; the proportion of children's looking time did not ( $p>.05$ ). Thus, hearing a constraining verb caused adults, but not children, to increase their consideration of the discourse-congruent referent.

We then examined fixation patterns within the verb window separately for the DCR and SCR to determine whether children's and adults' proportions of looking time to these referents differed. They did not significantly differ for either referent (both $p>.05$ ), nor did proportion of looking time to the SCR differ between children and adults in the no-story control condition ( $p>.05$ ). Next, we examined children's and adults' rates of looking against chance, calculated at .2 to account for looks to blank space on the screen, to establish whether both semantic coherence and discourse context influenced participants' interpretations of the sentence prior to hearing the noun. Both children and adults looked to the DCR at a rate above chance during the verb window, suggesting that both age groups relied to some extent on the discourse context to
interpret an unfolding sentence (children: $t(31)=2.59, p=$ .024 ; adults: $t(33)=3.81, p=.002$ ). Children, but not adults, also looked to the SCR at a rate above chance $(t(31)=4.75, p$ $=.001$ ). Thus, taking the verb window as a whole, both children and adults anticipated the DCR as the patient of the constraining verb, while only children anticipated the SCR.

Figures 2\&3. Time-course plots of proportion of looking time to potential referents on experimental trials containing constraining verbs (Figure 2), and on control trials with no discourse context containing constraining verbs (Figure 3).

## Neutral verb trials

Recall that neutral verb trials did not contain semantically congruent objects because the verb (e.g., "look at" was by definition compatible with all display objects. They instead contained two "discourse-congruent" objects in the sense that each story presented the character carrying out two unusual actions. For neutral verb trials, we therefore collapsed the proportion of looking time to both DCRs. As predicted, neither children nor adults made anticipatory looks to the DCRs during the verb window of the critical sentence. Adults and children looked similarly to the DCRs, and neither adults nor children looked to the DCRs at a rate above chance (all $p>.05$ ). This confirmed that patterns in the constraining verb conditions were not simply due to
attentional capture or interest in the images used as the SCR and DCR.

## Individual differences

Pearson correlations between individual difference measures and proportion of looking time to the DCR and SCR in the verb window were examined separately for adults and children. On control trials containing no story, none of the correlations were significant for children or adults (all $p$ $>.05$ ). On experimental trials, none were significant for adults on constraining or neutral verb trials, nor for children on neutral verb trials (all $p>.05$ ). Children's looking time on constraining verb trials was not correlated with inhibitory control, nor with semantic fluency (both $p>.05$ ). Contrary to expectation, children's working memory was negatively correlated with their looking time to the DCR $(r(30)=$ $-.50, p=.004$ ), and children's receptive vocabulary was positively correlated with their looking time to the SCR ( $r(30)=.46, p=.011$ ).

Linear regressions were conducted on the proportion of children's looks to DCR and SCR in the verb window. Working memory significantly predicted children's looking time to the DCR, $b=-.343, t(1,28)=-3.11, p=.004$, and explained approximately $26 \%$ of variance in children's looking time to the $\mathrm{DCR}, \mathrm{R} 2=.256, \mathrm{~F}(1,28)=9.57, p=.004$. Receptive vocabulary significantly predicted children's looking time to the $\mathrm{SCR}, \mathrm{b}=-.031, t(1,30)=2.82, p=.004$, and explained approximately $21 \%$ of variance in children's looking time to the $\mathrm{SCR}, \mathrm{R} 2=.210, \mathrm{~F}(1,30)=7.99, p=.004$.

## Discussion

This study demonstrates that while 7-year-old listeners to fantastical fiction find it difficult to override semantic congruence in favour of discourse congruence, the discourse context nevertheless competes with semantic relationships based on stored knowledge to direct their interpretation of fantastical fictional events. The results also demonstrate that the importance of different types of predictive information appears to change between grade school and adulthood.

In the absence of a story, children as well as adults generated expectations for the object that served as the most typical patient of an immediately preceding verb, as expected (e.g. Mani \& Huettig, 2012). Given a fantastical story, however, both children and adults used the discourse context to guide their appraisal of appropriate verb patients: they anticipated the DCR, which was congruent both with the discourse and with a constraining verb. However, children's anticipation of the discourse-congruent referent diminished over the time course of the verb phrase, whereas adults' anticipation of this object increased over the same time window, suggesting that children began to discount the early expectations that had been generated for a discoursecongruent noun.

Seven-year-olds had difficulty overriding an interpretation of the critical sentence based on stored semantic relationships and real-world knowledge,
generating expectations for the referent that was congruent with their semantic and world knowledge. Adults did not, although some late consideration of the semantically congruent referent is clearly apparent from an examination of the latter half of the verb window in Figure 2. This is not unexpected, as active prediction is often accompanied by a certain degree of thematic priming even when these effects are incongruent with sentence and discourse information (Kukona, Fang, Aicher, Chen, \& Magnuson, 2011).

Children with strong pre-existing networks of semantic relationships, as indexed by receptive vocabulary, found it difficult to override these networks in favour of the discourse context. On average, they showed less consideration of the discourse-congruent referent than did children with smaller receptive vocabularies. It is also possible that children who possess a large vocabulary have a well-developed sense of the need for a clear conceptual basis for any new semantic relationship. In future research, we will ask whether longer and more causally rich stories than those presented in the current study may improve such children's performance. However, on a different measure of semantic network strength (semantic fluency), there was no relationship with the extent to which the DCR was considered. This may be because this kind of word generation task also places demands on executive control: the inhibition of irrelevant information, and the deployment of strategic planning. Given that we did not find a relationship between our measure of inhibitory control and children's looking behaviour, it is possible that in this task, the process of suppressing semantic knowledge may not require inhibition of the prepotent semantically congruent interpretation. Rather, it may involve maintaining representations of both the semantically congruent and discourse-congruent interpretation, and discounting the latter relative to the former.

Contrary to expectation, the poorer children's working memory, the more they relied on the discourse-congruent referent to interpret the unfolding critical sentence. If this finding can be replicated, several possible explanations should be explored in future research. It is possible that weak representations of the discourse entail relatively more attention to the discourse-congruent referent in attempt to support effort towards recall of the role of the object in the story. It is also possible that the stronger the discourse information in children's working memory, the greater the co-activation in memory of stored semantic information, which then remains relatively highly activated in children in comparison to adults.

The real-time processing of fantastical discourse speaks to the interaction of several abilities and knowledge types stored semantic knowledge, vocabulary, working memory, and the moment-by-moment identification of thematic relationships - all of which influence children's mental representations of the events they hear about. This topic provides a rich opportunity to characterize the information processing skills underlying children's language comprehension at the discourse level.

