A total of 318 voluntary participants ( 218 women, 100 men) were recruited via ads in publicly accessible websites. The participants were paid an equivalent of 20 euros in Polish currency. The mean age was 24.4 years ( $S D=6.02$, range 18-45). Four participants did not complete all the applied questionnaires and were excluded from the analysis.

## Materials

## Smolensk Conspiracy Scale

Conspiracy theories are cultural phenomena. Studying particular conspiracy theories requires that the participants are familiar with them and their cultural context. Our choice of a theme for well-known conspiracy theory was the 2010 catastrophe in Smolensk (the Russian Federation), in which the Polish President's plane crashed, and all of the 96 crew and passengers, including President Lech Kaczynski, died. The Smolensk catastrophe was judged by official aviation experts (PCINAA, 2011) to result from the pilot's error as well as the improper organization of the flight. The crash had a specific political context: The death of President Kaczynski, who travelled across Russian territory, in order to commemorate Polish officers killed by Soviets during WWII, despite his tense political relations with the Russian government of President Vladimir Putin. Furthermore, President Kaczynski and his conservative camp strongly opposed the Polish government and its supporting liberal party, while the presidential campaign in Poland was about to start. All of this made an excellent context for various accusations and plot hypotheses, even though the explanation of the catastrophe is straightforward. Consequently, five years after the catastrophe, a public opinion survey (CBOS, 2015) showed that about $30 \%$ members of the Polish society considered the hypothesis of assassination of Lech Kaczynski plausible (among them 8\% were convinced it was true). Thus, the Smolensk catastrophe made a crucial and interesting case of conspiracy belief (henceforth we call it the Smolensk conspiracy). So, a twelve-item questionnaire was developed, with seven items measuring belief in the Smolensk conspiracy, and five reverse-scored items probing belief in the official explanation of the catastrophe.

## The Generic Conspiracist Beliefs scale

We used the validated 15 -item scale of Brotherton et al. (2014) to measure the general tendency for conspiracy belief. The scale covers general conspiratorial assumptions such as beliefs in prevalent government misconduct, secret groups exerting the control over global events, dangers to personal health and liberties (e.g., the mind control experiments), extraterrestrial cover-up, and the full censorship over information. The sample item was "The governments are involved in the murder of innocent citizens and/or well-known public figures, and keep this a secret".

## Pseudoscientific Belief Scale

We created an 18 -item questionnaire to measure pseudoscience belief and disapproval of scientific knowledge. The items covered range of topics (medicine/health, natural science, evolution, psychology, sexuality), and were mixed with 9 filler items dealing with general scientific knowledge. Sample test items were "Mercury in vaccines may increase probability of acquiring autism among small children" and "Crystals possess qualities which protect against negative influence of electromagnetic radiation".

## Paranormal Belief Scale

Our measure of paranormal belief was based on Revised Paranormal Belief Scale (Tobacyk, 2004). We removed four items concerning religious belief, as we applied a separate religious beliefs questionnaire in the session (not analysed in the present study). We removed another three items concerning extra-ordinary life forms (e.g. Loch Ness monster), as being outdated and possibly unfamiliar to our participants. The final version contained 20 items such as "In some cases it is possible to communicate with the dead".

## Fluid intelligence tests

We applied three Gf tests. The classic Gf test - Raven's Advanced Matrices (Raven, Court, \& Raven, 1983), as well as Figural Analogies (Chuderski \& Necka, 2012), were administered in shortened versions (18 items each). Each of the two tests was composed of odd numbered items from respective standard 36 -item versions. Their administration time was half of the standard one ( 20 and 15 minutes respectively). The third test was Number series, in which the task was to find the rule according to which the number sequence or the array is constructed, and to complete the sequence/array with the missing number. Participants were given 18 minutes to solve the 18 number series problems.

## Open-mindedness cognitive style questionnaires

The first questionnaire measuring open-minded thinking included 14 items from Actively Open-minded Thinking scale (Stanovich \& West, 2007), selected on the basis of our previous data. All 14 items were scored in such a way that higher scores represented a larger tendency toward rigid, dogmatic, categorical thinking, as well as the trend for sticking to one's beliefs even in the face of counterevidence (e.g., "Changing your mind is a sign of weakness"). The total score on the scale was reversed, so that higher total scores indicated more open-minded, flexible thinking. The second questionnaire was an 12-item openness to experience subscale of the Polish adaptation of the NEO-Five Factor Inventory (Costa \& McCrae, 1992).

In all of the questionnaires except the cognitive style measures, participants judged whether the given statements are true or false using a seven-point scale $(0=$ false for sure, $3=$ uncertain, $6=$ true for sure $)$. Five-point $(1=$ definitely disagree, $5=$ definitely agree) and a four-point scale were used in the Open-minded Thinking and the NEO-openness scales, respectively.

## Procedure

Participants were tested in a psychological laboratory, in groups of six participants on average. The Gf tests were applied in the fixed order (Raven APM, Figural Analogy Test, Number series test). All the questionnaires were completed via computers at the end of the study session. At the course of the session participants completed other tasks (working memory and cognitive control tests, religiosity questionnaires, etc.) unrelated to the topic of this study.

## Results

All the measures applied had at least satisfactory internal consistency (Cronbach's alphas > .71), including Smolensk conspiracy and GCB scales (Cronbach's alpha $=.88$, and .94 , respectively), and all of them fitted well the normal distribution (max. skew $=-0.28$, max. kurtosis $=-0.82$ ).

Firstly, the endorsement of the most extreme form of conspiracy theory, the assassination theory, was examined. Answers on the respective item ("The cause of the catastrophe was an assassination.") of the Smolensk Conspiracy scale showed that about $10 \%(N=32)$ of the participants considered it a possible option (answered "it is probably true"), $5 \%(N=16)$ answered "it is true", and $4 \%$ ( $N=12$ ) answered "it is true for sure". Thus, the support for Smolensk conspiracy in our sample was rather low.

The CFA model (Figure 1) correlated four latent variables: Conspiracy Belief (loading Smolensk Conspiracy scale and GCB), Irrational Belief (Paranormal and Pseudoscience), Gf (the three reasoning tests), and Openmindedness (NEO-openness and Open-minded Thinking).

The model fit was assessed with three indices (see Kline, 1998): $\chi^{2}$ statistic (its value divided by the number of degrees of freedom should not exceed $\chi^{2} / d f=2.0$ ), Bentler's comparative fit index (CFI should exceed .92), and the root mean square error of approximation (RMSEA should be less than .08 ). The fit of the model was good: $\chi^{2}(21)=36.01$, $\mathrm{CFI}=.981, \mathrm{RMSEA}=.047(90 \% \mathrm{CI}=[.017, .074])$.

All factor loadings (see Table 1) showed satisfactory validity of the applied measures, except for NEO-openness. Importantly, belief in Smolensk conspiracy was substantially related to GCB. Thus, Smolensk Conspiracy scale seems to be a valid measure of conspiracy belief.
In line with our expectations, the correlation between the Conspiracy Belief and Irrational Belief factors was strong, $r=.72, p<.001$. However, the negative link between the Conspiracy Belief and Gf was very weak ( $r=-.13$ ), and despite our large sample it was not statistically significant ( $p=.08$ ). Thus, Gf predicted only a negligible amount of variance ( $2 \%$ ) in conspiracy belief. However, as expected, there was a negative correlation between Gf and Irrational Belief, $r=-.31, p<.001$. In addition, the open-minded

Table 1. Factor loadings from the CFA model (all $p \mathrm{~s}<.001$ )

| Latent variable | Measure | Factor <br> loading |
| :---: | :--- | :---: |
| Gf | Raven Matrices | 0.84 |
|  | Analogies | 0.78 |
|  | Numbers | 0.66 |
| Irrational | Pseudoscience | 0.84 |
| Belief | Paranormal | 0.74 |
| Conspiracy | Generic conpiracist beliefs | 0.87 |
| Belief | Smolensk conspiracy | 0.50 |
|  | NEO-openness | 0.36 |
| Open-mindedness | Open-minded thinking | 0.96 |

cognitive style showed the substantial negative correlation with Conspiracy Belief and Irrational Beliefs. Thus cognitive style was a much stronger predictor of conspiracy and irrational beliefs than Gf.

## Discussion

We aimed to test whether conspiracy belief weakens with an increased reasoning ability (Gf). Contrary to our expectations, results showed that it virtually did not; Gf explained less than $2 \%$ of variance in conspiracy belief, and despite our large sample the link was not significant. On the other hand, Gf predicted about $9 \%$ of variance in paranormal and pseudoscience belief. Although the relationship was weaker than in previous studies, it is in line with these studies (Rindermann, Falkenhayn, \& Baumeister, 2014). Moreover, irrational beliefs shared half of variance with conspiracy belief, also replicating similar findings (Lobato et al., 2014; Brotherton \& French, 2014; Swami et al., 2011).
The robust relationship between conspiratorial, paranormal, and pseudoscientific beliefs suggests that they rely on a common underlying mindset/worldview, which reflects the tendency to believe in irrational, epistemically dubious claims and theories. There probably are specific social and cognitive factors (e.g. anomie, political cynism, distrust, radicalism) that seem to induce the conspiratorial mindset, and, to a lesser extent, the other kinds of dubious beliefs. However, the general tendency to believe in the irrational most likely stems primarily from interrelated personality traits and thinking dispositions, such as intuitive thinking and close-mindedness (the latter shown by the present data).
If so, why is conspiracy belief unrelated to Gf, as compared to paranormal and pseudoscientific beliefs? First, although more intelligent people more frequently hold to proper scientific explanations of facts (what makes them less likely to believe in pseudoscience), most of conspiracies (also the Smolensk conspiracy) needn't be inconsistent with the body of scientific knowledge (though are unsupported by facts). Plots, evil politicians, and secret organisations undoubtedly exist, but usually they are not the reasonable

Figure 1. Correlations between four latent variables in the CFA model. All correlation are significant at $p \mathrm{~s}<.001$, except for the one presented in the dashed line.
explanations of complex phenomena. Thus, even though intelligent people may easily suppress their intuitions favouring paranormal/unscientific phenomena as being unlikely and contradicting the general scientific knowledge, they may let their intuitions about political/social issues develop more freely.

Second, endorsing conspiracy theories may be seen as a process of motivated reasoning (Kunda et al., 1990; Saunders, State, \& Farhart, 2016), which is a kind of biased reasoning directed by motivation to arrive at the desired conclusions. In context of conspiracy theories, this process may satisfy the ideological and psychological needs such as the loyalty toward ideological groups (Saunders, State, \& Farhart, 2016). Conspiracy belief seems to be strongly motivated personally as well as engaging, as it touches the basic political and social opinions and values. Thus, people may have stronger motivation to rationalize their conspiracy beliefs, comparing to paranormal or pseudoscientific beliefs. Importantly, myside/confirmation bias - the tendency to evaluate and provide arguments in a manner biased towards our own views - is basically unrelated to intelligence (Stanovich, West, \& Toplak, 2013). Also, the more subjectively important the issue, the more strongly motivated the reasoning process becomes. Thus, intelligent and curious individuals may perform better at finding quality arguments supporting their worldview and prior beliefs, but they are not more inclined to objectively consider counterevidence and alternative perspectives, especially in cases of highly engaging issues. Moreover, more politically knowledgeable individuals may be even more likely to embrace conspiracy theories than the less knowledgeable ones (Saunders et al., 2016). Similarly, although providing relevant scientific information may change people's opinion on global warming (Ranney \& Clark, 2016), general scientific literacy/numeracy is unrelated to differences in opinion on global warming risk, but is related to a greater opinion polarization on the issue (Kahan et al., 2012). The opinion is instead well predicted by different values sets/worldviews. Also, at least in some cases, a high level of reasoning ability/reflective thinking may actually lead to more motivated reasoning (Kahan, 2013), and thus leading to greater polarization of prior beliefs, rather than alleviating their influence. To sum up, whether an individual embraces a conspiracy theory may be primarily dependent on his/her prior worldview and mindset, which directs the reasoning process to conclusions consistent with this worldview, and high intelligence may rather serve this process instead of hindering it. Consequently, sheer high intelligence may not be enough to prevent people from endorsing dubious conspiracy theories. Even some highly intelligent individuals may believe in conspiracies, as did some of our participants who scored really high on intelligence tests, but regardless of their high ability believed in assassination as the major cause of the Smolensk catastrophe.
More generally, our results serve as another example that intelligence and rationality should be treated as dissociable constructs (see Stanovich et al., 2013). Although some
irrationality indices (e.g., paranormal and pseudoscience) may be moderately related to intelligence, other may be weakly related, as probably is in the case of at least some conspiracy beliefs.
On the other hand, we should notice that conspiracy theories are not homogenous phenomena, and are also not irrational by definition. In some cases lack of healthy skepticism toward official information from seemingly reliable sources may be as harmful as unreflective belief in dubious conspiracy theories, and thus we do not think the less ones score on a conspiracy questionnaire the better. However, confidence in questionable conspiracy beliefs may be interpreted as irrational, as is confidence in dubious paranormal or pseudoscientific beliefs. Secondly, although we think that use of two measures of conspiracy belief dealing with different conspiratorial attitudes and beliefs provides a good measure of general conspiratorial mindset, we cannot exclude that the relation between belief in conspiracies and cognitive dispositions might be different in cases of some particular conspiracy theories.
In conclusion, our results make an important contribution to the conspiracy and rationality research, by showing conspiracy belief to be virtually unrelated to reasoning ability. Given the present data as well as numerous other cognitive, social, and personality variables that play role in prevalence of such complex socio-cultural phenomena as conspiracy theories, it seems that intelligence alone cannot prevent people from believing in conspiracy theories. Additionally, they provide more evidence for the strong conspiracy-irrationality relationship, supporting the view that the individual tendency to think in an irrational/ conspiratorial way may constitute a stable and important personality trait/cognitive style.

# The Motor System Does Not Use a Curvilinear Impetus Belief: Folk Physics and Embodied Cognition

Institute of Cognitive Science, 1125 Colonel By Drive<br>Ottawa, ON K1S5B6 Canada

#### Abstract

Previous work shows that people often believe, contrary to actual physics, that objects travelling in a curved path through a tube will continue to travel in a curved path after exiting the tube. In the present study, previous work was replicated, but accuracy increased in a new condition in which people were asked to catch an actual ball emerging from a tube. That is, in this case there is a discrepancy between how we believe the world works, and how our motor system responds to events in the world. This finding supports the theory that the perception and action systems of the brain use different methods to predict how things move in the world, and that the abstract reasoning systems used to explain how the world works are often in conflict with the action systems.

## Introduction

People are not only brains, they are bodies too, and these bodies experience the world and the laws that govern its physics every day. Both children and adults make similar mistakes when verbally describing how they would crawl on their hands and knees - even after they have just physically crawled (Piaget, 1976). With something so fundamental to our everyday experience, we should easily be able to describe its physics and procedures. The systematic discrepancies observed between the ability to do a physical task and the inability to accurately describe or depict it has been studied under the umbrella term of folk or "naïve physics."

Since Piaget (1976) detailed several of these phenomena, one of the most notable instances of this effect is the curvilinear impetus belief: the incorrect assumption that an object travelling in a circular motion will continue this curved path upon exiting a spiral. In previous studies the average percentage of curved lines predicted had been around $36 \%$, and $49 \%$ for participants that had no formal physics education (McCloskey, Caramazza, \& Green, 1980; McCloskey \& Kohl, 1983; Cook \& Breedin, 1994; Freyd \& Jones, 1994; Kaiser, Jonides, \& Alexander, 1986).

Some have suggested that the abstractness of the task affected accuracy (Freyd \& Jones, 1994; McCloskey \& Kohl, 1983). For instance, when people are presented with the spiral problem on paper, but are told it is a garden hose and water as opposed to a ball and tube, they accurately predict the straight trajectory of the water, but continue to make incorrect predictions about the ball (Catrambone, Jones, Jonides \& Seifert, 1995). Freyd and Jones (1994) theorized that in order to understand the abstract diagrams
presented on paper, the participants may be generating abstract theories that are separate from their experiences in the real world, or on patterns of motion observed in living objects as opposed to inanimate objects. Thus, even though the problem is essentially the same, a physical example that has likely been experienced by the participants before (the garden hose), generates more correct answers. Therefore, previous experience from seeing an object in motion may be recruited to solve abstract problems. If this is true, then it would indicate that people can make good predictions about situations they have seen, but have trouble transferring that skill to new domains.

To test whether observing motion could influence accuracy, McCloskey and Kohl (1983) presented participants with 3 conditions designed to alter the degree of motion in a curvilinear task. Participants viewed three training conditions: no motion (a paper and pencil diagram), dynamic rotation (where the ball on-screen simply orbited around the circumference), and dynamic trajectory (where the ball left the orbit). The trajectory condition produced both correct and curvilinear trajectories. Surprisingly, there was no significant difference between these groups. The perceptual experiences failed to facilitate accurate trajectories. The authors argued that visual information was not sufficiently embodied to produce accurate responses.

This led to postulating whether physical touch improved the accuracy of participants' responses. McCloskey and Kohl (1983) asked participants to physically push a puck through a slightly curved ' $C$ ' shaped path. The task could be accomplished if a straight-line method was used. The task was designed to add a motor component to test whether participants used curvilinear strategies to try to complete the exercise, which would result in a failure to complete the task. Still, 25 percent of the participants demonstrated some curvilinear impetus belief, and participants who failed to pass the puck through the curved area with the correct straight-line method demonstrated on a post-test questionnaire that an alternative method might have been curvilinear. Previous research, such as work on the Ebbinghaus Illusion, showed that the physical grasping of two identically sized objects was completed accurately by the motor system, while the perceptual system simultaneously perceived one as substantially bigger. This would suggest that the action system of the brain would not be fooled by perceptual illusions (Haffenden, Schiff \& Goodale, 2001). However, curvilinear impetus types of
problems are not visual illusions, but internal misconceptions involving object motion, which seem to form the basis of our understanding of object physics.

Reliance on curvilinear impetus concepts today may seem counterintuitive, but in the past they were part of a dominant theory of physics in Medieval Europe. It was believed that moving objects were imbued with their own force, or impetus, that compelled them to behave in a certain way (Kozhevnikov \& Hegarty, 2001). But the fact that most present-day people are ignorant of this theory suggests that these impetus beliefs are systematic and consistent between human beings. Impetus theories may provide a way of conceptualizing the world when no analogy or previous experience is accessible - a default physics in want of physical experience (Kozhevnikov \& Hegarty, 2001). If this is true, then these errors should persist even when people have abstract, rule-based physics knowledge. Kozhevnikov and Hegarty (2001) tested this by giving physicists and non-physicists a spiral diagram and asking them to draw the trajectory. In one condition, participants were given as much time as they needed to answer, and in the other condition they had to answer as quickly as possible. Interestingly, both groups fell back on curvilinear impetus beliefs in the time-pressured condition. Thus, even people who possess expert physics knowledge still fall back on impetus theory when under time constraints.

There is now some evidence that impetus theories, specifically curvilinear impetus theories, are part of a default physics. However, many experiments tested impetus beliefs using abstract stimuli, and were testing the production or prediction of trajectories rather than how people responded to them. For instance, people do not regularly predict where water will exit from a coiled hose; however, they do respond to it physically and accurately without effort.

Many of the experiments on curvilinear impetus belief overlook the way our motor system, which tends to respond to the environment accurately, predicts the motion of objects in the world (Oberle, McBeath, Madigan \& Sugar, 2005; Zago \& Lacquaniti, 2005). The ability of the motor system to respond to moving objects may be an entirely embodied phenomena, one that has been explained with complex abstract terms, but is easily accomplished with simple, embodied perception-action rules (Wilson \& Golonka, 2013).

For instance, complex motion problems like the outfielder problem can be easily explained with perception-action rules, rather than with abstract, representational explanations. The outfielder problem asks the question, 'how does an outfielder know where to be to catch a fly ball?' The traditional cognitive approach would suggest reasoning based on a model or rules-for example, that the outfielder calculates initial speed and angle, and uses laws of projectile motion to predict where the ball will land and moves there in a straight line. The embodied approach, on the other hand, would state that as the outfielder moves, they utilize a combination of their motion through space as
well as the ball's motion through space. The embodied approach claims that the outfielder simply follows two elementary, perceptually based rules; first, move in a curved path that mirrors the path of the ball, so that it appears that it is moving in a straight line, and second, match speed so that it appears that the ball is moving at a constant velocity (Wilson \& Golonka, 2013). Furthermore, most outfielders run in curved lines. There have been many elaborations on these simple embodied rules to catch a fly ball that rely entirely on reactionary rules (Chapman, 1968; McLeod, Reed, Dienes, 2006; Tresilian, 1995). To further add to the evidence that the motor system responds in real time to the environment, rather than following a previously simulated prediction, outfielders can catch fly balls in virtual reality whose paths actually defy physics, where it is impossible to predict trajectories (Fink, Foo \& Warren, 2009).

The apparent discrepancy between the motor system responding to a trajectory and the abstract prediction or production of one could explain why multiple studies report surprisingly high prediction errors in schematized spiral problems. This effect may be due to there being separate pathways for perception and action of visual stimuli (Goodale \& Milner, 1992; Haffenden, Schiff \& Goodale, 2001). For example, when a ball is dropped from a certain height, regardless of the weight, participants will react accordingly and catch the ball, and their implicit motor knowledge will even account for the mass by demonstrating stronger muscle activity in anticipation of a heavier object (Oberle et al, 2005; Zago \& Lacquaniti, 2005). Interestingly, the same participants will make incorrect Aristotelian assumptions about which ball will hit the ground first when posed the question abstractly, but will demonstrate implicit motor knowledge of Newton's Laws of Dynamics when responding physically. These results demonstrate that the motor system is responsible for accurately responding and accomplishing a task that the same participants are unable to accurately describe conceptually.

This discrepancy between being able to do something and being able to accurately describe it has produced some interesting theories to account for it. Rather than the embodied/abstract distinction, Tresilian (1995) proposes a dual system of object motion that is treated separately in the mind, using different mechanisms to process information: the cognitive-perceptual and the action-oriented. The cognitive-perceptual pathway would deal with more abstract information, based on prediction or using rule-based algorithms, whereas the action-oriented pathway mirrors what embodiment researchers have called the perceptionaction loop. This action-oriented pathway would consist of simple, automatic, and reactionary rules that utilize relational information between the body and the environment - information that sophisticated robots use to locomote or otherwise interact with their surroundings, or how an outfielder catches a fly ball (Raibert et al., 2008, Tresilian, 1995; Wilson \& Golonka, 2013). Tresilian proposed that we naturally conceptualize the world via the cognitive-perceptual pathway, and physically respond to the
world via the action-oriented pathway. The errors observed in folk physics research may be due to the cognitiveperceptual pathway processing information that is more naturally suited to processing by the action-oriented pathway. In Tresilian's model, the errors that are observed in curvilinear impetus belief problems are the result of the cognitive-perceptual pathway being forced to perform an inherently artificial task that it is not biologically suited to, whereas a real spiral and ball would have the action-oriented pathway perform as intended - quickly, accurately, and situated in the real world. Thus, a cognitive-perceptual pathway set opposite to an action-oriented pathway would account for all types of object motion perception, as well as the errors observed in the literature.

The goal the present study was to test the distinction between the cognitive-perceptual pathway and the actionoriented pathway by systematically increasing the degree of embodiment on variations of the spiral tasks used in McCloskey et al. (1980). The curvilinear impetus belief was tested in the abstract sense on paper, as well as in an embodied sense where participants were instructed to reach for a ball as it rolled out of a physical spiral. An intermediate condition was presented so that the spiral device was present, but the participant chose from multiplechoice correct and incorrect trajectories drawn on paper in front of the physical spiral. We hypothesize that, in the abstract condition, the brain will use the cognitiveperceptual pathway, which will result in many errors. In the prediction condition, both the cognitive-perceptual pathway and the action-oriented pathway will be engaged, which will result in fewer errors. In the action condition, only the action-oriented pathway will be engaged, resulting in the fewest errors of the three conditions.

## Method

The first group of participants were given a diagram from McCloskey et al. (1980) to control and replicate the findings, and to provide an abstract condition. They were asked to draw the trajectory of an imagined ball exiting a spiral on the diagram.

The second group was presented with a spiral device designed to carry a small metal ball, and the participants were asked to select a labeled trajectory similar to McCloskey and Kohl (1983), thus providing data for a prediction condition between abstract and action conditions, as the spiral no longer had to be imagined but was physically instantiated in front of them.

Participants in the third group, the action condition, were presented with the device and were asked to catch the ball as it exited the spiral. We recorded the distance from their hands to the correct trajectory of the ball.

All responses were recorded categorically as correct or incorrect.

## Participants:

A total of 72 adults, all undergraduate students were recruited to participate from February 28, 2015, to

November 27, 2016 through the online recruitment site at Carleton University in exchange for extra credit in a class. Two participants were excluded from the dataset due to a misunderstanding of the instructions. From the remaining participants, there were 40 females and 30 males. The average number of physics courses taken was 1.6 , and the average year of university of the participants was 2.2 . Participants were split into three groups: an abstract condition, a prediction condition, and an action condition. There were 24 participants for the abstract condition, 23 for the prediction condition, and 22 for the action condition, with a mean age of 20.6. All participants had normal or corrected to normal vision.

## Materials:

Participants in the abstract condition were provided with a pen, and a spiral diagram that was used in McCloskey et al. (1980) on $8.5 "$ x $11 "$ white standard weight paper.

The prediction and action conditions were presented with the physical device sitting on a table, positioned approximately 45 cm to the left of the participant. The device was 90 cm tall, with a diameter of 44 cm (See Figure 3). For the prediction condition, the device was set alongside pre-drawn predictions of correct and incorrect trajectories on a large sheet of $61 \times 90.2 \mathrm{~cm}$ graph paper, placed so that they appeared to emerge from the exiting end of the tube. The spiral was made of one inch clear tubing, 3-inch PVC pipe, and wood fittings. The metal bearing used in Condition 3 weighed 28.3 grams.

To determine where the participants were reaching in Condition 3, a Nikon P7700 Powershot video camera was placed above the area on a tripod so as to include the participant's hand, as well as 1 -inch measurement marks to measure correct or incorrect responses.

## Stimuli:

Figure 1: Spiral figure for the Abstract condition
The stimuli for the abstract condition was taken from McCloskey et al. (1980) in order to verify that the groups of students used in our experiment produced similar errors to the students in the previously mentioned paper, as well as provide data for an abstract condition (Figure 1).

In the prediction condition, participants were seated in the same orientation to the apparatus as the action condition to select from set trajectories. The participants were presented with the spiral apparatus (rather than solely a picture) and
were asked to verbally make a selection from the set of predefined trajectories. The trajectories were taken from the most likely errors in McCloskey et al. (1980) that were

Figure 2: Spiral figure used in conjunction with spiral device for the Prediction condition
subsequently used in the multiple-choice condition in McCloskey and Kohl (1983) (Figure 2).

In the action condition, participants were presented with the spiral apparatus and were asked to catch the ball as it exited the tube (Figure 3). A camera was employed to measure the reactions and catalogue the accuracy of the motor response.

Figure 3: Spiral device for the prediction and action conditions. Side view (left) and top view (right)

## Procedure:

In the abstract condition, the participants were presented with a paper and pencil test with the diagram from McCloskey et al. (1980), hidden beneath the short demographic questionnaire. They were then given the following instructions:

[^356]In the prediction condition, after completing the questionnaire, the participants were shown the physical apparatus and were asked to choose from 6 set trajectories from McCloskey and Kohl (1983). The participants in this condition were instructed as follows:
"This device will allow a small metal ball to travel down the tube. The ball will then exit the tube and travel on its trajectory. Your task is to pick which labeled trajectory the ball will most likely follow without using your hands. Please verbally indicate your answer."

In the action condition, after completing the questionnaire, the participants were shown the physical spiral device and given the following instructions:

> "This device will allow a small metal ball to travel down the tube. Once the ball is inserted into the tube, your task is to reach for the ball only when it passes the marked area in red so as to catch it in the palm of your hand. Please move your hand in a straight line away from you."

Participants were asked to wait until the ball had passed the marked area so that their hand would have to move late and fast, to prevent them from moving their hand in response to the perceived trajectory-we wanted to measure where their motor system thought the ball would go, not how it might change trajectory on the fly.

## Measures:

We counted any curved lines drawn in the abstract condition as erroneous and took them to indicate a curvilinear impetus belief. Similarly, we categorized as incorrect any curved responses selected in the prediction condition.

In the action condition, we coded any deviations away from the correct trajectory as erroneous. This was accomplished by measuring, on the video, how far the participant's knuckle on the index finger was from the correct trajectory. When the participants reached for the ball after it had passed the marker, any deviations from the correct trajectory exceeding 1 inch away from the zero line were recorded as errors. If while attempting to catch the ball, the knuckle of the hand was within one inch on either side of the zero line, the response was categorically correct.

## Design:

Participants were assigned to the three conditions in the order of abstract, prediction and action, in a between subjects design. A Chi Square Test for Independence was conducted for all three conditions, and between paper and prediction, paper and action, and prediction and action as post hoc analyses. The number of physics courses was split into three arbitrary groups of None (0), Some (1-3), and Many ( 3 or more), and were analyzed with the Chi Square test for independence as well. All post-hoc tests were corrected using the Bonferroni correction.

## Results

Participants in the action condition, where people actually reached for the ball rolling out of a curved tube, were much more accurate than participants who merely predicted the path of the ball on paper.

Over all three conditions, the accuracy of responses differed significantly between the conditions, though not in the predicted increasing fashion. A Chi Square test for Independence between the three groups produced $\chi^{2}=(2, N$ $=68)=26.31, p<.001$, Cramer's $V=.43$, which is statistically significant and indicates a large effect size.

Post hoc analysis illustrates that the main effect, between all three conditions, was primarily driven by the difference between the prediction condition and the action condition, as can be observed in Figure 4. Post hoc testing using the Bonferroni Correction for pairwise comparisons with the Chi Square test determined that there was a significant difference between the abstract and prediction comparison, $\chi^{2}=(1, N=47)=10.55, p<.017$, the abstract and action comparisons, $\chi^{2}=(1, N=47)=16.42, p<.017$, as well as the prediction and action comparisons, $\chi^{2}=(1, N=46)=$ 25.66, $p<.017$.

There was no relationship between the number of physics courses taken, $\chi^{2}=(2, N=70)=1.59, p=.45$. Post Hoc tests with the Bonferroni Correction also revealed no significant differences between groups, $p>.017$.

## Discussion

These results have provided some support for the original hypothesis that the degree of embodiment significantly influences the accuracy of responses. However, we did not observe the stepped increase from the abstract condition to the action condition. There was no effect of the number of physics courses on the number of correct responses, which supports Kozhevnikov and Hegarty's (2001) finding that physicists and non-physicists alike seem to rely on an incorrect default curvilinear physics for abstract problems. In the abstract condition, $62.5 \%$ of the respondents produced incorrect trajectories compared to the $36 \%$ and 49\% reported in McCloskey et al. (1980).

The original hypothesis that the difference between the abstract condition and the action condition would produce significantly different responses was supported. Surprisingly, however, the prediction condition had the fewest correct responses, with most participants choosing between two of the 6 options (E and D in Figure 2), whereas it was hypothesized that the prediction condition would have more correct responses than the abstract condition. Lastly, the action condition had the most correct responses, which supported our hypothesis that there is a dissociation between our action-oriented pathway and our cognitiveperceptual one.

With this paradigm in mind, the finding that many of the prediction condition responses were incorrect might be explained by the fact that both the cognitive-perceptual and the action-oriented pathways were in conflict, causing more errors. Alternatively, there was no participant motion involved, and this lack of a motor aspect in the prediction condition might have hindered its validity as a medium embodied condition. Also, the relatively high number of correct responses in the action condition suggests that physical responses are more biologically adapted for accuracy. Taking these findings into account, the act of drawing in the abstract condition may have allowed the action-oriented pathway to provide more correct paths of the imaginary ball, while the stationary aspect of the prediction condition may have only allowed the cognitive-perceptual pathway to be used. Thus, the abstract condition may have been more embodied than the prediction condition, which if true, would demonstrate the stepped increase hypothesized.

The significant differences observed in this experiment have illustrated the degree to which our minds are divided depending on the task and level of physical action. However, future research could expand the prediction condition of this experiment by investigating how participant motion, for example pointing to the correct trajectory or producing it alongside the spiral might increase the number of correct responses by activating the actionoriented pathway. Other areas of research may include asking participants to imagine the trajectory of the ball before choosing or drawing their prediction, to more accurately determine the capacities of the cognitiveperceptual pathway. Furthermore, the method for coding accuracy was done categorically and was measured differently between conditions, posing some reliability concerns. Because of these limitations, future projects should investigate the production of the trajectories, as in the abstract condition, in a setup identical to the prediction and action conditions, thereby increasing the generalizability of the results.

The implications of this research are broad. The pedagogical implications for teaching elementary physics could be substantial. Participants were largely incorrect when presented with abstract, as well as non-dynamic examples of this physics problem (i.e. prediction condition), so it might be beneficial for educational authorities to encourage more embodied examples of physics problems to
facilitate student understanding. The results partially support Tresilian's (1995) model that the cognitive-perceptual pathway demonstrates poorer performance on abstract physical tasks, whereas the action-oriented pathway does better on responsive and physical tasks.

These results have provided evidence for one of the cornerstones of embodied cognition: that cognition evolved for action (Wilson, 2002). This is not usually the case in many research papers, as much embodied research that is publically received involves associations between mental representations and bodily postures, types of movement, and even the types of clothes people wear (Adam \& Galinsky, 2012; Markman \& Brendl, 2005; Reutner, Hansen, \& Greifeneder, 2015). Although the results from these associational studies are interesting, they support a weaker version of embodied cognition; one that implies that cognition is merely influenced by the brain, the body and the environment. This study suggests a distributed view of the mind, one that engages the action-oriented pathway when solving embodied motion problems, yet falls back on the cognitive-perceptual pathway when motion is absent.

At present there is evidence for a dual-pathway system: one utilized when the mind is processing abstract conceptualizations, and one that utilizes the motor system when the mind is processing motion problems, using perception-action loops in a reactionary fashion. The classical view of the mind within cognitive science as a symbol manipulator falls apart when real world motion is involved, and embodied cognition and Tresilian's dual pathway system for object motion may provide a new way of conceptualizing how minds react and think about object motion.

# Network Analysis of a Large Sample of Typical and Late Talkers 

Eva Jimenez (E.Jimenez-Mesa@warwick.ac.uk)<br>Department of Psychology, University of Warwick, University Road, Coventry, CV4 7AL, United Kingdom<br>Thomas Hills (T.T.Hills@warwick.ac.uk)<br>Department of Psychology, University of Warwick, University Road, Coventry, CV4 7AL, United Kingdom

#### Abstract

The focus of this paper is to examine differences in semantic network structure of late talkers and typical talkers to elucidate potential learning strategies used by late talking children. To address this question, we conducted network analysis on the vocabularies of 2,912 children, with 566 of those being late talkers. Contrary to previously reported findings, the results show that late talkers have well-connected vocabularies as measured by median degree, clustering coefficient, and mean distance, with more well-connected networks in some cases than their typical talking peers. Further analysis of word order suggests that late talkers may be selecting based on frequency and connectivity of the words in the learning environment, more so than typical talkers. The language processing difficulties in late talkers appear not to be associated with their semantic network properties. In sum, late talkers may initially benefit from using word frequency and word connectivity strategies to build well-connected vocabularies.

Keywords: semantic networks; network analysis; corpus analysis; language acquisition; late talkers; word frequency

## Introduction

Children start learning words within the first and second year of life. Some children are slower than others, and some of the slowest children go on to show lifelong learning difficulties. These children, called late talkers, have been the subject of extensive research, both to understand how they learn but also to understand how their learning might be better facilitated to prevent lifelong problems. One of the outstanding questions in late talker research is to what extent late talkers are simply 'slower' versions of typical talkers? The alternative is that they show different learning strategies and therefore not only learn words more slowly but learn different words. In the present work we address this question using network analysis on the largest currently available sample of children's vocabularies. The aim is that by identifying similarities and differences in vocabulary acquisition, we can better identify the strategies that late talkers might be using, if indeed they are using strategies different from typical talkers. Before we explain our methods, we first briefly review the literature on network analysis and late talkers.

## Network Analysis in Language Acquisition

Semantic network analysis has allowed researchers to explore language processing in adults (Wachs-Lopes \& Rodrigues, 2016) and language acquisition in children (Hills,

Maouene, Riordan \& Smith, 2010; Hills, Maouene, Maouene, Sheya \& Smith, 2009). In network analysis, also known as graph theory, words are modelled as vertices and relationships between words are modelled as edges. Semantic relatedness amongst words is the focus of the present study, however, other relationships have been used in the past, including features, phonology, and free associations (e.g., Li , Farkas \& MacWhinney, 2004, Hills, Maouene, Maouene, Sheya \& Smith, 2009).

According to Watts \& Strogatz (1988) small world networks are "highly clustered, like regular lattices, yet have small characteristic path lengths, like random graphs". Smallworld properties have been reported not only in adult vocabulary but also in toddlers as young as 15 months (Beckage, Smith, \& Hills, 2011). Local structure, where words are connected in clusters, may represent semantic categories (Hills, Maouene, Maouene, Sheya \& Smith, 2009b). Words between clusters may facilitate transitions between clusters, and therefore are believed to be critical in language processing (Cancho \& Solé, 2001; Banavar, Maritan \& Rinaldo, 1999).

Networks statistics can be computed to evaluate the connectivity of a lexical network. Three of them are considered in this work. The degree of a word is the number of ties that word has with other words. Calculating the mean or median of this measure provides the overall level of cohesion in a network. The clustering coefficient explores the degree of clustering of nodes within a network. Finally, the mean distance of a network shows the average of the shortest paths between all pairs of words which gives an idea of its global access. Many studies have included these statistics in their analysis to examine research questions related to language acquisition, e.g. studies on lexical growth (Hills, Maouene, Riordan \& Smith, 2010), categorical memberships in the lexicon (Hills, Maouene, Maouene, Sheya \& Smith, 2009b), and the influence of bilingual first-language learning on early English acquisition (Bilson, Yoshida, Tran, Woods \& Hills, 2015).

## Language Acquisition in Typical and Late Talkers

Extensive research has already taken place around those children with small vocabularies compared to their normed peers (for a review, see Desmarais, Sylvestre, Meyer, Bairati \& Rouleau, 2008). Whereas many late talkers catch up with their peers in word production (so called 'late bloomers'; Thal, Tobias \& Morrison,1991), some others will have language difficulties that drag on, to be later diagnosed with Specific Language Impairment (SLI) (Leonard, 2000). For
the latter group, language problems will continue with comprehension, production and/or pragmatics (Leonard, 2000). Despite late bloomers' vocabulary improvement, they may still be more likely to experience difficulties in language-related tasks, such as reading (Rescorla, 2009). Defining and understanding the characteristics and strategies of late talker's vocabulary could help to develop effective early interventions.

The starting point for our research is Beckage, Smith and Hills (2011). In their study, network analysis was used to characterize the vocabularies of 66 typical and late talking children. Semantic relatedness of words, computed from word co-occurrence derived from the CHILDES database (MacWhinney, 2000), was used to connect the words in the child's vocabulary. Results showed that both typical and late talkers exhibit small-world structure, although late talkers present this to a lesser degree. The study suggests the existence of a relationship between the child's rate of lexical development and the connectivity of her individual network. This finding led the authors to hypothesize the possibility of an 'oddball' strategy used by late talkers: a preference to learn words that have lower semantic relatedness with words they already know. Thus, late talkers may use different learning strategies or have differences in their ability to discriminate word referents.

A later study by Nematzadeh, Fazly \& Stevenson (2014) challenged these results. By means of computational modelling, the authors simulated typical and late talking word learners to explore differences in their semantic networks. Surprisingly, neither type of simulated word learner showed a small-world structure. Referring to Beckage, Smith and Hills' work (2011), the authors questioned the use of the same edges to link words of the networks of both typical and late talkers as it assumes that both groups learn the same knowledge about words. Moreover, the authors called into question the 'oddball strategy' alleging that late talking children do not possess enough information about the words to discern similarities and dissimilarities between words. However, their methodological differences may also explain the differences in the results. Whereas in Beckage, Smith and Hills' study (2011) the co-occurrence of words in childdirected speech generated semantic relatedness between words, Nematzadeh, Fazly \& Stevenson (2014) used associative semantic information provided by a custom lexicon to link words with similar meanings.

Word frequency has also been investigated as one of the main influences in word learning. In Stokes (2010), two-year old typical talking children tended to acquire more high frequency words than late talking children, who in turn learned more words with a higher phonological neighborhood density. However, the question remains whether there is a difference between the two groups with respect to preferences for acquiring some words earlier than others, which may have given a different perspective of the learning strategies used by each group.

The present work further investigates the difference between early and late talkers using vocabularies taken from
the open repository website Wordbank (Frank, Braginsky, Yurovsky \& Marchman, in press), providing a sample of 2,912 children, of which 566 are considered late talkers. The methodology followed and the words selected are identical to those in Beckage, Smith and Hills (2011), the only differences being the number of children and the diversity of their backgrounds as they come from nine different American studies. Our principle question is, how does the semantic vocabulary structure differ between typical and late talkers? We ask two additional questions: (1) what is the relationship between word frequency and order of word learning for the two groups, and (2) what is the relationship between word frequency in the language learning environment and the connectivity between the words. These allow us to investigate additional pathways for language learning in late talkers.

## Methods

## Vocabulary

Publicly available vocabulary data for 5,450 children aged 16 to 30 months was downloaded on October 2016 from Wordbank (Frank et al., in press). Data is contributed by various researchers using the MacArthur-Bates Communicative Development Inventory (MCDI) (Fenson, Dale \& Reznick, 1993). The data set used in this work was downloaded by selecting 'Words \& Sentences' under forms and 'English' under language. To facilitate comparisons between late and typical talkers, we limited vocabulary sizes to between 20 and 220 words, a range where typical and late talkers overlapped that also allowed for meaningful network statistics. Few late talkers had a productive vocabulary size greater than 220 words. After limiting the vocabulary size, the final total number of children remaining was 2,912 . Of the 2,912 children (aged 15 to 30 months), 566 have a vocabulary size atypical for their age and 2,346 presented a normal vocabulary size for their age. Late talkers were at or under the $20^{\text {th }}$ percentile of their same-age peers. To calculate this, each child was assigned to a decile grouping according to their age and vocabulary size reported in the MCDI instrument. The decile grouping was looked up from a table of estimated percentiles on the Wordbank website created using a quartile regression with monotonic polynomial spline as the base function. Although the total number of words that can be recorded in the MCDI questionnaire is 680, in Beckage, Smith and Hills' study (2011) only 291 words were used which appeared on both the toddler and infant forms, allowing comparison across ages. The same words were selected in this study. The 291 words consist of 207 nouns, 50 verbs, 14 adjectives, 12 pronouns, 6 adverbs, 1 quantifier and 1 demonstrative. All categories in the MCDI were included except for 'Sound Effects and Animal Sounds', 'Helping Verbs', and 'Connecting Words'.

## Semantic Relationships Between the Words

To link the words in each child's productive vocabulary, semantic relatedness between words was computed using co-
occurrence statistics derived from an American English corpus of child-directed speech, CHILDES (MacWhinney, 2000). A surface proximity approach (see Evert, 2008) was used to determine the frequency in which each distinct word (node) in the corpus co-occurred with other words (collocates). An empty co-occurrences matrix was created and then populated by moving a window of span size 5 words forward through the corpus. As co-occurrences were encountered the count for that pair was incremented. A subset of this large matrix was created where the rows and columns intersected with the 291 words selected from the MCDI forms. Finally, the count values were converted to a simple binary representation.

## Random Acquisition Networks

In order to compare each individual child's network with similar size networks, 300 random acquisition networks were generated for each child. These networks have the same number of words $n$ as the child's network, but the words are selected randomly from the set of 291 words. Then, each random network was linked using the values from the CHILDES matrix explained above. The same statistical properties computed for each child's vocabulary network were also computed on the 300 random acquisition networks and then averaged. These random network statistics provide the structure inherent in the language context without including the particular word learning pattern of the child, thus providing a point of comparison for each child's network, allowing us to compare children with different size vocabularies against a 'random' learner.

## Word Frequency and Connectivity

Preferences for learning certain words over others was assessed with respect to vocabulary size. First, the sample was divided into two groups: late talkers and typical talkers. Then each group was ordered by increasing vocabulary size, creating subgroups. Within each subgroup and for each word a count was made of children that produced the word. Words were ranked based on their count. Differences in ranking between late and typical talkers was calculated by subtracting the respective ranking value for each word, allowing us to identify differences between the groups in their preference for learning certain words.

Only words with a minimum ranking difference of 20 or more are presented, but the results are not sensitive to this number. The frequency of each word was taken from CHILDES and compared between the two groups (see MacWhinney, 2000; Li \& Shirai, 2000). Within the $291 \times 291$ matrix of co-occurrences, some words are better connected (have higher degree) than others. This was calculated directly from the matrix by counting the total number of occurrences of a word with other words.

Table 1: Distribution of the children's vocabulary and mean age (in parenthesis)

| Vocabulary size |  |  |  |  |  |  |  |  |  |  |
| :--- | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  | $20-40$ | $40-60$ | $60-80$ | $80-$ | $100-$ | $120-$ | $140-$ | $160-$ | $180-$ | $200-$ |
|  |  |  |  | 100 | 120 | 140 | 160 | 180 | 200 | 220 |
| LT | 133 | 70 | 74 | 60 | 55 | 46 | 36 | 46 | 25 | 21 |

## Results

## Network Analysis

Analysis was carried out using R and the igraph package, version 1.0.1 (Csárdi \& Nepusz, 2006). Connectivity was assessed by computing three statistics of each directed network: median in-degree, clustering coefficient, and mean distance. Late talkers are unequally distributed across the sample: they have higher representation at lower vocabulary sizes and low or no representation at the higher vocabulary sizes. Therefore, the sample was divided into bins of children with similar vocabulary sizes in ranges of 20 words. The size of the bin does not influence our results, but does facilitate their visual presentation. Table 1 shows the number of late talkers (LT) and typical talkers (TT) in each bin, as well as the mean age in each group.

Stepwise linear mixed effects analysis ( $\operatorname{lm} 4$ package, version 1.1-12; Bates, Mächler, Bolker \& Walker, 2015) was performed to explore the relationship between each of the three network statistics and type of talker. The final three models includes vocabulary size and type of talker as fixed effects to predict each network statistic. No collinearity of these predictors was found (VIFs < 1.02). Intercepts were allowed to vary across vocabulary sizes as the values of each network statistic varies across the size contexts. The inclusion of vocabulary size as a fixed effect allowed us to control for network size and led to a better statistical fit. No significant difference in the model resulted when allowing slopes to vary by either vocabulary size or type of talker. The significant main effect for type of talker reveals a positive relationship between LT and median indegree (Estimate $=.061, S E=.025$, $p=.014$ ). A marginal main effect for type of talker indicates that being a late talker leads to higher clustering coefficient (Estimate=.003, $S E=.002, p=.063$ ). A negative main effect was observed for late talkers on mean distance (Estimate $=$ $.014, S E=.004, p=.0008$ ). These results indicate that LT's vocabularies are better connected and have better global access than TT's vocabularies when considering all the vocabulary sizes together.

We compared the observed networks statistics with those from the vocabulary size-matched random acquisition networks by calculating ratios (Figures 1, 2 and 3). Linear mixed effect analysis was also carried out to examine the relationship between these ratios and type of talker. The model had the same structure as used in the previous analysis.

Results indicate no main effect for the type of talker on indegree ratio (Estimate $=.024, S E=.014, p=.078$ ). Significant main effects were found on clustering coefficient (Estimate $=.009, S E=.005, p=.044$ ) and mean distance ratios (Estimate $=-0.008, S E=0.002, p=.0007$ ), indicating that late talking children tend to have higher clustering coefficient and lower mean distance in their networks.

Figure 1. Median degree ratio of the observed data to the RAN. Note: * p < 0.05

Figure 2. Clustering coefficient ratio of the observed data to the RAN. Note: * p < 0.05

Figure 3. Mean distance ratio of the observed data to the RAN. Note: * p < 0.05, ** p < 0.01

Table 2: Difference between typical and late talkers compared to random acquisition networks

|  |  | Networks M(SD) | $\begin{gathered} \text { RAN } \\ \text { M(SD) } \end{gathered}$ | t (df) | d |
| :---: | :---: | :---: | :---: | :---: | :---: |
| LT | In-degree | $\begin{gathered} 23.89 \\ (12.56) \end{gathered}$ | $\begin{gathered} 20.81 \\ (12.61) \end{gathered}$ | $\begin{gathered} 12.6 \\ (565) \end{gathered}$ | . 530 |
|  | Clustering coefficient | $\begin{aligned} & .58 \\ & (.07) \end{aligned}$ | $\begin{gathered} .54 \\ (.01) \end{gathered}$ | $\begin{gathered} 13.9 \\ (565) \end{gathered}$ | . 584 |
|  | Mean distance | $\begin{aligned} & 1.68 \\ & (.1) \end{aligned}$ | $\begin{aligned} & 1.73 \\ & (.02) \end{aligned}$ | $\begin{aligned} & 10.33 \\ & (565) \end{aligned}$ | . 434 |
| TT | In-degree | $\begin{gathered} 26.7 \\ (13.44) \end{gathered}$ | $\begin{gathered} 25.01 \\ (14.56) \end{gathered}$ | $\begin{aligned} & 13.81( \\ & 2345) \end{aligned}$ | . 285 |
|  | Clustering coefficient | $\begin{aligned} & 0.57 \\ & (.06) \end{aligned}$ | $\begin{aligned} & 0.55 \\ & (.01) \end{aligned}$ | $\begin{gathered} 18.81 \\ (2345) \end{gathered}$ | . 388 |
|  | Mean distance | $\begin{gathered} 1.7 \\ (.09) \end{gathered}$ | $\begin{aligned} & 1.72 \\ & (.02) \end{aligned}$ | $\begin{gathered} 10.23 \\ (2345) \end{gathered}$ | . 211 |

Standardized residual plots were visually inspected for the linear mixed models to check for homoscedasticity and normality, and a violation of these requirements was noted. To confirm these results, we carried out more analysis. Ttests were conducted to detect differences between LT and TT regarding the ratio of the observed statistics to the statistics of the size-matched RAN. Late talker's vocabularies have higher values of median in-degree ( $M=1.28, S D=.39$ ) and clustering coefficient ( $M=1.08, S D=.140$ ) than typical talking children (in-degree: $M=1.20, S D=.37$ ), $t(817)=$ 4.54, $p<.001, d=-.22$; clustering coefficient: $M=1.05, S D=$ $0.13), t(820)=-4.72, p=p<.001, d=-.23$ ). Late talking children also had lower values of mean distance ( $M=.97$, $S D=.06$ ) than typical talking children ( $M=.99, S D=.063$ ), $t(815)=5.18, p<.001, d=.25$.

Further analysis using the ratio data was conducted to check whether the same differences between LT and TT are also observed within each bin of vocabulary size. Significant results are signaled with an asterisk in Figures 1, 2 and 3. Late talkers obtained higher in-degree and higher clustering coefficient than TT in the vocabulary range 40 to 60 words. Significant differences in mean distance were found in three groups of vocabulary size, all of them present lower values for LT: 40 to 60 words, 60 to 80 words, and 140 to 160 words. The same t-test analysis in each bin was performed using only the observed data. Apart from mean indegree, in which any difference between the type of talkers were found, similar results were obtained in clustering coefficient and mean distance in the same vocabulary sizes. These results show that LT's vocabularies are better connected than TT's
vocabularies in certain vocabulary ranges, and also that TT resembles their RAN more than LT do in these ranges.

Paired t-tests were conducted to compare the properties of LT and TT networks with their corresponding size-matched RAN. Results can be seen in Table 2. Both LT and TT showed significantly higher values of median in-degree and clustering coefficients and significantly lower values for mean distance than their size-matched RAN. Thus, LT and TT seem to present vocabularies which are well connected and have good global access.

## Word Frequency and Connectivity

To investigate differences in the order in which LT and TT learn words, we examined the correlation between word order and word frequency in CHILDES. The order in which all 291 words are learned across vocabulary size is not correlated to word frequency for either type of talker (LT: $r_{s}=-.10, p=.082$, TT: $r_{s}=-.063, p=.28$ ). When the same analysis is performed on each vocabulary size bin, word order in LT was significantly related to word frequency in vocabulary sizes of 20 to 40 words ( $r_{s}=-.13, p=.023$ ), and 40 to 60 words ( $r_{s}=-$ $.16, p=.006$ ). Thus, the order in which LT learn words seems to be related to their frequency during the first stages of vocabulary development. Further correlation analysis revealed a relationship between connectivity and word order ( $r_{s}=-.13, p=.026$ ) in LT but not in TT ( $r_{s}=-.11, p=.071$ ). Analysis on each bin shows that, only for LT, this relationship is present in vocabulary sizes of 20 to 40 words ( $r_{s}=-.16, p=.008$ ), 40 to 60 words ( $r_{s}=-.18, p=.002$ ), 100 to 120 words ( $r_{s}=-.13, p=.032$ ), 120 to 140 words ( $r_{s}=-.13, p=$ .024 ), 180 to 200 words ( $r_{s}=-.12, p=.043$ ), and 200 to 220 words ( $r_{s}=-.12, p=.041$ ). In view of these results, it seems that connectivity and frequency of the 291 words are somehow related to word order in LT but not in TT. In addition, word connectivity seems to be more strongly related to word order in LT than word frequency.