# The impact of descriptions and incentives on the simultaneous underweighting and overestimation of rare events 

Garston Liang (garston.liang@unsw.edu.au),<br>Emmanouil Konstantinidis (em.konstantinidis@gmail.com), Aba Szollosi (aba.szollosi@gmail.com)<br>Christopher Donkin (christopher.donkin@gmail.com), \& Ben R. Newell (ben.newell@unsw.edu.au)<br>School of Psychology, UNSW, Sydney, NSW 2052, Australia

#### Abstract

We replicate and extend work demonstrating that choice and probability estimation can be dissociated through the coexistence of contradictory reactions to rare events. In the context of experience-based risky choice, we find the simultaneous underweighting of rare events in choice and their overestimation in probability judgement. This tendency persisted in the presence of accurate descriptions of rare event occurrence (Experiment 1), but was attenuated by incentivizing accurate probability estimates (Experiment 2). The implications of these results for popular models of risky choice are briefly discussed.

Keywords: Decisions from experience; probability estimation; risky choice; underweighting.

## Introduction

Decision-making research often uses a description format to present risk information. In the experimental context of monetary gambles, participants are (usually) presented with two options. One option is deemed "safe" as it provides a sure payoff (e.g., a loss of $\$ 3$ with certainty), while the other option (e.g., a loss of $\$ 4$ with 0.8 probability; no loss otherwise) is deemed "risky" as it bears the risk of a rare event (i.e., the 0.2 probability of no loss). In the description format, the participant is explicitly given this risk information and makes a single choice between the two options. For the aforementioned gamble, Kahneman and Tversky (1979) found that participants preferred the risky option. This has been explained by assuming that participants choose as though they subjectively overweight the probability of the rare event. When the same gamble is presented in the gain domain, participants prefer the safe option (\$3 with certainty), consistent with the explanation of overweighting the $20 \%$ chance of receiving nothing.
In experience-based tasks, participants are presented with the same two choices without the aid of written descriptions. In order to learn about the outcome distributions, participants must repeatedly choose between the two options and observe the outcomes over successive rounds of choices. When risk information is presented in this format, choice preferences are consistent with underweighting the rare event. That is, participants prefer the safe option in the above example because the probability of the rare event ( 0.2 probability of no loss) is subjectively underweighted.

## Probability judgement and underweighting

Fox and Hadar (2006) first proposed that erroneous probability judgements could be responsible for underweighting in experience-based choice. If participants judged the probability
of the rare event to be lower than the objective probability, then underweighting in choice would reflect this erroneous judgement. To examine this judgement error hypothesis, a number of studies have asked participants to estimate the probability of the rare event at the end of the experiment (e.g., Hau, Plesak, Kiefer, \& Hertwig, 2008). Using this retrospective method, studies have generally found probability estimates of the rare event to be accurate.

However, retrospective probes of this nature can create disparities between the information used during the task and judgements formed at the end of the task. Camilleri and Newell (2009) found that retrospectively generated probability estimates failed to predict participant choices during the experiment. One remedy for this is to prompt judgement probes throughout the task. In studies assessing awareness, Newell and Shanks (2014) suggested that assessments should be made as immediately as possible as to avoid forgetting and interference from other cognitive processes. This immediacy criterion can be applied to probability judgements as the large number of trials in experience-based tasks (e.g., 50 trials in Hau et al., 2008) may exacerbate any differences between retrospectively and immediately generated judgements.

## The Coexistence Hypothesis

Barron and Yechiam (2009) used a novel trial-by-trial design to examine probability judgements in an experience-based task. In their Experiment 1, participants were repeatedly presented with a choice between a safe option ( -3 points with certainty) and a risky option ( -20 points with $15 \%$ probability; 0 points otherwise). Note that the expected value of both options was equal so a preference for the risky option would be indicative of underweighting the rare event. After an initial phase of choices alone, participants were prompted to estimate the probability of the rare event for the next trial following each choice.

Barron and Yechiam (2009) found that while participants preferred the risky option in their choices, consistent with underweighting the rare event, they overestimated the probability of the rare event (i.e., the probability of the -20 outcome). This inconsistency occurred at the individual level such that the majority of the participants $(15 / 24)$ simultaneously demonstrated underweighting and overestimation of the rare event; a result that was named the coexistence hypothesis.
Barron and Yechiam (2009) also found evidence of opposing recency effects on choices and probability estimates. Following the observation of a rare event, participants were less likely to
select the risky option. In these same trials though, probability estimates of the rare event were lower, demonstrating a reasoning process akin to the gambler's fallacy. This paradoxical result was called the contingent recency effect.

The coexistence hypothesis and the contingent recency effect are problematic for traditional decision models, such as the Two-Stage Choice Model (Fox \& Tversky, 1998), because they present a dissociation between probability judgements and behavior. Most decision models like the Two-Stage model predict that choices can be mapped onto subjective representations of probability following a transformation according to the weighting function of Prospect Theory (Kahneman \& Tversky, 1979). This makes the coexistence hypothesis an interesting anomaly given that overestimation is inconsistent with underweighting in choices.

## Descriptions in decisions from experience

The existing literature separately compares decisions from experience to decisions from description. However, everyday decision making often utilizes a combination of both information sources (e.g., a doctor informed by both her clinical experience and empirical findings).
The limited number of studies examining decisions from experience in the presence of descriptions have produced inconsistent results. While some have found that the presence of descriptions influence choice in decisions from experience (Jessup, Bishara, \& Busemeyer, 2008) others have contended that the descriptions are neglected (Lejarraga \& Gonzalez, 2011). Aiming to resolve these contradictory accounts, WeissCohen et al. (2016) found that participants predominantly relied upon experience to inform their choices but could be influenced by descriptions that provided novel information. This dovetails with the recent finding that the additional presence of descriptive summaries increased underweighting behavior in experience based tasks (Yechiam, Rakow, \& Newell, 2015).

Taken together, these studies demonstrate that descriptions that explicitly provide probability information can influence choice in an experience-based task. However, less is known about how participants represent probability information when both sources of information are available. Given that risky choices are informed by probability judgements when each information source is presented separately, it is important to examine how individuals reconcile probability information in the presence of both descriptions and experience.