Further analysis considered only those words that differed considerably in word order between LT and TT. That is, there were some words that were learned earlier by one of the type of talker groups compared to the other group, we refer to them here as 'preferred words'. Figure 4 shows significant differences between the two types of talkers: LT learned more words that are highly frequent in the language environment $(M=3588, S D=897)$ than TT $(M=1060, S D=687), t(16.9)=$ $7.08, p<.001, d=3.16$. The connectivity within the matrix of co-occurrences of preferred words was compared between LT and TT. Children with language delay learn words that are well connected in the matrix ( $M=101, S D=11.4$ ), more so than TT $(M=75.8, S D=12.01), t(17.9)=4.79, p<.001, d$ $=2.14$. These results are consistent with this studies analysis of the network statistics, with LT learning more wellconnected words than TT. Results from a logistic regression using the preferred words indicated that frequency is not a good predictor of the type of talker ( $B=.007, S E=.008, p=.38$, Homes-Lemeshow $R_{2}=.85$ ), contrary to connectivity, which was a significant predictor $(B=.14, S E=.055, p=.009$, Homes-Lemeshow $R_{2}=.50, \quad 95 \%$ CI [1.06, 1.33]).

Additionally, we wanted to see whether word frequency in CHILDES and the connectivity of the 291 words within our matrix of co-occurrences are correlated. Results showed that these two measures are strongly related ( $r_{s}=.91, p<.001$ ). These results suggest that LT children may be more susceptible to these two word properties, however only the connectivity of the preferred words can predict the type of talker.

Figure 4. Word frequency by vocabulary size. Numbers at each point reflect number of preferred words used for analysis in each group.

## Discussion

The present study uses network analysis on a large sample of children's vocabulary to explore the idea that late talkers may have a different word learning strategy than typical talkers. Multiple results from different analysis fail to agree with the findings in Beckage, Smith and Hills (2011). The authors reported that children with language delay have networks with less clustering coefficient and less mean distance than their vocabulary size-matched RAN. Furthermore, the authors hypothesized that this may be due to LT using an 'oddball strategy' to learn words, i.e. late talkers may be attracted to those words that are not well connected in the learning environment, as opposed to the idea of 'preferential acquisition', in which the tendency is to learn earlier on the most contextually diverse words in the learning environment (Hills, Maouene, Riordan \& Smith, 2010). However, the use of a larger sample in this study suggested that LTs do not use an 'oddball strategy', rather they seem to learn words that are well connected in the environment.

Analysis of the frequency of these preferred words in the learning environment showed that LT learn a good proportion of highly frequent words earlier than TT. However, the relationship between word frequency and language delay is still unclear as it seems to not be a good predictor for type of talker. Nevertheless, these results seem to contradict the findings by Stokes (2010), who found that two-year old typical talkers learn more high frequency words than LT do. However, the inclusion of function words may partly explain
the difference between the present study's results and Stokes' results as their frequency in the learning environment is higher than open class words. The connectivity of the preferred words within the 291 words used in the present study indicate that LT also happened to learn well connected words earlier.

One of the reasons behind the findings may be that late talking child are more passively influenced by word frequency, consequently, learning more highly frequent words that happen to be well connected in the learning environment. As knowing these high frequency words can deliver a degree of communication success, the requirement to acquire advanced strategies may be further delayed.

In sum, the evidence reported in this study suggests that children with language delay have well connected vocabularies and good global access, in many cases better than the typically developing children. Late talkers may be more influenced by word frequency or connectivity, perhaps using a strategy to learn words that are contextually diverse in the learning environment as noted in previous work (Hills et al., 2009a). In order to elucidate whether these two types of talkers are using different word learning strategies, future research will need to examine the longitudinal development of vocabularies in LT and TT and a different approach to assign a more individualistic semantic relatedness between the words.

# Spatial language: Meaning, use, and lexical choice 

Kristen Johannes (kjohann@WestEd.org)<br>Science Technology Engineering and Mathematics Program, WestEd<br>300 Lakeside Dr., Oakland, CA 94612 USA

Barbara Landau (landau@cogsci.jhu.edu)<br>Department of Cognitive Science, Johns Hopkins University, 3400 N Charles St., Baltimore, MD 21218 USA

#### Abstract

Accounts of spatial language aim to address both the meaning of a spatial term and its usage patterns across diverse cases, but do not always clearly distinguish these from one another. Focusing on the case of English prepositions in and on, we set out to disentangle spatial language meaning from spatial language use by comparing judgments on a series of linguistic tasks designed to tap each aspect of spatial language. We demonstrate that judgments of truth-conditional meaning and patterns of naturalistic use show different distributional signatures, with judgments of meaning giving rise to a more uniform distribution than use patterns. We explore a third aspect of spatial language: lexical choice, and propose that choice is a key factor in shaping the distribution of spatial expression use. Our analyses reveal that the distribution of lexical choice judgments is highly correlated with the distribution of expression use in spatial descriptions for the same spatial scenes, supporting a model of spatial language that differs from traditional accounts of meaning and categorization.

Keywords: Spatial cognition; spatial language; semantics; language use

## Introduction

Spatial terms in languages of the world tend to constitute a small closed class set (Landau \& Jackendoff, 1993; Talmy, 1985). In English, for example, this set is typically limited to the spatial prepositions, including in, on, over, above, etc. To linguistically encode spatial relations with this limited inventory, a speaker must systematically abstract over fine-grained properties of objects and configurations and attend to coarse-grained spatial and/or mechanical properties of their relations. Modeling the nature of this abstraction remains a long-standing problem in the cognitive sciences. The systematic ways in which speakers encode relations (i.e., generate descriptions) is often confounded with the ways in which they decode spatial descriptions (i.e., understand the meaning of descriptions).

This problem has been exacerbated by a lack of separation between definitional questions about the meaning of a spatial term like in or on and categorization questions about the use of a term by a population of speakers questions that may ultimately have different answers. Meaning and use represent distinct and separable aspects of many semantic domains (Cruse, 2011). In keeping with this observation, we suggest that the task of formally defining
spatial terms such as in and on is separate from, albeit related to, the task of specifying the conditions under which speakers will use a spatial term to describe a location or configuration. For example, formal accounts of spatial meaning come under fire when proposed meanings cannot accommodate peripheral uses (see e.g., Bennett, 1975 for examples and e.g., Feist, 2000, and Herskovits, 1986 for commentary), while accounts of spatial categorization based on language usage patterns often propose all-or-none category boundaries that mimic binary truth conditional judgments (Regier, Khetarpah1, \& Majid, 2013). In this paper, we aim to disentangle spatial language meaning from spatial language use by comparing judgments on a series of linguistic tasks across the same sets of spatial stimuli, including a task designed to directly assess speakers' lexical choices, which we propose are key in accounting for spatial term use but are not necessarily active in spatial term meaning.

Below, we review a selection of research on spatial language categorization, focusing mainly on the prepositions in and on. We organize the review into work that explicates the formal meaning of spatial terms and work that targets speakers' use of spatial terms for categorization. We then introduce recent work that suggests that speakers' choice of spatial term from among candidates is a critical variable in reconciling categories of spatial term meaning with patterns of speakers' spatial term use. The current study addresses these relationships - between meaning, choice, and use - directly for the English prepositions in and on, evaluating two complementary hypotheses, outlined below.

## Defining spatial terms

Past and present, accounts of spatial meanings have also had to shoulder the burden of accounting for detailed patterns of spatial expression use (and, in some cases abstract uses of spatial expressions, see e.g., Jamrozik \& Gentner, 2015). Traditional simplified accounts of prepositional meaning such as Bennett (1975) ${ }^{1}$ attempt to define spatial prepositions as a function of geometric

[^357]properties of configurations as a means of abstracting away from specific objects. These definitional theories have been consistently criticized for being, on the one hand, too vague and allowing unlikely cases into the definition (e.g., an apple under an upside-down bowl fits Bennett's denotation of "in the bowl") and for failing, on the other hand, to predict the range of peripheral cases for which in and on can apply (e.g., an apple on top of other fruit contained by a bowl, cf. Feist, 2000). These accounts have been replaced by proposals that incorporate large sets of features in order to narrow and specify the meaning of in and on based on usage patterns (see e.g., Feist, 2000; Vandeloise, 2010; Xu \& Kemp, 2012), and by proposals that prioritize world knowledge and pragmatic inference (Herskovits, 1986), so as to preserve narrow denotations for in and on while accounting for peripheral cases that depend on additional processes such as chaining (Malt, Sloman, Gennari, Shi, \& Wang, 1999). The current study examines whether accounting for frequent or infrequent uses of a spatial term is a necessary goal for accounts of spatial meaning.

## Spatial categories inferred from language use

Studies of spatial language categorization typically measure speakers' usage of spatial terms for different spatial scenes and, based on these data, one can infer possible category boundaries for single terms and/or semantic structure across multiple terms. Many of these accounts do not start from any initial hypotheses about the semantic content or meaning of particular spatial terms, and instead use spatial descriptions to infer systematic groupings of scenes under spatial terms. One prevailing assumption, however, is that a given spatial scene will fall "all-or-none" into only one spatial term category (e.g., the same scene cannot be categorized as both in and on).

For example, Levinson and colleagues (Levinson et al, 2003) and Regier and colleagues (Regier et al., 2013) examined spatial descriptions for a diverse set of spatial scenes from the Topological Relations Picture Series (Bowerman and Pederson, 1993). Across a large sample of languages, both groups analyzed the spatial term(s) used by the majority of speakers in a language group to encode a given scene - a point we will return to shortly.

Levinson et al. used multidimensional scaling on these data and proposed underlying spatial categories that are shaped by a handful of "attractors" - salient spatial scenes that are encoded in similar ways across languages. Similarly, Regier et al. employed an inferential (semantic map) analysis to come to a similar solution. Both studies are agnostic to the lexical content of particular spatial terms, but the researchers' analytical choices reflect a critical assumption about how spatial language use relates to underlying spatial categories. Specifically, researchers in both studies identified the modal term used by the majority speakers of each language for each scene, treating languageinternal variation as noise. The result of this modal assumption is binary, all-or-none categorization of a scene by spatial terms in a language, partitioning spatial scenes
into language-based equivalence classes, reminiscent of binary truth-conditional meaning.

This all-or-none semantic category structure limits the inferences that can be made about the relationship between the meaning of a spatial term and its use in encoding different spatial scenes. In particular, it ignores the possibility that spatial terms might overlap in the spatial scenes they apply to, leading to probabilistic use of multiple spatial terms, and, in a similar vein, precludes the idea that spatial terms can compete with one another to encode the same spatial scene.

Recent work from Johannes and colleagues (Johannes, Wilson \& Landau, 2016; Johannes 2015; Landau, Johannes, Skordos, \& Papafragou, 2016) demonstrates that multiple spatial terms are used by English speakers to encode the same spatial scenes. Moreover, they find that tracking the fine-grained use of a single spatial term across a diverse set of spatial relation scenes reveals a graded, non-uniform distribution of expression use across scenes, suggesting that some terms are a "better fit" to a spatial scene than others. In this paper, we extend the observations of Johannes and colleagues, proposing that speakers' choice of spatial term, among many candidates, to describe a configuration is a critical variable in accounting for the non-uniform distribution found in spatial expression usage patterns.

## The Current Study

In the current study, we pursue two related hypotheses aimed at exploring how speakers evaluate the meanings of spatial terms and how this process differs from their decisions to use specific terms in spatial descriptions. We propose implicit lexical competition - speakers' choice of a particular spatial term among viable candidates - as a way of accounting for differences in speakers' judgments of spatial expression meaning and patterns of spatial expression use.

We test these hypotheses using the spatial terms in and on as a case study and compare data from three different linguistic tasks, outlined in Table 1, conducted using the same diverse sets of containment and support scenes (originally from Johannes, 2015, and Johannes, Wilson, Landau, 2016; see Figures 1 and 2). A truth-value judgment task is used to assess speakers' binary truth conditions for different expressions by simply asking whether a given expression applies to a given spatial scene. A spatial description task is used to observe speakers' self-generated spatial descriptions for each spatial scene. Finally, a forcedchoice judgment task is used to measure speakers' judgments about which of two (true) spatial expressions is a better fit to a given spatial scene.

Hypothesis 1: Speakers' judgments of the truth-conditional meaning of spatial expressions are subject to different criteria than their decisions to use these expressions in spatial descriptions. We predict that tasks that separate these two types of judgments (see Table 1) will show different distributional signatures across the same set of diverse
scenes, with usage patterns yielding a more articulated, nonuniform distribution. Moreover, speaker's truth value judgments for a given spatial expression are not necessarily predicted to correlate with their use of the same spatial expression for the same spatial scenes, as tasks are hypothesized to engage different linguistic processes.

Hypothesis 2: Speakers' truth-value judgments and patterns of spatial descriptions differ due to implicit competition among felicitous candidates, which at play in spatial description tasks but not in truth-value judgment tasks. We predict that the distribution of judgments from a lexical choice task (Table 1), wherein speakers must choose between two felicitous spatial terms for diverse spatial scenes, will align with speakers' usage pattern in a spatial description task for those same scenes, but are not predicted to correlate with truth-value judgments.

## Experiment

## Methods

Design. The experiment was structured as a betweensubjects design with five separate groups of adult participants. Each group completed a different pairing of a linguistic task with a spatial stimulus set (see Table 1).

Linguistic tasks. Table 1 provides an example of each of the linguistic tasks, along with the range of possible responses.

Table 1. Linguistic tasks used with each stimulus set, including example prompts and possible responses.

| Task | Example Prompt | Responses |
| :---: | :---: | :---: |
| Truth value judgment (Stimulus sets $1 \& 2$ ) | Is the following sentence true of the scene? <br> "The sandwich is on the plate." | Binary judgment: \{Yes or No\} |
| Spatial description (Stimulus sets $1 \& 2$ ) | Where is object A in relation to object B in the scene? <br> [A: strawberries; B: bag] | Natural language description: "The strawberries are in the bag." |
| Forcedchoice judgment (Stimulus set 1 only) | Which of these two sentences is a better description of the scene? <br> A: "The tape is on the box" <br> B: "The tape is stuck to the box" | Binary judgment: \{A or B \} |

Participants. A total of 175 adults (mean age $=19.6$ years) participated in the experiment through a series of self-paced online interfaces in return for course credit. Table 2 shows the number of participants that provided data for each linguistic task.

Table 2. Participant breakdown across tasks and stimuli sets.

| Stimulus set 1 Tasks | $\mathbf{N}$ |
| :---: | :---: |
| Truth value judgment | 50 |
| Spatial Description | 50 |
| Stimulus set 2 Tasks | $\mathbf{N}$ |
| Truth value judgment | 25 |
| Spatial Description | 25 |
| Forced-choice judgment | 25 |

Materials. We used two sets of stimuli to elicit linguistic judgments and descriptions. Stimulus set 1 was developed by Johannes (2015) and consisted of 64 containment scenes and 64 support scenes, for a total of 128 items (Figure 1). Stimulus set 2 came from Johannes, Wilson, and Landau (2016; adapted from Landau et al., 2016) and consisted of 18 containment scenes and 15 support scenes, for a total of 33 items (Figure 2).

Figure 1. Example containment (left) and support (right) scenes from Stimulus set 1.

Figure 2. Example containment (left) and support (right) scenes from Stimulus set 2.

Procedure. Participants completed each task using a selfpaced online interface. Tasks included critical trials, which probed linguistic judgments for the prepositions in and on for containment and support scenes (see Figures 1 and 2), respectively, as well as filler trials, which elicited judgments for other prepositions or descriptions for scenes depicting other types of spatial relationships (e.g., proximity). The number of critical trials in each task varied depending on the stimulus set: tasks employing Stimulus set 1 had 128 critical trials and 62 filler trials, while tasks that employed Stimulus set 2 had 33 critical trials and 11 filler trials.

## Results

We first examined the relationship between truthconditional meaning and expression use by comparing the patterns of participants' truth-value judgments to their expression usage patterns from the spatial description task, both carried out using Stimulus set 1 . We then explored the relationship between participants' truth-value judgments, spatial descriptions and lexical choice patterns for tasks carried out with Stimulus set 2 . We compared patterns of spatial expression use, from the spatial description task, across spatial scenes to patterns of truth-value judgments, from the truth value judgment task, and patterns of lexical choice, from the forced-choice task. Although participants judged, or described, both containment scenes and support scenes, we present, analyze, and discuss these spatial categories separately.

Comparing distributions of truth value judgments to spatial descriptions: Stimulus set 1. Figure 3 presents a subset of containment and support items side by side and respectively shows participants' average rates of use of in or on (i.e., proportion of descriptions using in or on) in the spatial description task (top black bars) and average truthvalue acceptance rates (i.e., proportion of "True" judgments) on the truth-value judgment task (bottom white bars). Truth-value acceptance rates were greater than or equal to rates of expression use for all but 5 containment items and all but 2 support items ${ }^{2}$.

We tested whether measures of spatial expression meaning and spatial expression use show similar distributional signatures across the same spatial scenes. Our reasoning was as follows: if participants are using the same knowledge in similar ways to make judgments about spatial expression meaning and decisions about expression use, then the resulting pattern of truth-value judgments for in and on should systematically relate to the pattern of in and on use in descriptions of the same scenes. That is, scenes that are frequently described with in or on should also show higher rates of acceptance on the truth value judgment task, and scenes for which in and on are used infrequently should show low rates of truth value acceptance. We tested this

[^358]prediction using Pearson correlations, computed separately for containment and support items, between rates of in and on use in the spatial description task and rates of in and on acceptance in the truth value judgment task. The pattern of spatial descriptions and the pattern of truth-value judgments for containment items showed a weak, negative, but reliable correlation ( $r=-.383, n=64, p<.01$ ), while support items showed no reliable correlations between usage and acceptance judgment patterns ( $r=.059, n=64, n s$ ). The weak relationship between participants' truth-value judgments and spatial descriptions aligns with the picture in Figure 3, wherein truth-value judgments show a uniform distribution across scenes, while spatial expression use in descriptions shows a more articulated usage profile.

Our analysis supports a disconnect between participants' judgments about the meaning and felicity of in and on, on the one hand, and their decision to use the expressions to describe containment and support scenes, on the other. While it is clear that meaning and use must be linked in some way (that is, speakers must have implicit knowledge of the meaning of a spatial expression in order to successfully use it to communicate), we suggest that this link is not direct and explore lexical choice - a speaker's decision about which of multiple expressions apply to a given situation - as an intervening process between meaning and use.

Figure 3. Patterns of expression use and truth-value judgments (bottom) of in (left panel) and on (right panel) across a subset of containment and support items.

Exploring lexical choice as an intervening variable between truth value judgments and spatial descriptions:
Stimulus set 2. We collected descriptions and judgments for items in Stimulus set 2 (33 items total). Participants' responses are displayed separately for containment (Figure
4) and support (Figure 5) items, which present patterns of responses from the spatial description task, forced-choice judgment task, and truth-value judgment task. As before, participants produced descriptions with in and on nonuniformly across containment and support items (top panels of Figures 4 and 5) and showed near-uniform truth value judgments across the same items (bottom panels of Figures 4 and 5). Participants' patterns of responses on the forcedchoice judgment task, like their patterns of spatial expression use, showed a non-uniform distribution across items (middle panels of Figures 4 and 5).

Figure 4. Patterns of use (top), forced choice judgments (middle), and truth value judgments (bottom) for in across containment items. Items on the $y$-axis are presented in the same order in all three plots.

Following our previous analysis, we first measured the relationship between participants' average rates of in and on use in their spatial descriptions and acceptance rates in their truth-value judgments. Pearson correlations between language use and truth value judgments were nonsignificant for both containment items ( $r=.306, n=18, n s$ ) and support items ( $r=.159, n=15, n s$ ).

Next, we explored the hypothesis that lexical choice, operationalized here as forced-choice judgments, serves as an implicit process in the generation of spatial descriptions
but not truth-value judgments. Forced-choice judgments were not reliably correlated with truth value judgments for either containment or support. However, forced-choice judgments were strongly related to patterns of in and on use for both containment ( $r=.538, n=18, p<.01$ ) and support items ( $r=.736, n=15, p<.01$ ), suggesting similar variation in speakers' constrained (forced-choice) decisions about which of two expressions best applies to a spatial scene and their unconstrained decisions about how to describe the same spatial scene.

Figure 5. Patterns of use (top), forced choice judgments (middle), and truth value judgments (bottom) for on across support items. Items on the $y$-axis are presented in the same order in all three plots.

## Discussion

In this paper, we compared behavior across three commonly used linguistic tasks in order to examine and elucidate the relationship between judgments of meaning, lexical choice and language use as they apply to spatial terms like in and on. We found that truth-value judgments of the meaning of in and on are nearly uniform across diverse containment and support scenes, demonstrating that these terms are true of the scenes. Speakers' use of these terms, however, is not uniform: some scenes are described more frequently by in and on than others.

Consistent with this distributional difference, we found no strong reliable statistical relationship between judgments of meaning vs. use for the same spatial scenes. However, when we measured judgments of lexical choice (between in and on and other truth-conditionally feasible alternatives), we discovered a non-uniform distribution of choices, similar to the distribution evidenced for spatial expression use. Our analyses confirmed a strong statistical relationship between participants' responses on these tasks across the same set of containment and support scenes. These results support a view of spatial expression meaning as partially distinct from spatial expression use.

## Consequences for the possible meanings of spatial

 expressions. Early accounts of the meaning of terms like in and on (e.g., Bennett, 1975) came under fire (and were subsequently replaced) owing to the underspecified nature of their proposed denotation. The reasoning behind the critical reception of these theories was that a useful definition of a term like in should apply to exactly those cases that we most often use the term for and should rule out cases for which the term is rarely used. However, including a layer of lexical choice in the spatial encoding system, as we suggest here, allows for underspecified meanings that may over-extend to cases where the term is rarely used precisely because other better-suited terms are used in its place. For example, Johannes $(2014,2015,2016)$ suggests an underspecified account of meaning for spatial terms like in and on, whereby speakers' use of these preposition is blocked by the presence of more informative lexical verbs (e.g., hang, attach).
## Consequences for the study of spatial categorization

 through language use. The majority of studies on spatial categorization start by identifying a single form class - for example, prepositions in English - that serves as the primary vehicle for spatial meaning. In contrast to this, the results of the current study suggest that fine-grained spatial categorization is a function of speakers' choices between multiple felicitous expressions and not only dependent on the truth-conditional meaning of a single expression. Thus, future work on spatial categorization should expand the spatial language inventory (beyond e.g., prepositions, see Johannes, Wilson, \& Landau, 2016) and focus on how categories carved out by individual spatial terms may overlap to give rise to a complex graded semantic space for this domain.
## Conclusions

We have demonstrated that, for English, speakers' judgments of the truth-conditional meanings of a spatial term are not necessarily aligned with their use of that term to describe the same spatial scene. We propose that the process of choosing a spatial term among a set of felicitous competitors gives rise to speakers' non-uniform distribution of spatial expression use.

# Belief Digitization in Economic Prediction 

Samuel G. B. Johnson ${ }^{1}$ \& Faith Hill ${ }^{2}$<br>(sgbjohnson@gmail.com, fahill@vassar.edu)<br>${ }^{1}$ Department of Psychology, Yale University, New Haven, CT 06520 USA<br>${ }^{2}$ Department of Psychological Science, Vassar College, Poughkeepsie, NY 12604 USA

#### Abstract

Economic choices depend on our predictions of the future. Yet, at times predictions are not based on all relevant information, but instead on the single most likely possibility, which is treated as though certainly the casethat is, digitally. Two sets of studies test whether this digitization bias would occur in higher-stakes economic contexts. When making predictions about the future asset prices, participants ignored conditional probability information given relatively unlikely events and relied entirely on conditional probabilities given the more likely events. This effect was found for both financial aggregates and individual stocks, for binary predictions about the direction and continuous predictions about expected values, and even when the "unlikely" event explicitly had a probability as high as $30 \%$; further, it was not moderated by investing experience. Implications for behavioral finance are discussed.

Keywords: Judgment \& decision-making; probabilistic reasoning; explanatory reasoning; behavioral economics.

## Introduction

Investors aim to buy low and sell high. Alas, this adage requires investors to predict the future-a feat known to be difficult for mortals (and even for economists).

People are famously biased in making predictions (Kahneman \& Tversky, 1973), relying on a variety of useful but fallible heuristics. In economic contexts, a particularly worrisome bias would be belief digitization, as found in some other contexts (Johnson, Merchant, \& Keil, 2015; Murphy \& Ross, 1994). That is, when a reasoner is presented with data more consistent with one hypothesis than another, the reasoner acts as though the higher-probability hypothesis is certainly true when making predictions following from the hypothesis.

For example, in one study (Johnson et al., 2015), participants read about a pond that had ecological problems explainable either by an infestation of one type of snail (a simple explanation), or by an infestation of two types simultaneously (a complex explanation). The simple explanation was, reasonably, seen as more likely (about a $66 \%$ chance) than the complex explanation (about 34\%). Yet, when using those explanations to make further predictions (e.g., about bacteria proliferation), people ignored this uncertainty. Manipulating the probability of bacteria proliferation given the simple explanation had a large effect on predictions about proliferation, but manipulating the probability given the complex explanation had no effect at all. People digitized the simple explanation, tacitly assigning $100 \%$ of their probabilistic weight to that possibility. Even though
people often explicitly quantify uncertainty, this uncertainty does not propagate to subsequent computations but is instead rounded, in effect, to 0 or 1.

Such findings pose a challenge to probabilistic theories of cognition that treat humans as Bayesian thinkers who integrate across possibilities rationally (e.g., Anderson, 1991). Nonetheless, in many contexts, this strategy may a reasonably adaptive way to solve an otherwise intractable problem. The inference in this case (from ecological problems to snail infestation to the probability of bacteria proliferation) involves a fairly short chain of reasoning, yet people treated the first step in the inference as certain when making the second step. But we often rely on lengthy chains of reasoning, and propagating uncertainty through the entire chain may well be beyond our cognitive limits. If we must limit the complexity of these computations by prohibiting the consideration of multiple possibilities at each stage (e.g., thinking only about the consequences of the one-snail explanation or the twosnail explanation, but not integrating across both), then it is best to focus on the single most likely possibility. A person could do worse than this kind of belief digitization, even as it leads us astray relative to the optimal answer.

The current studies test whether such a digitization bias would influence judgments in economic contexts. In particular, digitization could affect predictions about future asset prices. Consider the impact of some piece of news, such as information about the government budget. Such information often has uncertain implications for future valuations, so rational investors would assign distributions over these possible futures and value assets according to their expected value. If voters elect a conservative populist (to take an example that is, of course, entirely hypothetical), this introduces uncertainty about the probability of fiscal stimulus. Perhaps there is a $70 \%$ probability of stimulus (with one set of implications for future valuations) and a $30 \%$ probability of fiscal austerity (with a different set of implications). Investors should rationally incorporate both possibilities into their valuations of the market, with a $70 \%$ weight on one possibility and a $30 \%$ weight on the other. Yet, if investors digitize, they would treat the likely event as certain when predicting the future value of the market. Rather than considering both possible futures, they would value assets assuming only the single most likely future.

Although previous studies using non-financial stimuli are consistent with this possibility, it is not clear that digitization effects would generalize to these contexts. First, people are likelier to rely on multiple categories in category-based prediction tasks when the categories are
dangerous or threatening rather than emotionally neutral (Zhu \& Murphy, 2013). If people adopt a more reflective, normative strategy under higher-stakes situations, perhaps they also do so when making economically relevant predictions. Second, and related, people are sometimes more rational when making decisions rather than logically equivalent inferences (Johnson, Zhang, \& Keil, 2016). These two factors could lead people to integrate probabilities across potential futures.

Two sets of studies test whether people nonetheless make digitized predictions in economic contexts. Experiment 1 provides an initial test, asking participants to make probabilistic predictions about the direction of asset prices, given uncertain information. Experiment 2A tests whether digitization effects would occur only for binary predictions (i.e., will a price go up or not?) or would instead extend to predictions of expected value on a continuous scale. Finally, Experiment 2 B tests a possible boundary condition by giving participants explicit posterior probabilities for the market's future direction. After examining these studies individually, we pool the data to examine whether expertise can combat digitization biases. In the General Discussion, we assess the implications of these findings for behavioral finance.

## Experiment 1

Participants in Experiment 1 made predictions about the future prices of financial assets in light of information with uncertain implications. Experiment 1A looked at predictions about market aggregates (e.g., the S\&P 500) and Experiment 1B looked at predictions about individual stocks (e.g., GE). Given that individual stocks seem to be priced more efficiently than the market as a whole (see Shiller, 2005), perhaps digitization mechanisms do not apply as robustly to predictions about individual stocks.

Participants predicted the probability of an increase in an asset price, denoted as $\mathrm{P}(Z)$, based on information about two mutually exclusive possibilities, $A$ and $B$. For instance, $A$ might represent a stimulatory fiscal policy and $B$ an austere fiscal policy. Participants were given information implying that $\mathrm{P}(A)>\mathrm{P}(B)>0$, so that both $A$ and $B$ are possible even as $A$ is likelier-the government may not have made a decision on its fiscal policy, but a stimulus is probable. In addition, participants were given information about the probability of $Z$ conditional on $A$ and $B-\mathrm{P}(Z \mid A)$ and $\mathrm{P}(Z \mid B)$. If people take both more and less likely possibilities into account, then they should rely on both $\mathrm{P}(Z \mid A)$ and $\mathrm{P}(Z \mid B)$ when predicting $\mathrm{P}(Z)$. In contrast, if people digitize, relying only on the single most likely possibility, then only manipulations of $\mathrm{P}(Z \mid A)$ should propagate to predictions of $\mathrm{P}(Z)$.

## Methods

We recruited 200 participants from Mechanical Turk, divided between Experiments 1A and 1B.
Participants each completed three items. For each item, participants read about an uncertain event, where one
possibility ( $A$ ) seemed more likely than the other ( $B$ ), given the available information. These likely and unlikely possibilities differed in their implications for future prices of financial assets. In the high/low condition, the more likely event $A$ would have a high chance of leading to an increase in asset values (i.e., $\mathrm{P}(Z \mid A)$ is high), whereas the less likely event $B$ would have a low chance of leading to an increase (i.e., $\mathrm{P}(Z \mid B)$ is low). One item in the high/low condition of Experiment 1A read:

Imagine that a foreign government is deciding what level of spending to adopt in the next fiscal year.
If they increase public spending, the value of the US stock market is likely to go up.
If they decrease public spending, the value of the US stock market is unlikely to go up.
Suppose that the leader of this government is concerned about the distribution of wealth in the country and is considering increasing public spending.
Participants reading this information should conclude that possibility $A$ (public spending increase) was likelier than possibility $B$ (public spending decrease). For instance, an investor might assign an $80 \%$ probability to possibility $A$ and a $20 \%$ probability to possibility $B$.

Whereas $\mathrm{P}(Z \mid A)$ was high and $\mathrm{P}(Z \mid B)$ was low in the high/low condition, both $\mathrm{P}(Z \mid A)$ and $\mathrm{P}(Z \mid B)$ were low in low/low condition:

If they increase public spending, the value of the US stock market is unlikely to go up.
If they decrease public spending, the value of the US stock market is unlikely to go up.
Rationally, the probability of a price increase is lower in the low/low than the high/low condition, since possibility $A$ has positive (indeed, high) probability of being correct. Thus, both rational and digitizing investors would distinguish between the low/low and high/low conditions.

A third condition, however, generates different predictions for these two groups of investors. In this low/high condition, $\mathrm{P}(Z \mid A)$ is low and $\mathrm{P}(Z \mid B)$ is high:

If they increase public spending, the value of the US stock market is unlikely to go up.
If they decrease public spending, the value of the US stock market is likely to go up.
In this low/high condition, a rational investor would judge the probability of a price increase likelier than in the low/low condition, since possibility $B$ has positive probability (albeit lower than $A$ ). In contrast, if people digitize, tacitly assigning $0 \%$ weight to $B$, then the low/high and low/low conditions would not differ.

After reading each item, participants rated $\mathrm{P}(A)$ and $\mathrm{P}(B)$ (e.g., "Government intends to increase public spending" and "Government intends to decrease public spending") on a 0 to 100 scale. This measure was taken to ensure that people did not explicitly place a $0 \%$ weight on $B$, in which case rational prediction and digitization do
not diverge in their predictions. Further, explicitly quantifying uncertainty in the task produces a task demand to incorporate this uncertainty into predictions, working against our hypothesis.

Finally, on the same page, participants predicted $\mathrm{P}(Z)$ ("What do you think is the probability that the US stock market will go up?") on the same scale used above.

Experiments 1A and 1B differed only in the asset being judged. In Experiment 1A, the asset was the overall value of the US stock market and in Experiment 1B, the asset was the share price for stock in specific corporations.

The three probability conditions were counterbalanced with three different vignettes (one on fiscal policy, one on monetary policy, and one on regulatory policy) using a Latin square. The items were presented in a random order.

After the main task, participants completed 10 check questions and were excluded from analysis if they answered more than one-third incorrectly $(N=19)$. Another 14 participants were excluded because their total probability ratings for at least one item were not between $80 \%$ and $120 \%$. However, including these two types of participants does not alter the pattern of results. Finally, 49 participants were excluded because they did not rate the $A$ more likely than $B$ for at least one of the items, since our predictions are predicated on participants' belief that $\mathrm{P}(A)>\mathrm{P}(B)$. (See Experiment 2 B for a version that did not require the latter two categories of exclusions.)

Table 1: Results of Experiment 1

| Condition |  | Predicted P(Z) |  |
| :---: | :---: | :---: | :---: |
| $\mathbf{P}(\boldsymbol{Z} \mid \boldsymbol{A})$ | $\mathbf{P}(\boldsymbol{Z} \mid \boldsymbol{B})$ | Exp. 1A | Exp. 1B |
| Low | Low | $28.8(28.7)$ | $30.1(27.4)$ |
| High | Low | $73.0(17.7)$ | $75.6(12.8)$ |
| Low | High | $30.3(26.5)$ | $32.3(26.0)$ |

Note. Entries are probabilistic predictions, expressed as percentages. SDs in parentheses.

## Results and Discussion

As shown in Table 1, participants digitized in both Experiments 1A and 1B.

In both experiments, participants relied on $\mathrm{P}(Z \mid A)$ for in their predictions of future asset prices. The high/low and low/low conditions differed only in $\mathrm{P}(Z \mid A)$, and these conditions differed sharply in predictions $[t(62)=10.38, p$ $<.001, d=1.85$ and $t(54)=10.98, p<.001, d=2.13$ for Experiments 1A and 1B]. Thus, people take account of high-probability possibilities when making predictionsconsistent with both rational and digitizing strategies.

These two strategies differ, however, in their predictions about the low/high condition. This condition differs from the low/low condition only in $\mathrm{P}(Z \mid B)$. Thus, if people take account of less likely possibilities, they should differentiate between these two conditions, but if they digitize, these conditions should be rated similarly.

Supporting the latter possibility, there was no difference between these conditions for either experiment $[t(62)=$ $0.50, p=.62, d=0.06$ and $t(54)=0.47, p=.64, d=0.08$, respectively]. Since we predicted null effects for these comparisons, we also computed Bayes Factors (Rouder et al., 2009; scale factor 1), which strongly favored the null hypothesis $\left[B F_{01}=8.9\right.$ and 8.5 , respectively]. Further, based on participants' other judgments, we can calculate the normative mean difference between the low/high and low/low conditions (which would produce $M \mathrm{~s}=37.6$ and 40.3 for low/high, respectively). In both cases, the actual differences were less than these benchmarks $[t(62)=2.41$, $p=.019, d=0.30$ and $t(57)=1.73, p=.089, d=0.23]$.

Together, these results show that people fail to account for low-probability possibilities when making economic predictions. This was true both when predicting the overall level of financial aggregates as well as the value of stock shares in individual companies.

That said, one may raise some concerns about these results. Perhaps of most concern, the information given in the problem could plausibly have implied near-certainty in its predictions (e.g., "the leader of this government is concerned about the distribution of wealth in the country and is considering increasing public spending"). To assess this possibility, we looked at participants' explicit judgments about $\mathrm{P}(A)$ and $\mathrm{P}(B)$. Unlike their implicit judgments, which assigned essentially a $100 \%$ probability to $A$, participants assigned more reasonable probabilities when asked explicitly ( $83 \%$ and $82 \%$ in Experiments 1A and 1 B , respectively). Nonetheless, we address this concern head-on in Experiment 2B.

## Experiment 2

Experiment 2 examines two possible boundary conditions on belief digitization in economic contexts.

First, Experiment 1 asked for predictions about the probability of binary events (increases or decreases in value). The direction of future gains or losses is likely to be the dominant factor in real investing decisions, but the extent of these predicted gains or losses is also important. In some cases, people are better at reasoning about continuous rather than binary events (e.g., in covariationbased causal reasoning; Alloy \& Tabachnik, 1984). Experiment 2 therefore tests whether digitization effects extend to continuous judgments of expected value.

Second, participants in Experiment 1 arrived at estimates of $\mathrm{P}(A)$ and $\mathrm{P}(B)$ on the basis of other, ambiguous information, as has been the case in most prior work finding digitization effects (Johnson et al., 2015; Murphy \& Ross, 1994). Would such effects occur even when the problem explicitly quantifies the uncertainty? Experiment 2B addresses this question by assigning a $30 \%$ probability to the less likely event. This further rules out the concern that participants may have rationally ignored a low probability. This also addresses the concern that participants in Experiment 1 may have actually assigned extremely low explicit probabilities to the
unlikely events and reported biased explicit judgments due to task demands. In that case, it would not be their implicit judgments that are biased (for interesting reasons) but their explicit judgments (for deflationary reasons).

## Methods

We recruited 200 participants from Mechanical Turk, divided between Experiments 2 A and 2B.

The procedure of Experiment 2 A was identical to Experiment 1A, except that the dependent measure was a continuous price, on either the NASDAQ, DJIA, or S\&P 500 , instead of the probability of a directional change. Participants were given approximately the current value of one of these indices (e.g., "Suppose the current value of the United States stock market, as indexed by the S\&P 500 , is $\$ 2,000$ ") and then asked to predict the future value of that index ("Please estimate what you think the value of the S\&P 500 will be 3 months from today") on a scale ranging from $10 \%$ lower than its current value (e.g., $\$ 1800$ ) to $10 \%$ higher than its current value (e.g., \$2200).

Experiment 2B was identical, except explicit probabilities were given for $A$ and $B$ ("Analysts say there is a $70 \%$ chance that this foreign government will increase public spending, and a $30 \%$ chance that it will decrease public spending") and thus participants were not asked to rate the probabilities of these events.

After the main task, participants completed 10 check questions and were excluded from analysis if they answered more than one-third incorrectly $(N=14)$. Another 7 participants from Experiment 2A were excluded because their total probability ratings for at least one item were not between $80 \%$ and $120 \%$. Finally, 31 participants from Experiment 2A were excluded because they did not rate $\mathrm{P}(A)$ higher than $\mathrm{P}(B)$ for at least one of the items. Since Experiment 2B explicitly provided these probabilities, participants were not excluded for this reason. Analyses including all participants found similar results for both experiments.

Table 2: Results of Experiment 2

| Condition |  | Predicted Change |  |
| :---: | :---: | :---: | :---: |
| $\mathbf{P}(\boldsymbol{Z} \mid \boldsymbol{A})$ | $\mathbf{P}(\boldsymbol{Z} \mid \boldsymbol{B})$ | Exp. 2A | Exp. 2B |
| Low | Low | $-0.21 \%$ | $0.33 \%$ |
|  |  | $(2.96 \%)$ | $(3.44 \%)$ |
| High | Low | $2.86 \%$ | $3.57 \%$ |
|  |  | $(3.50 \%)$ | $(2.89 \%)$ |
| Low | High | $-0.32 \%$ | $0.37 \%$ |
|  |  | $(3.18 \%)$ | $(3.54 \%)$ |

Note. Entries are predicted changes in stock market value. SDs in parentheses.

## Results and Discussion

As shown in Table 2, participants once again digitized.
In Experiment 2A, participants predicted a significantly higher change in asset price in the high/low condition than
in the low/low condition $[t(56)=6.59, p<.001, d=0.95]$. Thus, participants did consider the likely event when making predictions. However, participants again ignored the less-likely event $B$, since they did not use $\mathrm{P}(Z \mid B)$. Predicted changes did not differ across the low/high and low/low conditions $[t(56)=-0.23, p=.82, d=-0.04$, $\left.B F_{01}=9.4\right]$. Further, as in Experiment 1, the difference in predicted changes between the low/high and low/low conditions was marginally lower than it normatively should have been (for a low/high mean of $0.59 \%$ ), based on the other judgments $[t(56)=1.93, p=.059, d=0.26]$. Thus, digitization occurs even for predictions made on a continuous scale rather than probabilities of binary events.
Experiment 2B provided explicit probabilities of $\mathrm{P}(A)$ and $\mathrm{P}(B)$, ensuring that the "unlikely" event $B$ had a rather serious chance of occurring ( $30 \%$ ). Nonetheless, the results are similar to Experiment 2A. While participants again differentiated between the high/low and low/low conditions $[t(90)=7.06, p<.001, d=1.02]$, they did not differentiate between the low/high and low/low conditions $\left[t(90)=0.08, p=.93, d=0.01, B F_{01}=12.0\right]$. Further, the difference between conditions was dramatically lower than it normatively should have been (for a low/high mean of $1.75 \%)$ [ $t(90)=3.41, p<.001, d=0.36]$. Thus, people are willing to ignore even a $30 \%$ probability of an event's occurrence when predicting assets' future value.

One possible objection is that participants may have been giving an appropriate answer, depending on their interpretation of the question. That is, whereas participants' judgments of probabilities in Experiment 1 normatively should accommodate the possibility of lowerprobability events (as is provable from the laws of probability), predictions of future value may be reports of the most likely single value, rather than the expected value. In fact, the single most likely value of the market does depend greatly on $\mathrm{P}(Z \mid A)$, given that $A$ is the single most likely event, but to a much lesser degree on $\mathrm{P}(Z \mid B)$.

However, there are two reasons to doubt this interpretation. First, although the maximum-probability and expected value interpretations of the question are both reasonable, participants would have to uniformly adopt the maximum-probability interpretation to produce our results. That is, if half of participants took the maximumprobability interpretation and therefore did not use $\mathrm{P}(Z \mid B)$ in their predictions, the other half of participants were still making a mistake in failing to use $\mathrm{P}(Z \mid B)$.

Second, even though ignoring $\mathrm{P}(Z \mid B)$ is appropriate in estimating the maximum-probability value of the price, people tend to probability-match rather than maximize in tasks of this sort. For example, suppose there is one button that has a $70 \%$ chance of giving a positive payoff and another button that has a $30 \%$ chance of giving the payoff. If you are supposed to predict which button will produce the payoff on a given trial, the rational thing to do would be to choose the $70 \%$ button every time. In fact, people will predict the $30 \%$ button a significant fraction (roughly $30 \%$ ) of the time. The only way to reconcile this
result with the current task is to assume that participants have tacitly assumed that the $30 \%$ probability event has a $0 \%$ chance of occurrence and can thus be safely ignored.

Overall, Experiment 2 helps to address alternative interpretations of Experiment 1, and shows that people do not need to arrive at estimates of event probabilities themselves in order to digitize them. Together, these two experiments demonstrate that digitization effects may be a pervasive force in investors' judgments of future value.

## Expertise Effects

Amateur investors are often referred to as "noise traders" in financial models (Shleifer \& Summers, 1990) and the behavior of these models depends greatly on these traders' beliefs and choices (Shleifer, 2000). Although professional investors may use different strategies from amateurs (but see Tuckett, 2011), the behavior of amateurs contributes to market dynamics and is therefore important to characterize. Given that our participants are laypeople, but some have investing experience whereas others do not (about half of Mechanical Turk participants own financial assets and about half have taken at least one finance course; Johnson \& Tuckett, 2017), would we see expertise effects within this sample?

Participants in both studies were asked to rate their investing experience and knowledge. If people who have more domain expertise are likelier to consider lowprobability events in making predictions, then the effect of $\mathrm{P}(Z \mid B)$-converted to a $z$-score to aggregate data across studies-ought to be larger for individuals with more experience and knowledge. This was not the case, either for self-reported experience $[r(264)=.02, p=.72]$ or for knowledge $[r(264)=-.02, p=.70]$.

This result, although preliminary, suggests that domain expertise may not be sufficient to overcome digitization effects even in a context like financial prediction that has obvious real-world implications. This does not necessarily undermine the argument often advanced by economists that highly incentivized individuals can avoid such biases, nor the possibility that in market contexts corrective forces can emerge if a subset of investors exploit the suboptimal behavior of others. Nonetheless, this result does suggest that quite extensive expertise-outside the range of experience of our sample-is necessary for such mechanisms to apply. Digitization appears to be a robust cognitive bias at the individual level, and is therefore likely to cause suboptimal performance from investors at a variety of skill levels unless explicitly checked.

## General Discussion

Economic choices, such as investment allocations, depend on our predictions about the future. Rational predictions require us to integrate over multiple uncertain possibilities; failing to do so leads to overconfident predictions that are too near to $0 \%$ or $100 \%$. Yet, participants in our studies consistently failed to account for lower-probability possibilities in making predictions.

Digitization is broadly consistent with conviction narrative theory (e.g., Tuckett, 2011), the idea that decisions in highly uncertain environments are made by constructing a narrative to explain the past, projecting this narrative into the future, and using emotional reactions to the projected narratives to guide choices. For example, amateur investors use company performance news to guide predictions and choices even once the market has had time to "price in" that information, particularly if the news concerns the future rather than the past (Johnson \& Tuckett, 2017). This follows from narrative thinking, since narratives are emotionally valenced and temporally oriented. Another important feature of narrative thinking is that it is linear-it concerns a single sequence of events rather than a web of possibilities. The current work shows that people indeed focus on a single narrative to explain the past and project the future, rather than integrating across multiple possible narratives.

In addition to this theoretical contribution, these results have two kinds of practical implications. First, these biases may persist at the market level, leading to mispricing. A previous study examined explanatory biases in the context of Wall Street Journal headlines (Johnson, 2016). For instance, one headline read "ECB Move Crushes Hopeful Markets." There had recently been a downturn in European markets because the European Central Bank (ECB) had chosen to follow a less inflationary monetary policy than markets had expected. Had investors been "counting on" monetary expansion, tacitly assigning it a $100 \%$ probability? Or had the market priced in this uncertainty already (as mainstream financial theory suggests; e.g., Malkiel \& Fama, 1970)?

Investors made an uncertain diagnosis (the meaning of the ECB chair's statements) and a prediction based on that diagnosis (the implications for monetary policy). Normatively, uncertainty about the interpretation of ECB statements should propagate to any predictions based on such inferences. If the market digitizes at an aggregate level, however, this could have led the market to react strongly to disconfirmed expectations: If the expectations are formed based on uncertain information treated as certain, the market would be overconfident. This could lead prices to be either too high or too low-and indeed to oscillate between those extremes. New information may cause an investor to rationally move from predicting, say, a $70 \%$ probability to a $30 \%$ probability of some event. If these probabilities are treated as $100 \%$ and $0 \%$, respectively, this will lead to a much larger shift in asset valuation than is justified by fundamentals.

That said, such an interpretation of these experimental results is controversial, as are many efforts in behavioral finance to generalize from individual behavior to marketlevel behavior (Shleifer, 2000). A common rejoinder from a neoclassical approach is that behavioral biases can often be neutralized in market contexts. Markets create incentives for accuracy, which are often lacking in behavioral experiments. Markets allow for specialization
so that investors can learn over time to correct their biases (though our expertise analysis suggests that such learning is non-trivial). And perhaps most importantly, selfcorrecting market-level phenomena may emerge. If some, potentially small, subset of investors comes to understand the biases of other investors, they can trade against that bias and capitalize on others' irrationality. Because of these mechanisms, market prices may be less likely to be seriously afflicted by digitization biases than are individual investors' decisions. However, given that stock markets appear to be more volatile than is justified by fundamentals (de Bondt \& Thaler, 1985; Shiller, 1981), digitization of hypotheses could be a partial explanation of this excess volatility. Nonetheless, this issue will not be adjudicated by lab experiments alone.

Second, however, these biases are troubling not only because of potential market inefficiencies they might cause. Even if financial markets do have self-correcting forces that lead experienced investors to profit from the errors of novice investors, the losses of these novices are still cause for concern. Digitized predictions of asset prices can lead to several errors in the investing strategies of amateur "noise traders." First, if one has a high valuation of an asset relative to the market, one may overpay for that asset. For instance, if one is purchasing a house and has an unreasonably high valuation of that house, the buyer may not adequately negotiate the price. Second, extreme asset valuations may potentially lead to suboptimal patterns of diversification. A very bullish assessment of the tech industry accompanied by a very bearish assessment of the financial sector may lead one to prioritize the former over the latter, when a diversified investor would spread her exposure over all sectors. Third, if one's valuations are oscillating faster than the market's valuations, this may lead investors to overtrade, which leads to portfolio value loss due to transaction costs. Finally, overconfident predictions about asset prices may lead investors to inadequately hedge: If the cost of insurance is high relative to the perception of the risk being insured, there is less incentive to insure. This may lead some investors to be overexposed to unexpected downturns in the market-why hedge against something that is deemed, at some level, to be impossible?

Nassim Taleb (2010) warns of "black swans""unknown unknowns" of high impact that we discount on the basis of their low probability. Our participants exemplified this problem, and indeed took it one step further: An event with a $30 \%$ chance is not exactly on the tail of a distribution. Investors would do well to consider all the swans-both black and white.

# Measuring Abstract Mindsets through Syntax: Improvements in Automating the Linguistic Category Model 

Kate M. Johnson<br>University of Southern California

Reihane Boghrati
University of Southern California
Cheryl Wakslak
University of Southern California
Morteza Dehghani
University of Southern California

#### Abstract

The Linguistic Category Model (LCM) was developed as a manual coding scheme for quantifying abstract mindsets in human language. Previous attempts to computationally automate the LCM have relied primarily on pre-coded semantic features, which fail to incorporate important contextual information integral to the LCM coding scheme. In this paper, we introduce Syntax-LCM, a novel method for automating LCM coding using syntax and dependency tree features as predictors of construal level. We compare the accuracy of Syntax-LCM to that of two previously used automated methods: LIWC LCM and Brysbaert concreteness ratings. We find support that the Syntax-LCM approximates the hand-coded LCM with higher accuracy compared to both the Brysbaert and the LIWC LCM. We also provide evidence that the syntactic features accounted for by Syntax-LCM mirror the inclusion criteria in the original coding manual and support theoretical relationships between distance and abstract thinking.

# Iconicity in Word Learning: What Can We Learn from Cross-Situational Learning Experiments? 

Matthew Jones (m.jones.12@ucl.ac.uk)<br>Gabriella Vigliocco (g.vigliocco@ucl.ac.uk)<br>Department of Experimental Psychology, University College London<br>26 Bedford Way, LONDON, WC1H 0AP UK

#### Abstract

Iconicity, i.e. resemblance between form and meaning, is a widespread feature of natural language vocabulary (Perniss, Thompson, \& Vigliocco, 2010), and has been shown to facilitate vocabulary acquisition (Imai, Kita, Nagumo, \& Okada). But what kind of advantage does iconicity actually give? Here we use cross-situational learning ( Yu \& Smith, 2007), to address the question for sound-shape iconicity (the so-called kiki-bouba effect, Ramachandran \& Hubbard, 2001). In contrast to Monaghan, Mattock, and Walker (2012), Experiment 1 suggests that the iconicity advantage comes from referential disambiguation rather than more efficient memory encoding. Experiments 2 and 3 replicate this result, and moreover show that the kiki-bouba effect is roughly equally strong for sharp and rounded shapes, a property that classic experiments were unable to confirm, and which has implication for the effect's mechanism

Keywords: iconicity; cross-situational learning; kiki-bouba, vocabulary acquisition; artificial language learning; soundsymbolism

## Introduction

## Iconicity as Widespread in Natural Language

The meaning of a word does not determine its form, but wordforms are often motivated by iconic relationships with meaning. In English, iconicity can be found in onomatopoeia, (e.g. bang, miaow). Outside the IndoEuropean family, iconicity is more pervasive. Large iconic lexica are reported for many unrelated languages, signed and spoken (see Perniss et al., 2010).

Such iconicity is not limited to sounds. In Japanese reduplication of syllables indicates repetition of an event, and voicing of an initial consonant indicates object size (e.g. gorogoro - heavy object rolling repeatedly; korokoro - light object rolling repeatedly; Perniss et al., 2010).

## Iconicity and Word Learning

Experimental work shows that Japanese sound-symbolic words are easier for 3 -year-olds to learn than non-iconic words, whether the children are Japanese or English speakers (Imai et al., 2008; Kantartzis, Imai, \& Kita, 2011; Yoshida, 2012).

Observational research suggests a role for iconicity in vocabulary acquisition outside the lab. Japanese children acquire iconic words early (Maeda and Maeda, 1983), and in keeping with this Saji and Imai (2013) find that Japanese caregivers use more sound-symbolic and onomatopoeic words speaking to their toddlers than to adults.

Perry, Perlman, and Lupyan (2015), analysing English and Spanish, found a negative correlation between iconicity and age of acquisition: even in Indo-European languages, it may play a role in acquisition.
However, substantial questions remain about what advantage iconicity confers on word learning. Does iconicity kick in after the problem of identifying a word's meaning has already been solved, with iconic words being encoded in memory more quickly or efficiently? Or does iconicity help by facilitating referential disambiguation? Experiment 1 will begin to address this question.