Experiment 1 examined the relationship between probability judgement and risky choice. We presented descriptions in an experience-based task that prompted trial by trial probability estimates similar to Barron and Yechiam (2009). We expected that participants given experience alone would show behavior consistent with the coexistence hypothesis (underweighting in choice and overestimation in judgement). Given that the descriptions explicitly stated the veridically experienced rate of rare events, we expected participants given description and experience to accurately estimate the rare event. However, as experience is primarily relied upon to inform choice patterns, we expected underweighting in choice would still emerge.

## Experiment 1

## Method

Participants Eighty undergraduate students ( $M_{\text {age }}=18.90$ years; $S D=1.66,53$ females, 1 other) from UNSW participated in exchange for course credit, and an incentive payment contingent on the participant's choices during the task ( $M=\$ 3.21$ AUD, $S D=0.18$ ).

Materials Participants were presented with two options associated with either a safe (S) or risky (R) distribution as follows:

Safe (S): -3 points with certainty
Risky (R): -20 points with probability $0.15 ; 0$ points otherwise
The expected values were matched, and so a preference for the risky option would be indicative of underweighting. The risky distribution used random sequences of 120 outcomes, of which exactly $15 \%$ (18 outcomes) were rare events. Each sequence was presented to one participant in each condition.

Design Experiment 1 used a between-subjects design with 2 risk information conditions $(n=40)$. The descriptionexperience (DE) condition completed the repeated choice task with descriptions that stated the outcome distribution of each option. For example, the description for the risky option read " $15 \%$ chance of $-20 ; 85 \%$ chance of 0 ". These descriptions remained visible for the duration of the experiment. The experience-only condition (E) completed the task without descriptions.

Procedure Participants were randomly assigned to the E or DE condition and presented with instructions on a computer screen. Participants were told their show-up payment of $\$ 5.00$ AUD had been converted into 1000 points and that their task was to retain as many points as possible. They were prompted to make a choice between the S and R options on the screen (the locations of which were counterbalanced). Following each choice, full feedback for both the selected and forgone option was provided, which remained visible until participants proceeded to the next trial.

After 40 choice-only trials, participants completed an additional probability estimation task following each choice. Specifically, they were asked "What is the probability that -20 will appear in the next round?", and inputted an integer between 0-100 representing a percentage. Feedback for the current trial remained visible during the estimation task. This choice-then-estimation pattern was repeated for the remaining 80 trials after which the participants were debriefed and paid according to the rate of 2 points $=\$ 0.01$.

## Results

Coexistence Hypothesis We found evidence of underweighting in choice in both the DE and E conditions.

[^128]

Figure 1. Risky choice and probability estimates data in Experiment 1. Error bars represent $\pm 1$ SEM.
(A) Mean PR rates (left) and probability estimates (right) by block of 10 trials.
(B) PR rates as a function of preceding trial outcome.
(C) Violin plots of the mean probability estimates in each condition as a function of preceding trial outcome.

Overall, participants preferred the risky option as indicated by mean PR rates (the proportion of risky choices per block) being significantly greater than 0.5 in E condition, $M=0.70, t(39)=$ $6.50, p<.001$, and the DE condition, $M=0.71, t(39)=6.79, p$ $<.001$. As the expected values of the options were equal, this preference for the risky option (i.e., PR rates $>0.5$ ) demonstrates that participants underweighted the rare event (Figure 1A, left panel).
We examined for differences between the conditions using a $2 \times 12$ mixed ANOVA with condition as the between factor and block (of 10 trials) as the within factor2. The main effect of condition was not significant, $F(1,78)=.42, p=.84$. This result indicates that we failed to find a significant difference in PR-rates between the experience-only condition and experience with explicitly stated descriptions.
Given that probability information was explicitly available, we expected that participants would accurately estimate the rare event. However, we found evidence of overestimation. Mean probability estimates were significantly greater than the objective probability of 0.15 in the E condition, $M=0.30, t(39)$ $=6.64, p<.001$, and the DE condition, $M=0.28, t(39)=5.65$, $p<.001$. The effect of condition was non-significant, $F(1,78)=$ $.22, p=.64$ (Figure 1A right panel).

Taken together, these results show the coexistence of inconsistent reactions to rare events in choice and probability judgement even in the presence of accurate descriptive information. Whilst underweighting suggests the rare event had less subjective impact than warranted on choices, overestimation suggests oversensitivity to the rare events’ appearance. Moreover, the majority of participants (27/40 in

[^129]the $E$ condition, 28/40 in the DE condition) exhibited this inconsistent pattern.

Contingent Recency Effect We separated participant responses into trials following a rare event (-20 outcome) and trials following a common event ( 0 outcome). This allowed us to assess for the impact of the most recently observed outcome, using a $2 \times 2$ mixed ANOVA with the outcome of the preceding trial as the within factor and condition as the between factor for both choices and probability estimates.

For choices, we found a significant interaction effect, $F(1$, $78)=4.41, p=.04$ (Figure 1B). This was qualified by a simple effects analysis which revealed a significant effect of preceding trial outcome for the E condition, $F(1,39)=8.25, p=.01$, with a non-significant effect for the DE condition, $F(1,39)=.10, p$ $=.76$. This result shows that in the E condition people were less likely to select the risky option after observing a rare event compared to the common event (PR|-20 = . 60 and $\mathrm{PR} \mid 0=.72$ ), whereas in the DE condition this effect was not significant $(\mathrm{PR} \mid-20=.70$ and $\mathrm{PR} \mid 0=.71)$.
For probability estimates (PE), we found a significant effect of preceding trial outcome, $F(1,78)=22.98, p<.001$ (Figure 1C). Averaged over conditions, participants estimated the probability of rare event to be lower following a rare event compared to following a common event ( $\mathrm{PE} \mid-20=.20$ and $\mathrm{PE} \mid 0$ $=.30)$. This is evidence of negative recency, which suggests that participants believed the chances of rare events in succession were unlikely. The effect of condition was not significant, $F(1,78)=1.00, p=0.32$.

Taken together, these two results demonstrate an inconsistent reaction to the appearance of the rare event at least in the E condition. On the trials following a rare event, participants were less likely to select the risky option. However,
participants simultaneously estimated the rare event to be less likely to occur. This contradictory pattern demonstrates a dissociation between choices and probability estimates, which replicates and extends the pattern observed by Barron and Yechiam (2009). (Note however, that Figure 1C shows different bimodalities in responding - a pattern that awaits further examination).

## Experiment 2

The novel contribution of Experiment 1 is evidence of overestimation even in the presence of descriptions that explicitly state the probability of rare events. This suggests that overestimation emerges from factors related to experience.
Experiment 2 examined two hypotheses about the emergence of overestimation in experience-based choice. The first is that overestimation of the rare event is due to the anticipation of the loss of points. In Experiment 1, participants were incentivized on the outcomes of their choices and so each observation of the rare event was paired with a tangible loss of their incentive payment. This aversive experience may have led participants to overweigh rare events in memory. If this is the case then accuracy might improve if probability estimation was decoupled from experiencing the consequential outcome.