## Sound-Shape Iconicity

A near-universal form of iconicity is the association between certain sounds (e.g. back vowels and high sonority consonants) with heavy, slow, rounded objects; and others (e.g. front vowels and low sonority consonants) with small, quick, jagged objects (Ramachandran \& Hubbard, 2001). In standard demonstrations, participants are given images of two 2 -dimensional shapes, one round, the other spiky. The majority pairs 'kiki' with a spiky shape, and 'bouba' with a rounded shape. (Dingemanse \& Lockwood, 2015).
The mechanism of sound-shape iconicity is, however, uncertain. The effect could arise from correlated input from different sensory modalities. Alternatively, Ramachandran and Hubbard (2001) suggest it is a reflection of cross-modal analogy between the articulatory gestures required to produce the labels and the visual properties of the shapes ( p . 19). They also suggest that 'cross-wiring' (p. 21) of auditory and visual brain maps may create an unmediated link.
Another possible explanation is more literal correspondences between speech sounds and lip shape. 'Bouba' involves literal rounding of the lips - visual or motoric representations of lip rounding could mediate between 'round' sounds and objects. This account predicts an asymmetry: round sound-shape associations should be stronger than spiky ones, because round sounds involve literal rounding of an articulator, whereas spiky sounds do not involve any comparable spikiness. Some prior ERP evidence suggests that the round association may be stronger than the spiky one in processing (Kovic, Plunkett, \& Westermann, 2010 - though their paradigm could not separate the associations behaviourally). This dissociation is not something that the classic kiki-bouba experiment is able to test: with two words and two shapes, one (hypothetically stronger) sound-shape pairing would automatically determine the other (weaker or absent) pairing. However our

Experiments 2 and 3 will represent some of the first work ever to address this question.

## Cross-Situational Learning

Monaghan, Mattock, and Walker (2012) established that the classic kiki-bouba effect is found using the cross-situational learning (CSL) paradigm. CSL takes the form of a series of trials where a word is appears along with a number of possible referents (Yu \& Smith, 2007). Any single trial is ambiguous, and initially participants must guess, but information can be integrated across trials to solve this triallevel referential ambiguity.

Monaghan et al.'s referents were round and spiky shapes, and their names were iconically round or iconically spiky nonwords. Half of shapes received iconically congruent names (e.g. rounded shape-round name), and the other half iconically incongruent (e.g. rounded shape-spiky name). In each trial the participant saw two shapes, heard one name, and indicated which shape the name belonged to. Would accuracy in choosing the correct referent would be higher for congruently named items?

Monaghan et al. found that congruence was no advantage in the first block, but became advantageous in later blocks. Moreover the advantage was only present in trials where the unnamed shape (the foil) was from the opposite category to the target. From the first result they concluded that iconicity indeed supports word learning (perhaps e.g. in the sense of facilitating more rapid or robust memory encoding of iconic names); from the second they that the advantage pertains to category level information, and not to information distinguishing individual words within categories.

These results are somewhat surprising. The classic kikibouba experiment involves guessing names. If iconicity is expressed there, then why wouldn't it be expressed in the first block, when participants are forced to guess namereferent pairings? If that bias were expressed from the start, then iconicity might support referential disambiguation. Experiment 1 takes up this question. Experiments 2 and 3 attempt to tease apart effects of round vs. spiky iconicity.

## Experiment 1

## Methods

Participants 24 adult native English monolinguals (13 women, $M=29.7 \pm 10.0$ ).

Visual Stimuli (Shapes) Sixteen shapes were created using the GNU Image Manipulation Program. Eight 'spiky' shapes were created using randomised parameters. Eight 'rounded' shapes were created by taking each spiky shape and using its corners as fixed points for Bezier curves, then scaled by eye to match for perceived size (see Figure 1). Stimuli were 600*600 pixel images comprising the shape in black on a white background.

Auditory Stimuli (Names) Names were constructed on the basis of LetterScore, a text-based index of sound-shape iconicity: All consonant-vowel pairings in English
orthography that feature consonants with only one canonical pronunciation ( $N=85$; c, g, q, and x were excluded) were rated by monolingual Anglophones who did not participate in other studies ( $N=28,12$ women, $28.5 \pm 12.0$ years old) on a ten-point scale anchored by a circle (1) and a star (10).

Eight of the names were constructed using syllables that received the spikiest ratings (example: tikiza), eight using the syllables that received the roundest ratings (example: mujo). For each category of name, two were one syllable long, four were two, and two were three. Recordings were made by a female native speaker of North American English, pronouncing the words as she considered natural.

Subsequently, word recordings were normed as part of a wider norming study. 101 native English speakers ( $M=32.4$ $\pm 9.7,41$ women) were each given 118 speech tokens to rate (largely from another study), meaning that each speech token was rated about ten times. The study was performed using Qualtrics (2015). In each trial, the participant saw a seven-point ratings scale. ' 1 ' represented the roundest rating, and ' 7 ' the spikiest (counterbalanced for half of participants). The mean of each token's ratings was then taken. This was its WordScore. Names for Experiments 2 and 3 were also rated for WordScore (see below). T-tests confirm that spiky names $(M=4.71 \pm 0.53)$ were rated as significantly spikier by WordScore than round names ( $M=$ $2.90 \pm 0.43)(p<.001, t(13.4)=7.54$, difference $=1.81$, $95 \% \mathrm{CI}$ [1.29,2.33]; Cohen's $d=3.77$ ).

Apparatus and Procedure The study was run using Matlab 7.4.0 on an IBM compatible PC equipped with a 15 " monitor (resolution: $1024 \times 768$ ). For each participant, half the shapes in each category received congruent names (e.g. round names for round shapes). The other half received incongruent names (e.g. spiky names for round shapes). Assignment of names to shapes was counterbalanced between participants.

The experiment took the form of a series of 256 trials, each featuring two shapes on screen (one to the left and one to the right - see Figure 1) and one name (played through headphones). The name belonged to one of the two shapes (this shape was the target, the unnamed shape being the foil). The participants stated which shape the name belonged to (by pressing the left or right arrow). Participants received no feedback and had to guess at first, but in time could infer which name belonged to which shape by noting that each name only consistently appears with one shape.

Figure 1: A cross-situational learning trial (note that names were presented aurally, not in text)

Trials were grouped into four blocks of 64 trials, as in Monaghan et al.. Within each block each name appeared four times, and each shape appeared four times as a target and four times as a foil. The number of times each shape appeared on each side of the screen in each role was counterbalanced, as was the number of appearances by each shape as a foil for a target from its own category vs. the opposite category. The same name was not permitted two trials in a row. Otherwise trials were randomised.

## Results

Trials with reaction times of less than 0.5 seconds or more than 25 seconds were removed.

Statistical Methods Data was analysed using the LMEM package lme4, version 1.1-12 (Bates, Maechler, Bolker, \& Walker, 2015) running in R version 3.2.1 ( R Core Team, 2015). In addition to random intercepts for names and participants, we also included random slopes. We aimed for a design-driven maximal random effects structure (see Barr, Levy, Scheepers, \& Tily, 2013), but were limited in the number of random effects we could fit. For participants we included random slopes for linear block, congruence, category of foil (coded as same or different to category of target), and the congruence-category of foil interaction. For names, we were limited to random effects slopes for congruence, category of foil, and their interaction. Block was coded linearly $(1=-1.5,2=-0.5,3=0.5,4=1.5)$, and both other variables were contrast coded (incongruent $=$ 0.5 , congruent $=0.5$; same category foil $=-0.5$, different category foil $=0.5$ ). Our predictor was accuracy: i.e. whether participants answered correctly on given trials.

Overall Analysis The omnibus model showed reliable effects only of linear block $(\beta=0.84,95 \%$ CI [0.658, 1.022], $z=9.066$ ): participants learned; and congruence ( $\beta=$ $0.417,95 \%$ CI [0.128, 0.706], $z=2.826$ ): participants performed better with congruent names (see Figure 2). The congruence-category of foil interaction was also significant ( $\beta=0.702,95 \% \mathrm{CI}[0.203,1.201], z=2.759$ ): congruence represents more of an advantage when the foil shape is from the opposite category to the target.

Figure 2: Graph of the predictions by block and congruence of the final omnibus model for Experiment 1. Error bars represent 95\% CIs.

See https://github.com/JMJofficial/Jones_Vigliocco_2017 more graphs, and for graphs of Experiments $2 \& 3$.

Block 1 Monaghan et al. found that congruence interacted with block. Crucially, there was no congruence advantage in the first block, implying that the benefit of congruence was to memory encoding rather than kiki-bouba style response bias. By contrast, we found no interaction between congruence and block ( $z<0.7$ ), suggesting an advantage from the first block. To test this, we fitted a model for the first block only. There were reliable effects of congruence ( $\beta=0.328,95 \% \mathrm{CI}[0.047,0.609], z=2.288$ ): performance was better in congruent trials; and of the interaction between congruence and category of foil ( $\beta=0.842,95 \% \mathrm{CI}[0.368$, 1.316], $z=3.484$ ): the benefit of congruence was stronger in different-category-foil trials. Note that this cannot be attributed to differences in design, as the number and structure of our trials was identical.
To exclude the possibility that this is the result of learning within the first block, we took the 187 trials with a different category foil where a participant encountered a name for the first time, and fitted a LMEM featuring only a fixed intercept, and random intercepts by participant. On $56.1 \%$ of trials participants chose the iconically congruent referent for the name. The model's intercept was not reliably different from zero under two-tailed interpretation $(\beta=0.247,95 \%$ CI [-0.048, 0.549], $z=1.678$ ), but under a one-tailed interpretation, the intercept was significantly different from zero at $p=.047$. Thus though this analysis has low power, it suggests a sizable bias towards iconic matches before learning has taken place, which can only be explained by the bias/referential disambiguation account.

In conclusion, we largely replicated Monaghan, Mattock, and Walker's (2012) findings, but found an advantage of iconicity from the first block. This difference with Monaghan et al. - and the fact that iconic congruence is only an advantage when the foil is from the opposite category - is consistent with the possibility that iconicity biased participants towards the right answer in trials where they were forced to guess, effectively assisting with referential disambiguation. The discrepancy with Monaghan et al. may be due to name stimuli: while we tailored ours to maximize iconicity, they created theirs on the basis of phonetic features, which do not correlate perfectly with iconicity (e.g. Monaghan et al. used plosives as spiky sounds, but [b] - a plosive - is widely deemed to sound round, cf. bouba). Next we move on to two further experiments aimed at testing the relative contribution of roundness and spikiness to sound-shape iconicity.

## Experiments 2 and 3

Experiment 2 and 3 aim to clarify the mechanism of soundshape iconicity by modifying Experiment 1 in order to test
the effect of round-to-round and spiky-to-spiky iconicity separately, something previous experiments have been unable to do. This is achieved by using iconically neutral names as well as round and spiky names. Experiment 2 yielded marginally significant results, so Experiment 3 was a replication to attempt to verify whether the effect was real. Both were then submitted to omnibus Bayesian statistics.

We opted for a two-condition design. Each condition is of the same format as Experiment 1, and each features both round and spiky shapes, but one condition features round and neutral names only, the other features spiky and neutral names only, thus avoiding problems related to tasks that involve discrimination between a round and spiky alternative. If one class of name is less iconic then we would expect minimal benefit of one class of shape being paired with that class of name vs. a neutral name.

## Experiment 2: Methods

Participants were 32 adult native English monolinguals (17 women, $M=23.3 \pm 4.4$ ).

Visual Stimuli (Shapes) The eight round and eight spiky shapes used in Experiment 1 were combined with an additional eight of each, created in the same manner.

Auditory Stimuli (Names) 32 names were generated using previously normed syllables (see Experiment 1) - eight from round syllables, eight from spiky, and 16 from neutral; and recorded as in Experiment 1. T-tests confirm that the spiky names $(M=4.71 \pm 0.53)$ were rated as spikier than the round names $(M=2.90 \pm 0.43)(p<.001, t(13.4)=7.54$, difference $=1.81,95 \%$ CI [1.29, 2.33]; Cohen's $d=3.77$ ). Moreover, neutral names $(M=3.77 \pm 0.80)$ were rated as less spiky than spiky names $(p=.002, t(20.0)=3.46$, difference $=0.94,95 \%$ CI $[0.37,1.51]$; Cohen's $d=1.31$ ), and less round than round names $(p=.002, t(21.8)=3.46$, difference $=1.04,95 \%$ CI [0.35, 1.39]; Cohen's $d=1.24$ ).

Apparatus and Procedure Every participant took part in a round and a spiky condition. Each condition was of identical form to Experiment 1 . One of the two conditions was the 'round' condition. In this condition half of the shapes were round and half spiky (eight of each), and, crucially, half of the names were round and half neutral. The other condition was the 'spiky' condition - which again had eight round and eight spiky shapes, but by contrast had eight neutral names and eight spiky names (fresh shapes and neutral names were used in the second condition). Shapes, neutral names, and condition order were counterbalanced across participants.

Here congruence is defined within whichever half of the putative round-spiky spectrum of sounds the condition in question covers. E.g. in the round condition, round nameround shape pairings were considered congruent and round name-spiky shape pairings were considered incongruent. However, neutral name-spiky shape pairings were considered congruent for the purposes of the following analysis. The reverse was done for the opposite condition.

This format was so that we could apply the same kinds of analysis as for Experiment 1 to keep results comparable.

## Experiment 2: Results

Data were analysed as in Experiment 1. The additional variable of condition was coded Round $=-0.5$, Spiky $=+0.5$.

In the omnibus model, both linear ( $\beta=0.722,95 \%$ CI [0.619, 0.824], $z=13.835$ ) and quadratic block $(\beta=-0.11$, $95 \%$ CI $[-0.179,-0.041], z=-3.116$ ) were reliable predictors: performance improved over the blocks, with improvement being faster between early than late blocks. Category of foil was also a reliable predictor ( $\beta=0.162$, 95\% CI [0.015, 0.309], $z=2.163$ ): performance was better on trials with foils from the opposite category to the target. Finally, the interaction between congruence and category of foil was reliable ( $\beta=0.286,95 \%$ CI $[0.013,0.56], z=2.05$ ): performance was better on congruent trials as long as the target and foil were from different categories (the main effect of congruence was not reliable: $\beta=0.027,95 \%$ CI [$0.14,0.194], z=0.317$; perhaps because iconic contrast was less pronounced than in Experiment 1).

The crucial interaction between condition and congruence was marginally reliable in the expected direction, implying that congruence was more of an advantage in the round condition ( $\beta=-0.208,95 \%$ CI $[-0.482,0.066], z=-1.486$ ): an inconclusive result (though the same was not true for the three way interaction adding category of foil: $\beta=-0.047$, $95 \%$ CI [-0.377, 0.283], $z=-0.277$ ).

As with Experiment 1, we analysed Block 1 in isolation. There was a reliable effect of condition $(\beta=0.177,95 \%$ CI [0.001, 0.354], $z=1.967$ ): performance was better in the spiky condition. Though there was no overall effect of congruence ( $z<1.3$ ), there was a reliable effect of category of foil ( $\beta=0.173,95 \%$ CI [0.022, 0.325], $z=2.246$ ): performance was better when the foil and target were from different categories, and a reliable interaction between congruence and category of foil ( $\beta=0.39,95 \%$ CI [ 0.105 , $0.675], z=2.679$ ): that congruence was advantageous when foil and target were from different categories. Given that previous results suggest that the congruence advantage is in different-category-foil trials, this means that as in Experiment 1, and in contrast to the results of Monaghan et al., iconic congruence was an advantage from the outset. Finally, there was a reliable interaction between congruence and condition: for Block 1 (as was marginally the case for the omnibus model), the effect of congruence was stronger in the round condition ( $\beta=-0.315,95 \%$ CI $[-0.628,-0.002]$, $z=-1.975$ ).

To summarise, Experiment 2 largely replicated the results of Experiment 1. Additionally, we did not find an unambiguously reliable difference between round and spiky conditions in terms of iconicity advantage. However, the marginally reliable interaction is possible evidence for round iconicity being stronger. Experiment 3 is a nearreplication aimed at clarifying this.

## Experiment 3: Methods

Participants were 32 adult native English monolinguals (21 women, $M=21.8 \pm 3.2$ ).

Visual Stimuli (Shapes) Were as Experiment 2.
Auditory Stimuli (Names) A fresh set of 32 names (eight round, eight spiky, and 16 neutral) were generated as in Experiment 2. An additional factor was controlled: number and distribution of phonemes in each category of name. Names were recorded as in Experiments 1 and 2.

T-tests confirm that the spiky names $(M=4.80 \pm 0.39)$ were rated for WordScore as spikier than the round names $(M=2.90 \pm 0.63)(\mathrm{p}<.001, t(11.7)=7.19$, difference $=$ 1.90, $95 \%$ CI [1.32, 2.47]; Cohen's $d=3.60$ ). Moreover, neutral names $(M=3.80 \pm 0.86)$ were rated as less spiky than spiky names $(p<.001, t(22.0)=3.91$, difference $=$ $1.00,95 \% \mathrm{CI}[0.47,1.53]$; Cohen's $d=1.35$ ), and less round than round names $(\mathrm{p}=.01, t(18.5)=2.89$, difference $=0.90$, $95 \%$ CI [0.25, 1.55]; Cohen's $d=1.24$ ).

Apparatus and Procedure Were as in Experiment 2.

## Experiment 3: Results

Data were analysed as in Experiment 2. The omnibus model featured reliable effect of linear block ( $\beta=0.739$, $95 \%$ CI [0.589, 0.889], $z=9.641$ ): participants learned. However, it featured no other significant predictors $(|z|<2.0)$. In this respect, it was different from Experiments 1 and 2, both of which showed some advantage of congruence. However, the coefficients for both congruence ( $\beta=0.177,95 \%$ CI [$0.003,0.357], z=1.929$ ) and the congruence-category of foil interaction ( $\beta=0.178$, $95 \%$ CI $[-0.081,0.437], z=$ 1.346) were in the expected direction, with congruence qualifying as marginally reliable. Crucially, the congruencecondition interaction did not approach reliability ( $\beta=$ $0.047,95 \%$ CI $[-0.326,0.233], z=-0.327)$, and neither did the interaction between congruence, category of foil, and condition ( $\beta=-0.147,95 \%$ CI $[-0.464,0.17], z=-0.908$ ) suggesting that if there was an effect of congruence, it was no stronger in the round condition.

Again we analysed Block 1 in isolation. This time there were no reliable predictors ( $z<1.3$ in each case). However note that this parallels the omnibus model, which featured no reliable predictors except block. Thus these results are silent on the question of the nature of the iconic advantage as the advantage failed to show up overall (probably due to a smaller iconic differences between words than in Experiment 1 leading to a weaker effect and Type II error).

Thus Experiments 2 and 3 gave somewhat contradictory results, with Experiment 2 showing a marginally reliable interaction between condition and congruence in the expected direction, and Experiment 3 showing no such thing. To attempt to resolve this, we submitted both sets of results to Bayesian statistics, which have the capability to confirm the null, and make it unproblematic to add more data to an analysis as one goes along (Kruschke, 2011).

Models Not having a clear prior for the alternative hypothesis, we opted for Bayesian parameter analysis (Kruschke, 2011). We use the R package rstanarm (Gabry \& Goodrich, 2016). We examined 95\% Highest Density Intervals for parameter estimates (HDIs): the highest average density continuous interval containing $95 \%$ of posterior probability distribution. If this region excludes zero we can treat a predictor as reliable.

We based our priors on Gelman, Jakulin, Pittau, and Su's (2008) recommendations. All variables were centred at zero and scaled so as to have a standard deviation of 0.5 . Priors (which were defined for the $\log$ odds ratios used as the models' parameters rather than for raw probabilities) took the form of Cauchy distributions.

Models were similar to the models used for Experiments 2 and 3, but a predictor and a by-subjects random slope were added for condition order. All two- and three-way interactions were included.

Results There were credible effects of linear $(\beta=1.638$, $95 \%$ HDI $[1.45,1.835]$ ) and quadratic ( $\beta=-0.155,95 \%$ HDI $[-0.255,-0.06]$ ) block, condition order $(\beta=0.472,95 \%$ HDI $[0.322,0.620])$, and category of foil ( $\beta=0.091,95 \%$ HDI [0.019, 0.164]): participants performed better on trials where the target and foil shapes came from different categories. The HDIs for the main effect of congruence encompass zero ( $\beta=0.087,95 \%$ HDI [-0.022, 0.198]), albeit narrowly. However, there is a credible interaction between congruence and category of foil ( $\beta=0.242,95 \%$ HDI [0.114, 0.369]), indicating that an advantage for congruence is present when the target and foil are from different categories. There were interactions between condition order and both linear ( $\beta=0.329,95 \%$ HDI [0.196, $0.462]$ ) and quadratic ( $\beta=-0.213,95 \%$ HDI [-0.333, $0.094]$ ) block, indicating that initial learning was faster in the second condition. There was also a difficult-to-interpret interaction between quadratic block, condition order, and congruence ( $\beta=-0.253,95 \%$ HDI $[-0.498,-0.009]$ ). However, overall, the Bayesian analyses confirm the earlier inferential statistics.

Turning to the crucial interaction of congruence with condition type: the posterior distribution for the interaction between congruence and condition type is narrow compared to the prior, and centred close to zero ( $\beta=-0.022,95 \%$ HDI $[-0.165,0.125])$. If we assume the largest absolute value in the HDI, and take the intercept as our baseline, the difference between the levels of the interaction is $84.2 \%$ versus $85.3 \%$. This is the same as the difference when the main effect of congruence is examined in the same way, assuming the mean of the posterior.

Even if we assume that the extreme values of the HDI are correct, the effect of the congruence-condition interaction is no bigger than that of congruence tout court (which applies to both conditions). Thus there is clearly less support for the interaction between congruence and condition type than for the effect of congruence across conditions, and given the

## Experiments 2 and 3: Bayesian Analysis

HDIs encompass zero, our results are consistent with their being no congruence-condition interaction.

## Discussion

We presented evidence that iconicity enhances performance in a statistical learning paradigm. Experiment 1 was a replication of Monaghan et al. (2012), and thus in a sense not novel, but (as small but theoretically interesting differences in our respective results underscore) the value of replication is increasingly recognised in cognitive science. Close analysis of the beginning of Experiment 1 (supported by the results of Experiment 2), and the consistent tendency for iconicity to be a greater advantage when the foil presented during the trial does not also match the name, suggest that the benefit of iconicity in these experiments is to do with picking out the right referent during a particular trial rather than in to do with learning in some other sense (contra Monaghan et al.). Thus one role of iconicity in vocabulary learning may be in referential disambiguation, in line with evidence that people guess iconic word meanings in unfamiliar languages above chance (Imai et al., 2008).

The second set of findings relate to the relative importance of rounded-rounded and spiky-spiky mappings in sound-shape iconicity. One hypothesis is that rounded sounds are associated with rounded lip shape, and that the iconicity arises from sound-shape correspondences during speech production and comprehension (Ramachandran and Hubbard, 2001). If this is indeed the mechanism for soundshape iconicity, we would expect rounded associations to be primary, and spiky associations to arise later through something like a principle of contrast. If this were the case then rounded associations should be stronger than spiky associations (as suggested in Kovic. et al., 2010).

Experiment 2 and 3 tested this possibility by separating round and spiky iconicity into two separate conditions, and seeing whether iconic congruence exerted a stronger effect in one or the other. Experiment 2 appeared to suggest (with marginal reliability) that iconicity improved performance in the round condition, but not the spiky. However, this asymmetry failed to replicate in Experiment 3. We therefore submitted data from both experiments to a Bayesian analysis. Though the results were somewhat inconclusive, they suggest that any asymmetry between the conditions is a smaller effect than the overall influence of iconic congruence, and indeed they are consistent with there being no asymmetry at all. However, this may be different in the case of production, which would force motoric and perceptual engagement with lip shape (Jones et al., in prep.).

Our results advance our understanding of iconicity's role, suggesting it supports referential disambiguation.

#### Abstract

During mindfulness-based interventions participants can be invited to bring aversive stimuli to mind while practicing mindfulness. This is thought to help the stimuli become less aversive. However, the mechanisms underlying this process are not fully understood. In this study we explored these by examining the effects of mindfulness practice and stimulus visualization on stimuli associated with electric shocks. Participants were trained on a discrimination between two visual stimuli using a standard electrodermal conditioning procedure, in which one stimulus (CS+) was paired with shock and the other (CS-) was not. They then visualized either the CS+ or CS-, while practicing mindfulness or performing a control activity. Following a number of extinction trials, the impact of these manipulations was assessed during a reacquisition test-phase. Both mindfulness and visualization of the CS+ led to slower reacquisition of the CS+/shock association, when measured physiologically, and their effects were additive. Moreover, these effects dissociated from participants' expectancy of shock. If confirmed in future work, these findings may have implications for the treatment of stimulus-specific anxiety.

Keywords: mindfulness, associative learning, extinction, reacquisition

## Introduction

In recent years there has been a rapid growth of interest in mindfulness (e.g. Mindfulness All-Party Parliamentary Group, 2015). This has been driven in part by the growing evidence for the efficacy of mindfulness-based therapeutic interventions, such as mindfulness-based cognitive therapy (Segal, Williams \& Teasdale, 2013), which has been shown to reduce the risk of relapse of depression relative to treatment as usual and more active controls (Kuyken et al., 2015). However, much remains to be understood about the nature and mechanisms of action of mindfulness (Tang, Holzel \& Posner, 2015; van der Velden et al., 2015). In this paper, we attempt to further this understanding in one particular area, namely how mindfulness interacts with basic human learning processes (cf. Treanor, 2011). To set the stage for this, it is helpful to first consider mindfulness in more detail.

## Mindfulness

Kabat-Zinn's (1994) frequently cited definition of mindfulness describes it as 'paying attention in a particular way: on purpose, in the present moment, and nonjudgmentally'. Mindfulness meditation practice is seen as a means of cultivating this way of attending. In a typical practice, 'mindfulness of the breath', participants are invited to pay attention to and be curious about their moment-bymoment experience of breathing, and to be gentle with themselves should their attention wander away from this (Kabat-Zinn, 1990).

In mindfulness-based interventions, such as mindfulnessbased cognitive therapy, after participants have developed some experience at practicing mindfulness, they are invited to deliberately bring attention to a difficult experience during mindfulness practice (Segal et al., 2013). Frequently this can be a memory or image associated with feelings of anxiety and/or low mood. This is thought to help participants learn to not engage in unhelpful rumination and worry when faced with a difficulty (cf. Segal et al., 2013), and to help them to build their ability to tolerate distress (cf. Lotan, Tany \& Bernstein, 2013). In addition, theories of associative learning would suggest that basic associative learning processes should be in play (cf. Treanor, 2011). However, the latter aspect has yet to be adequately investigated empirically. A laboratory model that can be used to examine such processes further is the electrodermal fear conditioning paradigm.

## Electrodermal Fear Conditioning

In this paradigm, a neutral stimulus, referred to as the conditioned stimulus (CS), becomes capable of eliciting fear through its repeated pairing with an aversive unconditioned stimulus (US), such as electric shock (see McAndrew et al., 2012 for details of the procedure used here). Participants' learning of this CS-US association is typically measured in two ways. The first is through their 'conditioned response' (CR), which in this case usually includes increased arousal following the CS, due to increased anxiety at the prospect of being shocked. This can be detected by measuring the

Table 1: The study's design

| Group | Training | Manipulation | Extinction | Reacquisition |
| :---: | :---: | :---: | :---: | :---: |
| MV+ | A+ B- | Mindfulness \& A | A- B- | A+ B- |
| MV- | A+ B- | Mindfulness \& B | A- B- | A+ B- |
| CV+ | A+ B- | Control \& A | A- B- | A+ B- |
| CV- | A+ B- | Control \& B | A- B- | A+ B- |

conductance of electricity between two electrodes on the skin, and is typically referred to as the skin conductance response (SCR). Secondly, when presented with the CS, participants can be asked to rate how much they expect a shock.
Under certain conditions, dissociations can be obtained between SCRs and expectancy ratings (e.g. Knight, Nguyen, \& Bandettini, 2003; Tabbert, Stark, Kirsch, \& Vaitl, 2006; McAndrew et al., 2012). These can be explained by dual process models of human learning, such as that proposed by McLaren, Green and Mackintosh (1994), and further developed in McLaren, Forrest, McLaren, Jones, Aitken and Mackintosh (2014). They argue that people can learn using both associative processes, which are similar to those found in other animals, and through rule-based processes capable of symbolic manipulation (though Lovibond and Shanks, 2002 take an alternative view). Thus, as well as having the potential to provide a useful laboratory model to investigate mindfulness further, the fear conditioning paradigm enables an examination of the degree to which mindfulness interacts differently with different learning processes.

## The current study

Therefore, in the current study we aimed to embed mindfulness practice in a human electrodermal, fear conditioning procedure. More specifically, we planned to train people to learn a 'CS'-> shock association (along with an appropriate comparison) before inviting them to practice mindfulness while visualizing the CS , in a similar way to how distressing events can be brought into attention during mindfulness practice. We then planned to examine what effects, if any, this mindfulness visualization had on the learning of the CS -> shock relationship, relative to various comparison groups. Furthermore, we sought to examine whether such mindfulness-based visualization had differential effects on the different learning processes tapped by SCR and expectancy. We hoped that this investigation would provide us with a better understanding of the learning processes in play during mindfulness practice, which in turn could help contribute to improving the efficacy of mindfulness-based interventions for anxiety.

## Method

## Participants

Ninety-six University of Exeter students participated in this experiment. There were 72 women and 24 men and their
ages ranged from 18 to 30 years, with a mean of 20.4 years ( $\mathrm{SD}=2.75$ ). All were paid $£ 6$. Participants were randomly allocated to the groups described below, constrained to ensure equal group sizes ( $\mathrm{N}=24$ in each group). The study received ethical approval from the University of Exeter, Psychology Ethics Committee.

## Design

The study began with a training phase during which all the participants learnt an $\mathrm{A}+\mathrm{B}$ - discrimination; that is, they learnt that one conditioned stimulus (the CS+ ), which we will refer to as A, was always followed by an electric shock, while a second, the CS- (B), never was.

Following this, each of the four groups received a different manipulation, as illustrated in Table 1. In the mindfulness visualization plus (MV+) condition, participants were invited to visualize the CS (i.e. A) that had been previously paired with shock while they practiced mindfulness. In the mindfulness visualization minus (MV-) condition, they visualized the unpaired CS (i.e. B) while practicing mindfulness. The two control conditions were identical to the mindfulness ones, with the exception that, instead of practicing mindfulness, participants were asked to listen to an excerpt from an audio book. Thus, in the control visualization plus ( $\mathrm{CV}+$ ) condition, participants listened to the audiobook while visualizing stimulus A , and in the control visualization minus (CV-) condition, participants listened to the audiobook while visualizing stimulus B.

Following this manipulation, all the groups received an extinction test phase, during which A and B were presented but neither were paired with shock. This was followed by a reacquisition test phase, during which all participants were again trained on the original $\mathrm{A}+\mathrm{B}$ - discrimination; that is, A was once again followed by a shock, whereas $B$ was not. This second test phase was included, as pilot work suggested it was more sensitive to the effects of the manipulation. This may be because extinction happens relatively quickly in this paradigm, resulting in very few trials that provide useful data from the extinction test phase.

Therefore, there were three independent variables; namely practice type (mindfulness vs. control), stimulus visualized (A vs. B), and stimulus tested (A vs. B), with the former two being between-subject factors and the later being a withinsubject factor.

## Stimuli

The two CSs were a brown cylinder $4.5 \times 6 \mathrm{~cm}$ onscreen, and a pink square $5.5 \times 5.5 \mathrm{~cm}$ onscreen. Each CS presentation lasted for 5 seconds. The use of these stimuli as CS A and CS B was counterbalanced across participants.
The unconditioned stimulus (US) was a 500 ms shock administered with a PowerLab 26T generator using stainless steel electrodes attached to the left proximal and medial phalanges of the index finger. At the beginning of the experiment, participants set their own shock level between 5 and 20 mA , to a level that was "definitely uncomfortable but not painful".

## Visualization Guidance

Mindful Visualization This period of practice began with 7.5 minutes of 'mindfulness of the breath' guided by audio CD. This practice was of the sort used in mindfulness-based cognitive therapy (Segal et al., 2013), and the CD had been recorded by the first author (who has a postgraduate qualification in teaching mindfulness). The intention of this initial period of practice was to help establish a more mindful state of mind before the participant began stimulus visualization. After 7.5 minutes, the CD guidance asked the participant to open their eyes, if they were closed, and look at the name (either 'pink square' or 'brown cylinder', as appropriate to the condition) that the experimenter had placed in front of them. The audio CD then invited them to close their eyes and continued as follows:
'... as best you can, remembering what this shape looked like in the first part of the study, and seeing if it is possible to hold an image of this shape in your mind. [pause] Don't worry if you find it hard to picture this shape, as this is more difficult for some of us than others, [pause] just doing your best to bring to mind whatever memories and images you have of this shape from the first part of the study. [pause] And if it seems to help, you might want to sometimes say the name of the shape to yourself. [pause] And if there are any feelings or bodily sensations that accompany the memory or image of the shape, just acknowledging those and allowing them to be present as you hold this shape in mind. [pause] And if at any point you forget which one of the shapes you are being invited to hold in mind, opening your eyes again briefly and re-reading the piece of paper.'

The CD guidance subsequently invited participants to expand their attention so that they both held in mind an 'image or memory' of the shape and attended to 'the experience of breathing'. This was followed by periods of silence, interspersed with guidance to the same effect. In total, the audio CD lasted 13 minutes 20 seconds.

Control Visualization In the control visualization conditions, participants were asked to listen to an excerpt from an audiobook by Bill Bryson. This material was chosen as the calm tone of delivery was similar to that for the mindfulness visualization guidance and the content was likely to be experienced as engaging but uncontroversial. As
with the mindfulness visualization conditions, after 7.5 minutes participants were asked to look at the name of the shape that the experimenter had placed in front of them, and then hold an image of this shape in mind. The wording and timing of the stimulus visualization instructions were identical to the mindfulness visualization conditions, with the exception that guidance pertaining to attending to the breath was omitted. In between visualization guidance, the audiobook continued to play. Each control visualization condition lasted for the same amount of time as each mindfulness visualization condition.

## Measures

Skin conductance Skin conductance response (SCR) was measured using LabChart software via MLT116F GSR electrodes attached to the medial phalanges on the left third and fourth fingers.

Expectancy Expectancy ratings for the US were recorded using a Contour Shuttle Xpress device. Participants were required to make an expectancy rating about the extent they thought the shock would happen during presentation of the CS. The device had five buttons and fitted nicely into one hand such that one button corresponded to one finger. The different expectancy values were: 1 "There will definitely not be a shock", 2 "There might not be a shock", 3 "Not sure either way", 4 "There may be a shock", and 5 "There will definitely be a shock". A continuously available legend explained which buttons represented which ratings.

State mindfulness As a manipulation check, the State Mindfulness Scale (Tanay \& Bernstein, 2013) was administered to all participants immediately after the visualization stage. This 21 -item, self-report measure asks participants to rate how well each item (e.g. 'I felt closely connected to the present moment') describes their experience over the past 15 minutes. It has satisfactory psychometric properties, for example Cronbach's $\alpha=.95$ (Tanay \& Bernstein, 2013). Higher scores indicate higher levels of state mindfulness. Therefore, if the mindfulness visualizations were successful at inducing a more mindful state of mind than the control visualizations, participants in the former conditions should score significantly more highly on this measure than those in the latter.

## Procedure

With the exception of the visualization stage (see below), the participants were told they would receive shocks to some of the visual stimuli throughout the experiment. They were asked to rate their expectancy that the shock would occur during each stimulus presentation, using the Shuttle Xpress device. Otherwise they were asked to remain still to avoid motion artefacts in the SCR. On shock (A+) trials, a 500 ms US was administered after 4500 ms of CS A being on screen, whereas on no shock (B-) trials no US occurred.

SCR recordings were taken on every trial, during the five seconds prior to CS onset (Pre-CS), five seconds while the

CS was on screen and five seconds after the CS (Post-CS). The inter-trial interval (ITI) was randomly varied between 30 and 40 seconds in order to stop participants timing the onset of the CS. Long ITIs were required to allow the SCR recording to reach baseline after the previous US.

This experiment had an initial training phase of 12 trials: six each of $\mathrm{A}+$ and B -, in a random order. This was followed by either the mindfulness visualization guidance or control visualization guidance, as appropriate for the condition. Participants were advised that there would be no stimuli on the screen and no shocks, during this stage of the experiment. Participants were then given a copy of the state mindfulness scale, with its name removed. They were asked to tell the experimenter their rating of each statement, rather than write it, so that they could keep their hands still and remain wired to the electrodes.

After this, participants were advised that the stimuli would be appearing on the screen again, and that some of these would be accompanied by shock. They were asked to rate their expectancy of shock in the same manner as previously. There were four extinction trials, in the order A, $\mathrm{B}, \mathrm{B}, \mathrm{A}$, (counterbalanced) during which no shocks were administered. These were followed immediately by eight trials of re-acquisition, comprising four A+ trials and four $B$ - trials, in a random order. During this reacquisition phase, CS A was accompanied by shock and CS B was not, in exactly the same manner as during the initial training. Participants were then asked whether they had previous experience of mindfulness practice. The word mindfulness had not been used up to this point, in case it influenced participants' responding, given the frequency with which this topic is currently covered in the UK mainstream media. Finally, participants were debriefed, thanked for their time and paid.

## Data Preparation

The SCR data were recorded in micro-Siemens in LabChart and exported to Excel. For each trial, a mean SCR was calculated for both the 'pre-CS' and 'CS' periods. These data were then transformed using a log transformation to reduce the variability between participants. In order to measure the change in SCR associated with the occurrence of the CS, for each trial a 'CS-SCR minus pre-CS-SCR' difference score was then calculated. This score was taken to be a measure of the conditioned response to the CS, and henceforth is simply referred to as the $\triangle$ SCR (change in skin conductance response). For the expectancy data, the rating in the CS period was used as the participant's expectancy of the US on that trial. Subsequent data analysis was conducted using SPSS version 22.

## Results

## Training Data

The $\triangle \mathrm{SCR}$ data from training were analyzed using a stimulus (A vs. B) by group (MV+, MV-, CV+, CV-) ANOVA. The main effect of stimulus was significant
( $\mathrm{F}(1,92)=12.46, \quad \mathrm{p}<0.005$ ), with participants exhibiting higher SCR scores after $\mathrm{A}+$ (mean $=0.069, \mathrm{SE}=0.007$ ) than B- (mean $=0.048, \mathrm{SE}=0.007$ ). This difference in SCR scores did not significantly differ between the groups $(\mathrm{F}(3,92)=1.14$, n.s.), as their training regime was the same.

This pattern was also observed in a stimulus by group analysis of the expectancy ratings from training. Specifically, participants had a significantly $(\mathrm{F}(1,92)=396.56, \mathrm{p}<0.001)$ higher expectation of shock on $\mathrm{A}+$ training trials (mean $=4.1, \mathrm{SE}=0.06$ ) than on B - training trials (mean $=1.9, \mathrm{SE}=0.07$ ). Furthermore, this difference did not significantly differ across the groups $(\mathrm{F}(3,92)=0.37$, n.s.). Thus, as expected, participants showed learning of the $\mathrm{A}+\mathrm{B}$ - discrimination in both the $\triangle \mathrm{SCR}$ and expectancy data, and this did not differ between groups.

## Manipulation Check

The state mindfulness scale data were analyzed using a practice type (mindfulness vs. control) by stimulus visualized (A vs. B) ANOVA. Participants in the mindfulness conditions had significantly higher state mindfulness scores than those in the control conditions ( $\mathrm{F}(1,92)=9.37, \mathrm{p}<0.01$; respective means: 76.2 ( $\mathrm{SE}=1.72$ ) and 68.7 ( $\mathrm{SE}=1.72$ )). This difference did not significantly differ across stimulus visualized $(\mathrm{F}(1,92)=0.01$, n.s.). Thus, as intended, the mindfulness practice appeared to have increased state mindfulness levels relative to control, and regardless of whether stimulus A or B was visualized.

## Test Data

The focus here is on the $\Delta \mathrm{SCR}$ and expectancy data from the reacquisition test-phase, as pilot work suggested this would provide a more sensitive test of any effects than the data from the extinction phase. It also included twice as many trials as the extinction phase, and so should produce less noisy data.

Figure 1: Mean change in skin conductance by Group and by CS tested, from the reacquisition test-phase. Error bars represent the standard error.

Considering the $\triangle \mathrm{SCR}$ data first, these were analyzed using a stimulus tested (A vs. B) by practice type (mindfulness vs. control) by stimulus visualized (A vs. B)

ANOVA. The means can be seen in Figure 1; note that in this figure the four combinations of practice type and stimulus visualized are represented by the four groups on the x-axis. As would be expected given the contingencies, there was a significant main effect of stimulus tested ( $\mathrm{F}(1,92)=18.32, \mathrm{p}<0.001$ ), with higher $\triangle \mathrm{SCRs}$ to stimulus A than stimulus B. In addition, there were significant two-way interactions between stimulus tested and practice type $(\mathrm{F}(1,92)=6.71, \mathrm{p}<0.05)$, and between stimulus tested and stimulus visualized $(\mathrm{F}(1,92)=6.10, \mathrm{p}<0.05)$. None of the other main effects, nor the three-way interaction, were significant (all $\mathrm{p}>0.4$ ). Thus the findings suggest that practice type and stimulus visualized had additive effects on the difference in $\triangle \mathrm{SCR}$ between A and B . More specifically, practicing mindfulness appeared to decrease the difference in $\triangle \mathrm{SCR}$ between the two, as did visualizing stimulus A . Hence the condition (MV+) containing both mindfulness and visualization of stimulus A had the smallest difference between A and B ; the condition containing neither (CV-) had the biggest difference between the two; and the other two conditions were somewhere in between.

Figure 2: Mean expectancy ratings by Group and by CS tested, from the reacquisition test-phase. Error bars represent the standard error.

Turning to the reacquisition expectancy data (Figure 2), these were analyzed using the same three-way ANOVA as above. As with the $\triangle$ SCR data, there was a main effect of stimulus tested $(\mathrm{F}(1,92)=677.26, \mathrm{p}<0.001)$, with a correct, higher expectation that a shock would follow stimulus A than B. However, none of the other main effects or interactions were significant (all $\mathrm{p}>0.1$ ). Thus, in contrast to the $\triangle \mathrm{SCR}$ data, none of the manipulations had a measurable effect on the participants' expectation of shock.

## Discussion

There are a number of results that emerge from this study. Perhaps the first point to make is that training was very effective, and produced good conditioning both in terms of conscious cognitive expectancy and in terms of change in skin conductance. There were no confounding differences during training across groups, and the manipulation check at
the end of the interposed activity indicated that mindfulness practice was also successful. We can be fairly confident, then, that the study we set out to conduct has actually taken place. We can now ask what the effects of mindfulness practice and visualization are on differential fear conditioning.

Starting with expectancy ratings for shock to the CS + and CS- during re-acquisition, the answer is equally straightforward. Our manipulations had no differential effect. All groups showed the same (highly significant) level of differential conditioning on this measure. Any account that would claim that conscious expectancy is what drives changes in skin conductance would thus have to postulate a similar pattern of results in the $\triangle \mathrm{SCR}$ measure, but this was not what we observed. Instead, $\Delta \mathrm{SCR}$ varied across groups, and in particular the extent to which differential conditioning was re-acquired differed across groups. Group MV+, which received mindfulness practise and visualised the CS+ at the same time, showed no differential conditioning. Group CV-, which listened to the audio book and visualised the CS- at the same time, showed strong differential conditioning, actually stronger than that during initial training. The difference, then, between these groups was considerable, and our analysis produced results that suggested that both mindfulness practise and visualisation of the CS+ had some protective effect against re-acquisition of differential fear conditioning.

This contrast between effects on expectancy and on $\triangle$ SCR suggests that after mindfulness practise and visualisation of the CS+, even though people knew that a shock was likely to occur to A and not to B , this had no effect on their physiological response to those stimuli. In some sense, then, their autonomic response has become decoupled from their conscious cognitive appraisal of the situation. We can argue that this has happened to a lesser extent for Groups MV- and $\mathrm{CV}+$, and not at all for CV-. This is not the only possible interpretation of these results, however, and we need to consider others that might generate the same pattern on our two measures.

One such possibility is that rather than visualisation of the CS+ having a protective effect, it was in fact visualisation of the CS- that simply extinguished any fear generalising to that stimulus and so led to stronger differential conditioning. We cannot rule this possibility out, but would expect visualising the CS + to have had an even stronger effect than visualising CS-. This is because the CS+ would have had stronger associations to shock after training, and the extinction would be expected to have been proportional to the strength of the association. This mechanism could, then, explain why visualising the CS+ seemed to impair differential conditioning, and visualising the CS- seemed to (relatively speaking) help it. On this account, the visualisation effect was just one of imagined extinction feeding through into re-acquisition. But understanding the effect of mindfulness practise in this way is probably not helpful. The effect was additive with visualisation, which indicates a different source for it, and claiming that listening
to Bill Bryson potentiated fear conditioning does seem a little unlikely (as well as unkind).

We can ask, however, why the effect we observed was on differential conditioning, and why the $\Delta \mathrm{SCR}$ for B was so high in the MV+ group. This was undoubtedly a contributory factor to our result, though the stronger effect across groups may have been the effect of our manipulations on A . In fact, it is quite striking that the average $\triangle \mathrm{SCR}$ to A and B was roughly the same in each group. Thus, we can argue that the overall physiological reactivity of each group was approximately constant, it was just how that was distributed over A and B that varied. If it was the case that the training data were mostly based on conscious expectancy of shock (and that would not be surprising in such a simple preparation), then the implication is that this factor was no longer effective in Group MV+ during reacquisition, since if participants' expectancies had driven their physiological reactivity in that case, we would have seen a difference in $\triangle \mathrm{SCR}$ to A and B equivalent to that in the other groups, but we did not. It is possible that instead we observed the effects of the underlying associative learning as a result of training, extinction and re-acquisition and that this had become decoupled from control by conscious cognitive expectancy. It is also possible that one belief about the contingencies had been replaced by another, though our expectancy rating data argues against this. Further research will be needed to establish exactly what the effective contribution of the mindfulness practise is here.

## Conclusion

We ran this experiment to try to understand what effect mindfulness might have on the processes underlying conditioned fear (and hence anxiety). We can be confident that it does have an effect, and that this effect appears to be separate from that of visualisation. Whatever the exact mechanism involved, mindfulness practise appears to protect against re-acquisition of conditioned fear after extinction, a result that must be worth pursuing and that may have implications for the treatment of stimulus-specific anxiety.

#### Abstract

Creativity is the ability to produce work that is both novel and appropriate. The study, funded by Indian government, analyzed the effect of one-year chess training on the creativity of children. A pretest and posttest with control group design was used, with 31 children in experimental and 32 in control group. The experimental group underwent weekly chess training. Wallach-Kogan Creativity Test (Indian Adaptation) was used. Analysis revealed that only the experimental group had statistically significant gains in total creativity and two nonverbal subtests. The authors conclude that systematic chess training inculcates in the child the ability to think divergently and creatively.

Keywords: Abstract Thinking; Chess Training; Creativity; Innovation; Divergent Thinking

## Introduction

Creativity is defined as the tendency to generate or recognize ideas, alternatives, or possibilities that may be useful in solving problems, communicating with others, and entertaining ourselves and others (Franken, 1982). Typically creativity is defined as "the ability to produce work that is both novel (i.e. original, unexpected) and appropriate (i.e. adaptive concerning task constraints)" (Sternberg, 1999). These definitions emphasize both the concept of fluency and novelty in the responses that have been generated.

Most theorists agree that the creative process involves a number of components, most commonly:

1. Imagination
2. Originality (the ability to come up with new and original ideas and products)
3. Productivity (the ability to generate a variety of ideas through divergent thinking)
4. Problem solving (application of knowledge and imagination to a given situation)
5. The ability to produce an outcome of value and worth

Creativity is commonly utilized divergent thinking. A creative or divergent thinker is described as the person who
pushes the boundaries of ability and knowledge and is able to reconsider the problem to find different perspectives and solutions and ignore distractions that can negatively affect his or her productivity (Saccardi, 2014). Creativity among children emerges gradually between grades one to three (Torrance, 1964). In general, the broad and complex multidimensional concepts of creativity can be measured by the Torrance Tests of Creative Thinking (TTCT: Torrance, 1964, 1990a, 1990b) and the Wallach-Kogan Creativity Tests (WKCT: Wallach \& Kogan, 1965).

There is a fairly common belief that creativity can be developed through training. Various recent studies that have assessed the effects of programs for stimulating creativity confirm this belief (Antonietti, 2000; Fleith, Renzulli, \& Westberg, 2002; Komarik \& Brutenicova, 2003; Saxon, Treffinger, Young, \& Wittig, 2003). Consequently, many countries are increasingly placing a high priority on stimulating creative thinking at the school level.

Since chess helps in developing strategic thinking and problem-solving skills of children, it may also be effective in improving their cognitive skills (Sigirtmac, 2016). Chess builds problem-solving abilities, enhance strategic thinking skills, and even improves self-esteem as well as higherorder thinking skills, which are known as meta-cognitive skills. In countries, where chess is intensely played by students, practicing students become among the top students in mathematics and science and they are able to recognize complicated patterns (Milat, 1997).

While a number of other models of creativity have brought out the steps involved in the creative process, Avni (1998) posited a four-step model specific to chess playing. According to him, an intelligent process in playing chess consists of four different steps: synthesis (opinion forming and plan shaping), gathering (collecting the raw materials during position evaluation), enlightenment (a sudden observation of an idea), and realization (translating the idea into practical lines of play). Thus, these four steps can be
used for a creative process that could also work in some other areas (Bushinsky, 2009).

India has a long history of chess playing but there are only a few studies on chess as a strategy to increase cognitive abilities. Further, there are no studies assessing the impact of chess intervention on the creativity of children. If research can establish that chess training can facilitate creativity, it can significantly impact educational programs to increase creative thinking.

The objective of the study was, therefore, to analyze the effect of one-year chess training program on the creativity of school-going children of both genders and to assess its effect on the verbal and nonverbal components of creativity. It was hypothesized that chess training would significantly increase creativity in children.

## Methodology

The research design used for the study was pretest and posttest with control group design. The independent variable was the Chess training program, and the dependent variable was Creativity of children.

The sample consisted of 63 children, 31 in the experimental group and 32 in the control group. The children in the experimental group were selected purposively and comprised children who volunteered for the chess program. The children in the control group were randomly selected using random numbers table generated online. The children in the control group were selected on the basis of no chess knowledge and were not given chess training. During the time of chess intervention for the experimental group, the control group children were engaged in other activities such as music, arts and in outdoor sports such as cricket, football, basketball, etc. The mean age for experimental group was 11.86 years ( $\mathrm{SD}=$ 1.44 ) and for control group was 12.03 years ( $\mathrm{SD}=1.14$ ). The experimental group consisted of 9 girls and 22 boys, and the control group consisted of 7 girls and 25 boys.

## Tools

Creativity was assessed by Indian adaption of WallachKogan Creativity Test. The WKCT (Wallach \& Kogan, 1965) is similar to the TTCT in that it focuses on divergent thinking and assesses both visual and verbal content. It includes three verbal subtests-Instances (e.g., name all the round things you can think of), Alternative Uses (e.g., for a newspaper), and Similarities (e.g., How are a cat and mouse similar?)—and two figural subtests—Pattern Meanings and Line Meanings (interpreting abstract patterns and lines). It is scored for fluency (number of ideas) and uniqueness (ideas not offered by others in the group being tested). Wallach and Kogan's (1965) major contribution was their belief that standardized test procedures were not conductive to creative performance and their insistence on a more relaxed and game-like atmosphere. The test is given individually, and no time limits are imposed. However, in the present administration, a time limit of three minutes was given for each subtest. The number of valid responses for each subtest
was summed to obtain the subtest totals. The total creativity scores comprised the sum of the subtest scores.

## Chess Training Methodology

The children were grouped into small clusters based on the chess ability and learning capacity and were trained for an hour starting from the basics. The training methodology comprised Winning Moves Chess Learning Program (Joseph, 2008) Episodes 1-22, lectures with the demonstration board, on-the-board playing and training, chess exercise through workbooks (Chess School 1A, Chess School 2, and tactics), and working with chess softwares. Further students' games were mapped and analyzed using score sheets and Chess software. The children were taught the ideas behind chess openings, and exposure to classical games was also given. The children participated in mock as well as regular tournaments. On an average, the children underwent one hour per week chess intervention for about 25-30 sessions. One coach was assigned for 8 students.

## Procedure

Baseline creativity assessment was done after obtaining informed consent, from the parents and the school authorities. The research was carried out on the approval of government of India, department of science and technology, Task force and the doctoral committee. Reassessment was carried out after an average duration of one year. The assessment environment was quiet without any disturbance and kept standardized. Psychologists were trained to administer the test in a uniform standardized method to minimize the testing error.

Clustering technique was used to form the training groups of six to eight children. The chess training consisted of once-a-week chess classes conducted for one hour during the end of school hours for a year (about 30 hours of chess training). The children were given a standardized Winning Moves Chess Learning Program (Joseph, 2008), and they played at tournaments also.

## Results

The analysis was carried out using SPSS. Paired $t$-test was carried out to analyze differences within groups, and independent $t$-test was used to assess differences between groups in the mean total creativity scores and mean subtest scores. Pre-intervention equivalence of groups on creativity was established for total creativity scores and the subtest scores.

Table 1: The Significance of the Difference between the Means of the Experimental and Control Groups on the Creativity Test using the Independent $t$-Test.

| Scores | Assess ment | Mean and Standard Deviation |  | $t$ |
| :---: | :---: | :---: | :---: | :---: |

*p<.05; **p<.01.
Table 1 indicates that there was a significant difference between the means of the post-intervention total creativity scores ( $p<.05$ ) Cohen's d indicated an effect size of ( 0.52 ), indicating that chess training had significantly increased creativity. Significant differences between the postintervention means were observed on the Line Drawing subtest ( $p<.01$ ) Cohen's d effect size ( 0.84 ) and the Pattern Meaning subtest ( $p<.01$ ) Cohen's d effect size (0.68) , indicating that chess training had significantly increased the scores on these two subtests. No significant differences were observed on any other subtest.

## Discussion

It can be inferred from Table 1 that systematic chess intervention increases creativity in children. As research has clearly established, chess is a game that stimulates cognitive processes and strengthens intellectual abilities and cognitive skills (Aciego, García, \& Betancort, 2012; Bilalic, McLeod, \& Gobet, 2007; De Bruin, Kok, Leppink, \& Camp, 2014). Moreover, it has shown that the intellectual gains have translated into increases in both IQ and academic scores (Aydın, 2015; Barrett \& Fish, 2011; Joseph, Easvaradoss, \& Solomon, 2016; Romano, 2011). Large Effect Sizes for Total Creativity (0.52), Line Drawing (0.84) and Pattern Meaning (0.68) where seen, indicating that chess had a significant impact on Total Creativity, Line and Pattern
subsets of the experimental group. This finding was in line with Sigirtmic (2016), findings who found a statistically significant difference between elaboration, resistance to premature closure and total creativity score of children in favour of those who received chess training.

In the present study, the children were taught chess systematically. They did not merely play chess but were strongly encouraged to challenge their own standards and also to play competitively. They analyzed their own games, identified their strengths, and understood their mistakes. They were also given opportunities to pit their skills against others as they played in tournaments. It is clear that the outcome of this rigorous, yet enjoyable, training methodology was the enhanced cognitive abilities that were reflected in increased creativity scores.

The intellectual strategies underlying chess playing have been spelt out by Avni (1998). According to him, chess playing involves an intelligent process that consists of four different steps: synthesis (opinion forming and plan shaping), gathering (collecting the raw materials during position evaluation), enlightenment (a sudden observation of an idea), and realization (translating the idea into practical lines of play). The child thinks beyond the usual solutions using divergent thinking, thinking abstractly, weighing options, evaluating outcomes, and making decisions. Insightful thinking also appears to play a role.

The Wallach-Kogan Test, which was used in the present study, requires the child to think divergently, quickly, and fluently, generating as many responses as possible on the different tasks. It is evident that similar abilities are utilized in playing chess where innovativeness and accuracy and both broad-based and precise thinking are required. The experimental group, which had undergone one-year training, in chess appears to have acquired these skills as indicated by a significant increase in overall creativity compared to the control group. Earlier studies have pointed to the positive impact that chess has had on academic scores, especially language and reasoning (Joseph et al., 2016). The components of creativity studied on the test are the ability to name objects that have common properties involving abstraction ability (Instances), to identify multiple uses for common objects involving divergent thinking (Alternate Uses), to perceive similarities between two different objects utilizing generalizing and abstracting ability (Similarities), to perceive meaning in meaningless stimuli involving innovativeness (Line Drawing), and to perceive meaning in structures stimuli involving the ability to form association (Pattern Drawing). The children in the experimental group have shown increases in all the post-intervention scores, though not all increments have reached significance.

Significant increases have been observed on the Line Drawing subtest ( $p<.01$ ) and the Pattern Meaning subtest ( $p<.01$ ) as seen in Table 1. On the Line Drawing subtest, the child is shown a line drawing for 30 seconds and is asked to generate as many responses as possible about what the drawing means to him or her. On the Pattern Meaning subtest, the child is shown a design (which is more
structured) and is asked to generate as many responses as possible about what the design means to him or her. This test measures fluency and the ability to uncritically generate ideas and possibilities, both commonplace and unique. The game of chess uses primarily visuospatial strategies. Systematic chess training inculcates in the child the ability to think divergently, visualizing the pros and cons of the various chess moves.

Garaigordobil (2006) studied the impact of a play program on the verbal and graphic-figural creativity. Results showed a positive effect of the intervention, as the experimental participants significantly increased their verbal creativity and graphic-figural creativity. This research primarily focused on structured cooperative play. The chess intervention in the present study also has structural characteristics that corroborate the finding of other studies that had indicated positive effects of play on the development of creativity. This structured quality helps the child to systematically visualize all the possible options and outcomes available to him or her. This ability, which has been acquired through chess training, has led to the increased total creativity scores and the increases on the visuospatial subtests.

## Implications

It is evident that systematic chess intervention increases creativity in children. The child thinks beyond the usual solutions-using divergent thinking, thinking abstractly, weighing options, evaluating outcomes, and making decisions. Significant improvement in the Line Drawing and Pattern Meaning subtest substantiates the fact that the game of chess primarily uses visuo-spatial strategies. Systematic chess training inculcates in the child the ability to think divergently, visualizing the pros and cons of various chess moves. It allows the child to conceptualize all the possible options and outcomes available to him or her. Increasing the creativity of children has possible far-reaching benefits for academic performance and generally for life skills. Systematically learning chess as part of school activities appears to have a broad spectrum of positive outcomes. The child who develops the ability to think in creative ways in playing chess is likely to transfer this learning to dealing with life challenges creatively.

#### Abstract

Modeling text document similarity is an important yet challenging task. Even the most advanced computational linguistic models often misjudge document similarity relative to humans. Regarding the pattern of misjudgment between models and humans, Lee and colleagues (2005) suggested that the models' primary failure is occasional underestimation of strong similarity between documents. According to this suggestion, there should be more extreme misses (i.e., models failing to pick up on strong document similarity) than extreme false positives (i.e., models falsely detecting document similarity that does not exist). We tested this claim by comparing document similarity ratings generated by humans and latent semantic analysis (LSA). Notably, we implemented LSA with 441 unique parameter settings, determined optimal parameters that yielded high correlations with human ratings, and finally identified misses and false positives under the optimal parameter settings. The results showed that, as Lee et al. predicted, large errors were predominantly misses rather than false positives. Potential causes of the misses and false positives are discussed.

Keywords: text document relatedness; semantic similarity; latent semantic analysis (LSA)

## Introduction

Modeling how humans judge the semantic similarity of text documents is an interesting topic in cognitive science with numerous practical implications. In an effort to better model human document similarity judgments, Lee, Pincombe, and Welsh (2005) compared several models of document similarity, including latent semantic analysis (LSA). They found that LSA's cosine similarity scores yielded higher agreement ( $r=.60$ ) with aggregate human ratings than other models, such as Tversky's (1977) ratio model ( $r=.50$ ). Considering that the inter-rater correlation among human raters is also about .60 , LSA seems to judge about as well as a single human rater. However, the moderate correlation between humans and LSA also suggests that LSA does not fully capture human similarity judgments 1 .

[^359]To better understand the weaknesses of LSA, and thereby improve models of text document similarity, this study investigated the pattern of discrepancy between LSA and humans with respect to their document similarity ratings. Specifically, we examined the frequency and degree of underestimation (misses) and overestimation (false positives) made by LSA relative to humans under favorable parameter settings of LSA.

## Misses vs. False Positives

Regarding the nature of the misjudgment by models, Lee et al. (2005) suggested that extreme misses would be a stronger cause than extreme false positives. They made this suggestion based on an observation that the common features model (Lee \& Navarro, 2002) occasionally misses the high similarity between documents that is readily apparent to humans. In a scatterplot of the model ratings against human ratings for each document pair, the authors found a cluster of points (document pairs) with low model ratings but high human ratings. That is, the model missed some of the strong document similarities that humans detected.

Lee et al.'s (2005) analysis above was based on the common features model, but it might apply to LSA as well. The common features model judges document similarity primarily based on the proportion of common features (words) shared by two documents. Notably, LSA's underlying model, the vector space model, determines document similarity in a similar manner. Therefore, Lee et al.'s findings suggesting more extreme misses over extreme false positives may also apply to LSA. This interesting hypothesis, if validated, would provide a valuable clue to improving models of text document similarity. However, it has not yet been rigorously tested.

Testing the hypothesis seems straightforward at first glance: compare human and LSA's document similarity ratings for a set of documents pairs. Then, document pairs with especially low LSA ratings compared to human ratings should be considered as misses and the reverse as false
positives. However, LSA's document representation depends on the parameters used such as the quantity and quality of the background documents (Bullinaria \& Levy, 2006), the dimensionality (Dumais, 1991; Landauer \& Dumais, 1997), and the local-global weighting schemes (Lintean, Moldovan, Rus, \& Mcnamara, 2010; Nakov, Popova, \& Mateev, 2001). Therefore, LSA's misjudgments relative to human judgments could vary depending on the parameters.

In this study, we attempted to investigate the nature of misjudgment by LSA under its optimal parameter settings. Therefore, we first identified LSA's optimal parameter settings by employing as many as 441 unique parameter combinations. Then, under the selected optimal parameter settings, we identified misjudgments by LSA as misses or false positives. Finally, we measured the degree of misjudgment of the two types using normalized scores.

The remainder of this paper has the following structure: (1) introduction to LSA, (2) an experiment identifying optimal parameter settings, (3) identification of misjudgments as misses and false positives under the optimal parameter settings, and (4) discussion of the underlying causes of the misses and false positives.

## LSA

LSA is based on a vector space model in which documents are first transformed into a word-by-document matrix. Rows of the matrix correspond to the unique words across documents, whereas columns correspond to individual documents. Cell values are the frequencies of words within each document. The cell values can be weighted in two respects: to what degree a word is important in representing a document's topic (local weighting), and to what degree a word is important in distinguishing one document from another according to their topics (global weighting). Using the weighted cell values, each document can be represented as a vector in a multidimensional space, where the dimensions correspond the unique words. Finally, the sematic similarity between two document vectors is typically measured using the cosine similarity score.

The core process that distinguishes LSA from the vector space model is singular value decomposition (SVD) implemented on the word-by-document matrix. SVD is a matrix factorization method that decomposes an original matrix (A) into three sub-matrices, $\mathrm{USV}^{\mathrm{T}}$, where U is a unitary w * r matrix (word-by-dimension matrix), S is an r * $r$ diagonal matrix with non-negative real numbers on its diagonal (singular value matrix), and $\mathrm{V}^{\mathrm{T}}$ is a unitary $\mathrm{r} * \mathrm{~d}$ matrix (dimension-by-document matrix). By multiplying these three sub-matrices, the original matrix can be retrieved, and this type of SVD is called full SVD.

In a modified version of the full SVD, called reduced SVD, small singular values located in the lower right corner of S are intentionally discarded, while preserving the first k largest

2 Background documents are included in the original corpus subject to LSA, along with the target documents. They are employed only for constructing the multidimensional space in which the target
singular values. The corresponding columns and rows of U and $\mathrm{V}^{\mathrm{T}}$, respectively, are discarded, too. The original $\mathrm{USV}^{\mathrm{T}}$, after discarding some values, then can be denoted as $\mathrm{U}^{\prime} \mathrm{S}^{\prime}\left(\mathrm{V}^{\mathrm{T}}\right)^{\prime}$, where $\mathrm{U}^{\prime}$ is a $\mathrm{w}^{*} \mathrm{k}$ matrix whose columns are the first $k$ columns of $U, S^{\prime}$ is a $k^{*} k$ diagonal matrix whose diagonal elements are the $k$ largest singular values of $S$, and $\left(\mathrm{V}^{\mathrm{T}}\right)^{\prime}$ is a $\mathrm{k} * \mathrm{~d}$ matrix whose rows are the first k rows of $\mathrm{V}^{\mathrm{T}}$. By multiplying these three reduced sub-matrices, one can obtain the least squares approximation of the original matrix. Finally, documents can be represented as vectors on a $k$ dimensional singular-value-space, which has k orthogonal axes. These dimensions are constructed so that the first axis explains the largest amount of variance of A , and the second axis explains the second largest amount of variance of $A$, and so on.

Furnas et al. (1988) was the first to apply the reduced SVD to the vector space model. This method was later called latent semantic analysis by Deerwester, Dumais, Furnas, Landauer, and Harshman (1990), who also demonstrated that LSA retrieves information better than traditional word-matching methods. Deerwester et al. argued that SVD uncovers latent semantic relations across documents that are buried in the corpus by removing noise (small singular values) in the original word-by-document matrix.

## Identification of Misses and False Positives under LSA's Optimal Parameter Settings

## Stimuli and Procedure

Target Text Documents We used the 1,225 document pairs from Pincombe (2004), which Lee et al. (2005) also adopted. These document pairs were generated by pairing 50 target news articles selected from Australian Broadcasting Corporation's news mail service. Each news article had a single paragraph containing 51 to 126 words (average: 82 words). They covered a variety of topics, such as terrorism and hunger in Africa. For each of the 1,225 document pairs, Pincombe collected about 10 human ratings by asking 83 university students to each rate the relatedness of a subset of the document pairs. Participants used a five-point scale, with one indicating "highly unrelated" and five indicating "highly related".

Background Documents Lee et al. (2005) used 314 news articles from the same Australian news corpus as background documents2. In this study, to explore the optimal parameter settings of LSA, we employed 4,172 additional news articles from the same news corpus (total of 4,486). These new background documents contained a single paragraph (average: 152 words). They also covered a variety of topics as the 50 target news articles did. In addition to the background document size used in Lee et al. (314) and the maximum size available in this study $(4,486)$, we examined
documents are represented. It is generally regarded that LSA's performance improves as the number of background documents increases (Bullinaria \& Levy, 2006).
five intermediate background document sizes by randomly selecting the following numbers of documents from the new set of 4,172 articles: $314,750,1,000,2,000$, and 3,000 (see Table 1).

Table 1. Seven background document conditions.

| Size | Source |
| :---: | :---: |
| 314 | The same 314 news articles as in Lee et al. (2005) |
| 314 | Randomly selected from the 4,172 articles |
| 750 | Randomly selected from the 4,172 articles |
| 1,000 | Randomly selected from the 4,172 articles |
| 2,000 | Randomly selected from the 4,172 articles |
| 3,000 | Randomly selected from the 4,172 articles |
| 4,486 | Combination of the 314 news articles from Lee et <br> al. and the new 4,172 articles |

Dimensionality Regarding the dimensionality of the reduced SVD, the maximum possible dimension for a given background document size corresponds to the total number of documents subjected to SVD (50 + the number of background documents). For example, in the 314background document condition, the maximum dimension is $364(=50+314)$. In most of the background document conditions employed in this study, higher dimensions than 364 were possible. However, following some researchers' arguments for the importance of maintaining 300 dimensions (Landauer \& Dumais, 1997), we selected the following seven dimensions for the reduced SVD (i.e., LSA): 50, 100, 150, $200,250,300$, and 364.

Other LSA Parameters Stemming, normalization, and removal of stopwords and alphanumeric words are known to improve LSA's document representation (Pincombe, 2004; Stone, Dennis, \& Kwantes, 2011). Therefore, they were applied to all LSA runs. Three local weighting schemes (tf, $\log$, and alt-log) and three global weighting schemes (idf, entropy, and p-inverse) were selected based on their significant effects observed in a pilot study (not reported here).

LSA cosine scores were computed for every possible (441) combination of the above parameters: 7 background document sizes $* 7$ dimensions $* 3$ local weighting schemes * 3 global weighting schemes.

Identifying Misses and False Positives To classify LSA ratings as misses and false positives relative to human ratings, we first normalized the human ratings and LSA's cosine scores using z -score 3 . The degree of misjudgment was measured as the absolute difference between the two normalized scores for a given document pair. If a document pair's normalized cosine score was smaller than the

[^360]normalized human rating by at least 1.0 , then the LSA's cosine score was considered a miss. But if a document pair's normalized cosine score was greater than the normalized human rating by 1.0 , then the LSA cosine score was considered a false positive.

## Results and Discussion

Optimal Parameters of LSA To determine which parameter settings are optimal for LSA's document similarity representation, we examined the correlation between LSA cosine scores and human ratings. The correlation was affected more systematically and strongly by the interaction of background document size and dimensionality than the local-global weighting schemes. Therefore, for the sake of simplicity, we merged the correlations across the nine weighting schemes at a given background document size and dimensionality. As shown in Table 2, the correlation increased markedly as we added more background documents, consistent with previous research (Bullinaria \& Levy, 2006). But this effect was more prominent at relatively high dimensions than at low dimensions.

Table 2. Correlations between human ratings and LSA cosine scores as a factor of the background document size and dimensionality. Correlations were merged across the nine local-global weighting schemes at a given background document size and dimensionality. Relatively high correlations ( $r \geq .67$ ) are shaded.

|  | Dimension |  |  |  |  |  |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| Background | 50 | 100 | 150 | 200 | 250 | 300 | 364 | Average |  |
| 314 | 0.53 | 0.55 | 0.55 | 0.56 | 0.56 | 0.57 | 0.59 | 0.56 |  |
| New 314 | 0.62 | 0.59 | 0.58 | 0.56 | 0.57 | 0.58 | 0.61 | 0.59 |  |
| 750 | 0.65 | 0.66 | 0.63 | 0.61 | 0.61 | 0.60 | 0.59 | 0.62 |  |
| 1000 | 0.62 | 0.66 | 0.66 | 0.64 | 0.62 | 0.61 | 0.60 | 0.63 |  |
| 2000 | 0.51 | 0.61 | 0.64 | 0.68 | 0.67 | 0.68 | 0.67 | 0.64 |  |
| 3000 | 0.53 | 0.61 | 0.64 | 0.64 | 0.66 | 0.67 | 0.69 | 0.63 |  |
| 4486 | 0.58 | 0.65 | 0.67 | 0.69 | 0.68 | 0.68 | 0.66 | 0.66 |  |
| Average | 0.58 | 0.62 | 0.62 | 0.63 | 0.62 | 0.63 | 0.63 | 0.62 |  |

To identify optimal parameter settings of LSA, we first selected the 10 combinations of background document size and dimension that yielded correlations of at least .67, averaged across all weighting schemes (see the shaded cells in Table 2). Then, for each of these 10 combinations, we chose the local-global weighting scheme that yielded the highest correlation with human ratings. Table 3 shows the specific parameter settings of these 10 selected combinations as optimal parameter settings. The table also shows the correlation, number of misses and false positives, and the average absolute z -score errors.
the z -score normalization yields more reliable results with respect to the frequency of misses and false positives.

Table 3. Ten optimal parameter settings of LSA selected for the identification of misses and false positives. The parameters, correlation with human ratings, number of misses and false positives, and the average of the absolute z -score errors are shown.

| Background <br> document <br> size | Dimension | Local <br> Weighting | Global <br> Weighting | Correlation | Number <br> of misses | Number <br> of false <br> positives | Average <br> misjudgment <br> (absolute z-score <br> error) for misses | Average <br> misjudgment <br> (absolute z-score <br> error) for false <br> positives |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| 2000 | 200 | tf | p-inverse | 0.70 | 112 | 86 | 1.57 | 1.43 |
| 2000 | 250 | tf | p-inverse | 0.68 | 121 | 67 | 1.60 | 1.56 |

| 4486 | 300 | tf | idf | 0.68 | 119 | 69 | 1.61 | 1.49 |

Nature of Misjudgments by LSA To determine the nature of LSA's misjudgments under optimal parameters, we used the z-score errors obtained from the 10 parameter settings shown in Table 3. As shown at the bottom of the table, misses $\left(\mathrm{M}_{\text {Miss }}=117\right)$ were much more common than false positives $\left(\mathrm{M}_{\text {False Positive }}=79\right), \chi^{2}(1, N=1,959)=73.324, p<.001$, just as suggested by Lee et al. (2005). Also, as the error magnitude increases, the ratio of misses to false positives also increases, which is consistent across the 10 optimal parameter settings. Figure 1 shows the frequency of the two types of errors (misses vs. false positives) as a function of the absolute z-score error.

Figure 1. The frequency of the two types of misjudgment by LSA as a function of the absolute z-score error.

Effect of the Parameters on the Frequency of Misses and False Positives Although the distribution of the two types of errors by LSA at optimal parameters was the primary focus of this study, we also examined the ratio of misses to false positives across all the 441 parameter settings. The results showed that the ratios were systematically affected by the interaction between the background document size and dimensionality. That is, the ratio of misses to false positives increased as the dimensionality increased. However, the degree of increase is getting less prominent as the background document size increases. In other words, although there were more misses than false positives in general, the disproportion of misses over false positives is more prominent at high dimensions with small number of background documents.

Effect of the Number of Background Documents on Correlation between Humans and LSA One of the most striking findings above was the strong effect of background document size on LSA's document similarity representation. As shown in Table 2, employing more background documents (combined with an appropriate dimensionality) tends to significantly improve LSA's document similarity judgments. To illustrate the significant effect of background documents, we plotted the correlation between LSA and human ratings for three background document sizes $(0,314$, and 4,486 ) and the nine weighting schemes as a function of dimensionality (Figure 2). The graph illustrates (a) the strong effect of the number of background documents, (b) important effect of dimensionality when the background document size is small (i.e., the left side of the graph), and (c) the relative unimportance of weighting schemes.

Figure 2. The correlation of ratings between humans and LSA for three background document conditions ( 0,314 and $4,486)$ and nine weighting schemes as a function of dimensionality.

One may suspect that including even more background documents would further increase the correlation. However, to make a positive impact on LSA's performance, the background documents should not only be numerous but also relevant to the content of the target documents (Foltz, Britt, \& Perfetti, 1995). For example, Stone, Dennis, and Kwantes (2011) tested the effect of various kinds of background documents on LSA's document similarity judgments, using the same 50 target news articles examined in this study. They tested 55,021 Canada Toronto Star newspaper articles (miscellaneous gossip paragraphs, from the year 2005) and 10,000 articles selected by the researchers from online encyclopedia, Wikipedia (http://www.wikipedia.org/). However, the highest correlation between humans and LSA obtained was about .10 with the gossip news articles as background and . 40 with the Wikipedia background documents. These correlations were significantly lower than the highest correlation of .60 obtained in Lee et al. (2005) and .70 in the current study, despite utilizing only 314 and 4,486 background documents, respectively. Therefore, not only the size but also the relevance of background documents to the target documents seem to be critical for LSA's document similarity judgments.

If target documents came from a certain population (e.g., specific news corpus), we recommend using documents from the same population as background documents. In our case, employing background documents of 4,172 news articles that came from the same population as the target articles increased the correlation between humans and LSA from .60 to .70 .

## Conclusion

Lee et al. (2005) suggested that the primary weakness of computational models of document similarity is failing to pick up on some of the strong document similarities that humans easily detect. To test this hypothesis, we compared the document similarity ratings made by humans and LSA based on a range of parameter combinations. Then we
identified the frequency and degree of large misses and large false positives under optimal parameters of LSA. The results confirmed that LSA makes more misses than false positives, especially among the most severe errors.

The results also suggest that if one attempts to further improve models of text document similarity by reducing its errors relative to humans, the misses rather than the false positive would be the primary focus of the revision. More specifically, one should look for ways to help models pick up on some of the strong semantic similarities that they currently miss.

## Potential Causes of Misses and False Positives

An obvious follow-up question of this study is what causes LSA's greatest misses and false positives. Considering that LSA's basis, the vector space model, judges document similarity based on the overall word similarity between two documents, a potential cause of error is that LSA misses or falsely overestimates the semantic similarity of some word pairs from two documents. In fact, there are various cases where LSA cannot help but miss some of the word similarities, which in turn would cause one type of error, miss. For example, although "United States", "US", "U.S.", and "U.S.A" refer to the same country, they may not be recognized as the same entity in the word-by-document matrix for various reasons: because they are not a single word (United States), too short to be included (US or U.S. after the special character removal), or happen to match an excluded stop word (US and the pronoun us). However, humans would correctly recognize them and utilize these words for document similarity judgment.

Also, some words (especially proper nouns including human names) may occur in the target documents but not in the background documents, preventing LSA from utilizing those words in judging document similarity. However, those words could be critical for humans to judge the document similarity. Then, LSA may judge document pairs including those words to be less related than humans would do (i.e., leading to a miss).

The above-mentioned potential cause of misses (i.e., LSA misses document similarity because it misses word similarity in document pairs) could be further supported if LSA's document similarity scores do correspond to the overall word similarity between two documents. To confirm this, we calculated the correlation between the 1,225 document pairs' LSA cosine scores and the average LSA cosine scores of every possible word pair from each of the document pairs. We found a correlation of .73 from this analysis, indicating that LSA's document similarity is heavily relying on the overall word similarity in document pairs.

Similar to the potential cause of misses by LSA addressed in the above, a potential cause of false positives by LSA is that LSA mistakenly perceives semantic similarity between words that are in fact unrelated. Table 4 shows 10 word pairs that were judged to be highly related by humans and LSA, respectively in one of the document pairs used in this study. Although LSA does generally make reasonable judgments on
word relatedness, some word pairs judged to be highly related by LSA do not seem to have a meaningful relationship. For example, design and document were the most strongly related word pair to LSA, despite being seemingly unrelated. Thus, LSA will occasionally overestimate the relatedness of the document pairs that include this word pair.

Table 4. The 10 most related words pairs to humans and LSA from a pair of news articles.

| Highly related <br> word pairs by <br> human | Ratings <br> $(1-5$ scale) | Highly related <br> word pairs by <br> LSA | Ratings <br> (z-score) |
| :--- | :---: | :--- | :---: |
| dollar-money | 5.00 | design-document | 6.87 |
| job-money | 5.00 | increase-rise | 5.61 |
| angrily-attack | 4.90 | paid-worker | 3.97 |
| plan-target | 4.83 | effect-target | 3.38 |
| increase-profit | 4.80 | group-work | 3.37 |
| money-profit | 4.80 | effect-increase | 3.08 |
| cost-lawsuit | 4.78 | disclosure-profit | 2.89 |
| job-meet | 4.75 | disclosure-financial | 2.83 |
| agreement-plan | 4.73 | commonwealth-deal | 2.41 |
| job-paid | 4.73 | australia-target | 2.32 |

An alternative hypothesis regarding the misses and false positives of LSA is that, when judging document similarity, humans do not rely on the overall word similarity as much as LSA does. As Griffiths, Steyvers, and Tenenbaum (2007) suggested, humans may catch the gist of each document and compare the semantic representations of the gist rather than relying on the overall similarity of words in the documents. Then, two documents with a large overlap of words but with different topics would be regarded unrelated by humans although they could be highly related to LSA (resulting in false positives). To assess to what degree human document similarity judgments rely on the overall word similarity, one could examine the correlation between human document similarity ratings and the average of the human similarity ratings for all the possible word pairs in a given document pair. If humans do not rely on the overall word similarity as much as LSA does, then the correlation would not be as high as the corresponding correlation of LSA.

# "The Polar Express" is Bipolar: Critical Film Reviews Influence Uncanny Valley Phenomenon in Semi-Realistic Animation Films 

Jari Kätsyri (jari.katsyri@maastrichtuniversity.nl)<br>Department of Cognitive Neuroscience, Oxfordlaan 55, 6229 EV Maastricht, The Netherlands

#### Abstract

Previous research suggests that semi-realistic animation films such as The Polar Express are representative of the uncanny valley (UV) hypothesis, which predicts that highly humanlike artificial characters can appear eerie. In the present study, we investigated the extent to which critical film reviews can influence the perceived eeriness of such films. The reviews were adopted from authentic ones and expressed either negative or positive attitudes towards the animation techniques. Audiovisual speech asynchrony, which is known to induce eeriness, was included as an objective manipulation. Our results showed large review tone effects for both implicit and explicit eeriness evaluations. In contrast, speech asynchrony failed to elicit significant effects. These results demonstrate that critical film reviews representing opposite attitudinal poles can elicit consistent changes in the viewers' evaluations of semi-realistic animations. The present findings cannot, however, be taken as evidence against the UV hypothesis itself in computer-generated characters.

Keywords: Uncanny Valley hypothesis; anthropomorphism; social influence; animation films

## Introduction

Realistic computer-generated (CG) characters are commonly used in lieu of human actors when creating social signal stimuli for neurocognitive experiments. Although this practice has several advantages such as the ease of creating and manipulating stimuli, it is conceivable that subtle flaws in highly realistic CG characters could elicit unintended negative reactions in human participants. The Uncanny Valley (UV) hypothesis predicted such reactions already in the 1970s. The original hypothesis suggested that observing highly realistic robots or other mechanical devices can elicit negative feelings characterized by eeriness and lack of familiarity (Mori, 1970/2012).

## Empirical Evidence for Uncanny Valley

Although the UV hypothesis is compelling and it seems to have plentiful anecdotal evidence (see below), empirical evidence for its existence is still elusive (Kätsyri, Förger, Mäkäräinen, \& Takala, 2015; S. Wang, Lilienfeld, \& Rochat, 2015). A lack of commonly agreed-upon operationalization is a fundamental problem for testing the hypothesis. According to a conservative interpretation, any artificial-to-human stimulus continuum should elicit a nonlinear evaluation curve in which the most negative evaluations occur at levels preceding the full degree of human-likeness. The bulk of empirical studies have, however, shown that increasingly human-like stimuli simply tend to elicit more positive evaluations in a linear manner (Kätsyri et al., 2015).

Although the UV is apparently not triggered by all artificial-to-human continua, it could still occur under some specific conditions. Accumulating evidence has shown that negative evaluations can be elicited by a mismatch between artificial and realistic features (Seyama \& Nagayama, 2007; MacDorman \& Chattopadhyay, 2016) or by categorization difficulty (Burleigh \& Schoenherr, 2015; Yamada, Kawabe, \& Ihaya, 2013; however, see MacDorman \& Chattopadhyay, 2016). Almost all of this evidence comes from rigorous manipulations of CG and human faces. A few other studies using naturalistic - and plausibly more ecologically valid - stimuli have provided evidence for the UV in pictures of prosthetic hands (Poliakoff, Beach, Best, Howard, \& Gowen, 2013) and real-world robot faces (Mathur \& Reichling, 2016).

## Uncanny Valley and Animated Film Characters

The UV hypothesis was rediscovered at the beginning of the present millennium (e.g., MacDorman, 2005) and has since received increasing research interest. First fully computeranimated films with deliberately realistic characters, including Final Fantasy (Aida, Lee, Sakai, Sakaguchi, \& Sakakibara, 2001) and The Polar Express (Goetzman, Starkey, Teitler, \& Zemeckis, 2004), were released roughly around the same time. Perhaps not coincidentally, these and some other animation films have been adopted as anecdotal examples of the UV, with frequent citations in scientific research reports (e.g., Piwek, McKay, \& Pollick, 2014) and popular scientific magazines (e.g., Spinney, 2017).

It seems plausible that semi-realistic animated film characters could appear eerie in the sense of the UV. Early computer graphics methods in particular tended to suffer from shortcomings in modeling light reflections from the skin and eyes, for example (e.g., Wechsler, 2002). These and other subtle flaws on otherwise quite realistic characters could elicit sufficient featural mismatch to make them appear uncanny. In general, semi-realistic animated film characters stand out from the intentionally caricatured and exaggerated characters that are the norm in traditional animation (Kaba, 2012).

To our best knowledge, semi-realistic animated film characters, cartoonish animated film characters, and human actors have been explicitly compared with each other only recently in our own previous study (Kätsyri, Mäkäräinen, \& Takala, 2017). The results showed that semi-realistic characters are considered more eerie and selected more often as representative examples of the UV hypothesis than cartoonish characters or human actors. These results suggest that semi-realistic animated film characters capture some aspects of the UV hypothesis.

## Critical Film Reviews and Uncanny Valley

Semi-realistic animation films, which are a rare exception among the traditional computer-animated films, have attracted a mixed but predominantly negative critical reception. Some of the published reviews have explicitly characterized the realistic characters as "soulless" and "creepy" (e.g., Savlov, 2004). In the present study, we explore the extent to which this kind of critical reviews can influence the evaluation of animated characters in semirealistic films.

A research tradition in social psychology has shown that individuals' attitudes and behavior are influenced by those of others (Bohner \& Dickel, 2011). In one form of social influence, credible information from others is accepted as valid evidence about reality (Deutsch \& Gerard, 1955). Perceived expertise on the subject matter has long been considered as one source of credibility (Kelman, 1956). On the other hand, negative attitudes are known to exert greater influence than equally intense positive attitudes (Cacioppo, Gardner, \& Berntson, 1997). An excellent demonstration of this is that negative peer reviews exert greater influence than positive reviews on individuals' attitudes towards consumer products (Lee, Park, \& Han, 2008). Taken together, negative reviews from film experts should exert an influence. Consistently, negative film reviews are known to elicit decreased box profit especially during early presentation weeks (Basuroy, Chatterjee, \& Ravid, 2003).

## Present Study

The present study aims to compare the effects of critical film reviews and objective differences between films on the UV phenomenon in semi-realistic animation films. When comparing small sets of individual films (as in Kätsyri et al., 2017), confound effects cannot be fully excluded. Instead, in the present study, we decided to manipulate audiovisual speech asynchrony in the same set of films. Audiovisual speech asynchrony was selected as the objective manipulation since a previous study has shown that it elicits eeriness in virtual characters (Tinwell, Grimshaw, \& Nabi, 2015). Increased eeriness was observed at a $200-\mathrm{ms}$ asynchrony at the earliest, and it was more pronounced when the auditory stream preceded rather than followed the visual stream. These findings are consistent with psychophysics literature, in which simultaneity judgments for audiovisual speech occur roughly in the time frame of -130 ms (audio first) to +220 ms (vision first) (Conrey \& Pisoni, 2006).

Participants were asked both to rate the eeriness of films immediately after viewing them (implicit evaluations) and to score how representative each film was of UV after having received full debriefing (explicit evaluations). Our main hypotheses were:

H1: Majority negative reviews will elicit higher implicit and explicit eeriness than majority positive reviews.

H2: Asynchronous audiovisual speech will elicit higher implicit and explicit eeriness than synchronous audiovisual speech.

## Method

## Participants

Forty participants ( 20 women) with a mean age of 29.7 years ( $\mathrm{SD}=8.5$ ) took part in the study. All participants were native Finnish speakers with a good command of written English. Three participants who scored poorly in a postexperimental reading comprehension test were replaced with new participants. Participants reported having normal hearing, normal (or corrected) visual acuity, and no history of dyslexia. Participants were compensated with two movie tickets. Study protocol was approved by the Aalto University Research Ethics committee.

## Stimuli

Animation Film Scenes Stimuli were four film scenes from animation films Final Fantasy (Aida et al., 2001), The Polar Express (Goetzman et al., 2004), Beowulf (Rapke, Starkey, \& Zemeckis, 2007), and Tintin (Jackson, Kennedy, \& Spielberg, 2011). Films were selected on the basis of our previous evaluation (Kätsyri et al., 2017). All films were fully computer-animated and used motion-capture techniques for character animation (most character motions were captured from real actors). Film scenes were extracted from official DVD releases, depicted spoken dialogue, and did not contain violence or nudity. These copyrighted materials were presented under an external license.

Audiovisual Speech Synchrony Original audiovisual tracks for the predominantly spoken film scenes were used for the synchronous speech condition. For the asynchronous condition, auditory stream in each film scene was modified to precede the visual stream by 200 ms .

Film Reviews For each film, six fictional but plausible film reviews (three positive and three negative) were created. For authenticity, all reviews were displayed in English. Available reviews were first extracted from Metacritic database (http://www.metacritic.com). Brief statements expressing positive and negative attitudes towards animation techniques were then extracted and modified to produce an initial set of 12 reviews (half positive). These reviews were evaluated by 19 additional participants for expressed attitude ( -4 very negative to +4 very positive). Negative and positive reviews were clearly differentiated $(\mathrm{M}=-2.1$ and $+2.6, \mathrm{SD}=1.2$ and 0.8$), F(1,18)=114.95, p$ $<.001, \eta_{\mathrm{p}}^{2}=.87$.

Final selected stimuli were three positive and three negative reviews with roughly similar lengths ( $M=82$ and 79 words) and similar mean ratings across films. The reviews focused on either specific visual features (e.g., "[...] their eyes, supposedly the windows to the soul, are more often dead than alive") or the overall impression generated by highly realistic animations (e.g., "[...] the soft-edged, photorealistic style - suspended somewhere between liveaction and animation, fairy tale and reality - feels entirely appropriate in this context").

Table 1: Counterbalancing between films and conditions.

| Group | Negative/ <br> Asynch. | Positive/ <br> Asynch. | Negative/ <br> Synch. | Positive/ <br> Synch. |
| :--- | :--- | :--- | :--- | :--- |
| 1 | F1 | F2 | F3 | F4 |
| 2 | F2 | F3 | F4 | F1 |
| 3 | F3 | F4 | F1 | F2 |
| 4 | F4 | F1 | F2 | F3 |

## Procedure

Film preference evaluation was used as a distractor task to avoid making the true study objectives too obvious. Specifically, participants were explained that the study aimed to investigate the effects of critical film reviews on attitudes and consumer behavior. Full debriefing was given at the end of the study.

Participants were assigned randomly to the conditions of a 4 (group) $\times 2$ (majority review tone: negative, positive) $\times$ 2 (speech synchrony: asynchronous, synchronous) mixed model design. Majority review tone and speech synchrony were counterbalanced with films using a $4 \times 4$ Latin square as shown in Table 1. Participants were asked to read film reviews carefully and told that a memory task would follow the evaluation. Each trial proceeded as follows:

- Title and a brief description of the film were presented with a minimum reading time of 20 s .
- Four reviews were presented (min. 10 s per each). For the majority negative/positive condition, three reviews were negative/positive and one was of the opposite valence. Reviews were paired randomly with fictional reviewer names (half female) and well-known magazine titles.
- An overview of the film scene was presented (min. 20 s ).
- The movie scene was played back ( 164 s to 182 s ).
- The participant answered a series of self-report questions.

The experiment was carried out on a desktop computer running Psychtoolbox (Brainard, 1997) for Matlab. Film stimuli were displayed on a 24 " wide-screen display (Eizo ColorEdge CG241W) at horizontal resolution of 1024 pixels and vertical resolution depending on aspect ratio (424 to 548 pixels). Participants were seated 80 cm from the display. Auditory sound tracks were standardized at -5 dB and played on closed earphones at a loud but comfortable level. The whole experiment took approximately 60-90 mins.

## Dependent Variables

Film Preference For attitude towards the film (cf. Voorveld, 2011), participants rated whether they enjoyed each film, were content with it, and found it interesting. This scale had a good internal reliability (Cronbach's $\alpha=0.96$ ). For consumption intent (cf. A. Wang, 2006), participants rated whether they would like to see the full film (again if seen), recommend it to a friend, and pay for seeing it (good reliability: $\alpha=0.91$ ). These and all other ratings were given on a 7 -step Likert scale ranging from total disagreement (1) to total agreement (7).

Table 2: Means (and SEMs) by majority review tone.

| Variable | Negative | Positive | $F(1,36)$ | $p$ | $\eta_{\mathrm{p}}{ }^{2}$ |
| :--- | :---: | :--- | :---: | :---: | :---: |
| Film attitude | $4.6(0.2)$ | $5.0(0.1)$ | 6.94 | .027 | .13 |
| Consumption intent | $3.8(0.2)$ | $4.4(0.2)$ | 8.72 | .006 | .19 |
| Human-likeness | $4.7(0.2)$ | $5.0(0.1)$ | 8.08 | .007 | .18 |
| Eeriness | $3.2(0.2)$ | $2.8(0.2)$ | 7.46 | .010 | .17 |
| Representativeness | $10.5(0.7)$ | $8.2(0.8)$ | 6.52 | .015 | .15 |

Eeriness (Implicit) and Human-likeness For eeriness, participants rated whether the characters appeared eerie, creepy, and strange (good reliability: $\alpha=0.84$ ). Although not included in any hypothesis, human-likeness scale was also included because it is a focal dimension of the UV (Mori, 1970/2012). Participants were asked to rate whether the characters appeared realistic, cartoonish, and similar to real people (adequate reliability: $\alpha=0.71$ ).

Representativeness (Explicit Eeriness) After finishing the film evaluation task, participants received a full debriefing of the experiment and the UV hypothesis. Participants were then given four plastic cards depicting the four animation films and asked to place these cards on a cardboard depending on how representative the films were of the UV (left side: not at all, right side: perfectly). Responses were scored from 0 to 100 based on the cards' physical positions.

## Analysis

Data were subjected to a mixed-design GLM analysis in SPSS (version 24). Effect sizes were quantified using partial $\eta^{2}$ values and classified as large ( $\eta^{2} \geq .14$ ), medium ( $\eta^{2} \geq$ .06), or small ( $\eta^{2} \geq .01$ ) based on Cohen's (1992) guidelines.

## Results

## Manipulation Checks

After the experiment, participants were asked to read 12 review statements for each film, and to tell whether they had read these reviews during the experiment (yes/no). Statements included four correct and eight incorrect options and an equal number of positive and negative reviews. Recognition performance, as indexed by $d$ ' sensitivity score (Stevens \& Pashler, 2002), was well above chance level ( $M$ $=1.47, S D=0.59), t(39)=15.80, p<.001$, showing that participants had attended and comprehended the reviews.

## Negative Reviews

As can be seen in Table 2, majority review tone elicited significant effects for all dependent variables. Supporting H1, majority negative reviews elicited higher eeriness ratings and representativeness scores than majority positive reviews. In the distractor task, majority negative reviews elicited decreased film attitude and consumption intent ratings. Human-likeness ratings were decreased for majority negative review reviews. Review tone had a medium effect for film attitude and a large effect for all other variables.

Table 3: Means (and SEMs) by speech synchrony.

| Variable | Asynch. | Synch. | $F(1,36)$ | $p$ | $\eta_{\mathrm{p}}{ }^{2}$ |
| :--- | :--- | :---: | :---: | :---: | :---: |
| Film attitude | $4.8(0.2)$ | $4.8(0.2)$ | 0.02 | .884 | .00 |
| Consumption intent | $4.2(0.2)$ | $4.0(0.2)$ | 0.46 | .503 | .01 |
| Human-likeness | $4.8(0.2)$ | $4.9(0.2)$ | 0.21 | .650 | .01 |
| Eeriness | $3.0(0.2)$ | $3.0(0.2)$ | 0.07 | .790 | .00 |
| Representativeness | $9.9(0.8)$ | $8.7(0.9)$ | 1.26 | .269 | .03 |

## Speech Asynchrony

As shown in Table 3, speech synchrony failed to elicit significant main effects on eeriness, representativeness, or any other variable. Asynchrony elicited slightly higher representativeness scores than synchrony; however, this effect was small and clearly non-significant. Hence, the results did not support hypothesis H2.

## Interactions

Fig. 1 illustrates interaction effects between review tone and speech synchrony. Visual inspection suggests that review effects for some variables were qualified by an interaction with speech synchrony. Consistently, significant and large interaction effects were observed for film attitude, $F(1,36)$ $=7.05, p=.012, \eta_{\mathrm{p}}^{2}=.16$, consumption intent, $F(1,36)=$ $6.42, p=.016, \eta_{\mathrm{p}}^{2}=.15$, and human-likeness, $F(1,36)=$ $7.59, p=.009, \eta_{\mathrm{p}}^{2}=.17$. Simple effect tests revealed that for these variables, negative reviews elicited lower ratings than positive reviews only in the asynchronous condition ( $p \leq$ . $001, \eta_{\mathrm{p}}^{2} \geq .254$ ). Importantly, interaction effects were not significant for eeriness, $F(1,36)<1, p=.643, \eta_{p}^{2}=.01$, or representativeness, $F(1,36)=1.21, p=.278, \eta_{p}^{2}=.03$. Hence, H1 was not affected by this interaction.

## Confounds

The following confound effects were tested and excluded using mixed model analyses (Hoffman \& Rovine, 2007): previous familiarity (film seen or not seen), awareness of UV, awareness of review manipulation, and awareness of asynchrony manipulation. A mixed model equivalent to GLM was first specified, and confounds were then added and tested individually. The pattern of significant results was not changed by the inclusion of any tested confound into the model.

Awareness variables were derived from a semi-structured interview conducted the end of the experiment. Briefly, UV awareness meant that participants (18\%) had heard about the UV hypothesis, were able to explain it correctly, and associated it with this experiment. For review awareness, participants $(30 \%)$ noticed that films were preceded unequally by positive and negative reviews, were able to choose which films received majority positive/negative reviews, and were aware of the manipulation. For asynchrony awareness, participants (30\%) mentioned audiovisual asynchrony spontaneously and were aware of the manipulation. Notably, only $8 \%$ of participants were able to choose asynchronous films correctly, however.

Figure 1: Means (and SEMs) by majority review tone and speech synchrony. Note that representativeness scores are truncated to 0-20.

## Discussion

The aim of the present study was to provide an objective comparison of the effects of critical reviews and objective differences (audiovisual speech synchrony or asynchrony) on the UV phenomenon in semi-realistic animation films. We hypothesized that critical film reviews focusing on the appearance of realistic animation technologies would exert an influence on both implicitly and explicitly evaluated eeriness. Indeed, our results showed that review tone (majority positive or negative) elicited large effects both on eeriness ratings given immediately after film viewing (implicit evaluations) and representativeness scores given after full debriefing of the UV (explicit evaluations). Unexpectedly, audiovisual speech asynchrony failed to elicit significant effects.

The present results demonstrate that social influence (Bohner \& Dickel, 2011) originating from critical reviews can exert a large influence on the subjective eeriness of semi-realistic animated film characters. Results from explicit evaluations are particularly important because they demonstrate that critical reviews can affect individuals' attitudes specifically in the UV context. A closer inspection of the results suggests that participants did not consider the animation films as particularly eerie: $95 \%$ confidence interval for the overall eeriness ratings was [2.7, 3.3] on the 7 -step scale (i.e., below midpoint) and for the overall representativeness scores [8.1, 10.5] on the visual scale from 0 to 100 . In the absence of strong effects in the stimuli, participants may have relied on information from the film reviews instead.

Although not predicted beforehand, majority negative reviews also elicited lower human-likeness ratings than majority positive reviews - but only in film scenes with asynchronous audiovisual speech dialogue. This result differs clearly from eeriness evaluations, which were not sensitive to the interaction between review tone and synchrony. This suggests that review effects were more robust for evaluated eeriness than for evaluated humanlikeness.

The failure to find significant effects for the $200-\mathrm{ms}$ audiovisual speech asynchrony is surprising given that such delay should be noticeable on human faces (Conrey \& Pisoni, 2006) and elicit eeriness in virtual characters as well
(Tinwell et al., 2015). We note that several participants ( $30 \%$ ) commented spontaneously upon asynchrony in the films even though much fewer ( $8 \%$ ) were actually able to identify which films were truly asynchronous. A possible explanation for this discrepancy is that animated lip movements were sufficiently inaccurate to begin with in some of the films so that additional delay had little or no effect on the perceived asynchrony. It is also possible that asynchrony effects may have been concealed by the stronger review tone effects. In partial support, secondary evaluations - but not eeriness evaluations - were affected by the interaction between review tone and asynchrony.

A significant limitation of the present study is that, in the absence of statistically significant effect for asynchronous speech, the magnitude of critical review effect cannot be meaningfully interpreted. Hence, the present results can tell us that critical film reviews exert a large influence on the perceived eeriness of semi-realistic animated film characters, but it cannot tell us whether these effects are weaker or stronger than those elicited by genuine physical differences in the stimuli.

The present results are nevertheless relevant for the UV phenomenon because semi-realistic animated film characters have already been linked to this phenomenon previously (Kätsyri et al., 2017). Methodological limitations in this previous study warrant some caution in interpreting the findings; for example, eeriness ratings were close to minimum for all film characters. It is particularly clear that semi-realistic animation films do not elicit any such aversion that could be implicitly or explicitly likened to human corpses or zombies (cf. Mori, 1970/2012). Nevertheless, semi-realistic animated characters received slightly but statistically significantly higher eeriness ratings and were considered more often as being representative of the UV hypothesis than other types of films. Hence, these previous findings provide support for subtle UV effects in semi-realistic animated film characters. The present results add to this by demonstrating that such effects can also be elicited by critical film reviews. It should be emphasized that the present study did not aim to "find" the UV for animated characters, as this was already done previously.

Precisely for the same reason, the present results should be considered meaningful even though the review effect was not tested for cartoonish animated characters or real human actors. In fact, the present film reviews that focused explicitly on the disadvantages of realistic animation techniques could not have been paired with any other types of films, at least not without arousing suspicion in the study participants. Although fictitious negative reviews focusing on the disadvantages of traditional animation could possibly have been created, it is likely that such stimuli would have been considered implausible as this kind of reviews do not appear to exist in reality.

Taken together, the present findings demonstrate that critical film reviews representing opposite attitudinal poles negative or positive - towards realistic animation techniques can elicit consistent changes in individuals' evaluations.

In this sense, the UV phenomenon in semi-realistic animation films could be characterized as being bipolar.

The present findings should obviously be interpreted with caution when it comes to explaining the complexities of attitude formation in real life. Allowing some speculation, it is possible that critical film reviews might have contributed to the wide-spread adoption of specific animation films as anecdotal examples of the UV. The present results empathetically cannot be taken to mean that the UV would be just a media phenomenon, however. First, the present study does not allow comparing the effects of critical film reviews to genuine differences between stimuli. Second, empirical evidence for the UV phenomenon has already begun to accumulate, especially from studies with featurally mismatching (Seyama \& Nagayama, 2007; MacDorman \& Chattopadhyay, 2016) and naturalistic stimuli (Mathur \& Reichling, 2016; Poliakoff et al., 2013).

Overall, the present findings highlight the importance of social factors in evaluating contemporary technological artefacts, in particular those that involve human-like characteristics.

## Acknowledgments

This study was carried out at the Department of Computer Science, Aalto University, Finland, with an individual research grant from the Emil Aaltonen Foundation. The work was also supported by the Marie Skłodowska-Curie Individual Fellowship (H2020 programme) under grant agreement 703493. The author wishes to thank Prof. Tapio Takala, M.Sc.(Tech.) Meeri Mäkäräinen, and D.Tech. Klaus Förger for previous collaboration, which provided the foundation for the present study.

# Self-other distinction in the motor system during social interaction: A computational model based on predictive processing 

Sebastian Kahl (skahl@uni-bielefeld.de)<br>Stefan Kopp (skopp@uni-bielefeld.de)<br>Social Cognitive Systems Group, Faculty of Technology, Bielefeld University, Inspiration 1, 33619 Bielefeld, Germany

#### Abstract

During interaction with others, we perceive and produce social actions in close temporal distance or even simultaneously. It has been argued that the motor system is involved in both processes, but how does it distinguish in this processing between self and other? In this paper, we present a model of self-other distinction within a hierarchical sensorimotor system that is based on principles of perception-action coupling and predictive processing. For this we draw on mechanisms assumed for the integration of cues to generate sense of agency, i.e., the sense that an action is self-generated. We report results from simulations of different social scenarios, showing that the model is able to solve the problem of the dual use of the sensorimotor system.

Keywords: perception-action coupling; social cognition; mirroring; dual-use; sense of agency; predictive processing

## Introduction

In everyday social interaction we constantly try to deduce and predict the underlying intentions behind others' social actions, like facial expressions, speech, gestures, or body posture. This is no easy problem and the underlying cognitive mechanisms and neural processes even have been dubbed the ,dark matter" of social neuroscience (Przyrembel, Smallwood, Pauen, \& Singer, 2012). Action recognition is commonly believed to rest upon principles of predictionbased processing (Clark, 2013), where predictions about expected sensory stimuli are continuously formed and evaluated against incoming sensory input to inform further processing. Such a predictive processing does not only inform our perception of actions of others, but also our action production in which we constantly predict the sensory consequences of our own actions and correct them in case of deviations.

Both of these processes draw on the human motor system constituting a perception-action coupling (Prinz, 1997). However, in dynamic social interaction, perception and production often need to be at work simultaneously and for both, actions of self and other. How does the sensorimotor system distinguish between self and other? And how does it interplay with higher-level cognitive processes like mentalizing to solve this social differentiation problem?

As of yet, it is not clear how exactly self-other distinction is implemented within the motor system, but there is evidence for a differentiated involvement supporting the motor system's key role in social cognition (Schütz-Bosbach, Mancini, Aglioti, \& Haggard, 2006). We aim to contribute a computational modeling perspective. In previous work we de-
vised a model of the interplay of mentalizing and predictionbased mirroring during social interaction. It demonstrated how mentalizing - even with minimal abilities to account for beliefs, desires and intentions - affords interactive grounding and makes communication more robust and efficient (Kahl \& Kopp, 2015). In that work two virtual agents interacted in a communication game, each of which equipped with models of a mirroring system and mentalizing system, respectively.

In this paper we present an extension of the predictionbased model of the sensorimotor system to enable it to differentiate actions of its own from the interaction partner's actions. We start with briefly introducing the hierarchical, prediction-based model of a sensorimotor system. Then we discuss how this model can be extended to deal with concurrent perception and production in social situations. This includes a basic ability to integrate predictive and postdictive cues to form a sense of agency (SoA) that helps to differentiate between self and other. Finally, we present and discuss results from simulation studies of different simple scenarios, which test the model's ability to infer SoA for its own actions.