The second hypothesis is that overestimation arises from psychophysical limitations with probability processing. The suggestion here is that although individuals may be proficient in tracking the frequency of events (e.g., Hasher \& Zacks, 1979), they may have difficulties in expressing this information as probabilities (cf. Gigerenzer \& Hoffrage, 1995). This explanation would predict that overestimation is not affected by consequential outcomes but arises due to an inherent incapability of accurately estimating probabilities. Therefore, even if risky choices were divorced from any loss of points, overestimation would still occur.
We tested these hypotheses by separating consequential choices from probability estimation using different incentive schemes. Specifically, participants were incentivized on i) choices only, ii) only the accuracy of probability estimates, or iii) both choices and the accuracy of probability estimates.

## Method

Participants In Experiment 2, 132 students ( $\mathrm{M}_{\mathrm{age}}=19.52$ years; $S D=1.64,100$ females) participated in exchange for course credit, and a performance-based incentive payment.

## Materials As in Experiment 1.

Design Experiment 2 used a between subjects design with 3 groups $(n=44)$ differing in incentive structure.
The choice-incentive group was incentivized on the outcomes of their choices, replicating the E condition from Experiment 1. The probability-incentive condition was incentivized on the accuracy of their probability estimates. In this condition, participants did not choose between the options but instead pressed a separate button that revealed the outcomes from both options simultaneously. The outcomes were financially inconsequential and their task was to track the
outcomes in order to accurately estimate the rare event. Accuracy was calculated as the percentage point deviation from the experienced probability of rare events on each trial. These deviations were tallied at the end of the experiment rather than during the experiment. This was done to avoid giving any feedback about the accuracy of the estimates which could have influenced responses during the probability estimation task. In the dual-incentive condition, participants were incentivized on both the outcomes of their choices and the accuracy of their probability estimates.

Procedure Participants were provided with instructions on a screen that explained the incentive scheme and the objectives of their respective conditions. Across conditions, participants were given a $\$ 5.00$ show-up payment from which an amount would be deducted contingent on their performance in the task.
In the initial stage, participants in the choice-incentive and dual-incentive conditions made repeated choices while those in the probability-incentive condition tracked the outcomes of both options. After 40 trials, all participants also completed the probability estimation task on each trial. Participants were then debriefed and paid accordingly. Choice incentive participants converted their remaining points at a rate of 2 points $=\$ 0.01$ ( $M=\$ 3.19, S D=.19$ ). Probability-incentive participants were penalized 0.05 cents per percentage point deviation ( $M=$ $\$ 4.44, S D=.31$ ). For the dual-incentive participants, their show-up payment was divided in half with each half paid according to different incentive structures. The "choice" half of the payment was calculated by converting their remaining points at a rate of 1 point $=0.5$ cents. The "probability estimate" half was penalized at 0.025 cents per percentage point deviation.

## Results

Coexistence hypothesis PR-rates were again significantly greater than .5 in the choice-incentive condition, $M=.72, t(43)$ $=7.28, p<0.001$, and the dual incentive condition, $M=.76$, $t(43)=12.98, p<0.001$ (Figure 2A, left panel). This suggests participants underweighted the rare event in their choices. A mixed $2 \times 12$ ANOVA, with condition as the between and block as the within factor, found that the effect of condition was not significant, $F(1,86)=1.46, p=.23$.
Participants overestimated the rare event in the choiceincentive, $M=0.33, t(43)=8.99, p<.001$, and dual-incentive conditions, $M=0.26$, $t(43)=4.50, p<.001$, shown by mean probability estimates significantly greater than the objective probability of 0.15 (Figure 2A, right panel). By comparison, mean estimates in the probability-incentive condition did not differ significantly from the objective probability of $0.15, M=$ $0.16, t(43)=1.09, p=.28)$. Using a $3 \times 12$ mixed ANOVA, we found a significant main effect of condition, $F(2,129)=17.51$, $p<0.001$. Post-hoc Scheffé comparisons showed that all groups significantly differed from each other. The interaction effect was not significant, $F(10.85,699.63)=1.14, p=.33$.

In summary, mean probability estimates were highest in the choice-incentive condition where participants were incentivized for the outcomes of their choices alone. However,

Figure 2. Risky choice and probability estimate data in Experiment 2. Error bars represent $\pm 1$ SEM. (A) PR rates (left) and probability estimates (right) by block of 10 trials.
(B) PR rates as a function of preceding trial outcome.
(C) Violin plots of the mean probability estimates in each condition as a function of preceding trial outcome.
if participants were additionally incentivized for accuracy as in the dual-incentive condition, estimate accuracy was improved. Mean probability estimates were most accurate when consequential outcomes were removed all together.

Taken together, these results replicate the coexistence hypothesis of underweighting in choice and overestimation in probability judgement. We found that 34/44 participants in the choice-incentive condition, and 26/44 participants in the dualincentive condition demonstrated this pattern of responding.

Contingent Recency Effects A $2 \times 2$ mixed ANOVA found a significant effect of preceding trial outcome for risky choices (Figure 2B). This showed that averaged over conditions, PRrates were lower following a rare outcome than following a common outcome (PR|-20 = . 66 and $\mathrm{PR} \mid 0=.76$ ), $F(1,86)=$ 18.91, $p<.001$.

The mean probability estimates contingent on the preceding trial outcome are presented in Figure 2C. We used a $3 \times 2$ mixed ANOVA with preceding trial outcome as the within factor to examine for recency effects. A significant effect of preceding trial outcome was found, $F(1,129)=4.42, p=.04$, which was qualified by a significant interaction between condition and preceding trial outcome, $F(2,129)=5.34, p=$ .01. Simple effects analysis revealed probability estimates in the choice-incentive condition were lower after observing a rare outcome than after observing a common event ( $\mathrm{PE} \mid-20=$ .25 and $\mathrm{PE} \mid 0=.34), F(1,129)=13.33, p<0.001$.

By comparison, the effect of preceding trial outcome was not observed in the probability-incentive condition (PE|-20 $=.18$ and $\mathrm{PE} \mid 0=.16), F(1,129)=0.90, p=0.35$, or the dualincentive condition $(\mathrm{PE} \mid-20=.23$ and $\mathrm{PE} \mid 0=0.25), F(1,129)=$
$0.88, p=0.35$. Taken together, the negative recency effect of preceding trial outcome was only found when participants were not incentivized to estimate accurately. (Note again however, that Figure 2C shows bimodality in responding - clustered around 50 and 0 - a pattern that awaits further examination).

## General Discussion

Across two experiments, we found the coexistence of underweighting in choice and overestimation in probability judgements at the individual level. Furthermore, inconsistency is evident in the trials immediately following rare events. Experiment 1 replicated the coexistence hypothesis in the presence of accurate descriptions. We failed to find a difference in choices and probability estimates between participants that received descriptions and those that did not. Experiment 2 used incentive schemes to show that overestimation emerges in the presence of consequential outcomes. We postulate that attention to the probabilities attenuated the degree of overestimation.

The results of our experiment suggest consequential outcomes biased attention away from probability tracking. Kahneman (1973) defined attention as a limited resource that is allocated according to the demands of the task. Overestimation may have occurred in anticipation of the loss of points associated with the rare event, driving attention towards the outcomes themselves. With respect to the dual-incentive condition, the presence of consequential outcomes in the choice task meant fewer attentional resources could be allocated to probability tracking. This competition for attentional resources between the two tasks would explain why
the degree of overestimation was attenuated, but still remained in the presence of consequential outcomes.

Our overestimation results are incompatible with the judgement error hypothesis (Fox \& Hadar, 2006). Therefore, the coexistence of overestimation and underweighting suggests that probability judgement and choice may reflect separate cognitive processes. The distinction between choice and judgement resembles the comparison between online and memory-based strategies. Hastie and Park (1986) distinguished between two types of strategies based on how information is processed to form a judgement. Online strategies involve step-by-step information processing whereby a judgement is continually updated with new information. By comparison a memory-based strategy involves a discrete instance in which all relevant information is recalled from memory to form a judgement (Haberstroh \& Betsch, 2002).

We propose that the choice process resembles an online strategy that involves continually updating a small mental sample of outcomes with recently observed outcomes. This is compatible with the explanation that underweighting emerges from small mental samples of outcomes (i.e., calculating the expected value of the last 5 observed outcomes, cf. Erev \& Roth, 2014). Concurrently, probability judgements resemble a memory-based strategy where aversive rare events are overweighted in memory, resulting in overestimation (e.g., Tversky \& Kahneman, 1973).

Separate processes for choice and judgement would be consistent with our findings of the contingent recency effects. In trials following the rare event, participants were less likely to choose the risky outcome yet, they paradoxically estimated a lower probability of the occurrence of the rare event. An online strategy for choices would involve a trial-by-trial updating process that incorporates each newly observed outcome into the decision process. Whilst the risky option usually provided the more attractive outcome (i.e., no loss of points), the occasional appearance of the rare event meant that the small sample from the risky option was momentarily less attractive than the safe option. This explains the reduced tendency to select the risky option after observing a rare event. In these very trials, a memory-based strategy that employs the gambler's fallacy would explain the lower probability estimates. Given a rare event on the preceding trial, participants may have reasoned that "lightning does not strike twice". Therefore, the gambler's fallacy may have served as a memory heuristic to simplify the more cognitively demanding memory-based estimation process.

In summary, we have shown the impact of descriptions and incentives on the simultaneous overestimation and underweighting of rare events.

#### Abstract

What is the optimal way to make a decision given that your time is limited and your cognitive resources are bounded? To answer this question, we formalized the bounded optimal decision process as the solution to a meta-level Markov decision process whose actions are costly computations. We approximated the optimal solution and evaluated its predictions against human choice behavior in the Mouselab paradigm, which is widely used to study decision strategies. Our computational method rediscovered well-known heuristic strategies and the conditions under which they are used, as well as novel heuristics. A Mouselab experiment confirmed our model's main predictions. These findings are a proof-of-concept that optimal cognitive strategies can be automatically derived as the rational use of finite time and bounded cognitive resources.

Keywords: Decision-Making; Heuristics; Bounded Rationality; Strategy Selection; Rational Metareasoning

## Introduction

Some situations require us to decide quickly whereas others call for careful consideration of all available options and potential consequences. People seem to master this challenge by choosing adaptively from a toolbox of diverse decision strategies (Payne, Bettman, \& Johnson, 1988; Gigerenzer \& Selten, 2002). This toolbox is assumed to include fast-andfrugal heuristics (Gigerenzer \& Goldstein, 1996) as well as slower and more effortful strategies. Fast-and-frugal heuristics include Take-The-Best (TTB), which chooses the alternative that is favored by the most predictive attribute and ignores all other attributes, satisficing (SAT) (Simon, 1956), which chooses the first alternative whose expected value exceeds some threshold, and random choice; slower strategies include the Weighted-Additive Strategy (WADD), which computes all gambles' expected values based on all possible payoffs. Except for WADD, all of these strategies are heuristics: they solve some problems very efficiently but err on others.

The systematic errors that result from people's use of heuristics are inconsistent with classic notions of rationality such as logic, probability theory, and expected utility theory (Tversky \& Kahneman, 1974). Making good decisions is remarkably constrained: decisions have to be made in a finite amount of time, people's cognitive resources are limited, and maximizing expected utility entails intractable computational problems. This makes expected utility theory an unrealistically high bar for human rationality. According to a more realistic normative standard, people should decide in a way that makes the best possible use of their limited cognitive resources (Griffiths, Lieder, \& Goodman, 2015). Previous research has applied this resource-rational approach to numer-
ical estimation (Lieder, Griffiths, \& Goodman, 2012), availability biases (Lieder, Hsu, \& Griffiths, 2014), and strategy selection (Lieder, Plunkett, et al., 2014). However, this approach has not been applied to the domain in which heuristics have perhaps been studied in greatest detail: multi-alternative risky choice. Work on risky choice suggests that people adaptively switch between multiple different strategies depending on how much time is available and whether one of the outcomes is much more likely than the others (Payne et al., 1988). Yet, it remains unclear how people's decision processes compare to resource-rational behavior.

To answer these questions, we model the decision process as a sequence of costly computations and formalize the optimal decision process as the solution to a meta-level Markov decision process. We combine this theory with an algorithm for approximating the optimal solution to create a computational method that can automatically derive optimal cognitive strategies. These rational heuristics can be interpreted as a fair normative standard for human decision making that takes into account that people's time is costly and that their cognitive resources are bounded. We are optimistic that this novel approach will lead to new insights about how decisionmakers cope with limited time and bounded computational resources, and advance the debate about human rationality.