## Computational model of a sensorimotor system

Like other attempts to model the motor system, we chose to make use of a hierarchical representation of increasing abstractions over motor commands (Wolpert, Doya, \& Kawato, 2003; Sadeghipour \& Kopp, 2010). In a three-level hierarchy (see Figure 1), we represent motor primitives on the lowest level (MPrim), followed by a motor sequence layer (MSeq), and motor schemas on the topmost level of abstraction (MSchema). Motor primitives represent single movement segments in space, motor sequences store lists of motor primitives, while motor schemas represent abstract clusters of motor sequences grouped by similarity. We assume that these representations are the basis for a prediction-based model of sensorimotor processing which underlies both action perception and production. To this end, we assume the representations to be multimodal, i.e., combining visual, motor and proprioceptive aspects of action, if available. Consequently, they are used as more or less high-level or visuomotor representations of action and their outcomes. During action perception, we further assume that the correspondence problem is solved in the sense that an observed action by another agent is mapped into one's own self-centered frame of reference. That is, we feed the perceived action trajectory directly and bottom-up into the sensorimotor system.

Figure 1: The predictive sensorimotor hierarchy, based on predictive processing and perception-action coupling. Predictions are sent top-down from state nodes $(S)$ and will be compared to sensory evidence in error nodes $(E)$ in order to drive updates within the hierarchy.

## Sequence matching

In the current model motor primitives are matched against sensory input, which is assumed to consist of a sequence of the last two perceived input coordinates. Motor sequences are matched against a temporary motor sequence concurrently collected from the motor primitive layer, yielding a best match and a prediction of the next motor primitive in the sequence. Motor schemas are likewise matched against the currently best matching motor sequence. In the case of the motor primitives, before the best match is searched, the input sequence is linearly interpolated to match the length of the motor primitives and it is scaled and translated to match the motor primitive's position and size in its coordinate system. Sub-sequence matching is solved by applying euclidean distance measures, which provides high accuracy in our domain size. The same matching algorithm is used for comparing motor sequences in the motor schema layer.

## Predictive sensorimotor hierarchy

The model realizes a predictive processing account resting upon assumptions of the predictive brain hypotheses (Clark, 2013). To that end, it stores representations in the form of discrete probability distributions that can be influenced both bottom-up, in the form of evidence for its last prediction from the next lower layer, and top-down in the form of a prediction by the next higher layer. Following the assumption that the main flow of information is top-down and that motor control is also just top-down sensory prediction, described as "actionoriented predictive processing", or "active inference" (Clark, 2013), all layers receive the next higher layer's prediction and evaluate it for their own bottom-up prediction in the next time step.

As shown in Figure 1, in any time step, the top layer is the first to update its discrete probability distribution in the state node ( $S$ ), given its prior distribution $\left(S_{t-1}\right)$ and the likelihood, calculated in the error node $(E)$ based on the evidence from the layer below. The updated state node $\left(S_{t}\right)$ will be used as a prediction for the current time step, influencing the layer below as a prior, and a copy will be stored in the error node for comparison in the next time step:

$$
S(\text { MSchema })_{t}=S(\text { MSchema })_{t-1} E(M S e q)_{t-1}
$$

Next, the state node at the layer of motor sequences will be updated given its prior distribution, the prediction from the motor schema layer and the likelihood, calculated from the evidence in the layer below:

$$
S(M S e q)_{t}=S(\text { MSchema })_{t} S(M S e q)_{t-1} E(\text { MPrim })_{t-1}
$$

The resulting posterior distribution will be sent as prediction to the layer below, and as evidence to the layer above. Finally, the state node at the motor primitive layer will receive an update given its prior from the last time step, the posterior from the motor sequence layer and the likelihood of the received sensory evidence ( $o$ ) given all motor primitives:

$$
S(\text { MPrim })_{t}=S(\text { MSeq })_{t} S(\text { MPrim })_{t-1} E(o)
$$

For a better understanding of the process of how the model matches the input to its hierarchical representation, see Figure 2 . We have recorded handwritten capital letters using a graphical tablet. All sequences of drawing the 26 characters of the alphabet are stored with a sampling rate of 25 frames per second. From this dataset (12 primitives, mapping onto 26 sequences, mapping onto 26 schemas) we can trigger the model to draw a character, and simulate the model perceiving somebody's drawing of a character in real-time (by simply feeding the trajectories into the system as input one coordinate after the other). Figure 2 depicts three steps in the prediction-based recognition process that leads to a high probability of perceiving the drawn character.

## Precision

The sensorimotor hierarchy learns motor sequences and motor schemas online, with each layer having to decide whether to add a new representation or not. One cognitively plausible

Figure 2: Prediction-based recognition process of the character $L$ being drawn: black dots indicate input coordinates, red dotted lines represent matched motor primitives.
way to determine the need to extend upon the available motor representations is to calculate the precision of each layer's prediction against the evidence in the next time step. Friston and Frith (2015) used precision (the inverse of the variance between prior and posterior probability distributions) as a sort of cortical gain control or neuro-modulation, as to control the influence of the feedback that their Songbird models received upon their song production. We use it as a measure of how well our model can predict its environment and update or extend it according to how similar the prior $\left(P=S_{t-1}\right)$ and posterior $\left(Q=S_{t}\right)$ are:

$$
\operatorname{Pr}(P, Q)=\frac{1}{\operatorname{Var}(Q-P)}
$$

This enables each layer to evaluate its predictive power and, by thresholding, to decide whether to extend its repertoire.

## Active inference

Following the assumption that overt action is basically actionoriented predictive processing (Friston, Daunizeau, Kilner, \& Kiebel, 2010), we allow high-precision prediction at the layer of motor primitives to be acted out. This leads to overt and automatic enactment of correctly predicted actions, similar to the automatic imitation seen in patients suffering from echopraxia (Ganos, Ogrzal, Schnitzler, \& Münchau, 2012). To control this motor execution, we introduced a signal into the top-layer of the hierarchy, which acts as a motor intention for a specific motor schema, including a strong boost of this motor schema's probability. This percolates down the hierarchy to boost associated representations and informs about the intention to act. Once it reaches the lowest layer of the hierarchy, and combined with the high precision threshold, the act to produce the motor representation will be allowed.

With the hierarchical model in place, we set out to find mechanisms to distinguish activations that stem from own action from those arising due to the interaction partner's action. One way is to make sure that the perceived action outcomes are correctly attributed. That is, we need to look at creating SoA, i.e., the sense that an action is self-generated.

## Self-other distinction and sense of agency

How does the human brain distinguish between information about ourselves and others? Or to be more specific, how can we distinguish ourselves from others so that we do not falsely attribute an action outcome to ourselves? These questions pertain to the more general mechanisms that give rise to a sense of "feeling of control", agency, and "self". Generally, a person's SoA is believed to be influenced through predictive and postdictive (inferential) processes, which when disturbed can lead to misattributions of actions as in disorders as for example in patients suffering from schizophrenia (van der Weiden, Prikken, \& van Haren, 2015). We aim to identify mechanisms in order to model these processes and their integration into a combined SoA.

The predictive process makes use of people's ability to anticipate the sensory consequences of their own actions. It allows to suppress, i.e., decrease the intensity of incoming signals which enables people to distinguish between self-caused actions and their outcomes and those actions and outcomes caused by others. One account to model these processes is based on inverse and forward models to account for disorders of awareness in the motor system and delusion of control (Frith, Blakemore, \& Wolpert, 2000). This view suggests that patients can no longer link their intentions to their actions, that is they are conscious of their intention, but not of the sensory consequences of the action. As research into schizophrenia has shown, reliable and early self-other integration and distinction is important not only for the correct attribution of SoA, but also in turn for the correct attribution of intentions and emotions in social interactions. This even suggests that the attenuation of perceived sensory outcomes correlates with activation in the mirror neuron system (van der Weiden et al., 2015). Weiss, Herwig, and Schütz-Bosbach (2011) showed that there is a social aspect to predictive processes that influence SoA by comparing perceived loudness of auditory action effects in an interactive action context. They found that attenuation occured also in the interactive context, comparable to the attentuation of self-generated sound in an individual context.

The postdictive process relies more on inferences drawn after the movement in order to infer whether our intentions are contingent and consistent with the observed events (Wegner \& Wheatley, 1999) and is also influenced by higher-level causal beliefs and thoughts. One important aspect of this inferential process relies on the temporal aspects of actionoutcome integration. It was shown that increasing action outcome delay decreases feeling of control (Sidarus, Chambon, \& Haggard, 2013). This is related to the "temporal binding window" (Colonius \& Diederich, 2004), in which the sensory signals related to the outcome of an action are integrated. The width of the window is dependend on the predictability of the action outcome. Since we have more experience in predicting our own body, the temporal binding window is more narrow for own action outcomes than for other people's actions. Being able to make such a distinction allows people to monitor,
infer and distinguish between causal relations for own and other's behavior. Another aspect informing the postdictive process relies on the valence attributed to an action outcome, where positive valence of an action outcome leads to stronger SoA (Yoshie \& Haggard, 2013).

In sum, there are two processes that can inform SoA and hence can help to distinguish actions of self and other in social interaction. A predictive process works on the content of the action, e.g., the motor command and utilizes forward models as a mechanism to predict the to-be-produced motor command. A postdictive process works with higher-level causal beliefs like the intention to act and temporal binding as mechanisms to infer the consistency of the action outcome.

But how do these two processes work together to inform SoA and what if their cues are unreliable? Cue integration was first studied by Moore, Wegner, and Haggard (2009) who found that when predictive cues are absent external cues become more influential. Nahab et al. (2010) found in an imaging study that there is a leading and a lagging network that both influence SoA prior to and after an action. The leading network would check whether a predicted action outcome would be perceived, while the lagging network would make use of these cues to further process SoA leading to its conscious experience. It seems that in order to generate SoA, both systems do not necessarily have to work perfectly together, as there is evidence for a weighted integration of cues for agency based on their reliability (Moore \& Fletcher, 2012). Also, if the reliability of the predictive process was reduced, the system put more weight on the postdictive inferential processes (Wolpe et al., 2014). Furthermore, the fluency of action-selection processes may also inform the selfother distinction, because the success of repeatedly predicting the next actions seem to accumulate over time to inform SoA (Chambon, Sidarus, \& Haggard, 2014).

## Modeling self-other distinction in social interaction

During online social interaction, the sensorimotor system potentially gets involved in simultaneous action perception and production processes. Our goal is to investigate how the prediction-based model can be extended to cope with the social differentiation problem during such dual-use situations. To this end, we integrate three cues from the predictive and postdictive processes into SoA for produced actions: In the predictive process, we have the match or mismatch of the predicted action-outcome. In the postdictive process, we have the intention to act and the delay in the action-outcome for temporal binding. However, it is not obvious how these cues are being integrated. As a first step, we test two simple ways to do so, namely, to connect them conjunctively or disjunctively. A conjunctive connection allows SoA to occur only if it is supported by both processes; in a disjunctive connection only one cue suffices to inform SoA, in a more flexible but potentially more error prone manner.

The predictive mechanism to differentiate self and other
works based on the content of the predictions that are being sent down the hierarchy. As described above, the predictability of actions by itself provides a predictive cue for a feeling of control, or SoA. Thus, the model needs to quantify the success of a prediction about the outcome of an acted-out motor representation. Since we already have a layer's precision as a measure of success of its predictions, we can directly utilize it as a cue to model SoA.

As the postdictive inferential mechanism we model the temporal binding window as a Gaussian with its mean $(\mu)$ at the predicted delay, which is informed by the perceived action duration during learning. The Gaussian's standard deviation $(\sigma)$ is scaled by the model's layer's predictive precision.

Figure 3: A model of self-other distinction based on the prediction of the consequence of an action and the postdictive integration of an intention to act with the perceived consequence of the action during a predicted temporal binding window, scaled by the predicting layer's precision.

In Figure 3 you can see a sketch of how the predictive and postdictive mechanisms work together to infer SoA for the produced action and its consequence that is perceived. The postdictive mechanism for temporal binding will be triggered by the sensorimotor hierarchy's intention to produce an action, in that it will receive a reference to the motor representation to anticipate. Information from this motor representation will then be used to model the temporal binding window. Now, when the anticipated motor representation is perceived the delay until this perception occurred $(x)$ will be used to calculate the likelihood in the temporal binding window's Gaussian,

$$
\operatorname{lh}(\sigma, \mu, x)=\frac{1}{l h_{\max }} \frac{1}{\sigma \sqrt{2 \pi}} e^{-\frac{x-\mu^{2}}{2 \sigma^{2}}}
$$

with $\sigma$ being scaled by precision (Pr), i.e., trust in the model's predictions. The resulting likelihood will be scaled to $l h_{\max }$, the Gaussian's peak. This postdictive cue has to be combined
with the predictive cue of the general precision of the predictions. We do this by assuming a winner takes all estimate for the predictive and postdictive cues, with a threshold at $50 \%$ probability. Postdictive and predictive cues will then be connected conjunctively or disjunctiveley to reach an estimate for a combined SoA. Since fluency is important for SoA (Chambon et al., 2014), we will integrate this estimate over time. The agency estimate will add to the overall SoA through a simplified Kalman filter,

$$
\begin{gathered}
\text { agency }_{t}\left(\text { agency }_{t-1}, \text { agency }_{\text {estimate }}\right)= \\
\text { agency }_{t-1}+\operatorname{Pr} *\left(\text { agency }_{\text {estimate }}-\text { agency }_{t-1}\right)
\end{gathered}
$$

By allowing the agency estimate (agency estimate ) to influence the overall SoA $\left(\right.$ agency $\left._{t}\right)$ only through this filter, strong fluctuations are dampened and with a gain controlled by precision ( $P r$ ) the influence of the estimate will strongly depend on the success of previous predictions. This means that an agency estimate will either have a strong influence if precision is high, or SoA can only accumulate slowly if precision is low.

This is our integrated model of predictive and postdictive mechanisms which will enable the hierarchical sensorimotor system to differentiate between actions initiated from self and others.

## Simulations and Results

To test the combined model's ability to solve the problem of the dual use of the sensorimotor system and differentiate between self and other we simulate a limited social situation. In this situation, the model will write a character while it either receives the correct action-outcome as feedback, or it receives delayed or different feedback than expected. This way we simulate the effect of concurrent perception of an interaction partner's action.

We test three scenarios for each combination of predictive and postdictive cues to form SoA. In the first scenario we trigger the intent to act out a motor schema and the model will perceive its own correct output as feedback. Here, the model will receive both cues correctly. In the second scenario we trigger the same intent to act, but now the model receives feedback with a delay, disrupting the postdictive cue. In the third scenario the model will again be triggered to act, while this time it receives unpredicted action-outcomes. Here, the model can receive correct cues only accidentally. The model will be triggered to produce and perceive the letter $L$ in scenario one and two. In scenario three, the model will perceive the letter $M$ being produced instead. We log the calculated SoA over time for each scenario.

The resulting plots in Figure 4 show SoA in the different scenarios. The upper row shows the resulting plots for the conjunctive and the lower row for the disjunctive cue integration. In scenario one, the integration of cues jumps strongly because predictive precision is high and small irregularities in timing have a strong effect. The conjunctive connection of cues does not allow for SoA in scenarios two and three, because both cues are not available simultaneously. The dis-

Figure 4: Resulting sense of agency over time for each scenario and each connection between predictive and postdictive cues.
junctive connection between cues fares better, since it allows for SoA even when only one of the cues is available.

In dynamic scenarios of concurrent perception and production, with feedback either from own or from other's actions, a more flexible distinction may be supported by results reported in the literature. A disjunctive integration is sound with regard to results where the reliability of the predictive process was reduced and the system put more weight on postdictive processes (Wolpe et al., 2014). Also, Moore and Fletcher (2012) found evidence for a weighted integration based on the cues' reliability. Another aspect which we found to also influence our results, was the fluent correct prediction of actions (Chambon et al., 2014). Especially in the conjunctive scenario one and the disjunctive scenario two, the accumulation of agency estimates over time was disrupted either through prediction-error or temporal binding errors.

Taken together, the results show that the model can correctly attribute its own action outcomes to itself, which contributes to distinguishing itself from an interaction partner. This differentiating role of the motor system and its strong involvement in social cognition was also proposed by (SchützBosbach et al., 2006). Our cognitive model and its simulation results support this suggestion.

## Conclusion

We have presented a predictive hierarchical model of the sensorimotor system, integrated with a model of self-other distinction that can solve the dual-use problem in dynamic social situations. Furthermore, we presented simulation results of different scenarios of simultaneous perception and production. We compared them to the literature on SoA and the influence of the motor system on social cognition. This comparison suggests that our model can correctly attribute SoA for its own actions, using a more flexible (disjunctive) integration of predictive and postdictive cues.

Taken together, our modeling approach supports the motor system's role in social cognition. Still, the literature on the social brain suggests that motor cognition, as well as the distinction of self and other are influenced by higher level
processes, causal beliefs, and by the mentalizing network.
We agree that the interplay between mentalizing and mirroring needs to be incorporated to meet the demands of truly social systems in interaction scenarios with multiple agents. In earlier work, we already combined our previous model of the sensorimotor system with a mentalizing model in a social scenario with two virtual agents (Kahl \& Kopp, 2015).

In future work, we want to improve our setup by making use of the differentiating information provided by the present model to inform higher-level cognition through an interplay with the mentalizing system. We conjecture this interplay can yield the distinction between one's own and an interaction partner's beliefs needed in social interaction, where informed reciprocity is the key to efficient and successful communication.

# A transfer advantage of learning diagrammatic representations of mathematics 

Jennifer A. Kaminski (jennifer.kaminski@wright.edu)<br>Department of Mathematics and Statistics, Wright State University 3640 Colonel Glenn Hwy, Dayton, OH 45435 USA

#### Abstract

This study examined learning and transfer of a simple mathematical concept when learning a symbolic sentential format versus learning a diagrammatic format. Undergraduate college students learned an instantiation of a cyclic group and were then given a test of a novel isomorphic group of the same order followed by a test of a novel non-isomorphic group of a higher order. The results were that both the sentential and the diagrammatic formats led to successful learning and transfer to the novel isomorphic group. However, only learning from the diagrammatic representation produced successful transfer to the non-isomorphic group. These findings suggest that learning a diagrammatic representation of a mathematical concept can have transfer advantages over learning strictly sentential formats.

Keywords: Learning; Transfer; Mathematics; Diagrams.

## Introduction

Mathematical concepts are often difficult for students to acquire. Part of this difficulty may be related to the fact that mathematics is generally expressed with abstract symbols, such as variables. Mathematical symbols can be challenging for students to interpret and use, leading to misconceptions and obstacles to learning. For example, many algebra students believe that if $x$ is an integer, then $y$ is the next larger integer (Wagner, 1981, 1983). Another common misconception is that equivalent equations with different variables, such as $7 \times w+22=109$ and $7 \times n+22=109$, have different solutions (Wagner, 1981, 1983).

Other evidence for the difficulty of using symbols comes from comparing performance on purely symbolic tasks to analogous contextualized tasks and finding an advantage for reasoning and problem solving in the contextualized formats (e.g. Saxe, 1988; Koedinger \& Nathan, 2004; Koedinger, Alibali, \& Nathan, 2008). For example, students are frequently more successful solving simple algebra problems when presented as story problems than when presented as symbolic expressions (Koedinger \& Nathan, 2004; Koedinger, et al, 2008). The advantage of contextualized situations may be that when contexts are familiar to students, they can derivate mathematical structure from the context itself (Bassok, 1996, 2003). For instance, given a situation involving 12 tulips and 3 vases, students tend to divide 12 by 3 instead of performing another arithmetic operation because a group of flowers is typically divided between a number of vases. Familiar contextualization may also facilitate learning of new concepts (e.g. Kaminski, Sloutsky, \& Heckler, 2013).

Although contextualized representations of mathematics may sometimes facilitate reasoning, problem solving, and initial learning, such representations can hinder transfer of mathematical knowledge to novel situations (Kaminski, Sloutsky, \& Heckler, 2008, 2013). When college students learned an algebraic system through a familiar context that facilitated initial learning, they were unable to transfer knowledge to a novel analogous domain. However, students who learned the same concept through a generic symbolic format successfully transferred knowledge. Transfer failure may be due to the fact that contextualized real-world instantiations of mathematics communicate more nonessential information than simple symbolic instantiations (Kaminski et al, 2013). This nonessential information is often salient and may divert attention from the less salient mathematical structure, making it difficult to recognize the mathematical structure in novel, superficially dissimilar situations (Kaminski, et al, 2008, 2011, 2013).

However, an important question remains. Does all extraneous information hinder transfer? Perhaps some representations of mathematics have extraneous information that can facilitate transfer. One possible type of representation is a visual display that helps communicate the relevant global relational structure. Such displays are diagrams, and include graphs, matrices, tables, as well as some nonstandard representations. These visual displays instantiate a system with minimal extraneous information, but contain perceptual information that helps spatially organize the elements of the system according to the relevant relational structure. Previous research has demonstrated that diagrams may have advantages over sentential representations for reasoning and problem solving (e.g. Cheng, 2002; Lakin \& Simon, 1987), analogical transfer (e.g. Gick \& Holyoak, 1983; Pedone, Hummel, \& Holyoak, 2001), and non-isomorphic transfer (Novick \& Hmelo, 1994).

The advantage of an effective diagram over a sentential representation may be increased salience of the relations between elements and an ability to accommodate a different number of relevant elements. Consider the example of probability. A sentential format would list relevant probabilities of events $A, B, C$, as $P(A), P(B), P(A \mid C)$, etc. A tree diagram could visually highlight the relationships between events and could be modified to include additional events. By doing so, diagrams may help to communicate higher-order structure, which may allow the learner to transfer knowledge not only to isomorphic situations (i.e. structurally analogous situations) but also to non-isomorphic situations of the same structural class.

For pedagogical reasons, it is important to examine conditions that promote both isomorphic and nonisomorphic transfer because application of mathematical knowledge involves both isomorphic transfer (e.g. transfer of solution strategies to analogous story problems) as well as non-isomorphic transfer (e.g. solution techniques for systems of two variables applied to systems of more than two variables). From a theoretical perspective, it is important to understand how both types of transfer processes are related. Many theories of analogical transfer posit that successful transfer requires alignment of structure across a familiar domain and an isomorphic target domain; this alignment places analogous elements in a one-to-one correspondence across domains (e.g. Gentner, 1983, 1988; Gentner \& Holyoak, 1997; Holyoak \& Thagard, 1989, 1997). From multiple instances, learners may form abstract schematic representations that reflect commonalities of the instances (Gick \& Holyoak, 1983; Novick \& Holyoak, 1991; Reed, 1993). These theories can account for transfer of mathematical knowledge across isomorphs. However, it is unclear how they can account for transfer across nonisomorphic domains in which structure cannot be aligned across instances. If learning of diagrams allows transfer to non-isomorphic situations, do learners align structure when transferring to an isomorphic situation?

The goal of the present research was to examine learning and transfer of a novel mathematical concept from a strictly sentential symbolic representation versus a diagrammatic representation. This study examined both isomorphic transfer (transfer to another system with the same relevant structure and the same number of elements) and nonisomorphic transfer (transfer to another system with the same relevant structure but a different number of elements). When learning the strictly sentential representation, participants may acquire only knowledge of isolated relations between elements and may not gain insight into the higher-order mathematical structure. When learning the diagrammatic representation, participants may learn more than isolated relations between individual elements. They may acquire a structural representation of the concept that can be modified to include more elements than initially learned. As such, the diagram may help communicate higher-order structure, and learning this diagram may facilitate recognition of this structure in novel isomorphic domains as well as non-isomorphic domains of the same type of structure. Therefore, it is hypothesized that both the sentential and diagrammatic representations will result in successful learning and isomorphic transfer, but only the diagrammatic representation will result in successful nonisomorphic transfer.

The concept under consideration was that of a cyclic group (defined in the Method section). Participants learned an instantiation of a cyclic group of order 3 (i.e. three unique elements) with or without the inclusion of a diagram. Participants were then tested on a novel cyclic group of order 3 to examine isomorphic transfer. They were also asked to match analogous elements across domains to
investigate whether there are differences in structural alignment when learning a strictly sentential versus a diagrammatic representation. Afterward participants were tested on a novel cyclic group of order 4 (i.e. four unique elements) to examine non-isomorphic transfer.

## Experiment

## Method

Participants Fifty-eight undergraduate students from a large Midwestern university participated in the experiment and received partial credit for an introductory psychology course.

Materials and Design The experiment included three phases: (1) training and testing in a learning domain, (2) testing in an isomorphic transfer domain, and (3) testing in a transfer domain of the same structure as the learning domain but higher order. Participants were randomly assigned to one of three conditions (Diagram, No Diagram, or Baseline). Participants in the Diagram and No Diagram conditions learned different instantiations of a cyclic group of order 3 during the first phase of the experiment. Participants in the Baseline condition proceeded directly to phase 3, omitting phases 1 and 2. The purpose for the Baseline condition was to measure spontaneous performance in the non-isomorphic transfer domain, without prior instruction on the concept. The isomorphic transfer domain (phase 2) was used in several previous studies (Kaminski, et al, 2008, 2013); without first learning an isomorphic domain, participants were unable to score above chance on this transfer domain.

The learning domain and two transfer domains were artificially constructed instantiations of the concept of a cyclic group. The learning domains and the first transfer domain were of order 3 (i.e. had three unique elements), and the second transfer domain was of order 4 (i.e. had four unique elements). A Cyclic Group of Order $n$ is a set of $n$ elements, or equivalence classes, and an associated binary operation over which the following algebraic properties hold: associativity, commutativity, existence of identity, and existence of inverses. This means that if the operation is denoted by "+", then the following are true. The Associative Property states that for any elements, $x, y, z$, of the set, $(x+y)+z=x+(y+z)$. The Commutative Property states that for any elements $x, y$ of the set, $x+y=$ $y+x$. Also, there is an element, $I$, in the set called the Identity Element, such that for any element, $x, x+I=x$. Finally, for any element, $x$, there exists an Inverse Element, $y$, such that $x+y=I$. In addition, a cyclic group is a group that can be generated by a single element. This concept is equivalent to addition modulo $n$.

The concept of a cyclic group can be instantiated in an unlimited number of ways. The instantiations used for both the Diagram and No Diagram conditions involved three arbitrary symbols, $\boldsymbol{\square}$, and 1. Participants learned the principles of a cyclic group instantiated as associations
between the symbols. The difference between the conditions was the presence or absence of a diagram, the procedure for using the diagram, and the associated cover stories.

In the No Diagram condition, the instantiation was described to participants as rules of a symbolic language in which combinations of two or more symbols yield a predictable resulting symbol. Statements were expressed as symbol 1 symbol $2 \rightarrow$ resulting symbol. Table 1 shows the symbols, the specific rules, and examples. In the Diagram condition, the cyclic group was described to participants as rules for a code-breaking device that can be used to decode sequences of symbols. The decoding device appeared as a circle with three equally spaced positions marked. One symbol was placed at each position. Given a sequence of two or more symbols, the decoder could be used to determine a resulting symbol by starting at the first symbol and moving clockwise around the dial shown in Figure 1. Figure 1 also presents the procedure for using the decoder, the specific rules, and an example.

In both conditions, participants were taught the same associations between sequences of symbols and saw the same sentential statements, symbol 1 symbol $2 \rightarrow$ resulting symbol. The rules, examples, and test questions were identical in both conditions. Aside from different cover stories, the only difference between the conditions was the inclusion of the diagrammatic representation (i.e. the decoding device) and its associated procedure in the Diagram condition. At the end of phase 1, participants were tested with a 24 -question multiple-choice test.

The second phase of the experiment was testing of an isomorphic transfer domain. This transfer domain was identical for both conditions and was also a cyclic group of order 3 involving three images of perceptually rich objects. It was described as a children's game where children sequentially point to objects and "the winner" points to a final object (see Transfer Domain 1 in Table 1). Participants were told that the correct final object is specified by the rules of the game (which were the rules of a cyclic group). Furthermore, in both conditions they were told that the rules were like those of the system they just learned. No explicit training in the transfer domain was given; instead, participants were shown a series of examples from which the rules could be deduced (see operands and results for Transfer Domain 1 in Table 1). Participants were asked to figure out the rules of the game by using their knowledge of the learned system. Then they were tested with a 24 -question multiple-choice test, isomorphic to the test in the learning phase of the Diagram and No Diagram conditions, but using the elements of the transfer domain.

Following the test, participants were asked to match analogous elements across the learning and transfer domains. Correct matching of elements was taken as an indicator of correct structural alignment between the learning and transfer domains. For cyclic groups of order 3, there are two possible correct mappings between groups. The identity element is unique; therefore a correct mapping must align these two elements across domains. However,
the mapping between remaining two elements is not unique. Therefore, a response was considered correct if (a) the mapping was one-to-one and onto (i.e., each learning element corresponded to a single transfer element and each element of the transfer elements were used) and (b) the mapping preserved the identity element. In other words, if a participant used each of the group elements and mapped the identity element correctly, then the response was correct. Because the critical aspect was correctly choosing the identity element and most participants were expected to form mappings that were onto, $33 \%$ accuracy was used as a conservative measure of chance for a group of participants.

The third phase of the experiment was testing of a nonisomorphic domain of the same structure as the learning domain (i.e. a cyclic group of order 4). Participants were given a paper and pencil ten-question multiple-choice test (see Table 2) and told that the knowledge of the system they learned first can help them figure out the new system. They were also given five example statements (the operands and results shown in Table 2) from which the complete set of rules could be deduced.

Procedure Participants were seen individually in a lab on campus. Phases 1 and 2 were presented on a computer. Participants proceeded at their own pace, with their responses recorded by the computer. The learning phase consisted of approximately 80 slides and required approximately 15 minutes to complete. The transfer phase (phase 2) consisted of 48 slides and took on average 10 minutes to complete. The second transfer phase (phase 3) took participants approximately 8 minutes to complete. All material in phase 3 was presented on paper.

## Results

Four participants (two Diagram and two No Diagram) were removed from the analysis because they failed to learn

Table 3. Mean accuracy (percent correct) on learning and isomorphic transfer. Note: Standard deviations are presented in parentheses. Chance performance is $37.5 \%$

|  | Learning | Transfer |
| :---: | :---: | :---: |
| No Diagram | $78.9(14.5)$ | $78.5(17.8)$ |
| Diagram | $85.2(8.95)$ | $74.5(22.1)$ |

the concept in phase 1 ; their learning scores were less than 11 and no different than the chance score of 9 (i.e. $37.5 \%$ ).

Note that for the following analyses, learning scores and isomorphic transfer scores were not normally distributed in the Diagram condition; the distributions were negatively skewed ( $S W s<.89, d f \mathrm{~s}=18, p \mathrm{~s}<.04$ ). In addition, nonisomorphic transfer test scores had bimodal distributions in both conditions. Therefore, non-parametric analyses were done to examine each of these scores.

Participants in both conditions successfully learned the concept (see Table 3). Learning scores were above chance in both conditions, Wilcoxon Signed Ranks Test, $Z \mathrm{~s}>3.72$, $p \mathrm{~s}<.001$. There were no significant differences in learning levels between conditions, Mann-Whitney $U$ test, $U=123.5$, $p=.22$.

In phase 2 (i.e. testing of an isomorphic transfer domain), participants also performed well in both conditions (see Table 3). Scores were above a chance score of $37.5 \%$, in both conditions, Wilcoxon Signed Ranks Test, $Z \mathrm{~s}>3.63$, $p \mathrm{~s}$ $<.001$. Note that previous research demonstrated that without initially learning an isomorphic domain, participants were unlikely to score above chance on this transfer task (Kaminski, et al, 2008, 2013). Therefore, it appears that participants in both conditions successfully transferred structural knowledge acquired in phase 1 to answer questions about the isomorphic domain in phase 2. No significant difference in transfer scores between the two conditions was found, Mann-Whitney $U$ test, $U=151.0, p=$ .74 .

In addition, most participants in both conditions accurately matched analogous elements across the learning and isomorphic transfer domains ( $83 \%$ in the Diagram condition and $78 \%$ in the No Diagram condition), suggesting that they successfully aligned analogous structure across the two domains. The percent of participants in both conditions was well above chance of $33 \%$ and not different between conditions, Fisher Exact test, $p \mathrm{~s}=1.00$.

While there were no differences in performance levels between conditions for phases 1 and 2, there were significant differences in performance in phase 3 (i.e. testing on a non-isomorphic domain of similar structure). Scores in the Diagram and No Diagram conditions had bimodal distributions; Table 4 presents the frequency of scores at different levels. Transfer scores were higher in the Diagram condition ( $M=67.8, S D=9.69$ ) than in the No Diagram condition ( $M=41.1, S D=7.79$ ), Mann-Whitney $U$ test, $U=$

Table 4. Percent of participants in each condition scoring at different levels on the non-isomorphic transfer task.

|  | Accuracy Level |  |  |
| :---: | :---: | :---: | :---: |
|  | $\underline{\text { Low }}$ | $\underline{\text { Middle }}$ | High <br> $(0-40 \%)$ |
| $(50-70 \%)$ | $(80-100 \%)$ |  |  |
| Baseline | 61 | 33 | 6 |
| No Diagram | 61 | 17 | 22 |
| Diagram | 39 | 0 | 61 |

$97.5, p<.04$. Furthermore, scores in the Diagram condition were higher than scores in the Baseline condition ( $M=$ $41.1 \%, S D=19.1 \%$ ), Mann-Whitney $U$ test, $U=107.0, p<$ .04 , one-tailed. However, scores in the No Diagram condition were not significantly different than those in the Baseline, $U$ $=144.5, p=.58$. This finding suggests that the majority of participants in the Diagram condition were able to transfer knowledge of the cyclic group order 3 to the non-isomorphic cyclic group of order 4, but the majority of participants in the No Diagram condition were not able to do so.

## Discussion

The goal of the present study was to investigate transfer of mathematical knowledge when learning a strictly sentential representation versus learning a diagrammatic representation. This study considered transfer to a novel isomorphic domain as well as transfer to a novel nonisomorphic domain of the same structural class. Both formats resulted in equally successful learning and isomorphic transfer. However, participants who learned the diagram were more successful at non-isomorphic transfer than those who learned only the sentential format. These findings suggest that although the diagram added nonessential information, this information did not hinder learning or isomorphic transfer. Moreover, the inclusion of this information resulted in a clear advantage for nonisomorphic transfer.
Previous research has demonstrated that learning instantiations that include extraneous information hinder transfer of mathematical knowledge to novel isomorphs because the extraneous information is generally salient and likely diverts attention from the relevant structure (Kaminski et al, 2008, 2011, 2013). Compared to strictly sentential representations, diagrams also communicate nonessential information to the learner. For example, in the present study, it is not necessary to include the diagram; the same rules and associations were learned equally well in the No Diagram condition. Clearly standard diagrams such as tree diagrams, matrices, and graphs also communicate nonessential information. However while the information added by a diagram is nonessential, it is not necessarily irrelevant. Effective diagrams use visual information to spatially organize elements of a system in a way that
highlights relations and relevant structure and does not divert attention from the structure. Such diagrams may help to communicate global structure of the system in manner that can be modified if necessary to incorporate a different number of elements.

In the current study, the diagram was circular and likely helped to communicate the cyclic nature of the group and the fact that any element can be obtained as a result of operations involving the other elements. It is more difficult to recognize the cyclic nature of the relationship between elements in the strictly sentential format. Even if learners had constructed a schematic representation of the concept from the sentential format without the diagram, the schema appears to reflect only local associations between three elements and not a more global structure that can be modified and applied to non-isomorphic situations.

With regard to structural alignment, participants in both conditions were equally accurate at matching analogous elements, possibly suggesting structural alignment. However it is not clear that this element-level matching is necessary when learning the diagram or whether global structure can be mapped from learned to target domains without one-to-one correspondence of elements.

Successful non-isomorphic transfer from learning the diagram suggests that participants have formed a more sophisticated internal representation of a structural class of mathematical entities, in this case cyclic groups of different orders. Recognizing that different mathematical entities can fall into the same structural categories is an important part of advancing mathematical knowledge. For example, algebra students should be able to modify techniques for solving systems of equations of two variables to solve systems of equations of more than two variables. Similarly, college students should recognize that slope of a line is an instance of derivative of a function. An effective diagram, if available, may help illuminate structure in a way that allows modification of the number of elements. Standard mathematical diagrams such as matrices, graphs, networks, and Venn Diagrams do precisely this.

At the same time, there may be limitations to the benefit of diagrams. The inclusion of diagrams may not always facilitate initial learning. Correct interpretation and use of diagrams requires additional learning beyond learning standard sentential representations. For some combinations of concepts, diagrams, and learners, such as those considered in this study, a diagram is easily learned. However, this is not always the case. For example, in middle school students, diagrams provided a benefit for solving algebraic word problems only for older students and high-achieving students, but not for younger students and lower-achieving students (Booth \& Koedinger, 2012). Some concepts may be simple enough to be learned without such additional representations. For more difficult concepts, some learners may be unable to fully learn the diagram and the relationship between the diagram and standard sentential formats such as equations.

It is also important to note that while a diagram is a visual representation of the elements and relations of a system, it is meaningless without knowledge of how to interpret it. The diagram used in the present study involved the visual representation in Figure 1 along with the procedure of how to use it. The same is true for common mathematical diagrams such as multiplication tables and Cartesian graphs. These well known diagrams easily communicate information to us only because we have been explicitly taught procedures for constructing and interpreting them.

Learning diagrams in addition to standard sentential mathematics may require additional effort. For some learners and some diagrams, this may be challenging. However, the benefit of well-designed diagrams is likely worth the effort. Once learned, diagrams likely can provide advantages for transfer to isomorphic situations and many non-isomorphic situations.

#### Abstract

Recent experimental evidence suggests that adults incorporate speaker knowledge into the derivation of pragmatic implicatures. Developmental studies report that 5 -year-old children also succeed in taking speaker knowledge into account in implicature computation, but 4 -year-olds fail. The present study investigated the pragmatic competence of 4-year-olds, specifically the ability to incorporate speaker knowledge into the derivation of ad hoc scalar implicatures. Using a simple paradigm inspired by referential communication, we found that 4 - year-olds are able to incorporate speaker knowledge into implicature derivation. These results have implications for our understanding of the linguistic, pragmatic, and epistemic abilities of young children.

Keywords: implicatures; pragmatics; speaker knowledge

## Background

As established by Grice (1989), communication involves partners in a conversation working towards the same cooperative goal (cf. also Sperber \& Wilson, 1986). To that end, speakers must be as informative as required by the purpose of the exchange. If a speaker is less than fully informative, as in (1), the listener will assume that - as far as the speaker knows - the stronger alternative in (2) is not true.
(1) Some chipmunks collect acorns.
(2) All chipmunks collect acorns.

The inference that the stronger statement in (2) does not hold is known as a scalar implicature and requires pragmatic reasoning. Scalar implicatures take their name from the fact that they rely on a comparison to a lexical item on an informativeness scale that the speaker could have used but did not (Grice, 1989). In the case of (1) and (2), the lexical alternatives involved form a scale ordered in terms of logical strength (Horn, 1998). Furthermore, this logically ordered scale is a feature of the language that needs to be accessed in order for the hearer to compute an implicature. Other types of scalar implicatures rely on ad hoc scales that depend upon contextual information. For instance, a speaker can utter (3) to communicate that the stronger statement in (4) does not hold:
(3) Chip and Dale collect acorns.
(4) Chip, Dale and Max collect acorns.

Past findings in the literature have indicated that children struggle with deriving scalar implicatures until late in development: unlike adults, they fail to reject weak (underinformative) statements when a stronger alternative is true (Chierchia et al, 2001; Noveck, 2001). Eye-tracking methods have also revealed weaknesses in early implicature computation (Huang \& Snedeker, 2009). However, 5-yearolds have increased success in computing scalar implicatures when task demands set up an expectation of a stronger utterance (Papafragou \& Musolino, 2003; Skordos \& Papafragou, 2016; Katsos \& Bishop 2011; see Papafragou \& Skordos, 2016 for a review), and even 3-yearolds succeed in deriving ad hoc scalar implicatures in a simple referent selection task (Stiller, Goodman, \& Frank, 2015; cf. also Barner, Brooks, \& Bale, 2011). At present, there is much discussion in the field about whether early failures with implicatures were due to children's increased pragmatic tolerance in judgment tasks (Katsos \& Bishop, 2011), lack of linguistic processing abilities (Chierchia et al, 2001; Reinhart, 2004), inability to access stronger lexical alternatives (Barner et al., 2011), failures in assessing which alternatives are conversationally relevant (Skordos \& Papafragou, 2016), or some combination of these factors.

The present study seeks to incorporate speaker knowledge into the task of implicature derivation (Sauerland, 2004; Fox, 2007; Chierchia, Fox, \& Spector, 2009). There is evidence that adults consult the speaker's knowledge state when computing implicatures (Bergen \& Grodner, 2012; Breheny, Ferguson \& Katsos, 2013). For instance, the hearer upon encountering a statement such as (1) or (3) is justified in concluding that the listener does not know whether the stronger alternative is true (or, in other cases, that the speaker knows that the stronger alternative is false). However, developmental studies have shown that young children have difficulties with such epistemic aspects of implicature computation. Hochstein and colleagues (2016) conducted a study with 4 - and 5 -year-olds investigating their ability to compute non-scalar "ignorance" implicatures which require the incorporation of the speaker's knowledge state into their derivation. They found that 5 -year-olds were able to succeed on this task but 4-year-olds failed.

In a study most closely related to the present experiment, Papafragou, Friedberg and Cohen (in press) found a similar pattern. In that study, 4- and 5-year-old children watched
short videos of two twins. In one video, an observer only saw part of one twin's action, and in the other video, the observer saw the whole action. Children themselves had access to the completed action that was the same in both videos (e.g., a girl colored a star). Children then heard a statement made by one of the observers about the action (e.g. 'The girl colored some/all of the star') and had to decide which observer said it. Five-year-olds were able to successfully incorporate speaker knowledge into their pragmatic reasoning, attributing weak statements to the partly informed observed and strong statements to the fully informed observer, but 4 -year-olds struggled. In later manipulations, when the observers' access to the actions was identical to the children's (and hence there was no need to reason about someone else's belief), 4-year-olds' performance improved.

The present paper revisits the issue of whether 4-year-olds can incorporate the speaker's knowledge state into the computation of implicatures, as 5 -year-olds and adults have been shown to do. The task designed for this experiment was created with the goal of keeping task demands as simple as possible. The design borrows from the referential communication paradigm (see, e.g., Nadig \& Sedivy, 2002). In this paradigm, speaker knowledge is established through the speaker's visual perspective without the need to set up an elaborate background scenario (cf. also Matthews et al., 2006). The task also has a clear goal (referent selection; see Stiller et al., 2014) and targets ad hoc scalar implicatures that rely on contextual knowledge set up within the experimental scene.

## Experiment

## Participants

Thirty-one 4-year-olds (mean age: 4;6, range: 4:0 to 4:11, 16 female) participated. Children were recruited from Newark (DE) preschools. A control group of 26 adult participants was also tested. Adult participants were recruited with a HIT posted on MTurk.

## Method

For the test phase, participants were shown pairs of pictures displayed side by side on a laptop screen (see Figure 1). Within a pair, each picture showed the same person sitting across a table behind a two-compartment box with identical objects (e.g. a spoon and a bowl), facing the camera. In one picture, the girl could see the contents of both compartments in her box (full access box), but in the other, she could only see the content of one compartment (e.g. the spoon) because the other compartment was blocked (limited access box). The participants could see the full contents of both boxes. Within a pair, the first (leftmost) picture was displayed for 2 seconds, followed by the appearance of the second picture that remained on the screen for 2 seconds. Then an audio recording of a sentence was heard (both pictures remained on the screen). The
sentences were either weak (e.g. "I see a spoon") or strong (e.g. "I see a spoon and a bowl").

Figure 1. An example stimulus.
Before the test phase, children were introduced to the limited access box and an explanation of how it worked. The explanation involved showing a picture of the girl with the limited access box in front of her and one object in the hidden compartment. The children were asked whether they could look through the open and closed compartments. For the closed compartment, the children were then asked why they could not look through it (answers typically mentioned that it was closed or blocked). They were asked if they thought the girl could look through the blocked compartment. The children were then asked whether the girl knew there was a hidden item in the blocked compartment. To remind children of the properties of the boxes, after the first 4 test trials, children were again asked whether they could look through both compartments of the limited access box and whether they thought the girl could look through both sides and knew there was an object there (for the importance of such reminders of the visual properties of the display, see Nadig \& Sedivy, 2002). Children who answered "yes" both times to the question of whether the girl knew there was an object in the hidden compartment were excluded because they did not understand the nature of the limited-access box $(\mathrm{N}=6)$.

The participants were given two pre-test trials. These trials involved a two-picture set-up, as in the test phase. Participants were told that they would see some pictures of the girl looking at a box that was open on both sides, and then looking at a box that was open on one side and closed on the other. The participants were told that the girl was going to talk about only one of the boxes. They were instructed that they would hear a sentence and would have to decide which box she was talking about. For the first pretest trial, the items in the two boxes were different across boxes rather than identical as in the test trials (a book and a cup in one box; an orange and a spoon in the other). The sentence unambiguously described the full access box ("I see a book and a cup"). For the second pre-test trial, the boxes had different objects again: the full access box had two objects but the limited access box only had an object in
the closed compartment, but no object in the open compartment. The sentence was: "I see nothing." Neither of the pre-tests involved perspective taking. One child failed both pre-tests and was excluded.
The test phase was identical to the pre-test trials, but with identical objects in the two boxes. After hearing either the weak or strong sentence, participants were asked, "Which box is she talking about?", and had to point to the correct picture. The pictures were counterbalanced in terms of whether the limited access box was on the left or the right within the pair. Participants were given 4 strong and 4 weak sentences in a mixed order. Two presentation lists were created; assignment of Type of Sentence (strong, weak) to pairs of pictures was counterbalanced across lists.

In order to succeed on the task, participants had to inhibit their own perspective, since both boxes had identical contents from the children's point of view. If participants successfully incorporated the perspective and knowledge of the speaker, they should say that the strong statement "I see a spoon and bowl" described the full access box, because the spoon was not visible to the speaker in the limited access box. For weak statements, such as "I see a spoon," participants should pick the limited access box because, although the full access box also had a spoon, it would be underinformative to only mention the spoon if the speaker could also see a bowl.

## Results

Results are presented in Table 1. In accordance with our predictions and adult judgements, correct answers were defined as choosing the full access box for the strong sentences and the limited access box for the weak sentences. For each of the participants, a mean score across the four trials was calculated for both the strong and weak conditions. Because most of the 4 -year-olds received a score of 0 or 1 in the critical weak condition ( 21 out of 26), participants were divided into passers (score $\geq .75$ ) and failers (score $\leq .50$ ).

Adults performed at ceiling in both the strong and weak conditions. For the 4 -year-olds, Fisher's exact test revealed a marginally significant difference in the number of passers and failers for the strong vs. weak condition ( $\mathrm{p}=.05$, 2tailed). Comparisons across age groups revealed a significant difference between adults and 4-year-olds in the weak condition ( $\mathrm{p}=.01$ ), but no significant difference in the strong condition $(p=1)$. Nevertheless, in the critical 4 -yearold weak condition the number of passers was significantly different from the expected ratio due to chance ( $\mathrm{p}=.029$ ).

Table 1: Task performance.

|  | Classification | Condition |  |
| :--- | :--- | :--- | :--- |
|  |  | Strong | Weak |
| Adults | Passers | 26 | 26 |
|  | Failers | 0 | 0 |
| Children | Passers | 25 | 19 |
|  | Failers | 1 | 7 |

## Discussion

This experiment investigated 4-year-olds' ability to incorporate speaker knowledge into the computation of ad hoc scalar implicatures. The results suggest that 4 -year-olds display the ability to incorporate speaker knowledge into implicature derivation. These findings lower prior age estimates of children's ability to take the epistemic step during implicature computation - but align with reports in the literature about the epistemic ability of very young children in non-linguistic tasks (Surian, Caldi \& Sperber 2007; Baillargeon, Scott \& He, 2010). Notice that epistemic stance per se was not as demanding (see strong sentences): when taking someone else's perspective was combined with computing an implicature that this person could have intended, given their knowledge state (weak sentences), performance dropped.

An interesting question is why 4 -year-olds were able to succeed at this task when they failed at prior studies targeting sensitivity to the speaker's epistemic stance in implicature-computation (Hochstein et al., 2016; Papafragou et al., in press). In the present experiment, 4-year-olds needed to compute implicatures, but they also needed to reason about what a person had access to, determine how that would affect the speaker's utterances, and inhibit their own perspective. Nevertheless, our paradigm was based on a simple, clear way of establishing that someone's knowledge differs from the child's own; furthermore, the present paradigm included a clear conversational goal (the identification of the box that the speaker is talking about). In both of these respects, the current study is simpler than past attempts to link the informativeness of a sentence to a speaker's mental state.

These findings and the paradigm used in this experiment provide fertile ground for a continued investigation into the pragmatic ability of young preschool children. It is possible that children younger than 4 could be found to demonstrate these abilities with an even simpler task. We are currently pursuing this possibility in ongoing work.

# A Hebbian account of entrenchment and (over)-extension in language learning 

Vsevolod Kapatsinski (vkapatsi@uoregon.edu) Zara Harmon (zforough@uoregon.edu)<br>Department of Linguistics, 1290 University of Oregon<br>Eugene, OR 97403 USA

#### Abstract

In production, frequently used words are preferentially extended to new, though related meanings. In comprehension, frequent exposure to a word instead makes the learner confident that all of the word's legitimate uses have been experienced, resulting in an entrenched form-meaning mapping between the word and its experienced meaning(s). This results in a perception-production dissociation, where the forms speakers are most likely to map onto a novel meaning are precisely the forms that they believe can never be used that way. At first glance, this result challenges the idea of bidirectional form-meaning mappings, assumed by all current approaches to linguistic theory. In this paper, we show that bidirectional form-meaning mappings are not in fact challenged by this production-perception dissociation. We show that the production-perception dissociation is expected even if learners of the lexicon acquire simple symmetrical form-meaning associations through simple Hebbian learning.

Keywords: Hebbian learning; word learning; mental lexicon

## Introduction

Extension of frequent forms to novel uses is one of the most common processes in language change, and results in the robust correlation between frequency and polysemy: upon examining a dictionary, it quickly becomes evident that it is the most frequent words that have the largest number of uses (compare get vs. obtain, Piantadosi et al., 2012; Zipf, 1949). Extension of familiar words and constructions to new uses is also one of the major mechanisms driving grammaticalization, a largely unidirectional process through which grammatical morphemes evolve out of lexical sources (Bybee, 2003, 2010). A well-studied example in English is the verb will, which was gradually extended from volitional lexical uses (e.g., I will it to happen) to grammatical future tense uses that no longer imply volition (e.g., I will get fired for suggesting this).

Extension can be observed not only in diachrony but also in online language use. In particular, novel extensions are frequently observed in children's use of both referential terms and verb-argument structure constructions. For example, a child may name a cow a kitty or extend the verb giggle to transitive use, as in don't giggle me (e.g. Naigles \& Gelman, 1995; Pinker 1989). The words that are so overextended tend to be the frequent ones, or else ones that are highly accessible in the moment because they have just been used (Gershkoff-Stowe et al., 2006; for adults, see also Ferreira \& Griffin, 2003; Burke et al., 2004). These patterns parallel the diachronic tendency for frequent words to acquire novel uses.

Crucially, a child can overextend a word in production without overextending it in comprehension. When presented with a word she over-extends in production and asked to pick out all the objects the word can refer to, the child often does not select the objects to which she over-extends the word in production as its possible referents (Naigles \& Gelman, 1995).

In fact, frequency appears to have opposite effects in comprehension and production. Whereas frequent words are extended to new uses in production, frequent words are likely to be restricted to the uses in which they have been experienced. For example, Xu \& Tenenbaum (2007) show that experiencing fep paired with a Dalmatian once leads children to think it plausible that fep refers to all dogs, but three fep-Dalmatian pairings are enough to restrict the set of referents to Dalmatians (see also Ambridge et al., 2008; Brooks \& Tomasello, 1999; Theakston, 2004; Wonnacott et al., 2008, for related results with syntactic constructions). Frequent exposure to a form-meaning pairing appears to convince learners that the form always co-occurs with this meaning.

## The Data

In recent work, we have confirmed the existence of this dissociation in adult learners of a miniature artificial language (Harmon \& Kapatsinski, submitted; Experiment 1). In our study, participants were exposed to a language with two plural suffixes ( $-d a n$ and $-s i l$ ) and two diminutive suffixes (-nem and -shoon). For each participant, one suffix was more frequent than others. Each participant was tested on both comprehension and production.

Participants experienced the language through passive exposure, with nouns bearing the suffixes (e.g. ostodan, zutishoon) presented auditorily, paired with pictures of their referents. Each trial began with a picture of the referent, followed 500 ms later by the spoken word. After the offset of the spoken word, the experiment advanced to the next trial, which began 400 ms later.

Nouns bearing plural suffixes were paired with pictures of multiple large creatures (with the kind of creature determined by the stem), whereas each noun bearing a diminutive suffix was paired with pictures of a single small creature.

For half of the participants $(\mathrm{n}=35)$, those in the Dan condition, the form -dan was more frequent than the others. For the other half, assigned to the Nem condition ( $\mathrm{n}=35$ ), the frequent form was -nem. The competing -sil and -shoon
forms were always equally frequent. The unsuffixed stems constituted the singular non-diminutive form of the noun.