We illustrate our approach in multi-alternative risky choice and test its predictions using the Mouselab paradigm that is widely used to study decision strategies (Johnson, Payne, Bettman, \& Schkade, 1989). Two known heuristics, TTB and random choice, emerged from our theory as resourcerational strategies for low-stakes decisions with high and low dispersion of their outcome probabilities, respectively. In addition, our computational method discovered a novel heuristic that combines TTB with satisficing. Our experiment demonstrated that people do indeed use the newly discovered heuristic and confirmed our rational model's predictions of when people use which strategy: people used simple heuristics more frequently when the stakes were low, employed fast-and-frugal heuristics less frequently when all outcomes were almost equally likely (low dispersion), and invested more time and effort when the stakes were high. This is the first demonstration that rational meta-reasoning can be used to automatically discover decision strategies used by people.

## Background

We will formulate our theory using the mathematical frameworks of Markov decision processes, bounded optimality, and
rational metareasoning, introduced in this section.

## Markov Decision Processes

Each sequential decision problem can be modeled as a Markov Decision Process (MDP)

$$
\begin{equation*}
M=\left(\mathcal{S}, \mathcal{A}, T, \gamma, r, P_{0}\right) \tag{1}
\end{equation*}
$$

where $\mathcal{S}$ is the set of states, $\mathcal{A}$ is the set of actions, $T\left(s, a, s^{\prime}\right)$ is the probability that the agent will transition from state $s$ to state $s^{\prime}$ if it takes action $a, 0 \leq \gamma \leq 1$ is the discount factor on future rewards, $r\left(s, a, s^{\prime}\right)$ is the reward generated by this transition, and $P_{0}$ is the probability distribution of the initial state $S_{0}$ (Sutton \& Barto, 1998). A policy $\pi: \mathcal{S} \mapsto \mathcal{A}$ specifies which action to take in each of the states. The expected sum of discounted rewards that a policy $\pi$ will generate in the MDP $M$ starting from a state $s$ is known as its value function

$$
\begin{equation*}
V_{M}^{\pi}(s)=\mathbb{E}\left[\sum_{t=0}^{\infty} \gamma^{t} \cdot r\left(S_{t}, \pi\left(S_{t}\right), S_{t+1}\right)\right] \tag{2}
\end{equation*}
$$

The optimal policy $\pi_{M}^{\star}$ maximizes the expected sum of discounted rewards, that is

$$
\begin{equation*}
\pi_{M}^{\star}=\arg \max _{\pi} \mathbb{E}\left[\sum_{t=0}^{\infty} \gamma^{\dagger} \cdot r\left(S_{t}, \pi\left(S_{t}\right), S_{t+1}\right)\right] \tag{3}
\end{equation*}
$$

## Bounded optimality and rational metareasoning

People and robots have to make decisions in a limited amount of time and with bounded cognitive resources. Given that these resources are scarce, which strategy should a decisionmaker employ to use its resources most effectively? The theory of bounded optimality and rational metareasoning (Russell \& Wefald, 1991; Russell \& Subramanian, 1995) was developed to answer this question for rational agents with limited performance hardware. It frames this problem as selecting computations so as to maximize the sum of the rewards of resulting decisions minus the costs of the computations involved.

Concretely, the problem of choosing computations optimally can be formulated as a meta-level MDP (Hay, Russell, Tolpin, \& Shimony, 2012). A meta-level MDP

$$
\begin{equation*}
M_{\mathrm{meta}}=\left(\mathcal{B}, \mathcal{C}, T_{\mathrm{meta}}, r_{\mathrm{meta}}\right) \tag{4}
\end{equation*}
$$

is a Markov decision process whose actions $\mathcal{C}$ are cognitive operations, its states $\mathcal{B}$ represent the agent's probabilistic beliefs, and the transition function $T_{\text {meta }}$ models how cognitive operations change the agent's beliefs. In addition to a set of computations $C$ that update the agent's belief, the cognitive operations also include the meta-level action $\perp$ that terminates deliberation and translates the current belief into action. The meta-level state $b_{t}$ encodes the agent's probabilistic beliefs about the domain it is reasoning about.The meta-level reward function $r_{\text {meta }}$ captures the cost of thinking (Shugan, 1980) and the reward $r$ the agent expects to receive from the environment when it stops deliberating and
takes action. The computations $C$ do not yield any external reward. Their only effect is to update the agent's beliefs. Hence, the meta-level reward for performing a computation $c \in C$ is $r_{\text {meta }}\left(b_{t}, c\right)=-\operatorname{cost}(c)$. By contrast, terminating deliberation and taking action $(\perp)$ does not update the agent's belief. Instead, its value lies in the anticipated reward for taking action, that is

$$
\begin{equation*}
r_{\text {meta }}\left(b_{t}, \perp\right)=\arg \max _{a} b_{t}^{(\mu)}(a) \tag{5}
\end{equation*}
$$

where $b_{t}^{(\mu)}(a)$ is the expected reward of taking action $a$ according to the belief $b_{t}$.

## Adaptive strategy selection in risky choice

Consistent with rational metareasoning, people flexibly adapt their decision processes to the structure of the problem they face. Concretely, Payne et al. (1988) found that people use fast-and-frugal heuristics, like TTB, more frequently when they are under time pressure and when one outcome is much more likely than the others. In this research, participants were given the choice between gambles $g_{1}, \cdots, g_{n}$. Each gamble was defined by the payoffs it assigns to each of four possible outcome whose probabilities are known $(P(O))$. Participants could inspect a payoff matrix $V_{o, g}$ with one row for each outcome $o$ and one column for each gamble $g$. Critically, each payoff is only revealed when the participant clicks on the corresponding cell of the payoff matrix using a mouse; this task is hence referred to as the Mouselab paradigm (see Figure 1).

The adaptiveness of people's strategy choices in the Mouselab paradigm suggests that their decision processes are efficient and effective. But it is difficult to test whether they are optimal, because it is unclear what it means to decide optimally when one's time is valuable and one's cognitive resources are limited. To clarify this, the following section develops a normative theory of resource-bounded decision making in the Mouselab paradigm.

## Boundedly-optimal decision-making

To model the meta-decision problem posed by the Mouselab task, we characterize the decision-maker's belief state $b_{t}$ by probability distributions on the expected values $e_{1}=\mathbb{E}\left[v_{O, g_{1}}\right], \cdots e_{n}=\mathbb{E}\left[v_{O, g_{n}}\right]$ of the $n$ available gambles $g_{1}, \cdots, g_{n}$. Furthermore, we assume that for each element $v_{o, g}$ of the payoff matrix $V$ there is one computation $c_{o, g}$ that inspects the payoff $v_{o, g}$ and updates the agent's belief about the expected value of the inspected gamble according to Bayesian inference. Since the entries of the payoff matrix are drawn from the normal distribution $\mathcal{N}\left(\bar{v}, \sigma_{v}^{2}\right)$, the resulting posterior distributions are also Gaussian. Hence, the decision-maker's belief state $b_{t}$ can be represented by $b_{t}=\left(b_{t, 1}, \cdots, b_{t, n}\right)$ with

$$
\begin{equation*}
b_{t, g}=\left(b_{t, g}^{(\mu)}, b_{t, g}^{\left(\sigma^{2}\right)}\right) \tag{6}
\end{equation*}
$$

where $b_{t, g}^{(\mu)}$ and $b_{t, g}^{\left(\sigma^{2}\right)}$ are the mean and the variance of the probability distribution on the expected value of gamble $g$ of the belief state $b_{t}$.

Given the set $O_{t}$ of the indices $\left(k_{o}^{(1)}, k_{g}^{(1)}\right), \cdots,\left(k_{o}^{(t)}, k_{g}^{(t)}\right)$ of the $t$ observations made so far, the means and variances characterizing the decision-maker's beliefs are given by

$$
\begin{align*}
& b_{t, g}^{(\mu)}=\sum_{(o, g) \in O} p(o) \cdot v_{o, g}+\sum_{(o, g) \notin O} p(o) \cdot \bar{v}  \tag{7}\\
& b_{t, g}^{\left(\sigma^{2}\right)}=\sum_{(o, g) \notin O} p(o)^{2} \cdot \sigma_{v}^{2} . \tag{8}
\end{align*}
$$

The meta-level transition function $T\left(b_{t}, c_{o, g}, b_{t+1}\right)$ encodes the probability distribution on what the updated means and variances will be given the observation of a payoff value $V_{o, g}$ sampled from $\mathcal{N}\left(\bar{v}, \sigma_{v}^{2}\right)$. The meta-level reward for performing the computation $c_{o, g} \in C$ encodes that acquiring and processing an additional piece of information is costly. We assume that the cost of all such computations is an unknown constant $\lambda$. The meta-level reward for terminating deliberation and taking action is $r_{\text {meta }}\left(b_{t}, \perp\right)=\max _{g} b_{t}^{(\mu)}(g)$.

## Approximating the optimal meta-level policy: Bayesian value function approximation

Unfortunately, computing the optimal policy for the metalevel MDP defined above is intractable. However, it can be approximated using methods from reinforcement learning. We initially used the semi-gradient SARSA algorithm (Sutton \& Barto, 1998) with limited success. We therefore developed a new algorithm that replaces the gradient descent component of that algorithm by Bayesian linear regression.

Our algorithm learns a linear approximation to the metalevel Q-function

$$
\begin{equation*}
Q_{\mathrm{meta}}(b, c) \approx \sum_{k} w_{k} \cdot f_{k}(b, c) \tag{9}
\end{equation*}
$$

whose features $\mathbf{f}$ include a constant, features of the belief state $b_{t}$, and features of the computation $c_{t}$. The features of the belief state were the expected value of the maximum of the gambles' expected values $\left(\mathbb{E}\left[\max _{g} E_{g} \mid b_{t}\right]\right)$ and the decision-maker's uncertainty about it ( $\left.\sqrt{\operatorname{Var}\left[\max _{g} E_{g} \mid b_{t}\right]}\right)$. The largest posterior mean $\left(\max _{g} b_{t, g}^{(\mu)}\right.$ ) and its associated uncertainty $\left(\sqrt{\mu_{t, g^{\star}}^{\left(\sigma^{2}\right)}}\right.$ where $g^{\star}=\arg \max _{g} b_{t, g}^{(\mu)}$ ), the second largest posterior mean and the decision-maker's uncertainty about it, and the expected regret $\mathbb{E}\left[\operatorname{regret}(g) \mid b_{t}\right]$ that the decision-maker would experience if they chose based on their current belief (where $\operatorname{regret}(g)=\max _{g} E_{g}-\max _{g} b_{t, g}^{(\mu)}$ for $E_{i} \sim \mathcal{N}\left(b_{t, i}^{(\mu)}, b_{t, i}^{(\sigma)}\right)$ for all gambles $\left.i\right)$. The features of the computation $c_{o, g}$ were its myopic value of computation $\left(\operatorname{VOC}\left(b_{t}, c_{o, g}\right)\right.$; see Russell \& Wefald, 1991), the current uncertainty about the expected value of the inspected gamble $\left(b_{t, g}^{(\sigma)}\right)$, the probability of the inspected outcome, the difference between the largest posterior mean and the posterior mean of the inspected outcome, a binary variable indicating whether the computation acquired new information, and the expected reduction in the expected regret $\operatorname{ER}(b)$ minus its cost (i.e. $\mathbb{E}\left[\operatorname{ER}\left(B_{t+1}\right) \mid b_{t}, c\right]-\operatorname{ER}\left(b_{t}\right)-\lambda$, where $B_{t+1}$ is the
unknown belief state resulting from performing computation $c$ in belief state $b_{t}$ and $\left.\operatorname{ER}\left(b_{t}\right)=\mathbb{E}\left[\operatorname{regret}\left(\arg \max _{g} b_{t, g}^{(\mu)}\right) \mid b_{t}\right]\right)$.

The weights $\mathbf{w}$ are learned by Bayesian linear regression of the bootstrap estimate $\hat{Q}(b, c)$ of the meta-level value function onto the features $\mathbf{f}$. The bootstrap estimator is

$$
\begin{equation*}
\hat{Q}\left(b_{t}, c_{t}\right)=r_{\text {meta }}\left(b_{t}, c_{t}\right)+\hat{w}_{t}^{\prime} \cdot \mathbf{f}\left(b_{t+1}, c_{t+1}\right) \tag{10}
\end{equation*}
$$

where $\hat{w}_{t}$ is the posterior mean on the weights $w$ given the observations from the first $t$ trials, and $\mathbf{f}\left(b_{t+1}, c_{t+1}\right)$ is the feature vector characterizing the subsequent belief state $b_{t+1}$ and the computation $c_{t+1}$ that will be selected in it.