After exposure, participants were tested on both production and comprehension. In the production test, were presented with meanings and asked to express them. Crucially, one of the meanings was a novel one, plural diminutive (multiple small creatures). Each trial began with the presentation of the picture of a novel singular object on the computer screen. The name of the novel object was presented auditorily over headphones as in the training stage. Once the sound finished playing, the picture was removed and replaced with a display of four pictures representing four different meanings: a single object of the same type, a miniature version of the same object, multiple objects of the same type, and multiple miniature objects of the same type. Three of these pictures disappeared, leaving the participants with the one target picture to name (i.e., meaning to express). Participants were asked to generate the form for the target meaning using the stem that was presented and say the form aloud. They had five seconds to do so.

Data were analyzed using logistic mixed-effects models with maximal random-effects structure using the lme4 package (Bates et al., 2015) in R (R Core Team, 2015). Significance was assessed by comparing models with and without a predictor using a log likelihood test. Participants were significantly more likely to use a given form if it was the frequent form during exposure (Figure $1 ; \chi^{2}(1)=21, p<$ .0001). This was not simply an effect of semantic feature frequency, i.e. DIM.PL in Dan, where PL was frequent, was not simply interpreted as PL: the synonym of a frequent form (-sil in Dan and -shoon in Nem) was no more likely to be used to express the novel meaning than the synonym of the infrequent form (-sil in Nem and -shoon in Dan; $p=.9$ ).

Figure 1: An illustration and results of the production test. A suffix is produced more often when it has been experienced more frequently (-dan in Dan and -nem in Nem), both to express the meaning with which it was experienced and to express the novel related meaning (DIMPL)

In the comprehension test, participants were presented with forms and asked to click on the corresponding meaning using the four-picture display briefly flashed in production. The meanings included the familiar meanings as well as the
novel meaning. In this task, participants were less likely to click on the novel meaning given a form that was frequent during exposure (Figure $2 ; \chi^{2}(1)=17, p=.000037$ ). As in production, these effects could not be accounted for by the relative frequencies of the meanings because the synonym of a frequent form was significantly more likely to be mapped onto the novel meaning than the synonym of the infrequent form ( $p<.001$ ). Thus, participants are not simply more likely to click on the more familiar meanings, rather they are more likely to click on familiar meanings in response to the forms that have been frequently paired with them in training. For forms that have been paired with the frequent meaning less frequently, the novel meaning is preferred, despite the fact that these forms are as frequent as synonyms of infrequent forms.

Figure 2: An illustration of the comprehension test and the corresponding results from Harmon \& Kapatsinski (submitted). Responding 'DIMPL' meant clicking on multiple small creatures; 'PL' meant clicking on multiple large creatures, and 'DIM' meant clicking on a single small creature. When a suffix occurred frequently in training (-dan in Dan Condition and -nem in Nem Condition), it became less likely to be mapped onto the novel meaning, DIMPL, and more likely to be mapped onto the meaning it was paired with during exposure.

The results therefore show a production-comprehension dissociation: the forms participants were most likely to use to refer to the novel meaning in production were the forms they were least likely to map onto the novel meaning in comprehension.

Thus, frequency of a form-meaning pairing appears to have opposite effects in production and comprehension. These results therefore appear, at first glance, to be problematic for simple Hebbian models of word learning (McMurray et al., 2012; Yu \& Smith, 2012) that learn symmetrical bidirectional form-meaning mappings based on form-meaning co-occurrence as well as for the notion, nearly universally accepted in linguistics (cf. Ramscar et al., 2010), that linguistic contructions, whether lexical or grammatical, are Saussurean signs - i.e., that there is a form representation that mediates the auditory-to-semantic mapping in comprehension and the semantic-to-articulatory mapping in proeuction. The aim of the present paper is to
show that, somewhat counterintuitively, the observed dissociation actually falls out of simple Hebbian learning of bidirectional form-meaning associations.

## The baseline model: Frequency counter

According to Hebb (1949), neurons that fire together wire together. We assume a distinction between cues and outcomes, where outcomes follow cues. On every trial, associations between the cues present on that trial and the following outcomes strengthen. How much they strengthen is determined by the salience of the cue, the salience of the outcome, and the learning rate. During the exposure trials in Harmon \& Kapatsinski (submitted), forms began 500 ms into the presentation of the referent. Therefore, we assume cues to be the semantic features of the referents (BIG, SMALL, MANY and ONE) plus a context cue, present on every trial (Pavlov, 1927; Rescorla \& Wagner, 1972). This order of presentation was chosen to reflect the temporal dynamics of real-life word learning (Pereira et al., 2014). Unlike error-driven models such as Rescorla \& Wagner (1972), we did not multiply the increment in association strength by prediction error. This is part of what makes the model Hebbian: it does not learn less on trials with unsurprising (or no-longer-surprising) outcomes, and would not exhibit cue competition effects such as blocking or overshadowing.

In essence, this base model is simply counting frequencies of form-meaning mappings. When it encounters a cue (meaning) followed by an outcome (form), it simply increases the weight of the link between them by a constant number, which we set to 1 in order to emphasize the model's nature as a simple frequency counter. The results do not change depending on what the number is.

## Linking hypotheses

In order to connect the model's knowledge to the experimental results, we need a set of linking hypotheses connecting the weights and activations of the model to the participants' responses in the experimental tasks. We assumed that production involves activating forms given the semantic features present on that test trial and the context cue. The activation of a form is simply the sum of connection strengths from the semantic and context cues present on the test trial to that form. The choice of the form is then determined stochastically (Luce, 1963): the form is chosen in proportion to its activation value relative to the sum of all forms' activation values given the cues present. Stochastic choice implements probability matching, an empirical universal in tasks that demand repeatedly choosing between the same alternatives (Azab et al., 2016).

The linking hypothesis for comprehension is more controversial. Note that the model, like the subjects, was trained only in the meaning $\rightarrow$ form direction. However, the comprehension task required participants to choose meanings given forms, reversing the cue $\rightarrow$ outcome mappings they were trained on. Participants were extremely accurate in the comprehension task, suggesting that they
were able to bring the knowledge they acquired to the task. The model must be able to do the same. We propose that the associations participants learn obey the Symmetry Principle: a cue $\rightarrow$ outcome association is as strong as the corresponding outcome $\rightarrow$ cue association (Asch \& Ebenholtz, 1962; Kahana, 2002). This is another way in which the proposed model differs from models that perform using prediction error, such as Rescorla \& Wagner (1972). This difference, however, is crucial for the model's ability to simulate the comprehension data.

We assume that a choice between two meanings depends on the difference in activations between the two meanings' contrasting features. For example, the probability of clicking on [small;plural] rather than [big;plural] when presented with -dan is proportional to the difference in association strengths between $-d a n \sim$ SMALL (=SMALL $\sim-d a n)$ and dan $\sim$ BIG (=BIG $\sim-d a n)$. The bigger this difference, the more likely participants are to click on the meaning that actually was paired with the form in training (Miller \& Matzel, 1988).

## Models between frequency and contingency

Besides the connections between the cues and outcomes present on a particular trial, there are three other sets of connections that could potentially be updated. Alternative theories of associative learning differ in their claims about whether these connections are indeed updated.

First, there are connections from the cues present on a trial to the outcomes absent from that trial. It is usually thought that these connections' weights are reduced, so that cues that are consistently paired with the absence of a certain outcome develop inhibitory connections to that outcome, with the subject learning the negative contingency present in the environment. Second, there are connections from the absent cues to the present outcomes. These connections are assumed not to be updated by Rescorla \& Wagner (1972). However, van Hamme \& Wasserman (1994) and Tassoni (1995) argued that - if participants know the set of cues that could occur on every trial - the absence of a cue could be salient. In other words, learners may notice the consistent absence of a cue on trials containing a certain outcome and develop a negative association between that cue and the outcome. Finally, one could argue that connections from absent cues to absent outcomes may also be updated, gaining strength: when a cue and an outcome are absent together, the learner is in a position to learn that absence of the cue predicts absence of the outcome (Tassoni, 1995). Thus, models of learning can be arranged from simplest (wiring together present cues and outcomes only) and least veridical - least able to faithfully reproduce environmental contingencies - to most complex and most veridical (updating all connections on every trial). In what follows, we examine the types of updating that are needed to capture the experimental results by independently varying whether each distinct set of connections undergoes updating. Table 1 summarizes the possible models from a simple frequency counter that updates only the connections
between present cues and present outcomes to a fully veridical contingency tracker that updates all four sets of connections (in the normative direction). We will refer to the models we evaluate with the abbreviations shown on the left sides of the table cells. For example, the RescorlaWagner model updates only the sets of connections in the top row and can therefore be abbreviated as $\left(p_{c}\right)$.

Table 1: The four distinct sets of cue-outcome connections on every trial and whether their weights should become more positive $(+)$ or more negative $(-)$ in a model that is able to capture environmental contingencies
veridically. The two subscripts c and o refer to cue and outcome respectively. Presence is denoted by p and absence by a.

|  |  | Outcome Present |  | Outcome Absent |  |
| :--- | :--- | ---: | :--- | ---: | :---: |
| Cue Present | $\left(\mathrm{p}_{\mathrm{c}} \mathrm{p}_{\mathrm{o}}\right)$ | + | $\left(\mathrm{p}_{\mathrm{c}} \mathrm{a}_{\mathrm{o}}\right)$ | - |  |
| Cue Absent | $\left(\mathrm{a}_{\mathrm{c}} \mathrm{p}_{\mathrm{o}}\right)$ | - | $\left(\mathrm{a}_{\mathrm{c}} \mathrm{a}_{\mathrm{o}}\right)$ | + |  |

## Extension of frequent forms in production

Table 2 shows predicted activations of the frequent suffix, its synonym, and the two other suffixes (which are always activated equally) by the semantic features of the novel meaning (MANY and SMALL) under all logically possible models of associative learning. The left column represents the simplest possible model, a frequency counter (Bybee, 2010). Columns 2-4 represent association sets that can be added to the frequency counter in order to make contingency learning more veridical, incorporating learning of connections involving absent cues and/or outcomes. Column 5 is the model that learns only from present cues (a Hebbian version of Rescorla \& Wagner, 1972). Column 6 is the full model that learns about all associations, including associations between absent cues and absent outcomes (a Hebbian version of Tassoni, 1995). Extension of frequent forms to novel meanings is predicted if the activation of the frequent form exceeds that of all other forms, including the frequent form's synonym. In other words, a preference to extend the frequent form to novel meanings is predicted whenever the largest number is in the top row.

As seen in Table 2, extension of the frequent form is predicted by increasing the weights of connections from present cues to present outcomes, as well as by decreasing the weights of connections from present cues to absent outcomes. Updating connections from absent cues (in the normative direction) acts against extension.

For the simulations reported in this table, it was assumed that an absence of a cue or outcome is noticed only half the time while its presence is always noticed. Associative learning in conditioning paradigms tends to be slower when reinforcement is signaled by the absence of a cue than when it is signaled by the presence of a cue (e.g. Wasserman et al., 1990). However, one might question whether absences are missed or ignored that often, and wonder whether noticing absences more would eliminate extension. It turns
out not to matter much: $a_{c}$ does not overpower $p_{c}$ even if absences are as salient as presences. All extant models of learning agree that absent stimuli are no more salient than stimuli that are actually presented and therefore all predict (over-)extension of frequent forms to related meanings in production.

Table 2: Activations of the frequent suffix, its synonym, and the other two suffixes given the novel diminutive plural meaning under alternative models.

| DIM.PL $\rightarrow$ | $\mathrm{p}_{\mathrm{c}} \mathrm{p}_{\mathrm{o}}$ | $\mathrm{p}_{\mathrm{c}} \mathrm{a}_{\mathrm{o}}$ | $\mathrm{a}_{\mathrm{c}} \mathrm{p}_{\mathrm{o}}$ | $\mathrm{a}_{\mathrm{c}} \mathrm{a}_{\mathrm{o}}$ | $\mathrm{p}_{\mathrm{c}}$ | all |
| :--- | :--- | :--- | :--- | :--- | :--- | :--- |
| Frequent | 72 | -42 | -18 | 15 | 30 | 24 |
| Synonym | 24 | -66 | -6 | 21 | -42 | -12 |
| Other | 24 | -66 | -6 | 21 | -42 | -12 |

## Entrenchment in comprehension

Table 3 reports activation differences between features that distinguish the novel meaning from the familiar meaning paired with a form in training. Because of the Symmetry Principle, the activation differences correspond to meaning $\rightarrow$ form connection weights involving the semantic features in question. For example, the activation difference between the non-diminutive and diminutive plural for -dan is the weight of the connection between -dan and BIG minus the weight of the connection between -dan and SMALL. The activation difference between the singular and plural diminutive for -nem is the weight of the connection between -nem and ONE minus the weight of the connection between -nem and MANY (cf. Miller \& Matzel, 1985).

Entrenchment is observed if this difference is larger (more positive) for a frequent form compared to the 'other' forms, i.e. if the value in the top row in Table 3 is larger than the value in the bottom row.

Table 3: Comprehension effects. Each cell contains activation difference between the meaning paired with a form in training and the novel, diminutive plural, meaning.
Activations of shared features of the competing meanings cancel out. Therefore, for plural suffixes this is the difference in activations between BIG and SMALL, and for diminutive suffixes it is the difference between ONE vs.
MANY. Entrenchment is predicted if Frequent $>$ Other.

| Right-New | $\mathrm{p}_{\mathrm{c}} \mathrm{p}_{\mathrm{o}}$ | $\mathrm{p}_{\mathrm{c}} \mathrm{a}_{\mathrm{o}}$ | $\mathrm{a}_{\mathrm{c}} \mathrm{p}_{\mathrm{o}}$ | $\mathrm{a}_{\mathrm{c}} \mathrm{a}_{\mathrm{o}}$ | $\mathrm{p}_{\mathrm{c}}$ | all |
| :--- | :--- | :--- | :--- | :--- | :--- | :--- |
| Frequent | 36 | 0 | 36 | 6 | 36 | 78 |
| Synonym | 12 | -12 | 12 | -6 | 0 | 6 |
| Other | 12 | 12 | 0 | 0 | 24 | 24 |

Table 3 shows that entrenchment is favored by strengthening $\mathrm{p}_{\mathrm{c}} \mathrm{p}_{\mathrm{o}}$ connections between present cues and present outcomes, weakening $\mathrm{a}_{\mathrm{c}} \mathrm{p}_{\mathrm{o}}$ connections between absent cues and present outcomes, and strengthening $a_{c} a_{0}$ connections between absent cues and outcomes. Because updating $\mathrm{p}_{\mathrm{c}} \mathrm{p}_{\mathrm{o}}$ and $\mathrm{p}_{\mathrm{c}} \mathrm{a}_{0}$ weights pull in different directions, entrenchment only occurs if absent outcomes are less salient
than present outcomes. In other words, weights of connections to absent outcomes must change less than the weights of connections to present outcomes. This appears to be a reasonable assumption (e.g. Tassoni, 1995), though not all extant models make it. For example, the Naïve Discriminative Learner (Baayen et al., 2011), which uses equilibrium equations for the Rescorla \& Wagner (1972) model from Danks (2003: 116), does not show entrenchment because the learning rates for present and absent outcomes in Danks' equations are equal, a simplifying assumption (Danks, 2003: 115-116).

## Conclusion

Studies of comprehension suggest that frequently encountering a form-meaning pairing convinces the learner than the form cannot be used in any other way (Braine \& Brooks, 1995; Brooks \& Tomasello, 1999; Regier \& Gahl, 2004; Stefanowitch, 2008; Xu \& Tenenbaum, 2007). Nonetheless, frequent forms are the ones most likely to be extended to new uses. Using a frequent form in a novel way seeds the process of language change because that novel use can then be picked up by others, spreading through the speech community. As the novel use diffuses through the community, it becomes conventional. Over historical time, extension of frequent forms results in the well-documented correlation between frequency of use and number of senses: in every language, it is the most frequent forms that are most polysemous (Piantadosi et al., 2012; Zipf, 1949).

Conventionalization of extensions is the primary mechanism behind the diachronic process of grammaticalization (Bybee, 2010; Heine, 2011). The importance of this diachronic process can hardly be overstated as it is the primary source of grammar: almost all grammatical morphemes, whether bound affixes or independent functors like prepositions, determiners or auxiliaries are former lexical words that have been gradually extended to new and new uses (Bybee, 2003; 2010; Christiansen \& Chater, 2016).

Despite the correlation between frequency and semantic extension, the causal mechanisms behind grammaticalization remain controversial. For example, Haspelmath (1999) has argued that increases in frequency seen in grammaticalization are caused by the extension of the grammaticalizing form to new uses, which are in turn caused by semantic broadening. Bybee (2003) agrees that semantic broadening causes extension but suggests that high frequency causes semantic broadening. Like Haspelmath (1999), Heine (2011) does not allocate frequency a causal role in the process but suggests that extensions result in broadening.

In our recent experimental work, we have documented that the same speaker may extend a frequent form to a new meaning in production despite being least likely to map it onto the new meaning in comprehension. This suggests that the speaker may extend a form to a new meaning, thereby seeding the process of language change, without necessarily considering the form to be the best way to express that new
meaning. Use in a new context can therefore be caused by high frequency and precede semantic broadening.

In the present paper, we have argued that this productioncomprehension dissociation falls out of simple, Hebbian associative learning models, which acquire symmetrical form-meaning associations based on cue-outcome cooccurrence (Hebb, 1949; Miller \& Matzel, 1985; see also McMurray et al., 2012; Yu \& Smith, 2012). While such dissociations have previously been used to support the idea that form $\rightarrow$ meaning associations are distinct from meaning $\rightarrow$ form associations (Kapatsinski, 2009), the present results indicate that a single set of bidirectional associations suffices.

Remarkably, all that is required to obtain the divergence between frequency effects in production and comprehension - entrenchment of the frequent in comprehension, and extension in production - is the assumption that cue and outcome absences to be less salient than present cues and outcomes, an uncontroversial assumption (Tassoni, 1995; Wasserman et al., 1990) that is also normatively justified: almost every stimulus is absent more often than it is present, hence the presence of a stimulus is typically more informative about the contingencies in the learner's environment than its absence (McKenzie \& Mikkelsen, 2007). Despite being surprising to human theorists, frequency-driven semantic extension is predicted by every associative learning theory.

#### Abstract

Deaf children born to hearing parents are exposed to language input quite late, which has long-lasting effects on language production. Previous studies with deaf individuals mostly focused on linguistic expressions of motion events, which have several event components. We do not know if similar effects emerge in simple events such as descriptions of spatial configurations of objects. Moreover, previous data mainly come from late adult signers. There is not much known about language development of late signing children soon after learning sign language. We compared simple event descriptions of late signers of Turkish Sign Language (adults, children) to age-matched native signers. Our results indicate that while late signers in both age groups are native-like in frequency of expressing a relational encoding, they lag behind native signers in using morphologically complex linguistic forms compared to other simple forms. Late signing children perform similar to adults and thus showed no development over time.

Keywords: sign language; late acquisition; spatial relations; left right

## Introduction

The most frequently preferred way of spatial encoding in sign languages requires the use of morphologically complex linguistic forms and use of signing space analogue to how the entities are located with respect to each other in the real space (e.g., Emmorey, 2002). In these forms, called classifier predicates (CLs), signers use their hands to represent the location and motion of the entities, as shown in Figure 1a below. Morphological complexity of these forms comes from the need for choosing the correct handshape for the entities (e.g., index finger for long and thin entities) and simultaneous coordination of both hands in the signing space to express their locations (e.g., Supalla, 1982). The relative spatial location of these forms in signing space represents spatial relations among entities in an analogue way - unlike the categorical forms (i.e., ad positions or spatial nouns) in spoken languages.
Earlier studies on spatial language acquisition of native signing deaf children, mostly focused on motion events, have claimed such morphological complexity to be a hindering factor compared to hearing children (e.g.

Engberg-Pedersen, 2003; Slobin, 2003). However, recent work has found that Turkish Sign Language (TID) acquiring deaf children learn to encode static location of the objects placed on a lateral axis (e.g., pen left to paper, apple right to box) earlier than their hearing peers (Sümer, 2015; Sümer, Perniss, Zwitserlood, Özyürek, 2014). Even though these children mostly used classifier predicates, they also used specific lexical signs (i.e., relational lexemes) for left and right, which are body-anchored in TID (see Figure 1b), as frequently as the native signing adults. Thus, classifier predicates and/or body anchored relational lexemes seem to facilitate the learning of static spatial relations for deaf children who have been exposed to sign language input since birth (native signers).

Figure 1: Descriptions from adult native signers of TiD for the spatial relation of the pen with respect to the paper using (a) classifier predicates and (b) body anchored relational lexeme for 'left' (Sümer et al., 2014).

It is not known however if similar patterns also emerge in language development of deaf children with delayed sign language exposure (late signers). A previous study with deaf children (ages 5-6 yrs.) who were never exposed to a sign language (i.e., home signers) found no evidence of relational encoding for spatial relation (Gentner, Özyürek, Gürcanli, Goldin-Meadow, 2013). Here, we investigate whether spatial encodings of a similar type studied by Sümer and her colleagues (2014) can also be learned within a short time by late signing children after brief exposure ( 2 years) to sign language (after the age of 6 ) or whether late exposure to sign language is a
drawback in mastering spatial language in general. Moreover, we investigate the effects of delayed language exposure on both late signing children as well as adults to see if any developmental pattern emerges in such delayed exposure to language and if yes how.

A body of evidence on the effects of late sign language acquisition by deaf individuals posits that adult late signers lag behind adult native signers in several domains such as general cognitive abilities (Bebko \& McKinnon, 1990; Mayberry \& Waters, 1991; Parasnis et al., 1996; Wilson, Bettger, Niculae, \& Klima, 1997) and sign language comprehension (Emmorey, 1993; Emmorey \& Corina, 1992; Mayberry \& Eichen, 1991). Nevertheless, most of the studies were restricted only to sign language comprehension, and there are only a few studies on sign language production which focus only on adult patterns. Question of how late signing children perform in production compared to late adult signers and also to their age-matched native signing peers could be informative in understanding the impact of delayed language exposure for adult and child late signers, and to what extent development plays a role in delayed language acquisition.

In series of studies, Newport (1988; 1990) investigated language production of adult late signers through descriptions of motion events. She found that they described motion events by using fewer classifier predicates (CLs) than native signers, but rather preferred simple forms such as lexical verbs. Given that the motion events consist of several components, such as Figure, Ground, Path, Manner (Talmy, 1985), it raises the question of whether similar patterns emerge for late signing children and adults in describing static events which has fewer components, such as only Figure and Ground. In addition, a previous study (Sümer, 2015) revealed that adult-like descriptions of static spatial relations are acquired earlier for static locations than for motion event descriptions in TİD by native signing deaf children. We do not know if these patterns also apply to late signing children and adults of TİD and if there are any developmental patterns in late signers.

## The Present Study

To answer above questions, this study investigates the effects of late sign language exposure on the ability to encode static spatial events for left-right spatial relations by late signers of TID and compares them to those of native TİD signers, which were already reported by Sümer et al. (2014) and Sümer (2015). We also compare the descriptions of late signing children and adults to those of native children and adults obtained earlier by Sümer (2015) to see if there is any developmental pattern in late signers.

## Participants

Seven adult late signers ( $30 ; 0-49 ; 0, M=39.14$ years), 7 child late signers $(7 ; 3-10 ; 9, \mathrm{M}=7 ; 8), 10$ native adult signers $(18 ; 5-45 ; 10, M=31 ; 4)$, and 10 native child
signers $(7 ; 2-9 ; 10, \mathrm{M}=8 ; 3)^{1}$ participated in the study. All late signers had learned TiD after age 6 when they started a school for the deaf. Late signers did not have any prior exposure to sign language because according to the Turkish Education System, age 6 is the earliest age for starting school in Turkey. Before starting school, these signers mainly stayed at home with their non-signing parents. As a result, late signing children participated in this study, had exposure of 2 years of sign language at the time of testing. Before starting to school, both children groups got two hours of speech therapy every week. At the end of the study, adult participants received a small monetary compensation; child participants received a gender neutral color pencil kit.

## Stimuli and Procedure

Stimuli included a set of 36 displays. In each display, there were 4 pictures ${ }^{2}$ consisted of two entities placed in various spatial configurations (Left, Right, In, On, Under, Front and Behind) to each other. Within each display (four-picture set), only one picture was considered to be the target, which was marked with a red outer frame. The experimental displays we focused on in this study consisted of 6 displays, in which the target picture depicted either Right or Left configurations (Figure 2).

Figure 2: Example of a display. The target picture (apple to the right of the box) to be described is framed in red.

Participants were seated across a confederate deaf addressee who was a native signer of TİD. Stimuli were presented through a $15^{\prime \prime}$ MacBook Pro computer. Computer screen was only visible to the participants. Participants were asked to describe the target pictures to the addressee and were not instructed to use any specific strategy. In order to create an interactive nature, addressee was given a booklet containing the same displays and was asked to point at the picture that the participant described. At the end of the experiment, participants filled out demographics and language background surveys.

[^361]
## Coding

Descriptions for the target items were coded for the presence of spatial encoding and choice of linguistic strategies used to describe spatial relationship between two entities by using ELAN, a free annotation tool (http://tla.mpi.nl/tools/tla-tools/elan/) for multimedia resources developed by the Max Planck Institute for Psycholinguistics, The Language Archive, Nijmegen, The Netherlands (Wittenburg et al., 2006). We categorized three main linguistic strategies used to encode, specifically, Figure object's relation to Ground object: Classifier predicates CLs (Figure 1a), Relational Lexemes like LEFT and RIGHT (Figure 1b), and other alternative linguistic forms. Other forms included showing the location of objects through pointing (59\% of the cases; Figure 3), placing the objects in the signing space through virtually drawing by hand (SASS), using a lexical verb to infer objects (e.g. using sign for "to sit" to represent location of a boy).

Annotation of data from the native signers were done by hearing research assistants and a native TID signer and coded by the second author of this study. Annotation of data from the late signers were done by hearing research assistant and coded by the first author of this study. Later, all annotation and coding was checked by the second author of this study. All annotators and coders had knowledge of TiD.

(b) RH: CL(house)locR LH: Point (horse)locL

Figure 3: Descriptions from late signers of TiD for two objects located on the lateral axis by using pointing by (a) an adult TİD signer (middle finger point) and (b) a child TID signer (index finger point).

## Results

Mean proportions of linguistic strategies were calculated for each participant. Arcsine transformation was applied to all data to ensure normality. The mean proportions and standard errors (SEs) in the table and the graphs are reported from the untransformed data.

First we investigated the frequency of encoding a spatial relation of entities by different groups in each language status. Results of the 2 (Age: Adults, Children) X 2 (Status: Native, Late) Between Subjects ANOVA on mean proportions of encoding a spatial relation revealed no main effect of age, $F(1,30)=2.918, p=.098, \eta^{2}=$ $.089, M S E=.381$, no main effect of status, $F(1,30)=$ $.373, p=.546, \eta^{2}=.012, M S E=.049$ and no interaction, $F$ $(1,30)=768, p=.388, \eta^{2}=.023, M S E=.100$. These results indicate that all groups of participants generated equal amount of relational encodings (Table 1).

Table 1: Mean Proportions and SEs of frequency of encoding a spatial relation as a function of Age and Status.

| Participants | Native Signers | Late Signers |
| :--- | :---: | :---: |
| Adults | $0.97(.02)$ | $0.98(.03)$ |
| Children | $0.92(.05)$ | $0.81(.11)$ |

As the next step, we investigated what types of linguistic strategies were preferred by each age group and status. The results of a 2 (Between Subject, Age: Adults, Children) X 2 (Between Subject, Status: Native, Late) X 3 (Within Subject, Linguistic Strategy: CLs, RLs, Other) Mixed ANOVA yielded a main effect of Linguistic Strategy, $F(1.32,12.42)=37.114, p<.001, \eta^{2}=.533$, $M S E=.314$, no main effect of age, $F(1,30)=.347, p=$ $.560, \eta^{2}=.011, M S E=.008$, no main effect of Status, $F$ $(1,30)=1.385, p=.249, \eta^{2}=.044, M S E=.008$. Due to a marginal interaction between Linguistic Strategy and Status, $F(1.32,12.42)=3.628, p=.053, \eta^{2}=.108, M S E=$ .314 , separate analyses were conducted for each Status.

## Linguistic Strategies used by Native Signers

The results of 2 (Between Subjects, Age: Adult, Child) X 3 (Within Subjects, Linguistic Strategy: CLs, RLs, Other) mixed ANOVA showed no main effect of age, $F(1,18)=$ 1.214, $p=.285, \eta^{2}=.063, M S E=.028$ but a main effect of Linguistic Strategy, $F(1.25,22.53)=60.186, p<.001$, $\eta^{2}=.770, M S E=.183$, without an interaction between them, $F(1.25,2.53)=.251, p=.674, \eta^{2}=.315, M S E=$ .183. Tests of within subject comparisons showed that classifier predicates were preferred more frequently than relational lexemes ( $p<.001$ ) and other linguistic forms ( $p$ $<.001$ ). The frequency of using relational lexemes and other forms found to be similar to each other ( $p>.05$ ). The lack of main effect for age indicated that deaf children used the linguistic forms in three different categories as frequently as deaf adults. See Figure 4 below.

Figure 4: Mean proportions and SEs of linguistic descriptions of native signers as a function of age.

## Linguistic Strategies used by Late Signers

The results of 2 (Between Subjects, Age: Adults, Children) X 3 (Within Subjects, Linguistic Strategy: CLs, RLs, Other) mixed ANOVA showed no main effect of age, $F(1,12)=.097, p=.761, \eta^{2}=.008, M S E=.015$ but a main effect of Linguistic Strategy, $F(1.18,14.10)=6.771$, $p=.017, \eta^{2}=.036, M S E=.588$, without an interaction between them, $F(1.18,14.10)=.450, p=.544, \eta^{2}=.036$, $M S E=.588$. Tests of within subject comparisons showed that relational lexemes were used less frequently than classifier predicates ( $p<.01$ ) and other forms ( $p<.05$ ). The frequency of using classifier predicates and other forms are found to be similar to each other $(p=573)$. The results indicate that late signers -unlike native signers- use other forms as frequently as classifier predicates. See Figure 5 below.

Results showed that native and late signers show different production patterns in their descriptions of the location of the objects when they are placed to left or right to each other. Namely, native signers show a significant preference over using the morphologically complex CLs in describing, however, late signers employ other simpler forms as frequently as CLs. Moreover, this tendency is significant for all age groups.

Figure 5: Mean proportions and SEs of linguistic descriptions of late signers as a function of age.

## Discussion and Conclusion

Our study has two key findings. First, late signing adults and children differ from native signing adults and children in their linguistic descriptions. Namely, late signers do not
show a preference for CLs. Rather they employ simpler other forms as frequently as CLs compared to native signers. These findings clearly indicate that late exposure to sign language by deaf individuals has long-term effects on their production patterns. Second, late signing children perform similar to late signing adults in their static spatial event descriptions and show no further developmental trajectory in their preferred linguistic devices.

Results of this study complement the previous literature - yet in another sign language - showing a tendency towards decreased preference for CLs and increased preference for other simpler forms not only for complex event descriptions, as found in ASL (Newport, 1988; 1990), but also for simple static events (Sümer et al., 2014; Sümer, 2015). In the case of native signers of TID, both adults and children prefer CLs more than RLs and other forms while the nature of this distribution is different for late signers of TİD, who use CLs and simpler other forms such as pointing in similar amounts while they prefer RLs for left and right less frequently. The body-anchored relational lexemes in TİD were very rarely used by late signing adults and not at all by the late signing children. Thus, the use of CLs and RLs did not seem to ease acquisition for these children as they did for native children. However, we should be cautious in generalizing the effects of these comparisons due to relatively few number of participants we could investigate especially from late signing group.

Considering the high proportion of relational encodings shown on Table 1, 2-year exposure to sign language after age 6 seems to be enough to initiate spatial language production in late signing children to become adult like. This is a rather striking finding since Gentner and her colleagues (2013) found that home signing children (deaf children never exposed to a sign language) in similar age range do not produce gestures in a way that would encode spatial relations, which indicates the necessity of sign language input for relational encoding to emerge at all. This pattern also shows that while relational encoding might emerge as the earliest feature of encoding a spatial event, and as less sensitive to delayed exposure, morphologically complex forms or body anchored relational lexemes such as LEFT and RIGHT might be more resistant to the timing of the input to develop.

The difference in the preference for linguistic forms to encode spatial relations between native signers and late signers provides evidence for the role of maturational constrains in language acquisition. Moreover, previous studies have been mostly on comprehension of sign language (e.g., Mayberry \& Eichen, 1991), our results indicate that these effects are not only restricted to comprehension, but also observed in production, as also shown by Newport (1988; 1990). Furthermore, it shows that these results on motion event expressions can be extended to those of static events.

Our study also uniquely displays these patterns for late signing children for the first time in the literature. Although, late signing adults of TİD have lengthier language experience compared to late signing children, who have only a 2 -year of sign language exposure, we still observed similar preferences in how frequently they prefer CLs and other forms. It seems that the hindering
effects of delayed language exposure persist in language production despite many years of language use. This finding is also in line with other studies that show the significance of age of acquisition, rather than the length of exposure, in both sign and spoken language development (Mayberry, 2010).

Finally, late signing children were not only exposed to sign language late but also the kind of language they were exposed to, that is the language used by their late signing peers in the primary school, was also non-native. Thus, future research should also investigate the effect of type of language input (i.e., non-native input) in addition to age of acquisition in late signing children and adults on late signers' language production.

## Acknowledgements

This work has been supported by European Research Council (ERC) Starting Grant and NWO VICI Grant awarded to the third author. We thank our deaf assistant Sevinç Yücealtay Akın and our hearing assistant Hükümran Sümer for their help with data collection and annotation. Moreover, we thank directors and teachers at ÇED and Rotary Tuzla Primary School for the Deaf in Istanbul, Turkey.

#### Abstract

Since its design in 2003, the joint Simon task and corollary joint Simon effect (JSE) have been invaluable tools towards the study of joint action and the understanding of how individuals represent the action/task of a co-actor. The purpose of this meta-analysis was to systematically and quantitatively review the sizeable behavioural evidence for the JSE. Google Scholar was used to identify studies citing the first report of the joint Simon task (Sebanz, Knoblich, \& Prinz, 2003) up until June 23, 2015. After screening, thirtynine manuscripts were included in the meta-analysis, thirteen of which included individual go/no-go (IGNG) control data. Separate random-effects models were conducted for both the joint Simon and IGNG datasets, and meta-regression models were used to assess potential moderators that may impact the strength of the JSE. The results provide an important quantitative summary of the literature and serve as a foundation for future research surrounding the JSE.

Keywords: joint action; spatial compatibility; corepresentation

## Introduction

Throughout the day, people engage in a variety of social interactions that mold our behaviour, and even independent events can be shaped by those around us. In recent years, much research has been devoted to better understanding how individuals mentally represent the presence, tasks, and actions of others, and how such representations influence one's own behaviour, in contrast to matched behaviours performed alone. A valuable experimental paradigm towards this end has been a spatial compatibility task, more specifically the Simon task, which can be performed in an individual (e.g., Simon, 1969) or joint setting (e.g., Sebanz, Knoblich, \& Prinz, 2003).

## The (Joint) Simon Task

In a typical two-choice Simon task, stimuli are presented to the left or right of centre. A non-spatial stimulus feature (e.g., colour, shape, tone pitch) informs the participant whether to make either a left or right key press response. For example, a triangle requires a left key press response while a circle requires a right key press response. Even though the stimulus location (left, right) is irrelevant to the task, it nevertheless modulates responses, such that responses are faster and more accurate when the spatial
location of the stimulus and response are compatible (e.g., left-left) than when they are incompatible (e.g., left-right). This phenomenon, known as the spatial compatibility or Simon effect, has been shown to be robust, with this pattern of results replicated in many studies (for review, see Lu \& Proctor, 1995).

In a social variant of the Simon task, two people are each assigned a stimulus-response mapping, such that a go/no-go protocol is completed independent from, yet complementary to the other's task. The emergence of a spatial compatibility effect (henceforth referred to as a joint Simon effect, JSE) in the joint setting was taken as evidence that representations were formed for not only one's own part of the task but also their co-actor's (Sebanz et al., 2003), since the effect was noticeably absent when participants performed the same go/no-go protocol alone (individual go/no-go task, IGNG) (see Callan, Klisz, \& Parsons, 1974).

## Interpretations of the Joint Simon Effect

The JSE was originally interpreted in terms of the action corepresentation account (e.g., Sebanz et al., 2003; for elaboration and more detailed review of this and subsequent interpretations, see Dolk et al., 2014). According to this account, individuals represent a co-actor's task quasiautomatically; it is the representation of the alternative stimulus-response mapping that is thought to increase response conflict, eliciting the JSE. Other authors have posited the actor co-representation account, whereby response conflict emerges from the representation of the coactor, as opposed to the co-actor's specific task, such that conflict surrounds which agent should act when (Wenke et al., 2011). However, these accounts do not explain why the JSEs are induced in non-social contexts (e.g., Guagnano, Rusconi, \& Úmilta, 2010). In efforts to offer a more comprehensive explanation for the JSE, Dolk, Hommel, Prinz, and Liepelt (2013) formulated and tested the referential coding account. This account posits that greater similarity across action event representations can lead to a greater emphasis on their discriminating features (e.g., location). In a series of five experiments, they manipulated the social nature of the experimental setup in two ways: (1) absence of a biological co-actor, and (2) removing any event character (e.g., sound). They showed that the JSE could be
elicited by non-social action events (e.g., Japanese waving cat) but not if the "event-like character of the sounds and movements" are eliminated (Dolk, Hommel, et al., 2013, p. 1255). What makes the referential coding account particularly appealing is that it can explain not only the occurrence of the JSE in non-social contexts, but also the more pronounced JSEs observed when there is increased self-other integration (Colzato, de Bruijn, \& Hommel, 2012), as presumably within friendly partnerships (e.g., Hommel, Colzato, \& van den Wildenberg, 2009), in-group interactions (e.g., Iani, Anelli, Nicoletti, Arcuri, \& Rubichi, 2011; McClung, Jentzsch, \& Reicher, 2013; Müller, Kühn, et al., 2011), and cooperative contexts (e.g., Iani et al., 2011; Iani, Anelli, Nicoletti, \& Rubichi, 2014).

## Current Meta-Analytic Review

The current meta-analysis offers several novel contributions to the field of joint action. First, to our knowledge, it is the only application of quantitative methods to evaluate the substantial body of work that has emerged since the introduction of the joint Simon task (Sebanz et al., 2003). As such, it complements recent qualitative literature reviews (e.g., Dolk et al., 2014) while providing unique insights into the nature of co-representation, as indexed by the JSE. Second, we explored the size of: (1) the overall JSE, (2) the JSE when the original conditions were conceptually replicated (see Sebanz et al., 2003, Experiment 1), and (3) the JSE when an elimination or reversal of the effect was anticipated. The inclusion of these latter moderator analyses enhances our understanding of the JSE and its sensitivity to experimental manipulations. Third, we included an analysis of the IGNG task, which is considered an important control when investigating the JSE and enriches interpretations of joint effects (e.g., Sebanz et al., 2003).

## Methods

## Search Strategy and Study Selection

On June 23, 2015, two authors (AK and MYL) conducted an electronic search in Google Scholar for all citations of Sebanz et al. (2003). Following the addition of Sebanz et al. (2003) to the search results and removal of duplicates, 329 records were screened for eligibility. The following exclusion criteria were used to screen the articles: (a) manuscripts that were not published or translated into English; (b) manuscripts that did not include a joint Simon task; (c) studies that did not report response times (RT) and standard deviations (SD) or standard errors (SE); (d) studies examining children ( $<18$ years old). It should be noted that articles examining joint action in special populations (e.g., individuals with schizophrenia) were not excluded, but only the data for healthy controls were included in the analyses.

Two authors (AK and MYL) screened articles by title and abstract according to these criteria. These same authors then used the criteria to screen the remaining 61 articles by full text for inclusion. When there was disagreement, the authors discussed the articles in question until consensus was
reached. A total of 42 manuscripts remained eligible for inclusion in the quantitative analysis, but 3 of these manuscripts were subsequently excluded as they were doctoral dissertations whose eligible studies were also published (and included) as distinct manuscripts (Anelli, 2012; Müller, 2013; Sellaro, 2013). The 39 manuscripts remaining in the meta-analysis comprised 104 independent groups of participants (contributing 95 joint Simon datasets and 35 IGNG datasets), as some manuscripts contained multiple experiments and/or multiple groups of participants. ${ }^{1}$

## Data Extraction

Two authors (AK and MYL) independently extracted data from each manuscript relevant to sample size, experimental manipulation, and response time (means and SDs or SEs). ${ }^{2}$ When necessary, data were manually estimated from reported figures. These two authors discussed any discrepancies between their extractions until consensus was reached with respect to the data included in the analyses.

## Data Analysis

Cohen's $d$ was calculated directly from the extracted RT data and the pooled between-subject SD . In cases of repeated measures designs, data were averaged across conditions such that each independent group of participants contributed only one effect size to each analysis. The effect sizes and variances were entered into a random-effects meta-analysis using the 'metafor' package in R (R Core Team 2014; Viechtbauer, 2010) and the DerSimonian and Laird method of estimation (Borenstein, Hedges, Higgins, \& Rothstein, 2011). Effect size calculation was arranged such that effects favouring a JSE always had a positive value (i.e., incompatible mean RT - compatible mean RT). An effect size of zero indicated no difference between compatible and incompatible trials.

Custom scripts were written to test random-effects models for the overall effect of spatial compatibility within joint Simon and IGNG tasks (Cooper, Hedges, \& Valentine, 2009), and Egger's test of asymmetry was used to assess bias (Egger, Davey Smith, Schneider, \& Minder, 1997). Considering the wide range of experimental manipulations within the joint Simon task literature, we also conducted two moderator analyses using meta-analytic regression. First, conditions conducted as controls (control moderator) were compared to all other conditions, ${ }^{3}$ to provide an index of the JSE unmodulated by experimental variables. Second,

[^362]conditions hypothesized by the original authors to eliminate or reverse the JSE (wipeout moderator) were compared to all other effect sizes. ${ }^{4}$ Unlike the "overall" random-effects model of the JSE, in cases of repeated measures designs, we preferentially submitted a group's 'control' or 'wipeout' data (when available) towards the relevant meta-regression model (rather than averaging across within-group conditions). Details regarding the raw data, moderator coding, and analysis scripts are available online at https://github.com/keithlohse/social_simon_meta.

## Results

## No Spatial Compatibility Effect in IGNG Contexts

As expected, the IGNG studies $(n=35)$ yielded no evidence of a spatial compatibility effect (i.e., the RT difference between incompatible and compatible trials was not statistically different from zero), $d=0.07,95 \%$ confidence intervals (CI) $[-0.01,0.16]$. A statistical test of asymmetry revealed the distribution was not skewed, $t(33)=-0.76, p=$ .45.

## Evidence of Positivity Bias and Small Effect Sizes Across Joint Simon Studies

Prior to analysis, a funnel plot revealed an extremely positive and imprecise effect size (from Dolk et al., 2012, see data point in bottom right corner of Figure 1A) which was removed from all subsequent analyses.

Figure 1A shows the distribution of joint Simon task effect sizes as a function of the standard error in each study ( $n=94$ ). Even with the Dolk et al. (2012) data point removed, a statistical test of asymmetry confirmed the positive skew in these data, $t(92)=3.25, p=.002$, indicating significant bias, with more small, positive studies being published. The random-effects model summary effect size was $d=0.26,95 \% \mathrm{CI}[0.21,0.30]$.

Considering the significant positive skew across the dataset, we also ran a second random-effects model restricted to large samples in efforts to remove bias. ${ }^{5}$ Restricted to the largest studies $(n=20)$, the distribution was not skewed, $t(18)=0.96, p=.35$, and the summary effect size was reduced, $d=0.17,95 \%$ CI $[0.10,0.25]$.

## No Evidence Control Conditions Moderate the JSE

We used meta-regression to compare the effect sizes derived from control conditions $(n=23)$ to all other conditions ( $n=$ 71), to broadly assess any modulation of the effect by experimental manipulations. There was no significant difference between the effect sizes of control conditions, $d=$ $0.34,95 \% \mathrm{CI}[0.24,0.44]$, compared to non-control

[^363]conditions, $d=0.24,95 \%$ CI [0.19, 0.29], $p=.074$. As shown in Figure 1B, the distribution of the effect sizes remained significantly skewed, $t(92)=3.33, p=.001$.

Figure 1: The funnel plots for the JSE (incompatible (IC) mean RT - compatible (C) mean RT) showing effect sizes (d) as a function of precision (standard error) for the A) overall random-effects model; B) meta-regression of the control moderator (triangles $=$ controls; circles $=$ noncontrols); and C) meta-regression of the wipeout moderator (triangles = wipeouts; circles = non-wipeouts). Positive values show a difference in favour of a JSE (i.e., faster RTs on compatible trials)

## Wipeout Conditions Decrease the JSE

Considering that 'non-control' conditions encompass both those experimental designs hypothesized to augment and to diminish the JSE, we conducted an additional metaregression model to assess any moderating effects of conditions explicitly hypothesized by the original authors to eliminate or reverse the JSE $(n=16)$ compared to those that were not ( $n=68$ ). The summary effect size of wipeout conditions ( $d=0.12,95 \%$ CI $[0.01,0.22]$ ), was significantly smaller than that of non-wipeout conditions ( $d=0.33,95 \%$

CI [0.27, 0.38]), $p<.001 .{ }^{6}$ As shown in Figure 1C, the distribution remained skewed, $t(82)=2.77, p=.007$.

## Discussion

Since its design in 2003, many researchers have used the joint Simon task to explore the nature, extent, and boundaries of shared representations, as indexed by the JSE (for review, see Dolk et al., 2014). The present metaanalysis provides the first, much-needed quantitative summary of the literature, and serves both as a snapshot of the research to date, and a foundation on which to build future inquiries.

Across 39 manuscripts, our meta-analysis suggests the JSE is a reliable, albeit small, effect (summary $d=0.26$ ). However, this analysis also revealed significant asymmetry within the data, potentially indicative of publication bias. Specifically, the data are positively skewed (even after removing an outlier), such that more small "positive" studies are being published than those with "negative" results. When we limited our analysis to large samples, the distribution was no longer skewed, but it revealed that the "real" effect size is likely even smaller than it first appeared ( $d=0.17$ ). This has two principle implications: (1) researchers studying this effect need an adequate sample size to achieve statistical power, and (2) there is probably limited "practical" significance of this effect, although it is still useful as a behavioural assay to understand cognitive processes (when conducted with sufficient power).

The small JSE effect size also reinforces the importance of the IGNG random-effects model, where we confirmed that a compatibility effect did not arise under individual task conditions. It should be noted that of the 39 manuscripts eligible for the joint Simon analysis, only 13 included an IGNG condition. The failure to include such a condition is of potential concern as it has been shown that a small but significant spatial compatibility effect can be observed in a go/no-go task (see Callan et al., 1974). In the case that a significant effect is found in the IGNG condition, then this compromises interpretations of the JSE.

Given the sizeable body of research included in the random-effects model of the JSE, we sought to parcel out factors that could be moderating the size of the JSE. We began with an exploration of control versus non-control task conditions. The meta-regression analysis revealed no evidence that control conditions yielded JSEs that were reliably different to those of experimental conditions. A possible explanation for our finding is that task conditions have been manipulated to elicit a range of effects on the JSE (e.g., reverse, eliminate, decrease, increase), which could result in cancellation effects and account for the lack of statistical difference between the size of the JSE under control and non-control conditions. Another plausible

[^364]interpretation is that the JSE is sufficiently robust that there is some leeway in what one can do experimentally and still elicit the JSE. ${ }^{7}$

As a next step, we classified experimental conditions anticipated to eliminate or reverse the JSE as 'wipeout' conditions, and used a meta-regression model to assess their potential moderating effect on the size of the JSE. As anticipated, the summary effect size of the wipeout conditions was significantly smaller than the non-wipeout conditions. However, we wish to add a note of caution when interpreting this analysis. Our coding was based on the original authors' predictions, which we assume to represent a priori hypotheses, but it is possible some were made $a$ posteriori, reflecting post hoc justifications for the findings (Kerr, 1998; Lohse, Buchanan, \& Miller, 2016). An important message to convey to authors is to ensure they are transparent about whether their hypotheses are a priori or a posteriori. In the case that a hypothesis is generated based on theory or prior research, then they should be clear to outline why they believed a condition would eliminate or reverse the JSE. Alternatively, if after data collection potential explanations for what has been found are devised, then authors should be upfront about this. While a posteriori hypotheses tend to be looked at less favourably, they do offer a springboard to test other methods or experimental designs. Nevertheless, the current results confirm that the JSE is sensitive to manipulations 'designed' to diminish its presence.

As the first quantitative description of the joint Simon literature, a clear future direction would be to metaanalytically capture the studies not included here, for example with respect to special populations (e.g., de la Asuncion, Bervoets, Morrens, Sabbe, \& De Bruijn, 2015; Liepelt et al., 2012). Additionally, and particularly in light of the asymmetry present in the current data, subsequent researchers could attempt to solicit unpublished 'file drawer' data, which might help to counter the observed positivity bias, and provide a more accurate picture of the conducted research and estimate of the underlying effect. Also missing from the present analyses are studies not reporting enough data to calculate their associated effect sizes (e.g., no error bars on figures, or not specifying what measure the error bars represent). As such, we urge researchers and reviewers to be diligent towards the reporting of all results, to avoid such omissions in the future.

As a final note, we encourage researchers who are designing an experiment to investigate the JSE to perform (and report) an a priori power analysis (Cumming, 2012; Lohse et al., 2016). A shortcoming of some joint Simon studies is the inadequate sample size. Indeed, across all the

[^365]studies included in this meta-analysis, not one reported estimating sample size. The effect sizes presented in this paper could be used to conduct a power analysis, and this simple procedure will help ensure that the JSE that is (or is not) being detected is a real effect. Since the joint Simon task is commonly used to explore joint action and corepresentation, it is of great import to establish that the observed effect is appropriately powered if we are to infer its underlying mechanisms and influence on behaviour.

# A Toolbox of Methods for Probabilistic Inference 

Charles Kemp (ckemp@cmu . edu)<br>Department of Psychology, Carnegie Mellon University<br>Pittsburgh, PA 15213 USA<br>Caleb Eddy (cweddy@andrew. cmu . edu)<br>Department of Psychology, Carnegie Mellon University<br>Pittsburgh, PA 15213 USA

#### Abstract

We propose that probabilistic inference is supported by a mental toolbox that includes sampling and symmetry-based reasoning in addition to several other methods. To flesh out this claim we consider a spatial reasoning task and describe a number of different methods for solving the task. Several recent process-level accounts of probabilistic inference have focused on sampling, but we present an experiment that suggests that sampling alone does not adequately capture people's inferences about our task.

Keywords: probability judgment; probability estimation; reasoning; sampling; symmetry

Certainty is often unattainable, and people must therefore maintain degrees of belief. A prominent tradition in cognitive science explores where these degrees of belief come from and how they are updated given evidence. One line of work focuses on normative accounts of reasoning under uncertainty, and many of these accounts rely on probability theory. A distinct but related line of work focuses on process-level accounts that attempt to characterize how probabilistic inference is implemented by the mind and brain.

Recent work on process-level accounts has emphasized the idea that the mind approximates probabilistic inference by sampling (Griffiths, Vul, \& Sanborn, 2012; Sanborn \& Chater, 2016; Bonawitz, Denison, Griffiths, \& Gopnik, 2014). We believe, however, that sampling is just one among many methods that people use for probabilistic inference. Other possible methods depend on symmetrybased reasoning (Strevens, 1998; Vasudevan, 2012), counting events (Johnson-Laird, Legrenzi, Girotto, Legrenzi, \& Caverni, 1999; Fox \& Levav, 2004), computing sums (Fischbein, 1975), products (Fischbein, 1975) and ratios (Zhao, Shah, \& Osherson, 2009), and ignoring irrelevant information (Grove \& Koller, 1991). This paper lays out an initial proposal about a mental toolbox of such methods. The long term challenge is to understand which methods belong in the toolbox, when they are applied, and how they are flexibly combined. Addressing this challenge is far from straightforward, but essential in order to understand probabilistic inference at the process level.

A longstanding debate in the reasoning literature pits model-based approaches against those that rely on mental proofs. Model-based inference relies on representations of concrete states of affairs, and mental proofs are constructed by applying abstract rules. We believe that both approaches have their merits, and that people draw on both in different
contexts. Our toolbox of methods therefore includes modelbased approaches such as sampling alongside alternatives that require the construction of mental proofs. A pluralist approach, of course, does not immediately resolve the issues at stake in the debate about models and proofs. Detailed work is needed to establish when people rely on model-based approaches and when they construct mental proofs.

## Spatial reasoning task

Because different tasks may elicit different reasoning methods, a comprehensive theory of probabilistic inference should be able to account for a wide range of tasks. As a starting point, we focus here on one simple task. Figure 1a shows a Tshaped rock in a square pond. Suppose that a blue beetle and a gold beetle are both located somewhere on the rock. If the blue beetle is north of the gold beetle, what is the probability that the blue beetle is also east of the gold beetle?