Given the learned posterior distribution on the feature weights $\mathbf{w}$, the next computation $c$ is selected by contextual Thompson sampling (Agrawal \& Goyal, 2013). Specifically, to make the $t^{\text {th }}$ meta-decision, a weight vector $\tilde{w}$ is sampled from the posterior distribution of the weights given the series of meta-level states, selected computations, and the resulting value estimates experienced so far, that is

$$
\tilde{w} \sim P\left(\mathbf{w} \mid\left(b_{1}, c_{1}, \hat{Q}\left(b_{1}, c_{1}\right)\right), \cdots,\left(b_{k-1}, c_{k-1}, \hat{Q}\left(b_{k-1}, c_{k-1}\right)\right)\right) .
$$

The sampled weight vector $\tilde{w}$ is then used to predict the Q-values of each available computation $c \in \mathcal{C}$ according to Equation 9. Finally, the computation with the highest predicted Q -value is selected.

## Application to Mouselab experiment

As a proof of concept, we applied our approach to the Mouselab experiment described below. The experiment comprises $50 \%$ high-stakes problems and $50 \%$ low-stakes problems. Since participants are informed about the stakes, we learned two separate policies for high-stakes and low-stakes problems, respectively. Half of each of those problems had nearly uniform outcome probabilities ("low dispersion") and for the other half one outcome was much more likely than all others combined ("high dispersion"). The parameters of the simulated environment were exactly equal to those of the experiment described below. Our model assumed that people play each game as if they receive the payoff of the selected gamble. We estimated the cost per click to be about $\lambda=3$ cents. This value was selected to roughly match the average number of acquisitions observed in the experiment.

To approximate the optimal meta-decision policy for this task, we ran our feature-based value function approximation method for 4000 low-stakes training trials and 4000 highstakes training trials, respectively.

## Model predictions

The meta-level MDP described above formalizes the costs and benefits of acquiring and processing additional pieces of information: acquiring additional information can improve the decision that will be taken later on but also incurs an immediate cost. Hence, the optimal solution approximated by our computational method executes a cognitive operation or sequence of operations if and only if the resulting improvement in decision quality is larger than cost of those

Figure 1: The Mouselab paradigm, showing an example sequence of clicks generated by the SAT-TTB strategy, which was discovered through approximate rational metareasoning.
operations. Intuitively, this means that the decision process prescribed by our model achieves the optimal tradeoff between decision quality versus decision time and mental effort. This tradeoff depends on the stakes of the decision such that higher stakes usually warrant more deliberation. Likewise, since processing probable outcomes is more likely to improve the quality of the resulting decision than processing improbable outcomes, we expect our model to prioritize probable outcomes over less probable outcomes-especially in high-dispersion trials.

Our computational method automatically discovered strategies that people are known to use in the Mouselab paradigm as well as a novel strategy that has not been reported yet. Our method rediscovered TTB, WADD, and the random choice strategy. In addition, it discovered a new hybrid strategy that combines TTB with satisficing (SAT-TTB). Like TTB, SAT-TTB inspects only the payoffs for the most probable outcome. But unlike TTB and like SAT, SAT-TTB terminates as soon as it finds a gamble whose payoff for the most probable outcome is high enough. On average, this value was about $\$ 0.15$ when the payoffs ranged from $\$ 0.01$ to $\$ 0.25$ (i.e., low-stakes trials). Figure 1 illustrates this strategy.

Furthermore, our model makes intuitive predictions about the contingency of people's choice processes on stakes and outcome probabilities. First, our model predicts that people should use fast-and-frugal heuristics more frequently in highdispersion trials. This is intuitively rational because high dispersion means that one outcome is much more likely than all others and fast-and-frugal heuristics ignore all outcomes except for the most probable one(s). Concretely, our model generated TTB as the strategy of choice for $100 \%$ of the highdispersion problems with low-stakes, but for low-dispersion problems with low-stakes the model considered the random choice strategy to be optimal in the majority ( $56 \%$ ) of cases; it used the SAT-TTB hybrid strategy for $24 \%$ of such trials, and it indicated the TTB strategy only for the remaining $20 \%$.

Second, our model predicts that people should use simple heuristics, like TTB, SAT-TTB, and random choice, primarily when the stakes are low. This, too, is intuitively rational because fast and frugal heuristics tend to be faster but less ac-
curate than more effortful strategies. Our model used these heuristics for $100 \%$ of the low-stakes problems. But for highstakes problems, the model never used any of these or other frugal strategies. Instead, the model typically inspected the vast majority of all cells ( $24.8 / 28$ for low-dispersion problems and $23.7 / 28$ for high-dispersion problems). The few cells that it did not inspect were mostly the payoffs of lesslikely outcomes of the best gamble when its inspected payoffs for the most likely outcome(s) were high enough to guarantee that it would be optimal.

Third, our model predicts that when the stakes are high people should invest more time and effort $(F(1,396)=$ $9886.8, p<0.0001$ ) to reap a higher fraction of the highest possible expected payoff $(F(1,339)=135.24, p<0.0001)$. This, too, is consistent with the rational speed-accuracy tradeoff inherent in our theory. When the stakes were low the model inspected only 4.3 payoffs on average and reaped only $87 \%$ of the possible reward; but when the stakes were high the model inspected 24.3 of the 28 possible payoffs and reaped $99 \%$ of the best expected payoff on average. In $97 \%$ of these trials, the model achieved this near-maximal performance while being more efficient and more frugal than the WADD strategy which it employed for only $3 \%$ of these problems.

## Experimental test of novel predictions

To test the predictions of our model, we conducted a new Mouselab experiment that manipulated the stakes and dispersion of outcome probabilities within subjects in an identical manner to the model simulations.

## Methods

Participants We recruited 200 participants on Amazon Mechanical Turk. The experiment took about 30min. Participants received a base pay of $\$ 1.50$, and one of their twenty winnings was selected at random and awarded as a bonus to motivate them to take each trial seriously (avg. bonus $\$ 3.53$ ).

Procedure Participants performed a variation of the Mouselab task (Payne et al., 1988). Participants played a series of 20 games divided into two blocks. Figure 1 shows a screenshot of one game. Every game began with a $4 \times 7$ grid of occluded payoffs: there were seven gambles to choose from (columns) and four possible outcomes (rows). The occluded value in each cell specified how much the gamble indicated by its column would pay if the outcome indicated by its row occurred. The outcome probabilities were described by the number of balls of a given color in a bin of 100 balls, from which the outcome would be drawn. For each trial, participants were free to inspect any number of cells before selecting a gamble, with no time limit. The value of each inspected cell remained visible onscreen for the duration of the trial. Upon selecting a gamble, the resulting reward was displayed.

Experimental design The experiment used a $2 \times 2$ within subjects design. Each block of ten trials was either low-stakes