The inferences we consider can be formalized using the graphical model in Figure 1f. Variable $T$ specifies the topography of the pond, and $z_{b}=\left(x_{b}, y_{b}\right)$ and $z_{g}=\left(x_{g}, y_{g}\right)$ indicate the positions of the blue and gold beetles respectively. These positions depend on $T$ because both must fall on a rock rather than in the water. Variables $r_{x}$ and $r_{y}$ indicate relations between the beetles along the $x$ and $y$ axes respectively. For example, $r_{x}=1$ indicates that blue is east of gold, $r_{x}=-1$ indicates that blue is west of gold, and $r_{x}=0$ captures the rare case in which neither beetle is east of the other.

In this setting, a model is a pair $\left(z_{b}, z_{g}\right)$ that specifies the locations of both beetles. One example is shown in Figure 1 b . Our task is deliberately chosen so that it is impossible to enumerate all possible models. In contrast, some previous research on probabilistic inference focuses on problems for which the set of models is discrete and relatively small, which allows inference methods that depend on enumeration or counting (Fox \& Levav, 2004).

Our task has several other appealing properties. It is closely related to a family of tasks known as three-term series problems that have been prominent in the reasoning literature (Clark, 1969; Jahn, Knauff, \& Johnson-Laird, 2007). One such problem asks "if A is west of B and B is west of C , is A west of C ?" Compared to these problems, one advantage of our task is that it allows for a wide range of normative responses. For example, the normative responses to the questions in Figures 1a and 1e are 0.5 and 0.75 respectively, and by varying the shape of the rock it is possible to create a ques-
(a)

(b)

(c)

(d)

(e)

(f)

The blue beetle is north of the gold beetle. How likely is it that the blue beetle is east of the gold beetle?

Figure 1: (a) Our task requires participants to reason about the relative locations of two beetles in a pond. The rock surface is shown in grey, and both beetles are located somewhere on the rock. (b) A complete model that specifies the locations of both beetles. (c) A partial model that specifies the location of the gold beetle only. (d) The normative answer to the canonical question below the ponds can be computed by dividing the area marked with horizontal lines by the area marked with vertical lines. (e) A pond that produces a normative response of 0.75 . (f) Graphical model showing the relationships between variables described in the text.
tion with any desired probability as the normative response. A second advantage of our task is that it admits a range of variants that can potentially provide insight into probabilistic inference. One such variant is to ask the same question but to display the position of one beetle, as shown in Figure 1c. Finally, the next section illustrates that our task is useful for exploring probabilistic inference because it can be solved in principle by several methods.

## A toolbox of probability estimation methods

We now describe a toolbox that contains eight methods for estimating a conditional probability $P\left(r_{x} \mid r_{y}\right)$. This probability corresponds to the strength of an argument in which the premise is $r_{y}$ (e.g. "blue is north of gold") and the conclusion is $r_{x}$ (e.g. "blue is east of gold"). To simplify our notation we treat the topography $T$ as background knowledge and drop it from our equations.

Each method is intended to represent a family of related approaches rather than a single precisely-defined algorithm. After introducing each method, we describe one concrete instantiation of the method, but other instantiations of each method are possible.

1. Sample complete models. One way to estimate the probability $P\left(r_{x} \mid r_{y}\right)$ is to think of a number of models that make the premise true, and to consider how many of these models also make the conclusion true (Johnson-Laird et al., 1999). We refer to this approach as complete sampling, because each model considered provides a complete specification of the positions of the beetles. A normative version of complete sampling is:

$$
\begin{align*}
P\left(r_{x} \mid r_{y}\right) & =\int_{z_{b}, z_{g}} P\left(r_{x} \mid z_{b}, z_{g}\right) P\left(z_{b}, z_{g} \mid r_{y}\right) d z_{b} d z_{g} \\
& \approx \frac{1}{m} \sum_{i=1}^{m} P\left(r_{x} \mid z_{b}^{i}, z_{g}^{i}\right) \tag{1}
\end{align*}
$$

where each pair $\left(z_{b}^{i}, z_{g}^{i}\right)$ is a sample from $P\left(z_{b}, z_{g} \mid r_{y}\right)$. Equation 1 shows how sampling $m$ models is a way to approximate
an integral over all possible locations of the beetles, and the approach is normative in the sense that the approximation approaches the probability $P\left(r_{x} \mid r_{y}\right)$ as the number of samples becomes large.
2. Sample partial models. An alternative to complete sampling is to work with partial models such as the example in Figure 1c that specify the location of one beetle only. For example, a reasoner might imagine several possible locations of the gold beetle, and assess the probability of the conclusion in each case. A normative version of this method is:

$$
\begin{align*}
P\left(r_{x} \mid r_{y}\right) & =\int_{z_{g}} P\left(r_{x} \mid r_{y}, z_{g}\right) P\left(z_{g} \mid r_{y}\right) d z_{g} \\
& \approx \frac{1}{m} \sum_{i=1}^{m} P\left(r_{x} \mid r_{y}, z_{g}^{i}\right) \tag{2}
\end{align*}
$$

where each $z_{g}^{i}$ is a sample from $P\left(z_{g} \mid r_{y}\right)$. In Equation 1, the term $P\left(r_{x} \mid z_{b}^{i}, z_{g}^{i}\right)$ is either 1 or 0 , and can be computed by inspecting whether location $z_{b}^{i}$ lies to the east or the west of $z_{g}^{i}$. The analogous term in Equation 2 is $P\left(r_{x} \mid r_{y}, z_{g}^{i}\right)$, which can be computed using the ratio in Equation 3 below, or one of the other methods in the toolbox.

A premise such as "blue is north of gold" locates a figure object (blue beetle) with respect to a ground object (gold beetle), and Equation 2 could be used by reasoners who focus on the ground object. Another approach is to sample possible locations of the figure object. This approach can be formalized using a variant of Equation 2 in which $z_{g}$ is replaced by $z_{b}$.
3. Construct a model-based proof. If the process of sampling models (complete or partial) is accessible to awareness, then reflecting on this process may be enough to derive some conditional probabilities. Suppose for example that a reasoner samples the mental model shown in Figure 1ba model in which blue is north of gold (as required by the premise) and in which blue is east of gold (as stated by the conclusion). An alert reasoner may notice that this model can be paired with a twin that is identical except that the posi-
tions of blue and gold are reflected about the rock's axis of symmetry. In the twin model the premise still holds but the conclusion does not. Further reflection may establish the conviction that each model can be paired with a twin in this way, which means that every model that supports the conclusion is paired with a twin that rejects the conclusion. The predictions based on the models and their twins therefore "cancel out," revealing that $P\left(r_{x} \mid r_{y}\right)=0.5$. The overall chain of reasoning can be formalized as a mathematical proof that refers to models chosen "without loss of generality."
4. Exploit symmetry. The proof sketched in the previous section has two distinctive characteristics: it refers to specific models and it makes use of symmetry. Symmetry, however, can also be used to derive probabilities without needing to consider any specific models. In Figure 1a, a reflection in the T-shaped rock's axis of symmetry maps east onto west and vice versa, but leaves the shape of the rock unchanged. As a result, inverting east and west in any probability statement concerning the rock leaves the probability unchanged. For example, $P$ (blue east of gold|blue north of gold) must equal $P$ (blue west of gold|blue north of gold), and because these two probabilities sum to one both must equal 0.5 .

Symmetry can also be used to derive an unconditional probability such as $P($ blue east of gold $)=0.5$. It is vanishingly improbable that the beetles have identical x coordinates, which means that blue is either east or west of gold. Given that no available information distinguishes between these states, the principle of indifference (Strevens, 1998) implies that both must have a probability of 0.5 .
5. Ignore irrelevant information. A basic strategy for simplifying probabilistic inference is to ignore information that has no bearing on the conclusion. If the pond contains an upright square rock, for example, the $x$ and $y$ coordinates of a beetle are statistically independent-knowing one of these coordinates places no constraints on the other. It follows that $P\left(r_{x} \mid r_{y}\right)=P\left(r_{x}\right)=0.5$, where the final step follows from the principle of indifference as described in the previous section.
6. Apply the ratio rule. Suppose that $z_{g}$ (the position of the gold beetle) is known, as shown in Figure 1c. The conditional probability $P\left(r_{x} \mid r_{y}, z_{g}\right)$ can be computed using

$$
\begin{equation*}
P\left(r_{x} \mid r_{y}, z_{g}\right)=\frac{P\left(r_{x}, r_{y} \mid z_{g}\right)}{P\left(r_{y} \mid z_{g}\right)} \tag{3}
\end{equation*}
$$

Equation 3 is simple to compute by estimating the area of two regions in a diagram like Figure 1c. The denominator $P\left(r_{y} \mid z_{g}\right)$ is proportional to the area of rock that is north of $z_{g}$ (indicated with vertical lines in Figure 1d). The numerator $P\left(r_{x}, r_{y} \mid z_{g}\right)$ is proportional to the area that is north and east of $z_{g}$ (indicated with horizontal lines in Figure 1d).
7. Apply Bayes rule. Bayes rule can be applied as follows:

$$
\begin{equation*}
P\left(r_{x} \mid r_{y}\right)=\frac{P\left(r_{y} \mid r_{x}\right) P\left(r_{x}\right)}{P\left(r_{y}\right)}=P\left(r_{y} \mid r_{x}\right) \tag{4}
\end{equation*}
$$

where the final step follows from the observation above that $P\left(r_{y}\right)=P\left(r_{x}\right)=0.5$. In general $P\left(r_{y} \mid r_{x}\right)$ will be no easier to compute than $P\left(r_{x} \mid r_{y}\right)$, so applying Bayes rule may not be useful. There may be cases, however, in which one of these probabilities is easier to compute than the other.
8. Enumerate cases. One general strategy for solving a difficult problem is to break it down into a set of simpler subproblems. In Figure 1e, a reasoner may estimate $P\left(r_{x} \mid r_{y}\right)$ by considering 4 cases: either both beetles are on the bottom left rock, both are on the top right rock, blue is bottom left and gold is top right, or blue is top right and gold is bottom left. This strategy can be captured formally by introducing a variable $v$ that indicates which of the 4 cases obtains:

$$
\begin{equation*}
P\left(r_{x} \mid r_{y}\right)=\sum_{v} P\left(r_{x} \mid v, r_{y}\right) P\left(v \mid r_{y}\right) \tag{5}
\end{equation*}
$$

Each of the sub-problems is simpler than the original. For example, if both beetles are on the same rock, then $P\left(r_{x} \mid r_{y}\right)=$ 0.5 , as argued in our discussion of method 5 .

Using the toolbox. We suspect that all eight methods in the toolbox and possibly others are available to human reasoners. Given a problem, a reasoner must therefore decide which method or methods to try. Sometimes two or more methods will need to be combined: for example, methods 2 and 8 ("sample partial models" and "enumerate cases") both express the original probability as a function of several probabilities, which must be estimated in turn.

At present, a detailed mechanistic understanding of probability estimation seems remote. Establishing that people rely on one method for a given task is difficult, because numerous other methods must be ruled out. Establishing that people do not rely on a given method may be more tractable, because only one hypothesis must be ruled out. Given the recent emphasis on sampling as a mechanism for probabilistic inference, we designed a study to explore whether sampling is a plausible account of inference in our setting.

## Experiment

We suspect that people rely on sampling when other methods are unavailable, but are able to exploit symmetry when relevant. If so, then people's responses to symmetric ponds might be systematically different from their responses to other ponds. Our experiment was designed to test this possibility.
Participants. 36 participants were recruited using Amazon Mechanical Turk and paid for their participation.

Materials. Participants were asked to reason about the 26 ponds shown in Figure 2. The first 19 ponds are categorized as "double symmetry," "single symmetry" or "no symmetry" ponds depending on whether they have both vertical and horizontal symmetry, only one of these symmetries, or neither vertical nor horizontal symmetry. The next 5 ponds are "non50 " ponds, or ponds for which the normative response is other than 50.

Figure 2: Ponds used in the experiment. The normative response for all ponds in the first three categories (no symmetry, single symmetry, and double symmetry) is 50 . Ponds (l), (q), (s) and (x) all have rocks that enclose a body of water.

Procedure. Participants read an introduction that described an eccentric businessman who owned many square ponds. Each pond was said to contain a single gold beetle and a single blue beetle. Participants were told that the beetles could not swim, so each beetle was located somewhere on a rock. They then answered three simple questions that tested their comprehension of what they had just read. They remained on the introductory screen until they had answered all three questions correctly.

Each participant then saw the 24 ponds in Figures 2a-2x in a random order. For each pond, they read that "In this pond the blue beetle is $r 1$ of the gold beetle." They were then asked "How likely is it that the blue beetle is $r 2$ of the gold beetle?", and required to give their answer on a 0-100 scale with labels at 0 ("Not likely") and 100 ("Very likely"). For each pond and each participant, $(r 1, r 2)$ was a pair of perpendicular directions (e.g. (north, east), (north, west)) randomly drawn from the set of 8 such pairs.

After the 24 ponds participants responded to two catch trials that had unambiguous answers. One stated that "the blue beetle is east of the gold beetle" and asked participants to rate the likelihood that the blue beetle is west of the gold beetle. The second was similar but used the north-south instead of the east-west axis. The rocks used for these questions are shown in Figures 2y and 2z.
Results. We computed normative responses for each pond by assuming that the location of each beetle was generated from a uniform distribution over the rock surface. For single symmetry and double symmetry ponds, the normative response is always 50 . Normative responses for the non-50 and no symmetry ponds were computed by using complete sampling and drawing 100,000 samples. When creating the no symmetry ponds, the dimensions of the ponds (e.g. the relative lengths of the two T-segments in Figure 2a) were adjusted until complete sampling returned a normative result between 49.5 and 50.5.

Because the question associated with each pond was randomized, all responses were con-

Figure 3: (a) Mean human responses versus normative responses (b) Histogram of correlations achieved by individuals
verted to responses to the canonical question $P$ (blue north of gold|blue east of gold). Our conversion assumed that $P$ (blue north of gold|blue east of gold) $=$ $1-P$ (blue south of gold|blue east of gold), and similarly for other pairs of opposite directions. We also assumed that $P\left(r_{x} \mid r_{y}\right)=P\left(r_{y} \mid r_{x}\right)$, as discussed in Method 7 above. We expect that intuitive judgments do not always respect or even approximate this latter identity, but assuming that they do allows for a simple first look at our data.

16 participants failed to give ratings of 0 on both catch trials, and were dropped from all subsequent analyses. Figure 3a shows that mean responses among those who remained roughly tracked normative responses. Each point in the scatter plot corresponds to a pond. For example, the point at the top right of the plot corresponds to Figure 2t. The overall correlation between human and normative responses is 0.83 , and Figure 3b shows the correlations achieved by individual participants. Some participants had correlations near zero, but half had correlations exceeding 0.5. Overall, Figure 3 suggests that humans perform relatively well at the task.

The comparison of primary interest is between no sym-

Figure 4: Mean distance from 50 for no symmetry, single symmetry and double symmetry ponds. Results are shown for (a) experimental data (b) complete sampling model with $m=8$ (c) partial sampling model with $m=3$. These $m$ values were chosen to approximately match the variability in the human data.
metry ponds, single symmetry ponds and double symmetry ponds. The normative response for these ponds is always 50 , and we therefore analyzed the extent to which responses differed from 50. Figure 4a shows that responses for the double symmetry ponds tended to be closer to 50 than responses to the other two kinds of ponds. A Mann-Whitney test indicated that the distance from 50 was greater for no-symmetry ponds (median $=16, \mathrm{n}=120$ ) than for single-symmetry ponds (median $=13, \mathrm{n}=120$ ), $\mathrm{U}=5998, p=0.012$. A second test indicated that the difference between single-symmetry ponds and double-symmetry ponds (median $=0, \mathrm{n}=140$ ) was also statistically significant ( $\mathrm{U}=5260, p<0.001$ ). A natural interpretation of these results is that some participants relied on symmetry-based reasoning.

Complete and partial sampling can both be implemented in different ways, but the implementations suggested by Equations 1 and 2 are especially appealing. These implementations are relatively simple, and both approximate the normative response as the number of samples becomes large. Figures 4 b and Figures 4 c show results for these two implementations. In both cases, the number of samples is chosen so that the model matches the average distance from 50 in the human data. Although matched to humans in this respect, the two sampling models do not account for the special status of the double symmetry ponds in the human data. For example, the complete sampling model predicts no difference between the no symmetry and double symmetry ponds.

A second challenge for a sampling model is whether it can account for the human data given a psychologically plausible number of samples. For the sake of argument, assume that each of our participants is using complete sampling, and that each draws the same number of samples $m$ in Equation 1. Figure 5 shows how the predicted variability in the human data decreases as $m$ increases. If each participant drew one sample only, then some would give responses of 0 and others would give responses of 100 , and the average distance from 50 would be 50 for no symmetry, single symmetry and double symmetry ponds alike. If $m$ were very large, then each participant would give a response very close to 50 . Figure 5a shows that setting $m$ to 5 or 6 is enough to account for the variability in responses to the no symmetry and single symmetry ponds.

Figure 5: Distance from 50 predicted by (a) complete and (b) partial sampling as the number of samples increases. In (a) a single model curve is shown in black because model predictions are identical for no symmetry, single symmetry and double symmetry ponds. In (b) three model curves are shown because the model predictions for the three classes of ponds are close but not identical.

For double symmetry ponds, however, $m$ must be set higher than 20 in order to match the human data. A value this high does not seem psychologically plausible, and challenges the hypothesis that people rely on complete sampling when reasoning about double symmetry ponds.

Figure 5b shows the analogous plot for partial sampling. In this case, setting $m$ to 10 or so is enough to account for the variability in responses to the double symmetry ponds. This value seems high, but perhaps not high enough to definitively rule out partial sampling as a psychological account. The dif-
ference in the human data between double symmetry and both single and no symmetry ponds, however, remains a challenge for models that rely on partial sampling.

Discussion. Although our implementations of complete and partial sampling do not account well for our data, it is possible that other implementations of these methods will perform better. Our implementations assume that models are randomly sampled from the set of all models consistent with the premise of a given argument, but in reality people may sample some kinds of models more often than others. For example, perhaps people prefer to locate the beetle mentioned first towards the left of the pond (Jahn et al., 2007) or towards the top (Levelt \& Maasen, 1981). Previous accounts of spatial reasoning have documented effects like these (Jahn et al., 2007), and it seems likely that similar effects will emerge in our setting.

In addition to left-right and up-down preferences, people may also prefer to sample models in which the beetles are located along axes of symmetry. A preference of this kind could help to explain results that are also consistent with symmetrybased reasoning. In Figure 1a, for example, a partial sampling method that uses just one sample will generate the normative response of 50 provided that the single sample locates the gold beetle along the rock's axis of symmetry.

Throughout we have mostly considered inference methods that compute or approximate normative responses. Our data suggest that people's responses to our task are roughly consistent with normative inference, but in other settings people make inferences that are far from normative. For example, base-rate neglect may occur if people apply Bayes rule without including the prior (Kahneman \& Tversky, 1973). In other cases people may rely on sampling but sample from the "wrong" distribution-for example, some of our participants may have sampled from $P\left(z_{g}\right)$ rather than $P\left(z_{g} \mid r_{y}\right)$ in Equation 2. Each method in the toolbox can be applied in normative and non-normative ways, and detailed work is required to understand how a method is applied in any given setting.

## Conclusion

We suggested that people make use of a mental toolbox that includes several qualitatively different methods for probabilistic inference. Each of these methods has several variants, and some methods can be combined with each other. We therefore believe that people can draw on a set of inference methods that is relatively large, which makes understanding probabilistic inference at the process level very challenging indeed.

Like previous researchers we believe that behavioral experiments can provide some insight into the processes that support probabilistic inference. We described a spatial reasoning task that appears to be a natural candidate for inference by sampling, but our results suggest that any simple sampling method is unlikely to fully capture the way in which people approach the task. Ruling out one simple hypothesis about inference is one thing, but providing a comprehensive account
of probabilistic inference is another thing entirely. We confess to some scepticism about whether behavioral data alone are enough to reveal the mind's algorithms for probabilistic inference.

# The Narrow Conception of Computational Psychology 

#### Abstract

One particularly successful approach to modeling within cognitive science is computational psychology. Computational psychology explores psychological processes by building and testing computational models with human data. In this paper, it is argued that a specific approach to understanding computation, what is called the 'narrow conception', has problematically limited the kinds of models, theories, and explanations that are offered within computational psychology. After raising two problems for the narrow conception, an alternative, 'wide approach' to computational psychology is proposed.

Keywords: narrow conception, individualism, computation, psychology, explanation

## Introduction

Cognitive science has gained a good deal of theoretical and methodological impetus from thinking about how psychological processes can be described, studied, and simulated using different types of models. One particularly successful approach to modeling is computational cognitive modeling or, more simply, computational psychology. Computational psychology explores psychological processes by building and testing computational models with human data (Sun, 2008).

In this paper, it is argued that a specific approach to understanding computation, what is dubbed the 'narrow conception', has problematically limited the kinds of models, theories, and explanations that are sometimes offered within computational psychology.

The impetus for the current study arises from a growing debate around the role, nature and status of computation within psychological investigations. Several authors have begun to re-examine what computationalism stands to offer the cognate disciplines (Piccinini, 2015; Milkowski, 2015). The current discussion stands to contribute to this growing trend by exploring and examining one important assumption that underwrites a notable swath of research within computational psychology. The goal is to show that computational psychology has overlooked an important constraining assumption.

## Computational Psychology

For many, computational theory provides a theoretically flexible and expressively powerful tool for exploring cognition (Anderson 1983; Pylyshyn, 1984; Newell, 1990; Anderson \& Lebiere, 1998, 2003). The computational approach allows researchers to construct detailed accounts of the mechanisms, structures, and processes that underwrite cognition. In testing and extending the theories of other domains, such as cognitive psychology and artificial intelligence, computational investigations offer a functionally viable yet mathematically rigorous way of exploring cognitive or psychological processes.

A good deal of the explanatory value of computational psychology lies not only in the ability to produce computer simulations, but also in using those simulations to make predictions about human data. By matching the 'fit' of human data with computer simulations, researchers establish systematic relationships between computational models and psychological processes, which can reveal the underlying structure and form of cognitive functionalities (Sun \& Ling, 1998).

Consider three illustrative examples of computational psychology in action. First, consider Shiffrin and Steyvers' (1997) REM model of episodic memory. Shiffrin and Steyvers' model is one instance of a class of abstract, computational models that attempt to explain recognition judgments. These models employ a 'global matching' procedure. The global matching procedure produces a familiarity signal that indicates whether or not an item has been previously presented to the model - a test cue, for example, that matches two features of one item will yield a higher familiarity judgment than a test cue that matches one feature of each of the two items.
Shiffrin and Steyvers' model puts a Bayesian twist on the global matching procedure. The REM model calculates the likelihood of whether a cue item matches or corresponds to particular stored memory traces by assigning values to each of the stored items. When the model is tested to see if it can identify whether cue items are new or old, the cues are compared with each trace item in memory such that the model calculates the likelihood of the retrieval cue and the trace item matching. Recognition judgment is explained in terms of a probabilistic familiarity process operating within memory.
According to Shiffrin and Steyvers, the REM model accounts for a number of distinct memory effects. One example is the word frequency mirror effect. The word frequency mirror effect says that subjects often make more false alarms on high-frequency lures (foils) versus lowfrequency lures and more correct "old" responses to lowfrequency targets versus high-frequency target when making recognition judgments (Glanzer et al., 1993). The REM is able to accommodate the word frequency effect in virtue of the fact that low-frequency words have more unusual features than high-frequency words (e.g., more syllables). The REM model is able to use a slightly lower value when generating low frequency lures items during matching, which results in these items having slightly higher feature values.

The relevance of the REM model is that in measuring the fit of the model to behavioral data and by adopting a Bayesian approach to the global matching procedure, the REM model focuses on both the essential interplay between modeling and experimental data and formalizing cognitive processes in a computationally rigorous way.

Next, consider Dienes’ (1992) connectionist model of implicit language learning. Dienes' model attempts to computationally instantiate how language users come to implicitly understand artificial grammars using artificial neural networks. In particular, Dienes' model uses a feedforward autoassociator network.

In a feed-forward autoassociator network - which is a version of the more standard multilayer network - activation passes through the connection weights of the network just once to produce the output activation. The feed-forward autoassociator contrasts with recurrent autoassociator networks, in which the output activation arrives back at each node and is passed through the weights again until a stable state is reached.
In terms of network training, Dienes' model was presented with the same learning material as human subjects, which included arbitrary strings of letters, such as MTTTTV or MTTVT. These features of strings were represented as activations to the network's input layer. Depending on whether the feature was present or absent, the unit coding the feature would have an activation of either 1 or 0 . Once the network learned the arbitrary training strings, similar to experimental tests, the model was then made to make grammaticality judgments on new strings of letters. The goal was to see if the network had learnt the underlying grammatical principles that implicitly structured the arbitrary strings being presented.

When Dienes' tested the model, it was found the network was able to distinguish grammatical versus ungrammatical strings. The network was able to reproduce the training strings by adding or subtracting strings from an exemplar case. The model predicted each feature of a string based on some set of the remaining features from an exemplar. When Dienes' compared network results to that of human subjects, it was found that the network could classify test strings as well as people could. The network tended to reproduce grammatical test strings more faithfully than nongrammatical test strings.
Dienes' connectionist model stands as a further interesting example of computational research, as it provides a computational account of implicit artificial grammar learning that measures the fit of the model with behavioral data. By investigating how artificial neural networks handle artificial grammar tasks, Dienes' attempts to undercover the computational processes and representations underlying implicit language learning.
A third example comes from Osherson et al.'s (1990) declarative model of inductive reasoning. Osherson et al.'s (1990) model attempts to investigate the computational underpinnings of 'inductive' reasoning - inductive reasoning is the process by which premises are thought to lend non-conclusive support to the truth of specific conclusions.
In Osherson et al.' model, inductive reasoning is explained in terms of the assessment of propositional statements according to the similarity between premise and conclusion categories For example, consider two inferential chains: (i)

Mice have property X/All mammals have property X and (ii) Horses have property X/All mammals have property X. The category of 'mammal' in the conclusion covers both mice and horses. For Osherson et al., understanding how humans are able to make inferences about mice and horses depends on understanding how structural relationships between different categories are established - for example, understanding that mice and horses are instances of the subordinate category mammal.
Two features allow Osherson et al.'s model to make sense of cases such as the above. The first is that the model assesses the similarity between premise categories and conclusion categories. The second is that the model measures how well the premise categories covers the superordinate category. Coverage between premise and conclusion categories is assessed in terms of the average similarity of the premise category to members of the superordinate category. For instance, to the extent that horses are more typical mammals than mice, and therefore more similar to other kinds of mammals, (ii) will have greater coverage than (i).
Osherson et al.'s model is interesting because it addresses a number of empirical phenomena. One example is similarity effects. Similarity effects occur when people make inferences based on the perceived similarity between items in different inferential chains. Osherson et al. (2008) found, for example, that when people were given a choice between two syllogistic arguments about $95 \%$ chose the argument that they perceived to contain the greater similarity between premise and conclusion categories, e.g., sparrows to robins and blue jays versus geese to robins and blue jays. Osherson et al.'s model was able to accommodate such cases by assessing the relationship between the subordinate and premise categories.

Similar to the previous models, Osherson et al.'s declarative model is an illustrative example of computational psychology, because it is not only informed by and tested against empirical data, but it also attempts to identify the computational procedures and properties underlying complex cognitive processes, such as inductive reasoning.

The point of the previous survey is that each of the three models provides a paradigmatic example of computational psychology. Each model attempts to undercover the computational underpinnings of various cognitive processes via the construction and testing of computer models with human data. These models help to tease out the underwriting assumptions within computational research.

## The Narrow Conception

With the domain of analysis laid out, the task now is to examine one approach to understanding computation that underlies a good deal of the research within computational psychology, what is labeled the 'narrow conception'.
In order to get a better handle on the narrow conception, consider what Segal (1991) says about computational cognitive systems, he writes: "It seems likely that whole
subjects (or whole brains) make up large, integrated, computational systems...the whole subject is the largest acceptable candidate for the supervenience base because it is the largest integrated system available" (p.492). For Segal, the individual or whole subject (which is plausibly identical to the whole brain) is the largest unit available for computational, psychological investigation. Newell et al. (1989) offer a similar view, writing: "Symbol systems are an interior milieu, protected from the external world, in which information processing in the service of the organism can proceed" (1989, p.107). Here, again, computational systems are limited to the boundary of the individual.

Consider Fodor (1983) next: "Mechanisms of transduction are thus contrasted with computational mechanisms: whereas the latter may perform quite complicated, inference-like transformations - the former are supposed - at least ideally - to preserve the information content of their input" (1983, p. 41). Fodor's contrast between sensory transducers and computational mechanisms is indicative of where he thinks computational systems are located. Computational systems are sandwiched between transducers and motor outputs. Finally, consider what Egan (2000) says on the matter: "A computational theory prescinds from the actual environment because it aims to provide an abstract, and hence completely general, description of a mechanism that affords a basis for predicting and explaining its behaviour" (p.191). Only by abstracting away from the embedding environment and focusing on the individual can one begin to provide successful computational analyses. Once again, the outer limit of formal analysis for computational systems is the individual.

Common to each of these views is the idea that the individual or some sub-module, conceived of in terms of the primary unit of action, constitutes the largest organizational system amendable to computational description (i.e. computational modeling). The individual marks the conceptual boundary for computational, psychological investigations. Here is one way the view might be formulated:

## The Narrow Conception: Computational cognitive

 systems are, and should be studied as if they were, located entirely within the individual or some submodule.Something in the spirit of this claim seems to have operated implicitly within a good swath of computational psychology. The narrow conception, if true, represents a principled claim about where and how computational cognitive systems should be studied. It constitutes a plausible and substantive proposal for computational psychology.
Consider the methodological implications of the narrow conception. If computational systems are wholly interior to the individual, then computational modeling should have as its target only those systems and processes that are
individual-centered. As Segal diagnosis the situation: "Whole subjects plus embedding environments do not make up integrated, computational systems" (1991, p.492). The embedding environment plus individual will always fail to be adequate for computational analysis. Only the individual or some sub-system will be sufficient for computational modeling.

One motivation for adopting the narrow conception is that it provides a powerful way of explaining the causal powers of cognition. If cognitive systems are computational systems and computational systems are located within the individual, then identifying the causal properties and powers of computational systems provides insight into causal power of cognitive processes and abilities. Memory effects, such as primacy and recency affects, for example, will be best explained by focusing on the computational search strategies used by individuals during various tasks (e.g., exhaustive versus terminal search) (Sternberg, 1969). Only by identifying the distinct functional and causal properties intrinsic to the individual are rigorous computational, psychological explanations provided.
What is interesting about the narrow conception, besides its relatively straightforward nature, is that it is plausibly supported by and conforms to a good deal of research within computational psychology. This is why authors such as Segal claim that it is "likely" that the whole subject is the largest unit of analysis. The narrow approach is an empirical wager on how computational cognitive systems are distributed in nature.
Return to the three previous models to see why. First, consider how Shiffrin and Stevyer describe their model: "This cued recall model is meant to illustrate one plausible way in which retrieval from episodic images and retrieval from lexical/semantic images could work hand in hand to allow recall to take place" (1997, p.160). The emphasis on retrieval and storage is indicative of the narrow conception: the computational processes under investigation are localized within the individual. It is only once items are learned and internalized that computational processes can operate over them. The Bayesian matching procedure applies to items stored internally within an individual's episodic memory.

Consider, next, how Dienes' conceives of his model, he writes: "[L]awful behaviour may be produced by a connectionist network in which rules or hypotheses are not explicitly represented" (1992, p.40). A little later he writes: "the subject of the models obeys the rules, but does not represent them symbolically"(1992, p.70). Again, the message is plain. The artificial neural network represents a cognitive system that employs internal representations and rules that solve artificial grammar tasks, and the human data helps to reveal these internal computational processes and structures. The connectionist network is meant to represent the internal computational system within a subject that is used to carry out the cognitive task.
Finally, consider Osherson et al.'s model. In studying inductive reasoning, Osherson et al. adopt the following
position: "The similarity-coverage model assumes that the existence of a pre-established hierarchy of categories that classify the instances figuring in an argument. The success of the model in predicting the qualitative phenomena...testifies to the approximate soundness of the model's assumptions" (1993, p.200). What emerges, again, is a particular interpretation of what has been revealed about the underlying computational system. Reasoning about inference chains is an internal computational process that requires the deployment of particular categorical hierarchies. The boundary of the cognitive system is once again fixed at the formal system detecting relationships between argument stimulus input and subordinate categories.

Each of the three examples conforms, in varying degrees, to the narrow conception. The individual or some subcomponent is the complete and natural unit of computational theorizing. The individual, in each case, is conceived of, and studied as if it were, the largest organized set of components capable of supporting computational investigation.

But notice that in addition to helping researchers to better understand models, the narrow conception also helps to structure the way in which researchers go about identifying and constructing investigations. The narrow conception also offers a means for thinking about where and what to look for when during investigation. It proposes methodological guidelines for studying computational cognitive systems.

Recall, for instance, that each of the three models addressed particular problems, proposed different solutions, and provided different explanations. Shiffrin and Stevyers' model, for instance, conceived of recognition as a problem of item matching. This meant that the computational processes involved searching through memory traces using a global matching procedure. Dienes' model, on the other hand, conceived of implicit learning as a form of pattern recognition. This led to looking for the internal exemplar representations and rules that allowed the network to identify and classify new letter strings. Finally, in Osherson et al.'s study, inference was taken to involve detecting structural category relations. This meant that it attempted to build a model around understanding how such categorical relationships could be structured.

One way to understand why each study offers the types of model it does and measures the fit of its model(s) against the types of experimental data that it does is as a result of the constraining influence of the narrow conception. In directing attention to the individual and its sub-components, the narrow conception sets up certain implicit conceptual boundaries. It limits which computational explanations are seen as viable, which properties and processes are taken to be necessary for investigation, and which solutions are considered plausible. The explanatory space of options surrounding computational theorizing is delimited. The narrow conception curbs the conceptual and methodological understanding of computation available for use within investigations.

## The Wide Conception

The discussion up until this point has been largely descriptive. The goal has been to articulate what the narrow conception amounts to and provide a sense of the way in which it imposes interpretative and methodological constraints on research. In this final section, the aim is to provide a critical analysis of the view. Two problems are raised.
The first problem follows on the heels of the constraining influence of the narrow conception. The issue is that if the narrow conception limits the theoretical and explanatory horizons of computational investigations, then it also limits the kinds of research that can conducted. This is an undesirable state of affairs insofar as a healthy domain of investigation should have the broadest range of alternatives available when conducting research. If researchers are limited in the potential avenues they might explore, then the range of theories, explanations, and models they end up offering may turn out to be impoverished. In an ideal world, there will be as few constraining or biasing assumptions as possible during investigation. Insofar as the narrow conception operates as a constraining assumption on computational psychology, it forms a barrier to conducting successful research.
The history of behaviorism offers an instructive example. In both its logical and philosophical forms, behaviorism eschewed recourse to 'mental' vocabulary. It held that only 'observable behaviour' was the proper subject of psychological investigation. One result of its constraining influence was North American psychology made little reference to mental structures and processes. It took almost 30 years to reclaim the conceptual territory lost to behaviorism (Gardner, 1985). The claim here is not quite so negative, but the moral is the same. The narrow conception has potentially closed off interesting avenues of computational research because of its constraining influence.
One might respond by arguing that the above concern is only a really problem if the narrow conception turns out to be false. But that given the wealth of empirical support the view enjoys, there is really no reason to think that the narrow conception is in fact not the right view to hold. The problem with this response is that gets the order of explanation backwards. It is not that the narrow conception is true because computational research conforms to its strictures. Rather, it is because the narrow conception imposes certain restrictions on research that computational investigations conform to its strictures. The narrow conception problematically limits the range of alternatives considered before, during and after investigation.
The second concern is that the narrow conception, on occasion, provides explanatory weaker accounts of psychological phenomena in virtue of its over emphasis on individual-bound systems. Because the narrow conception emphasizes the individual as the limit of computational explanations, investigations based on its strictures can fail to
identify the important computational role played by environmental elements.
Consider an example from the history of cognitive science. Problem solving was traditionally thought to involve a search through problem space (Newell, Shaw, \& Simon, 1960). One way this approach was computationally instantiated was to simulate agents searching mentally through a virtual problem space during various tasks (Newell \& Simon, 1976). One issue with these early approaches is that cognizers often interactively explore problems by physical manipulating external structures (Kirsh, 2009). These types of actions are more than just pragmatic, as they crucially help cognizers to simplify and transform complex problems. Computational models that focused narrowly on internal searches missed out on the simplifying computational role of epistemic actions (see Wilson, 2004; Clark, 2008).
Insofar as computational explanations fail to pay sufficient attention to elements of the environment that offload and distribute cognitive activities, they stand to provide weaker accounts of psychological phenomena. Computational explanations that are overly reliant on the narrow conception, such as in the above case, can supply explanatorily weaker accounts (Wilson, 2014). This is not to say that every computational explanation that subscribes to the narrow conception is explanatorily weaker. Rather, it is to point out that because there are blind spots imposed by the narrow conception, some computational explanations may, on occasion, be weaker than potential alternatives.

The previous two concerns should not be taken to undermine the narrow conception in its entirety. Instead, the concerns are better understood as forming a negative case against the sufficiency of the narrow conception as a global thesis. Given this, it will be worth exploring a possible alternative approach to understanding computation.

Wide computationalism is the idea that at least some of the elements of computational cognitive systems can reside outside the individual (Wilson, 1994, 1995; Hutchins, 1995; Kersten, 2016; Kersten \& Wilson, 2016). Wide computational systems are those systems that recruit computational units from the larger embedding environment. Similar ideas have also been offered about cognition under the label of 'situated, embedded and extended' cognition (see Wilson, 2004; Clark 2008).

The viability of wide computationalism follows from the location neutrality of computational individuation. Wilson, for example, writes: "There is nothing in the method of computational individuation itself... which implies that the class of physical features mapped by a realization function cannot include members that are part of the environment of the individual" (1994, p.355). Because formal systems are medium neutral, it is at least possible that some of the computational elements include parts outside the individual. Wide computationalism stands in contrast to the narrow conception insofar as it pushes computational analysis outside the individual. Wide computationalism also gains
support from a number of empirical studies in human and animal psychology (see Kersten, 2016).

Wide computationalism is a locational thesis about the realization or supervenience base of computational cognitive systems. It is a view about the scope of physical systems, processes, and components that are capable of supporting computational analysis. What this means is that although wide computationalism is compatible with either an individualist (Segal, 1991) or an externalist (Shagrir, 2001) interpretation, it is, strictly speaking, non-committal on issues of representational or semantic individuation.

For present purposes, the truth of wide computationalism is less important than the alternative it presents. This is because wide computationalism provides one potential alternative for understanding computation within computational psychology. In articulating a conception of computation that moves beyond the individual, wide computationalism stands to supply an importantly distinct approach to understanding computational investigations. By exploiting the location neutrality of computational individuation, wide computationalism re-conceptualizes the study of computational cognitive systems as at least partially requiring analysis of the embedding environment.
Investigations based on this wide approach stand to pay closer attention to the role of the environment, given their explicit focus on computational systems spreading out across the brain, body and world. Examples of the wide conception in action, for example, include agent-based models or swarm behaviour models (see Dawson, 2010). One way to view wide computationalism, then, is as an alternative conception of the underlying concept of computation that may be used within computational psychology.

Another way to make the point is to say that whereas the narrow conception might be construed as a restrictive monistic and a priori assumption about how cognitive states and processes are studied, wide computationalism provides an alternative pluralistic, empirical approach to investigation. Instead of viewing the narrow conception as exhausting the logical space of investigation, wide computationalism might be seen as a further, important additional explanatory strategy that can be used when thinking about computational investigations. Some phenomena may be more amendable to wide investigation, while others may conform more closely to the narrow conception. It may be that in some cases a narrow approach is preferable, while in others a wide approach is more suitable. In opening up the logical space, computational psychology is better positioned to precede both methodologically and theoretically.

This is only the briefest of sketches, but it should begin to provide a sense of how computational psychology may move beyond the narrow conception. However, the wide approach is not offered as a replacement to the narrow conception, but rather as a supplement. Wide computationalism is simply an extension of the logic inherent within computational psychology. The point is that
it can step in when computational investigations run up against the limits of the narrow conception. On the proposed view, research that conforms to the narrow conception, such as the three examples surveyed, still makes a valuable and important contribution to cognitive science and psychology.

The general point to note in concluding is that in demonstrating the commitment of three paradigmatic examples of computational research to the narrow conception and outlining two problems the view faces, the case for the existence and problematic influence of the view has been at least partially motivated. The narrow conception has, on occasion, problematically structured at least some of the thinking within computational psychology, and that in doing so it has laid down some of the conceptual track on which the computational research train has run. Given this, further examination of previously underexplored approaches, such as wide computationalism, may help enrich the range of theories, models, and explanations offered within computational psychology.

# Resolving Two Tensions in 4E Cognition Using Wide Computationalism 

Luke Kersten (L.M.Kersten@sms.ed.ac.uk)<br>School of Philosophy, Psychology, and Language Sciences, University of Edinburgh<br>3 Charles Street, EH89AD, Edinburgh, UK<br>Joe Dewhurst (s0819473@sms.ed.ac.uk)<br>School of Philosophy, Psychology, and Language Sciences, University of Edinburgh<br>3 Charles Street, EH89AD, Edinburgh, UK<br>George Deane (s1670299@sms.ed.ac.uk)<br>School of Philosophy, Psychology, and Language Sciences, University of Edinburgh<br>3 Charles Street, EH89AD, Edinburgh, UK

#### Abstract

Recently, some authors have begun to raise questions about the potential unity of 4E (enactive, embedded, embodied, extended) cognition as a distinct research programme within cognitive science. Two tensions, in particular, have been raised: (i) that the body-centric claims embodied cognition militate against the distributed tendencies of extended cognition and (ii) that the body/environment distinction emphasized by enactivism stands in tension with the world-spanning claims of extended cognition. The goal of this paper is to resolve tensions (i) and (ii). The proposal is that a form of 'wide computationalism' can be used to reconcile the two tensions and, in so doing, articulate a common theoretical core for 4 E cognition.

Keywords: 4E cognition, wide computationalism, bodycentrism, extended functionalism, autopoietic theory

## Introduction

Enactive, embodied, embedded and extended cognition, or simply 4E cognition, has often been thought to form a collective challenge to traditional or classical cognitive science (Menary, 2010). Common to many of these views is the idea that cognitive processes are often integrated with and heavily dependent on bodily and environmental structures (Varela, Thompson, \& Rosch, 1991; Clark \& Chalmers, 1998; Haugeland, 1998; Hutto \& Myin, 2013).
More recently, some authors have begun to raise questions about the potential unity of 4 E cognition as a distinct research programme within cognitive science (Clark, 2008a; Clark \& Kiverstein, 2009; Menary, 2010). Two tensions, in particular, have been raised: (i) that the body-centric claims embodied cognition militate against the distributed tendencies of extended cognition and (ii) that the body/environment distinction emphasized by enactivism stands in tension with the world-spanning claims of extended cognition. These two tensions constitute a problem for cognitive science insofar as 4 E cognition is thought to form distinct field of study, and not merely a loose set of alphabetically related approaches (Ward \& Stapleton, 2012).
The goal of this paper is to resolve tensions (i) and (ii). The proposal is that a form of 'wide computationalism' can be used to reconcile the two tensions, and, in so doing,
articulate a common theoretical core for 4 E cognition. It is argued that wide computationalism satisfies the various demands of the embodied, enactive and extended theorists in virtue of placing a simultaneous emphasis on abstract analysis and functional mechanisms.

## Two Tensions in 4E Cognition

Following Clark and Kiverstein (2009), three 'strands' can be identified as generating the two tensions within 4E cognition, these include: body-centrism, extended functionalism, and autopoietic theory.

The first strand is body-centrism. This is the idea that the body has a non-trivial role in determining mental states and functioning, that the details of a creature's embodiment have a profound affect on the nature and functioning of the mind (Noë \& Reagan, 2001; Noë, 2004; Gallagher, 2005). Shapiro, for instance, writes: " $[\mathrm{P}]$ sychological processes are incomplete without the body's contributions. Vision for human beings is a process that includes features of the human body. This means that a description of various perceptual capacities cannot maintain body-neutrality" (2004, p.190). The body is depicted as 'intrinsically special.' Body-centrists hold that without discussion of the unique contribution of bodily structures and activities, cognitive explanations are crucially lacking. The view is also sometimes called the "constitutive-contribution claim" (Clark, 2008a).

Support for body-centrism comes from research highlighting the functional dependences of mental processes on bodily structures and activities (Clark, 2008a, b). Work on embodiment and conceptualization, for example, demonstrates that understanding abstract concepts, such as love, often depends on the metaphorical expansions of more familiar concepts, such as up and down or front and back (Lakoff \& Johnson, 1980).

The second strand is extended functionalism. For the extended functionalist, cognitive systems are functional wholes distributed across diverse sets of components and processes. Cognitive activities involve a complex balancing act between brain, body and world (Harman 1998, Clark \& Chalmers, 1998; Wilson 2004; Wheeler, 2010). The spirit of
extended functionalism is embodied in what Clark and Chalmer's (1998) call the 'parity principle', which says: "[i]f, as we confront some task, a part of the world functions as a process which, were it done in the head, we would have no hesitation in recognizing as a part of the cognitive process, then that part of the world is (so we claim) part of the cognitive process" (p.29). The parity principle stresses the location neutrality of cognitive analysis. It highlights abstract, functional analysis in place of detailed physiological investigations. The view is also sometimes called the "distributor role" in discussions of embodied cognition (Wilson \& Foglia, 2016).

Support for extended functionalism comes from research focusing on the way in which cognizers often exploit, scaffold, and distribute cognitive activates across bodily and environment structures (Clark, 2005, 2008b). Work on problem solving, for example, shows that people often simplify and transform complex problems, such as the Tower of Hanoi, by manipulating physical environments (Kirsh \& Maglio, 1995; Kirsh, 2009).

The final strand to consider is 'autopoietic theory.' The central claim of autopoietic theory is that cognitive systems are created by the reciprocal interaction of internal and external components in the service of some larger function, such as homeostasis (Weber and Varela, 2002). Autopoietic theory connects to 4 E cognition via the notion of 'sense making'.

Autopoietic theory maintains that because living systems, such as cognition, are autonomous, self-regulating systems, and sense making is required for maintaining a system's boundary, autopoietic systems produce and maintain a physical boundary between the organism and its physical environment. Because sense making is a self-regulating act, organisms often bring forth meaning on the basis of their autonomy - autonomy in this context means actively sustaining identity under precarious circumstances. A system maintains its organization by regulating its interactions with the environment via sense making (Thompson, 2007; Wheeler, 2009).

Consider how each of the three strands fit within 4E cognition. First, enactivism and embodied cognition often endorse body-centrism in virtue of emphasizing what they take to be the unique contributions of bodily structures and activities, such as sensorimotor knowledge. Second, extended cognition often endorses extended functionalism by assigning a non-trivial role to environmental elements in sustaining cognitive activities. Third, enactivism is often framed in terms of autopoietic theory insofar as sense making is treated as a constitutive element of demarcating the organism/environment boundary.

Not every version of enactivism is committed to autopoietic theory, and not every version of embodied cognition is committed to body-centrism. There is, at least in principle, some compatibility between the various views. Nonetheless, because some versions of each view are, as a matter of fact, committed to the different strands, the two
tensions do represent a substantial challenge for 4E cognition.

Consider, then, how the three strands generate the two tensions. The first tension follows from the fact that if the body has a non-trivial role in determining mental states, then cognition cannot also be location neutral; the converse of which is that if cognition is location neutral, then the body cannot have a privileged status in cognition. If the body is simply an instrument through which larger functional complexes are realized, then bodily structures cannot form the exclusive realization base of cognitive activities. Extended functionalism precludes the constitutive contribution claims of body-centrism, while body-centrism precludes the possibility of cognitive systems extending beyond the boundary of the individual.

The second tension emerges from the idea that if extended functionalism is correct, and cognitive systems can stretch out into the world, then living systems cannot also be coextensive with cognitive systems, as per enactivism. Here is Clark and Kiverstein (2009) diagnosing the situation:

> If living systems and cognitive systems are identical, both systems must have boundaries that coincide. However, the boundaries of the living systems are the physical boundaries of the organism. If extended functionalism is correct, the boundaries of cognitive systems can criss-cross the physical boundaries of the organism. This is precisely what the enactivists cannot allow. (p.2).

Extended cognition requires that cognitive systems recruit resources outside the boundary of the individual. Enactivism, however, denies this possibility. It therefore undercuts the identification of cognitive systems with extended systems by maintaining a sharp distinction between the physical boundaries of the organism and the environment, assuming also that each view is taken to be a global thesis about cognition.

Tensions (i) and (ii) emerge as a function of the opposing elements within 4E cognition. Tension (i) emerges as a result of body-centrism's emphasis on the unique contribution of the bodily structures, while tension (ii) follows from the location-neutrality of extended functionalism. The tensions are important for at least two reasons. One is that they stand to undermine the collective thrust of 4 E cognition by showcasing fractures within the larger framework (Clark, 2008a). Another is that they reveal a lack of 'deep theoretical core' within 4E cognition. They expose a conceptual gap at the centre of an otherwise vibrant and animated collection of research (Clark \& Kiverstein, 2009).

One constructive proposal that has been offered to resolve the first of the two tensions is Clark (2008a). Clark's suggestion is that the body plays an enabling computational role within cognitive processes that selectively impacts both conscious and non-conscious computational strategies. Clark's view is that the first tension can be resolved by
viewing bodily structures in terms of enabling different kinds of information processing. The cognitive significance of the body resides in the functional role it occupies within 'intelligent' organization - this is what explains the intuition that the body makes a special contribution to cognition.

Clark's proposal, although not explicitly, also provides a solution to the 'deep theoretical core' problem. This is because it articulates, at least in principle, a common 'computational/functional core' for 4 E cognition. Embedded, embodied, and extended approaches are unified by a shared emphasis on distributed functional complexes supporting cognitive activities. What is important is that bodily or environmental structures are situated within a larger computational/functional framework during investigation. Some systems will be individual bound (as per enactive and embodied cognition), while others will spread out across brain, body and world (as per extended cognition).
One problem with Clark's response, despite its advantages, is that it fails to specify the relationship between physical mechanisms and computational systems finely enough. It fails to cash out what it is that allows the body to play its 'enabling role' in cognitive activities in the first place. If the body is merely one element within a larger brain-body-world complex, why should it have such a constraining and enabling role? The problem is not that Clark is wrong in proposing that the body has an enabling computational role, but that the suggestion alone does not suffice to specify what the role amounts to and why it should prove important.

## Two Tensions Resolved

In what follows, we argue that Clark's proposal can be supplemented and further developed by appealing to the notion of 'wide computationalism'. We begin by outlining and motivating wide computationalism and then turn to showing how the view addresses each of the two tensions.
Wide computationalism is the view that some of the units of computational cognitive systems reside outside the individual (Wilson, 1994, 1995, 2004; Hutchins, 1995; Clark \& Wilson, 2009; Kersten, 2016; Kersten \& Wilson, 2016). Wide computationalism stakes a claim on the scope of physical systems, processes, and components that are capable of supporting computational analysis. A wide computational perspective opens up the possibility of exploring computational units that include the brain and aspects of the beyond-the-head environment.
Wide computationalism gains a theoretical foothold via the location neutrality of computational individuation. Since formal systems are indifferent to physical medium and computation is a formal system, it is possible that at least some states and processes relevant to a computational system may reside outside the individual. Nothing in the method of computational individuation precludes the possibility of wide computational systems.
Traditionally, wide computationalism has been committed to what some call "causal mapping accounts" of
computation (Chalmers, 1994; Chrisley, 1995). Causal mapping accounts maintain that in order for a physical system to implement an actual computation there must be a mapping of computational states to physical states such that transitions between the physical states result in corresponding transitions between the computational states. Causal mapping accounts, whether wide or narrow, articulate the conditions for ascription of computational implementation in terms of isomorphic mappings between computational descriptions and physical descriptions via transitions between physical states.
More recently, some have argued that wide computationalism should adopt a 'mechanistic' approach to computation (Kersten, 2016). Wide mechanistic computation differs from causal mapping formulations in that it frames the conditions of concrete computation in terms of functional mechanisms (Milkowski, 2013, 2015; Piccinini, 2015; Dewhurst, 2016). Mechanistic accounts maintain that concrete computations occur wherever there is a physical system that has an organization of spatiotemporal components such that it computes an abstract function in virtue of manipulating medium-independent vehicles. The mechanistic approach emphasizes functionally integrated systems that compute at least one abstract function via vehicle manipulation.
The wide account of computation extends the mechanistic reasoning to brain-body-world systems. It maintains that whether or not functional mechanisms, ones that process medium-independent vehicles, are constituted by spatiotemporal components squarely localized within the individual or crisscrossing into the world is an a posteriori question. Since the mechanistic conditions on concrete computations are medium and location neutral, the question of wide computational systems is an open one - some physical computing cognitive systems may be ensconced within the body, while others may be spread out over brain, body and world.
In addition to its theoretical plausibility, wide computationalism also gains support from studies in animal and human psychology. There is a natural set of phenomena productively studied by wide computationalism.
Research in form perception, for example, shows that formal primitives in the environment are often relevant to computationally explaining the construction of complex, internal representations. Wilson $(1994,1995)$ takes such work to be indicative of a wide computational system, as it acknowledges the unique computational role of states beyond the individual within perceptual processing.
Research on the spatial navigation of bats has also been used to support wide computationalism. Kersten (2016), for instance, argues that bats' navigation system instantiates a wide computational system in virtue of employing a functional mechanism that spans the brain, body and world, and which processes medium-independent acoustic vehicles. Bat morphology, acoustic signals and neural processing conspire to support object detection along vertical planes using a wide computational system (MacIver, 2009).

Finally, Hutchins (1995) has argued for the presence of wide computation in the context of ship navigation. Hutchins' claim is that members of a navigation team carry out computational tasks that extend beyond the local actions of individual team members, which is indicative of a wide computational system.

The central message is that wide computational systems are not only theoretically plausible, but they are actually implemented in a number of cases. Research in human and animal psychology delivers several examples of concrete computational systems that extend beyond the boundary of the individual. In what follows, we adopt the wide mechanistic account of computation, though, for ease of exposition, we refer to it simply wide computationalism.

Consider how wide computationalism might address the first of the two tensions. Noë (2004), for instance, writes: "If perception is in part constituted by out and out possession and exercise of bodily skills...then it may also depend on our possession of the sorts of bodies that can encompass those skills, for only creatures with such a body could have those skills" (p.25). Noë and other body-centrists are at pains to highlight the role and contribution of bodily actions in cognitive processes. Such considerations motivate the claim that bodily-structures are constitutive of cognitive processes.

The wide mechanistic account can accommodate these types of considerations by focusing on functional mechanisms. A system is a functional mechanism when it consists of a set of spatiotemporal components that contribute to the system's overall function in virtue of the organization and interaction of its component parts (Piccinini, 2015, p.119). For the wide computationalist, the set of bodily and neural structures responsible for delivering visual perception are the functional mechanism that carry out the larger, computational task under investigation. This means that the claims of the body-centrist can be reframed in terms of 'wide' functional mechanisms; these are mechanisms whose component parts are spread out over internal and environmental elements (see Menary, 2007, ch.2). The constitutively embodied systems, such as in the case of vision, are the wide functional mechanisms localized to the body-brain complex. One way to understand bodycentric theorists, then, is as making fine-grained statements about wide functional mechanisms.

Consider the extended functionalist side of the equation. In applying the method of computational analysis to worldindividual spanning systems, wide computationalism maintains a commitment to the location neutrality of cognition. What matters for the wide computationalist is the functional capacity being investigated, not the physical medium through which it is realized. The implication is that extended functionalism's emphasis on medium independence and abstract analysis is preserved within wide computationalism. The view retains the abstract form of analysis crucial to the extended functionalist.

A resolution to the first tension is in sight. By reenvisaging body-centrism in terms of the implementation of
wide computational systems space is opened up for the tight, causal integration of bodily and neuronal processes in support of cognitive processes (i.e., wide functional mechanisms) and the locational neutrality of computational individuation (i.e., wide computational analysis). The special status of bodily structures turns out to be species of a more general class of wide mechanistic systems. The only difference is that whereas some wide functional mechanisms are instantiated within individuals (as highlighted by bodycentrism), others are instantiated by the brain, body and world (as highlighted by extended functionalism).
Consider the second tension. Enactivism, of the autopoietic variety, was unimpressed by the blurring of the organism/environment boundary within extended functionalism. The enactivist claimed that if cognitive systems were autopoietic systems then it followed that cognitive systems could not be extended, the underlying assumption being that autopoietic systems were organism bound.
One route to reconciling the two views is to show that autopoietic theory is compatible with computationalism more generally, assuming also that extended functionalism is congenial to wide computationalism more generally (see Wilson, 2004). Insofar as wide computationalism is a species of computationalism, the compatibility of computationalism with autopoietic systems theory suffices to show the compatibility of extended functionalism with autopoietic theory.
One reason to think that autopoietic theory is compatible with computationalism is a common emphasis on mechanistic explanation (Machamer, Darden, \& Craver, 2000; Bechtel, 2008). Consider, for instance, what Maturana and Varela (1980) write about the methodology of autopoietic theory:

An explanation [of autopoietic theory] is always a reformulation of a phenomenon showing how its components generate it through their interactions and relations...the elements used in the explanations are bodies and their properties...they are relations and their relations, independently of the nature of the bodies that satisfy them...This mode of thinking is not new, and is explicitly related to the very name of mechanisms. (pp. 75-76).

Autopoietic theory is, at root, a functional or mechanistic approach to explanation. What matters is that systems are explained in terms of the interaction of component parts with each other and the environment, regardless of whether the systems under investigation are biological or cognitive in character. There is a functional/mechanistic mode of explanation underlying autopoietic theory.

Compare this with computationalism. Computational analysis involves detailing how the arrangement and interaction of various components conspire to process information bearing vehicles. The mechanistic account requires showing how concrete, functional mechanisms compute medium-independent vehicles in virtue of
processing some portion of their physical structure. Computational analysis is also a species of mechanistic explanation (Milkowski, 2013).

There turns out, then, to be little incompatibility between computationalism and autopoietic theory. Both approaches employ something like a mechanistic explanatory strategy when investigating phenomena, although autopoietic theory is generally pitched at lower-level biological phenomena than computationalism. The common focus on mechanistic explanation ensures that there will be an overlapping set of phenomena productively studied by both approaches.

Why, then, the perceived tension? One reason is that many of the systems analyzed by autopoietic theory are located or ensconced within the organism. Most autopoietic systems are contained within the organism as a matter of empirical fact. However, this alone does not imply that all systems must be analyzed so as to localize within the individual; parts of the environment may still come to be included within the larger analysis. In principle, autopoietic theory, similar to computationalism, is location neutral.

Another reason for the perceived tension is that some within the enactivism literature assume that computationalism implies a commitment to representation and/or information processing theories (Di Paolo, 2009). These authors assume that because computationalism entails a commitment to representation and information processing theories, and autonomous, self-regulating systems stand in contrast to these views, enactivism must be opposed to computationalism.

However, as the previous discussion of mechanistic computation illustrates, there are a number of viable accounts of computation that are minimal in their commitment to representation or information processing theories (Stich, 1983; Egan, 1995; Piccinini, 2008). There is little reason to think that an opposition to representation and information processing commits enactivism to an opposition to computationalism more generally.

The point to note is that because wide computationalism places a greater emphasis on the way in in computational processes are grounded in particular physical mechanisms it creates a link between the body-centric claims of enactivism and embodied cognition, on the one hand, and the functional considerations of extended cognition, on the other. It is in virtue of analyzing mechanisms from several vantages some quite fine-grained, others quite coarse-grained - that wide computationalism is able to mediate the competing claims of the three strands. The view offers a philosopher's stone of sorts through which to translate the various claims of the enactivist, embodied and extended theorist.

To be a bit more specific, tension (i) is resolved by the fact that wide computationalism allows the claims of the body-centrist to be reframed in terms of wide functional mechanisms, while tension (ii) is resolved by the fact that wide computationalism, in virtue of being a species of computationalism more generally, is theoretically compatible with the basic methodology of autopoietic theory. The success of wide computationalism, therefore,
stems from the fact that it retains several of the central insights and elements that prove important to embodied, enactive and extended theorists.

One interesting implication of the preceding analysis is that it reveals what might be called the 'computational/mechanistic' core of 4E cognition. The discussion of wide computationalism goes some way to showing that something akin to 'computational/mechanistic' explanation may underwrite a fair amount of 4E cognition. Mechanistic explanations, which are explanations of systems in terms of the activities and organization of component parts, turn out to be important not only for cognitive science and psychology more generally, but for 4E cognition specifically (Craver, 2006). This point is only provisional, of course. But it does point to a promising future line of inquiry. A continued focus on the 'computational/mechanistic' underpinnings of 4E cognition may well serve to further clarify and unify the field as a whole.

## Conclusion

The preceding discussion is only the first step in a larger analysis. More still needs to be said. Nonetheless, the discussion is important because it offers one route to resolving the two tensions troubling 4E cognition. What's more, the discussion shows that a renewed focus on computationalism, particularly of the wide variety, may have key role to play in illuminating the conceptual foundations of 4 E cognition. This result is both interesting and novel, as discussions of 4 E cognition sometimes eschew mention of computation. By showing that a form of computationalism provides a theoretically flexible yet robust vehicle through which to understand and translate the various strands of 4 E cognition, the current discussion provides not only a partial vindication of wide comptuatiaonlism, but also helps to shed light on an important set of issues facing a growing research programme within cognitive science.

# Processing Spatial Relations: A Meta-Analysis 

Ann-Kathrin Kießner (Ann-Kathrin.Kiessner@ venus.uni-freiburg.de)<br>Center for Cognitive Science, University of Freiburg, 79098 Freiburg, Germany<br>Marco Ragni (ragni@informatik.uni-freiburg.de)<br>Cognitive Computation Lab, Technical Faculty, University of Freiburg, 79110 Freiburg, Germany

#### Abstract

The ability to reason about relations is relevant for many spatial cognitive processes. This can involve: (i) to represent spatial information mentally, (ii) to manipulate the spatial representation, and (iii) to infer new spatial information. Several cognitive theories make assumptions and predictions about the underlying processes. A detailed and systematic overview and analysis of ireliable effects across studies is missing. This article presents a meta-analysis of 35 studies about spatial relational reasoning. Studies were classified according to different factors including the ambiguity of the spatial description, i.e., if it the description allows for more than one representation, the presentation of information, i.e., if the information has been presented auditorily or in a written form, and the task, i.e., if a conclusion or model of the premises needs to be generated or verified. Implications of the findings for the mental model theory and working memory are discussed.

Keywords: reasoning; spatial relations; meta-analysis.

## Introduction

Spatial cognition allows us to perform a variety of everyday actions, such as sharing spatial information, navigation, and even assembling diverse kinds of objects. A successful spatial interaction requires us to represent spatial relational information and to reason with and about this information. Human communication mainly uses qualitative descriptions to specify relationships between spatial objects ${ }^{1}$ instead of a numerical or quantitative data description that is used in robot navigation. Relations which are expressed linguistically by the comparative, such as 'greater than', have been extensively investigated in the past century by using behavioral experiments (e.g., Hunter, 1957; Störring, 1908). Within an experiment, problems are often reduced to their essential characteristics limiting irrelevant information. Consider the following example:

## Premise 1: The post office is left of the train station.

Premise 2: The train station is left of the main crossroad.
Conclusion: The post office is left of the main crossroad.
The premises contain spatial information ("left of") about the relationships among spatial objects (e.g.,"post office"). A deductive inference makes implicit given information, e.g., the relation between the post office and the main crossroad explicit. While this inference is easy, and most participants solve it correctly, such transitive inferences can be at the core of more difficult inference problems with more objects and more relations. In the following we will give a brief overview

[^366]about reported factors of reasoning difficulty in the literature and present briefly implications of two cognitive theories relevant to our analysis. Cognitive psychologists have disagreed about the exact character of underlying mental processes (Goodwin \& Johnson-Laird, 2005) and the main question is, what reliable findings need to be explained by cognitive theories?

## Factors of Reasoning Difficulty

In general reasoning difficulty can appear on all levels: in comprehending the presented information (the language level), generating a mental representation (the representational level including working memory) or reasoning about the representation (reasoning level). The literature reports several factors that can be related to these levels.

Behavioral findings support that the presentation format affects spatial relational reasoning (Van der Henst \& Schaeken, 2005): In comparison with simultaneous premise presentation, accuracy is significantly lower in sequential presentation of the premise information (Roberts \& Sykes, 2003; Schaeken \& Johnson-Laird, 2000; Van der Henst \& Schaeken, 2005). This difference presumably reflects that during simultaneous premise presentation reasoners have all information available until they respond in contrast to sequential premise presentation posing more demand on working memory (Ormrod, 1979; Schaeken \& Johnson-Laird, 2000). Models of working memory, e.g., Baddeley's Working Memory Model (WMM; Baddeley, 1986) support the assumption that human reasoning is restricted by the limited capacity of working memory (Klauer, 1997) and that there are different components with specific limitations and modalities. Based on Baddeley's WMM, factors such as presentation form, task type and number of terms may influence spatial relational reasoning. Similar to premise presentation, it can be assumed that the presentation form (written vs. spoken language) may affect the way a problem is processed (Ormrod, 1979).

If premises are presented auditorily the spatial information is presented sequentially and thus more load on working memory is placed (Ormrod, 1979). According to the WMM, the larger the number of terms within a problem, the higher is the amount of information that must be retained (Clevenger \& Hummel, 2014). Lastly, the task type may have an influence as well. In conclusion generation tasks reasoners have to generate a conclusion. Whereas during verification tasks, reasoners have to check if a putative conclusions follows. This type of task captures only the ability to recognize a solution, but not producing it and thus requires smaller amounts of work-
ing memory (Klauer, 1997; Kubinger \& Wolfsbauer, 2010).
Another factor is the so-called indeterminacy effect (Byrne \& Johnson-Laird, 1989). While Example 1 above allows only for one possible arrangement (that we call model) and is called a determinate problem, indeterminate problems are possible. Consider the following example:

Premise 1: The post office is left of the train station.
Premise 2: The train station is left of the police office.
Premise 3: The crossroad is right of the post office.
Conclusion: The police office is right of the crossroad.
An indeterminate problem is more difficult to solve than a determinate one (e.g., Boudreau \& Pigeau, 2001; JohnsonLaird \& Byrne, 1991). Determinate problems allow only one qualitative arrangement (in contrast to quantitative differences, e.g., metric distances), while indeterminate problems allow for multiple different arrangements - as explained by the (preferred) mental model theory (MMT: Byrne \& Johnson-Laird, 1989; Ragni \& Knauff, 2013):
(1) post office - crossroad - train station - police office
(2) post office - train station - crossroad - police office

Most people construct just one or two models at most and often neglect other models consistent with the premises. These models differ qualitatively, e.g., there is mentally a different arrangement of the train station and the crossroad possible from the indeterminate description.

So far no systematic review of the recent literature has been carried out and no uniform and unambiguous conclusions about differences in accuracy have been drawn. For this reason, a cross-study meta-analysis of behavioural data from spatial relational reasoning is conducted. The aim of this paper is to test whether the predictions of individual studies and the predictions of MMT and WMM hold generally and to give an detailed overview that can serve as a potential benchmark for theories about spatial reasoning. This analysis investigates differences in accuracy depending on indeterminacy, premise presentation, presentation form, and type of task as well as number of terms. Resulting from the theoretical background and empirical findings to spatial relational reasoning, predictions are:

1. In spatial relational reasoning, determinate problems are easier to solve than indeterminate problems (e.g., Boudreau \& Pigeau, 2001; Johnson-Laird \& Byrne, 1991).
2. Compared with problems presented in spoken language, problems in written language appear with higher accuracy (e.g., Ormrod, 1979; Van der Henst \& Schaeken, 2005).
3. Reasoners solve more problems correctly when the task is to verify instead of generating conclusions/models.
4. Problems consisting of three terms are less difficult to solve than four-term problems.
5. In case of simultaneous premise presentation, accuracy is higher than in case of sequentially premise presentation.

In the following, these predictions are analyzed with the aim of gaining differences in accuracy specific to the various types. The results of the analysis are evaluated and interpreted with respect to predictions of the mental model theory and implications from working memory limitations.

## The Meta-Analysis

Paper Acquisition In order to acquire sufficient and suitable data for the meta-analysis, we needed to find experiments in which the participants drew their own conclusions to all sorts of tasks in spatial relational reasoning. An initial set of eligible studies came from a meta-analysis database of coded studies about spatial relational reasoning from the Cognitive Computation Lab (University of Freiburg, Germany) the database incorporated a comprehensive search for studies reported until 2013. The database contained the literature using the online platforms PubMed and Google Scholar for entries by the following main query: '(relational) AND (reasoning) OR (reasoning) AND (about) AND (relations) OR (transitive reasoning)'. All the studies in that database were reviewed for eligibility and an independent search was conducted: Online literature searches were performed on the 29th of October, and 29th of November 2016 using PubMed and Google Scholar. For the first PubMed and Google Scholar search, the same term like in 2013. For the second PubMed search, conducted on the 29th of November, the query '(spatial) AND (reasoning) AND (relations) OR (spatial reasoning) AND (relations)' was used, since the initial query was too unspecific for this search engine.

Criteria for Inclusion of Studies Experiments were assessed and selected for this meta-analysis if they met not only the search terms but also the following criteria: Experiments containing spatial relations and in cases of visuo-spatial relations, experiments emphasizing on spatial representations were also considered. All the experiments had to involve healthy, adult participants and use a within-subjects design to keep the homogeneity among different conditions. Participants had to know beforehand that their task was to reach a conclusion and there had to be no secondary-tasks. These criteria were used to ensure that the reasoning process was actually taking place and to eliminate other cognitive processes as a biasing factor. Moreover, only peer-reviewed and published studies of both, behavioural and neurophysiological experiments conducted in any country were considered. Outcome results of accuracy must have been presented in a quantitative form that permitted computation or reasonable estimation of an effect size statistic representing the difference in accuracy. Finally, information on factors of interests had to be given in the study. The literature search identified 138 experiments of 84 articles reporting results from psychological studies. Of these, 32 experiments (23\%) (e.g., Knauff \& Johnson-Laird, 2002a) did not report behavioral data or did not present spatial realtions by means of language.

Twenty experiments ( $14 \%$ ) were rejected because they did not report or measured accuracy (e.g., Brüssow et al.,

Table 1: Means and standard deviations of the overall accuracy for the studies (in \%).

| Dataset with indeterminacy condition | determinate problems | indeterminate problems |
| :--- | :---: | :---: |
| simultaneous-verbal presentation | $70(7)$ | $52(8)$ |
| sequential-verbal presentation | $65(4)$ | $42(13)$ |
| sequential-auditory presentation | $63(10)$ | $34(19)$ |

Values are rounded to integers. Indeterminacy (simultaneous-verbal): Experiments with simultaneous premise presentation, generation task, verbal presentation form and 5-term problems. Indeterminacy (sequential-verbal): Experiments with sequential premise presentation, generation task, auditory presentation form and 5 -term problems. Indeterminacy (sequential-auditory): Experiments with sequential premise presentation, generation task, verbal presentation form and 5-term problems.
2013). Seventeen experiments (12\%) did not report information about either indeterminacy, presentation form, type of task or number of terms nor premise presentation (e.g., Fangmeier et al., 2006). For 13 experiments (9\%) the original study was not available (e.g., Hagert, 1984). Eight experiments ( $6 \%$ ) used secondary-task methods (e.g., Knauff et al., 2004), six experiments ( $4 \%$ ) used a between-subjects design (e.g., Boudreau \& Pigeau, 2001) and three experiments (2\%) included children or patients (e.g., Knauff \& May, 2006). In two experiments ( $1 \%$ ) a recognition task was performed (e.g., Mani \& Johnson-Laird, 1982) and two other experiments ( $1 \%$ ) used a visual presentation form (e.g., Knauff \& May, 2006). In total, 206 raw differences in means of accuracy between different types of spatial relational reasoning problems and other types of (relational) reasoning met the inclusion criteria for this meta-analysis. An asterisk precedes each of these reports in the reference list.

Paper Classification After paper selection, experiment characteristics were coded by the authors for the following characteristics: indeterminacy, premise presentation, presentation form, number of terms, task and sample size. The sample size for each experiment was defined as the number of participants at the time of the final measure of logical correct answer. The first division of data was made between determinate and indeterminate problems. Furthermore, the data was subdivided into groups of simultaneous and sequential premise presentation. All premises were either displayed at the same time and remained available (simultaneous), or were presented one at a time and disappeared with the onset of a new premise (sequential). Moreover, it was coded whether the participants had to listen to the premises in form of audio recording using spoken language (auditory form) or whether the premises were presented by means of literacy language on screen or on paper (verbal form). Likewise, the data was grouped into experiments with either three, four, or five terms. Finally, experiments were assigned to the group of verification task when the reasoners had to verify a outative conclusion or to select the correct model from a given set of models. If the participants had to generate a model (an arrangement of objects) or to draw a conclusion, tasks were characterized as generation tasks. For each factor, the data was divided into subgroups finding the combination of variants that had the
most values for comparison of two variants of a factor. For this purpose, cross-classifying factors were used to build a contingency table of the counts at each combination of factor levels resulting in eight combinations of data. In Table 2, the datasets for all types of factors and its characteristics are presented. The factor number of participants within an experiment was not included in matching since otherwise, the number of raw means within subgroups would have been too small for statistical analysis. For the results reported in this study, statistical analysis consisted of non-parametric tests using one-sided Wilcoxon Rank-Sum Tests and a significance level of $\alpha=.01$ was defined. All statistical analysis was performed using R (R version 3.2.2, 2015-08-14; R Core Team, 2015).

## Results and Discussion

The data was corrected for outliers by excluding percentages of accuracy with values greater than two standard deviations from the mean value. All the statistical analysis reported is based on the data corrected by outliers. We analysed the percentage of correctness for all eight combinations of data. ${ }^{2}$ Table 2 summarizes the descriptive statistics in all conditions.

The analysis shows that in the indeterminacy (simultaneous-verbal) sample, significantly more correct responses were given if the problem was determinate than indeterminate (Wilcoxon Rank-Sum Test $W=168$, $p<.0001$, one-sided). The same trend is also visible for the sequential-verbal and sequential-auditory indeterminacy cases (Table 1). One-sided Wilcoxon Rank-Sum Tests showed that both trends were statistically significant (indeterminacy (sequential-verbal): $W=30, p<.05$; indeterminacy (sequential-auditory): $W=30, p=.01$ ). These results supports several empirical findings (e.g., Byrne \& JohnsonLaird, 1989) and can be explained by MMT as well as Baddeley's WMM. For an indeterminate description, it is necessary to construct not one but several mental models in order to correctly represent its meaning. The larger the number of models that reasoners must consider, the higher is the load on working memory. The attempt to construct

|  | seq | 15 | 255 | $90(10)$ | 68 | 89 | $90(11)$ | 98 | 98 |

All values were rounded to integers. Factor labels refer to auditory vs. verbal presentation form (audi/verb), determinate vs. indeterminate problems (det/indet), model generation vs. model verification task (gen/veri) and sequential vs. simultaneous premise presentation (seq/sim). $n_{\text {rawmeans }}$ : number of raw differences in means; $n_{\text {participants }}$ : number of participants. Indeterminacy (simultaneous-verbal): Experiments with simultaneous premise presentation, generation task, verbal presentation form and five-term problems. Presentation form 1: Experiments with sequential premise presentation, verification task, determinate and three-term problems. Presentation form 2: Experiments with sequential premise presentation, generation task, determinate and four-term problems. Task: Experiments with sequential premise presentation, verbal presentation form, determinate and three-term problems. Number of terms: Experiments with sequential premise presentation, verbal presentation form, verification task and determinate problems. Premise presentation: Experiments with verbal presentation form, verification task, determinate and three-term problems. ${ }^{* * *}$ significant $p<.001,{ }^{* *}$ significant $p<.01$
several models may overload working memory capacities so that no models would be constructed. Likewise, the accuracy was significantly higher if the problems were presented verbally than during auditory presentation (Wilcoxon Rank-Sum Tests, presentation form 2: $W=283, p<.01$, one-sided). A similar but not significant trend showed in the presentation form 1 condition (Wilcoxon Rank-Sum Tests, $W=176, p=.07$, one-sided). Spoken language can only be presented in a serial way. Thus, the spatial description has to be stored in the phonological loop using a language-based form. At the same time, mental models are built in the visuo-spatial sketchpad. When working memory load increases it becomes harder to keep track of all the premises and inferences separately. Additionally, written language already implies information about spatial relations and is, therefore, more similar to the information contained in the problem description than in case of auditory presentation. Furthermore, a one-sided Wilcoxon Rank-Sum Test supports the prediction that reasoning difficulty is lower in verification tasks ( $W=332, p<.01$ ). Thereby, reasoners have to build a model based on the premises presented and verify a proposed model or conclusion. In addition to model construction, reasoners have also to draw a conclusion to solve the generation task correctly. This requires a larger amount of working memory (Klauer, 1997). The descriptive results for the dataset number of terms are consistent with the predictions. Three-term problems were higher in accuracy than four-term problems (Table 2). However, the Wilcoxon Rank-Sum Test showed no significant difference ( $W=641$, $p>.1$, one-sided). One explanation could be the limited
capacity of the working memory that is roughly three to five objects or role bindings (Clevenger \& Hummel, 2014). Both three-term and four-term problems do not exceed the capacities of working memory. However, descriptive results assume a tendency for an increasing memory load in four-term problems. Contrary to the predictions, there was no significant difference between accuracy in case of simultaneous and sequential premise presentation ( $W=0$, $p>.1$, one-sided Wilcoxon Rank-Sum Test). Furthermore, descriptive results indicate that problems with sequential premise presentation are less difficult to solve than simultaneously presented problems (Table 2). This result was unexpected and contradicts previous findings (Roberts \& Sykes, 2003; Van der Henst \& Schaeken, 2005). With regard to the data used in this study, the following differences can be observed which may have influenced the result: In case of simultaneous presentation, the total number of participants tested is higher than in sequential condition ( $N=3504$ vs. $N=255$ ). The difference in sample size might have influenced the results. In addition, the factor premise order was not controlled in this study. The dataset of simultaneous premise presentation contained discontinuous problems. However, in the set of sequential premise presentation, the factor premise order was either unspecified or continuous. Studies have shown that accuracy is higher in case of continuous premise order (Knauff et al., 1998). Thus, an effect of premise order can not be excluded here. A further explanation may be that the amount of information must be processed is reduced as a result of sequential presentation. Hence, attention control may be facilitated and a model can
be constructed incrementally from the premises (principle of economicity, Manktelow \& Galbraith, 2012).

## General Discussion

Despite a century of research on spatial relational reasoning and more than a hundred articles there is still no systematic analysis of which factors do contribute to the human difficulty in reasoning about spatial relations. The quality of the reported experimental data differs, sometimes all relevant information is reported, sometimes the standard deviation is missing. Hence, only a limited number of experiments could be included in our review. We identified reliable differences in accuracy between determinate and indeterminate problems, auditory and verbal presentation form and also between tasks of model generation and verification. This meta-analysis confirmed previous empirical findings that are predicted by the mental model theory and influenced by the limited-capacity working memory as predicted by WMM (see Klauer, 1997): The effect of indeterminacy is the strongest effect (see Table 2) that is directly related with the number of models that need to be generated in the reasoning process. The same holds for the task where the verification is easier (the constructed models need to be compared with a given one), while in the conclusion generation process all models need to be checked. And, finally a generation task with four terms (Presentation form 2 in Table 2) can lead to more demands on both the construction and storing the model in memory.

This systematic review has, however, a few limitations related to the results and their interpretation and leads to some new questions. First, the number of studies considered is a limiting factor to the expressive power of the analysis results. Furthermore, most of the studies included in this metaanalysis did not report any information about the premise order (e.g., if the premise information is continuosly), so it was not possible to control for this factor. Likewise, with regard to the small number of raw means, it was not possible to factor in the sample size of each experiment. The next step of analysis in this study will focus on this particular point and investigates questions, such as the variability in effects across studies and how this variability can be explored in terms of moderator variables. Identification of the moderator variables that describe the study characteristics associated with larger and smaller effects is another kind of contribution meta-analysis can make to understanding difficulties in spatial relational reasoning. Of particular importance is the role such moderator analysis can play in ascertaining which variants of spatial descriptions are most effective for reasoning.

Taken together this study illustrates a use of meta-analysis for data interpretation beyond conventional statistical analysis. Some cross-experimental results can be formulated: First, determinate problems are easier to solve than indeterminate problems. Second, compared with auditory presentation, problems in form of written language are less difficult. Further, the accuracy was better for tasks that require the verification of conclusions or models than in tasks that require to
generate conclusions or models. This meta-analysis confirms some previous empirical findings, and supports predictions of the spatial mental model theory together with assumptions from a limited spatial working memory.

# Decoding Virtual Agent's Emotion and Strategy from Brain Patterns 

Eunkyung Kim, Sarah I. Gimbel, Aleksandra Litvinova, Jonas T. Kaplan and Morteza Dehghani<br>\{eunkyung; sgimbel; alitvino; jtkaplan; mdehghan\}@usc.edu<br>University of Southern California, Los Angeles, CA 90089 USA

#### Abstract

Recent advances in technology have paved the way for humanagent interactions to become ubiquitous in our daily lives, and decades worth of research on virtual agents have enhanced these interactions. However, for the most part, the effect of different types of agents on the human brain is unknown, and the neuroscience of human-agent interactions is rarely studied. In this study, we examine the underlying neural systems involved in processing and responding to different types of negotiating agents. More specifically, we show that different brain patterns are observed for various types of virtual agents; consequently, we can decode the strategy and emotional display of the agent based on the counterpart's brain activity. Using fMRI data, we analyzed participants' brain activity during negotiations with agents who show three different emotional expressions and use two different types of negotiation strategies. We demonstrate that, using Multi-Voxel Pattern Analysis, we can reliably decode agents' emotional expressions based on the activity in the left dorsal anterior insula, and also agents' strategies based on the activity in the frontal pole.

Keywords: Human-Agent Interaction; Negotiation; Emotion; Decision-Making; fMRI

## Introduction

Virtual agents have become a part of our daily lives. From commercial websites that make use of chat agents for answering users' questions in personalized settings to educational and training software that incorporate virtual agents to provide better learning experiences, our numbers of interactions with virtual agents have dramatically increased in the past couple of years.

Parallel to this increase, various lines of research have studied the interactions between humans and virtual agents. For example, research has examined the contributing factors to user engagement (Bickmore, Schulman, \& Yin, 2010; Castellano, Pereira, Leite, Paiva, \& McOwan, 2009) and establishment of bonds with virtual agents (Cassell \& Thorisson, 1999; Wang \& Gratch, 2009). Bickmore et al. (2010) showed that people engage more with life-like virtual agents, such as a relational agent who remembers past history and relates to that history when communicating. Moreover, Wang and Gratch (2009) demonstrated that virtual agents who give nonverbal immediacy feedback, such as eye contact and gestures, are found to establish rapport with human partners.

Related to our research, the effects of emotion and strategies are among the most widely explored topics in humanagent interaction research (Maldonado et al., 2005; Kim, Dehghani, Kim, Carnevale, \& Gratch, 2014; Van Kleef, De Dreu, \& Manstead, 2004). These factors are particularly important because they are central in providing clues about the internal states and the intentions of the counterpart in any type of interactions (Jurafsky, Ranganath, \& McFarland, 2009; Rafaeli \& Sutton, 1987). Previous studies on
the effect of emotion include the work of Maldonado et al. (2005) where they demonstrated that people who interact with an emotional agent perform better on a test than those who interact with an emotionless agent in a web-based learning environment. Van Kleef et al. (2004) argue that automated agents who express emotions, such as anger or happiness, elicit different levels of concessions based on the type of expressed emotions. Also, several researchers have examined the effects of different types of negotiation strategies during human-agent interactions. For example, Das, Hanson, Kephart, and Tesauro (2001) demonstrated that the agreed trade prices from human-agent interactions are different for two types of agent strategies; one strategy is to maximize its expected surplus using trade history and the other strategy is to make small random adjustments to the trade price continuously. Similarly, Grosz, Kraus, Talman, Stossel, and Havlin (2004) demonstrated that there are particular agent strategies that elicit more concessions during negotiations.

These, along with numerous other studies, have helped the field establish sets of features that influence the quality of human-agent interaction, resulting in a more enhanced and realistic experience for the human user. However, with a few exceptions (e.g., Sanfey, Rilling, Aronson, Nystrom, and Cohen (2003)), the majority of these studies have for the most part treated the process and the mechanism through which these features affect the human counterpart as a black box; they demonstrate that a particular type of agent, with particular emotion and strategy, enhances a user's experience (e.g. performance on a test). However, the question of how these features affect the underlying neural mechanisms of the user that result in such enhancement still remains unanswered. For instance, even though it is established that interacting with an emotional agent results in better performance on a test than interacting with an unemotional agent (Maldonado et al., 2005; Karacora, Dehghani, Krämer-Mertens, \& Gratch, 2012), the neuroscience of these interactions are not fully understood.

In this paper, we investigate the underlying neural systems that are activated when participants interact with agents who show different emotional expressions and apply different negotiation strategies. As various emotions and strategies have been related to diverse reactions in previous studies, we assumed that we could find differences between the neural processes that are activated when these factors are manipulated. To examine these differences, we studied people's neural activation while they were interacting with a virtual agent. We hypothesize that distinct patterns of brain activity would be observed for each agent type.

To study brain activity during human-agent interaction,
we used functional magnetic resonance imaging (fMRI). We used a human-agent negotiation platform for the experiment in order to capture active interaction between a participant and a virtual agent while they are trying to reach an agreement. The virtual agent was designed to display three different emotional expressions and apply two fixed negotiation strategies, for six combinations of emotional expression and negotiation strategy. During the experiment, we had participants engage in several rounds of negotiations with the virtual agent inside the fMRI scanner. We then analyzed their brain patterns during the decision-making period using Multi-Voxel Pattern Analysis (Norman, Polyn, Detre, \& Haxby, 2006).

We focused our analyses on the anterior insula and the frontal pole. Anterior insula is a well-known emotion-related brain region that is consistently activated when processing basic emotions such as anger and sadness, as well as social emotions such as empathy and vicarious emotions (Kober et al., 2008; Lamm \& Singer, 2010). It has been repeatedly reported that both observing the emotional facial expression and feeling the emotion activate the anterior insula (Zaki, Davis, \& Ochsner, 2012). On the other hand, the frontal pole is one of well-known decision-making-related brain regions. It has been shown that frontal pole plays a significant role in thinking about the future (Okuda et al., 2003), and people with frontal pole impairment make disadvantageous decisions (Anderson, Bechara, Damasio, Tranel, \& Damasio, 1999).

We hypothesize that an agent's negotiation strategy can be predicted based on the activity in the frontal pole, and an agent's emotional expression can be predicted based on the activity in the anterior insula. To validate these hypotheses, we compared participants' brain activities in these regions during negotiations in terms of an agent's emotional expression (angry, neutral, and sad), and an agent's negotiation strategy (conceding and non-conceding).

Our research contributes to a fast growing field of humanagent interaction, and is one of the first lines of work that investigates the underlying neural systems involved in the process of human-agent negotiation. This paper is organized as follows. First, we introduce our negotiation platform, the Objects Negotiation Task. Next, we explain our experimental settings and the design of our virtual agent. Then, we describe the parameters used to record fMRI data and how this data were analyzed. Finally, we show our results and discuss our findings.

## Objects Negotiation Task

The Objects Negotiation Task is a multi-round human-agent negotiation platform (Dehghani, Carnevale, \& Gratch, 2014) where a human negotiator and a virtual agent can negotiate diverse items over multiple rounds. We used a modified version of this task tailored for use in the fMRI. Common fruits were used as negotiation items, and the payoff for each item for both players were explicitly specified on the screen. In order to make sure all participants had the same goal during
negotiations, they were asked to focus on maximizing their total payoffs. To ease the calculation of total payoffs, the system automatically calculated the player's total payoff as well as the agent's total payoff, and displayed whenever the items are redistributed.

When the negotiation starts, items are placed in the middle row indicating that they do not belong to anyone. After the participant distributes all the items, the 'Go!' button on the right bottom corner is enabled and the participant can propose his/her offer by clicking the button. The participant is then asked to wait until the virtual agent accepts or rejects the offer. If accepted, both parties get the proposed items and the negotiation ends. If rejected, the participant is asked to wait for the virtual agent to propose a counteroffer. Next, the virtual agent's offer is shown and the participant reviews the offer for five seconds. During this time, the participant simply observes the counteroffer and cannot relocate the items. For the fMRI version of the task, this review time was introduced to make sure that we can separate brain activity between the offer-making period and the non-offer-making periods. After the review, the participant decides whether to accept or reject the virtual agent's offer. If he/she accepts the virtual agent's offer, the negotiation ends. If rejected, the participant is again asked to wait for five seconds and then is redirected to the first step. Figure 1 shows an example of the timeline of the Objects Negotiation Task.

In our study, we used six types of agents characterized by the three types of emotions they expressed and the two types of offer sets representing their negotiation strategies. More details about these features are described in the following two sections.

## Agent's Emotional Expressions

The role of emotional displays in negotiation has been extensively documented (Lerner, Li, Valdesolo, \& Kassam, 2015). To find the neural mechanisms involved in processing different emotional displays in human-agent interactions, we used three types of facial expressions to express agents' emotions; angry, neutral (no emotion) and sad. Figure 2 shows agents' emotional expressions that were used in the experiment. In angry and sad conditions, the virtual agent's face starts as neutral and changes to the emotional expression for five seconds on the first, third, and fifth rounds of negotiation. In the neutral condition, the agent's face starts as neutral and does not change.

## Agent's Negotiation Strategies

We used two sets of pre-programmed agent offer strategies: non-conceder and conceder. In the non-conceder strategy, the agent starts with no concession and continues with gradually increased concession. In the conceder strategy, the agent starts with some concessions and keeps conceding further in the next rounds.

When the virtual agent decides whether to accept or reject a participant's offer, the agent calculates the summed payoffs and compares it with its next offer. If the summed pay-

Figure 1: Timeline of the Objects Negotiation Task used in the fMRI experiment. During a negotiation, a participant and a virtual agent take turns in making a proposal. If the proposed offer is accepted, the negotiation ends. If rejected, the player who rejected the offer makes a new proposal.

Figure 2: Agent's emotional expressions. Angry (left), neutral (middle), and sad (right).
offs are larger than the summed payoffs of the next offer, the agent accepts the offer. Otherwise, the agent rejects the offer and proposes a new offer. The same payoff matrix was used across all six negotiation tasks so that we could control for the potential effect of varying payoff values. However, we randomized the order of items shown on the screen in each task to give participants the impression that they were playing a new negotiation task every time.

## Experiment

## Participant

We recruited ten participants through an online bulletin board at the University of Southern California. Prior to the study, all participants completed a checklist to make sure they were eligible to take part in an MRI study. All procedures were approved by the USC Institutional Review Board and participants were provided with a written informed consent for the study. One participant's data was later excluded from the analyses because of technical problems with the obtained images.

## Procedure

Upon arrival, participants completed the informed consent and each participant was asked to read the following hypothetical scenario:

You are a restaurant owner in a small town. There has been a major fire in the market providing the necessary fruits for your restaurant and as a result only a limited number of fruits are available. Because of this you have to split the available fruits with another restaurant owner. You and the other owner value each fruit differently. In order to run your restaurant you need to get as many fruits as possible.

In the task that follows, you will negotiate about how to distribute the fruits between you and the other restaurant owner.

After reading the scenario, participants were first invited to play a trial negotiation so that they got used to the interface of the task. Then participants performed six negotiation tasks inside an fMRI scanner. The total scan time for each participant was approximately 45 minutes.

## Data Analysis

To study brain patterns during negotiations with various agents, we analyzed participants' brain activity using general linear models (GLM) analysis and multi-voxel pattern analysis (MVPA).

## General Linear Model Analysis

To extract brain activity of the offer-making period from the whole negotiation period, we ran a general linear model (GLM) analysis using tools from the FMRIB's Software Library (FSL) (Smith et al., 2004). First, we pre-processed
our fMRI data using FSL to reduce the noise of our dataset. Data pre-processing included the following mostly standard steps: (1) Motion-correction with MCFLIRT to fix head motion artifacts during scans, (2) Slice timing correction for interleaved acquisitions to compensate for timing difference between slices of functional images, (3) Non-brain structures removal with Brain Extraction Tool to remove non-brain regions, such as the scalp, (4) Spatial smoothing with a Gaussian kernel of full width at half maximum 5 mm to increase statistical power by improving the signal to noise ratio, (5) High-pass temporal filtering to let high frequencies, such as activities relevant to experimental conditions, pass and to remove low frequencies such as signal drifts.

For each negotiation for each participant, changes in the blood-oxygen-level dependent signal were modeled with regressors for the offer-making period. Then the regressors were convolved with a double-gamma hemodynamic response function. The non-offer-making periods were modeled as baseline.

## Multi-Voxel Pattern Analysis

When analyzing fMRI data, it is important to take into account the activity of the voxels, as well as the interactions between them because the activity in neighboring voxels is interdependent. However, given the univariate nature of GLM, the model fits to each voxel's time-course separately. To overcome this drawback, we used multi-voxel pattern analysis (MVPA) (Norman et al., 2006) which uses patternclassification techniques to extract the pattern of response across multiple voxels.

We preprocessed the GLM analysis results and used them as inputs for the MVPA. The preprocessing included linear de-trending which removes any bias resulting from scanner drift over the acquisition time, and z-scoring which normalizes the range of each voxel. We used leave-one-participantout cross-validation for MVPA, in which a classifier is trained on eight participants' data and then tested with the last participant's data.

Previous studies have shown that the anterior insula (AI) is activated when processing emotions (Kober et al., 2008; Lamm \& Singer, 2010), and the frontal pole (FP) is activated when making a decision that affects the future (Okuda et al., 2003). We therefore hypothesized that the agent's negotiation strategy can be predicted based on the participant's brain activity in the FP, and the agent's emotional expression can be predicted based on the participant's brain activity in the AI. To test our hypothesis, we chose the AI and the FP as our regions of interest (ROIs), and performed ROI MVPA. In the following section, we explain the ROI MVPA approach.
Region of Interest Multi-Voxel Pattern Analysis To find the relationship between an agent's expressed emotion and brain activity as well as an agent's negotiation strategy and brain activity, we performed region of interest (ROI) MVPA with both the AI and the FP. The AI on each side of the brain can be divided into two subregions with distinct patterns of
connectivity: dorsal anterior insula (dAI), connected to the dorsal anterior cingulate cortex; and the ventral anterior insula (vAI), connected to the pregenual anterior cingulate cortex (Deen, Pitskel, \& Pelphrey, 2011). We ran ROI analyses for all four AI regions. On the contrary, the FP does not have widely accepted subregions (Moayedi, Salomons, Dunlop, Downar, \& Davis, 2014). Thus, we ran ROI analysis for the whole FP labeled by the Harvard Center for Morphometric Analysis (Desikan et al., 2006).

To make sure brain activity in the AI or the FP is responsible either for agent's emotional expressions or negotiation strategies, we ran ROI analyses for both conditions, i.e., we calculated the prediction accuracy of agent's negotiation strategies using both the AI and FP as ROIs. We assumed that the prediction accuracy with their expected ROI would be significantly higher than the chance level, but the prediction accuracy with their unexpected ROI would be indistinguishable from chance.

We trained a linear Support Vector Machine (SVM) classifier using voxels from each of our ROIs separately using feature selection. Feature selection is a common approach used to reduce the number of features (voxels) by selecting only relevant features as input to a classifier. Classification performance improves with feature selection as it only picks features that vary significantly between categories (Guyon \& Elisseeff, 2003). In our analyses, we used the GLM analysis results to compute the $F$-score for each voxel, and then used an analysis of variance (ANOVA) measure to select the top $10 \%$ of features with the highest F-scores.

Each participant's brain was transformed into standard MNI space (Evans et al., 1993) to have a brain that is more representative of the population. After performing this process for all participants, individual-level analyses were combined for a group-level analysis.

## Results

As discussed previously, the AI is a brain region known to respond to emotional expressions, and it can be divided into two subregions with distinct patterns of connectivity. Therefore, we first ran ROI MVPA for all four (left/right $\times$ ventral/dorsal) AI regions separately. The prediction accuracies of emotional expression using our ROI MVPA with four AI regions indicate that ROI MVPA with the L-dAI has the best prediction accuracy ( $38.40 \%$ ), while the prediction accuracy of other AI regions are indistinguishable from the chance level of $33 \%$. A binomial test revealed that the prediction accuracy of the ROI MVPA with the L-dAI is significantly above chance ( $p=0.0566$ ). Therefore, we focus our analysis on the results of ROI MVPA with the L-dAI.

The prediction accuracy for decoding an agent's emotional expressions is higher for the L-dAI decoder ( $38.40 \%$, compared to $33.87 \%$ for the FP $(p=0.0960)$ or chance ( $p=$ 0.0566 ). The prediction accuracy using the FP ROI MVPA was not different from chance ( $p=0.4266$ ). This supports our hypothesis that an agent's emotional expression can be

Table 1: Prediction accuracy on an agent's emotional expression and an agent's strategy from ROI MVPA. One-tail binomial tests were performed for each condition compared to the chance level, and significant results $(p<0.05)$ were marked with (*).

| Region of <br> Interest (ROI) | Condition | Prediction <br> Accuracy | Chance <br> Level |
| :---: | :---: | :---: | :---: |
| Left Dorsal <br> Anterior Insula <br> (L-dAI) | All Emotions | $38.40 \%\left(^{*}\right)$ |  |
|  | Angry | $45.07 \%\left(^{*}\right)$ | $33.33 \%$ |
|  | Neutral | $29.60 \%$ |  |
| Frontal Pole <br> (FP) | All Strategies | $40.53 \%\left(^{*}\right)$ |  |
|  | Conceder | $47.96 \%\left(^{*}\right)$ | $50.00 \%$ |
|  | Non-conceder | $70.42 \%\left(^{*}\right)$ |  |

reliably predicted using brain activity in the AI which is an emotion-related brain region, but not with information in the FP.

Similarly, the accuracies for predicting an agent's negotiation strategy using the ROI MVPA with the FP was $58.96 \%$. A binomial test again confirmed that this performance is significantly higher than the chance level of $50 \%(p=0.0085)$. The prediction performance was almost at chance (52.71\%) for the L-dAI ( $p=0.2581$ ). This result validates our hypothesis that counterpart's negotiation strategy can be predicted based on brain activity in the FP, which is activated when people do active decision-making, but not with the insula, which is involved in emotion processing.

In order to examine these results in more detail, we broke down the predictions. Specifically, we analyzed the prediction accuracy for each agent's emotional expression and negotiation strategy from ROI MVPAs with anterior insular regions and frontal lobe (Table 1). Our results indicate that brain patterns in the L-dAI can predict angry and sad conditions but not neutral agent facial expressions. Also, brain patterns in the FP can predict the non-conceder negotiation strategy but not the conceder strategy.

Overall, our results confirm that negotiating with different types of agents results in activity in different brain regions, and these activity patterns can be used to further decode the specific type of interaction agent.

## Discussion

The neuroscience of human-agent interactions is a rarely studied topic and the majority of studies treat the processes by which various agent features affect human participants as a black box. To answer the question of how these features interact with underlying neural mechanisms, we investigated brain activity during human-agent interactions. More specifically, participants engaged with virtual agents who showed three different emotional expressions (angry, neutral and sad) and used two different types of negotiation strategies (conceding and non-conceding). Using a human-agent negotiation platform, participants interacted with virtual agents in an fMRI
scanner, and their brain activity during the interaction was recorded. We hypothesized that an agent's emotional expression could be predicted based on patterns in emotion-related brain regions, and an agent's negotiation strategy could be predicted based on patterns in decision-making-related brain regions. Therefore, we focused our analyses on the AI and the FP, as previous studies have shown that AI is activated when people engage in emotional tasks, and the FP is activated when people perform active decision-making tasks.

Our ROI MVPA results support our hypothesis; prediction accuracy of an agent's emotional expression based on brain patterns in the L-dAI, and that of agent's negotiation strategy based on brain patterns in the FP are well above the chance level. These results indicate that different features are likely processed in different brain regions. Finding which information is processed in certain brain regions would allow us to reliably decode the feature of the agent from users' brain activity. More detailed analyses revealed that brain patterns in the L-dAI could be used to predict angry ( $45.07 \%$ ) and sad ( $40.53 \%$ ) conditions, but not the neutral condition ( $29.60 \%$ ). This indicates that there are clear differences in brain patterns in the L-dAI between angry and sad conditions. We hypothesize that the reason why the patterns in this region failed to predict the neutral condition is that the neutral facial expression is the default expression throughout the experiment. The facial expression of the agent only changes when it morphs into sad or angry. We plan to tackle this problem by only showing the agent's face during the decision making phase.

With regard to agent's negotiation strategies, predictions using brain patterns from the FP showed significantly higher accuracy compared to the chance level ( $50 \%$ ) for the nonconceding condition ( $70.42 \%$ ), but not for the conceding condition $(47.50 \%)$. We assume that this is because participants expected to deal with a counterpart that acted like a conceding and fair agent, i.e. an agent who might start with a slightly unfair offer but over time it makes adjustments toward a fair offer. It is possible that the distinct patterns in the FP witnessed during negotiations with the non-conceding agent is because this agent acts in a very greedy and tough way that is not typical in social interactions. This could result in unique patterns of activity in the FP.

While our sample size could be considered small, we would like to note that sample size tends to be small in fMRI studies. Also, it is worth mentioning that the probability of finding the same effect as one found in the original experiment is not dependent on sample size, but dependent on $p$ value (Killeen, 2005). This is because large effect sizes produce significant results, even with small sample size.

In conclusion, our results indicate that there is a link between an agent's emotional expression and brain activity in the L-dAI, and also between an agent's negotiation strategy and brain activity in the FP. Even though the results are preliminary, our work sheds light on the links between certain brain regions and different agent features. In future studies, we plan to continue investigating these links with other
features such as voice tone and gestures, and hopefully over time construct a map of the brain regions activated by various agent features and compare these regions to human-human interactions.

#### Abstract

People interact differently with humans than they do with computers, but there is minimal research on what brings about these differences. Using agents labeled as either "another participant" or a "computer program", we investigated the differences in people's behavior and brain activity during the course of a negotiation paradigm. Our results indicate that people perceive human-labeled agents more human-like than computerlabeled agents, and the level of concession in the negotiations is dependent on agent type. We have also found that these differences can be captured in brain activation by showing that parts of the Theory of Mind neural correlates are activated in human-labeled agent conditions, but not in computer-labeled agent conditions. We further demonstrate that brain activity can predict whether the negotiation agent was introduced as a competing human player or a computer program. Overall, our study suggests that labeling an interaction partner as either another human or a computer program leads to significant impacts on one's decision making.

Keywords: Human-Agent Interaction; Negotiations; fMRI

## Introduction

Can computer agents act as substitutes for human beings during the course of an interaction? This has been a popular topic in sci-fi movies for decades. In fact, some computer agents that were thought to exist only in movies a few decades ago, are now widely used in daily life. Smartphones, for example, are commonly used to execute voice commands through programs like Siri, and movie theaters now have more ticket vending machines than guest personnel.

However, human-agent interactions are often quite different from human-human interactions (Gray, Gray, \& Wegner, 2007; Melo, Marsella, \& Gratch, 2016), and many factors contribute to these differences. Researchers have continuously tried to identify what these disparities are and why they occur, with the hopes to bridge the gap between humanhuman and human-robot/agent encounters.

A robot's appearance has been found to be paramount in the interaction style of the human subjects. For example, when people interface with robots that have mechanical, nonhuman like features, even when the robot performs human-like actions, they are often unable to overlook these traits (Hegel, Krach, Kircher, Wrede, \& Sagerer, 2008). Thus, robots designed to have eyes similar to humans (Banh, Rea, Young, \& Sharlin, 2015), or baby face-like heads (Powers \& Kiesler, 2006), were found to be more effective in evoking a more human-like interaction.

These differences have also been extensively studied using brain imaging techniques, especially regions associated
with Theory of Mind (ToM), due to their importance in social interactions. ToM refers to the ability of one person to reason about another person's mental states, including their intentions and beliefs (Premack \& Woodruff, 1978). Previous fMRI studies have demonstrated that cortical activity in the neural structures related to ToM tend to be more active when participants were told they were facing a human partner compared to a computer program (Kircher et al., 2009). Research also demonstrated that activity in these same regions scaled according to the human-likeness of their interaction partner when using computer-animated characters or nonhuman agents (Chaminade, Hodgins, \& Kawato, 2007; Krach et al., 2008).

Many previous behavioral and neuroimaging studies have used negotiation platforms to examine human-agent communication, because negotiations involve complex cognitive effort and established social interaction techniques. For example, studies show that when participants play the Ultimatum Game against computer partners, they are more likely to accept unfair offers compared to when they play against human partners, where they tend to be less willing to accept offers of unequal value (Sanfey, Rilling, Aronson, Nystrom, \& Cohen, 2003). Studies have also shown that people have stronger emotional reactions to unfair offers made by other humans (Vant Wout, Kahn, Sanfey, \& Aleman, 2006).

Using a multi-round, multi-object negotiation platform for our research, we explored whether a computer agent introduced as another human was perceived more anthropomorphically than one that was introduced as a computer program. We then investigated whether agent type produced behavioral differences, and whether one type of agent resulted in more concessions compared to the other. In a follow up experiment, we compared brain activity during interactions with humanlabeled and computer-labeled agents to determine whether these perceptual differences were also observable in brain patterns. Following collection of fMRI data, we investigated whether classifiers could be trained to determine whether the participant was playing against a human-labeled or computerlabeled agent.

We hypothesized that participant behavior and brain activity would be different during interactions with humanlabeled agents, compared to interactions with computerlabeled agents, even though both agents used exactly the same strategies and emotions. Our initial experiment consisted of an online negotiation task intended to explore perceptual and

Figure 1: Objects Negotiation Task Timeline
behavioral differences pertaining to anthropomorphic characteristics in human and computer-labeled agents. Next, we adapted our negotiation framework into an fMRI experiment, attempting to find neural differences for the two distinct partner conditions. In addition to these studies, we also ran a prediction algorithm and multi-voxel pattern analysis (Norman, Polyn, Detre, \& Haxby, 2006) based on the fMRI data.

This work is distinct from previous studies due to the use of an identical computer agent, regardless of what partner type was specified. The majority of previous studies employed computer-animated characters or robots that had differing levels of anthropomorphism. We demonstrate that even though the same computer agent is used, perceptual differences were captured in behavioral and brain data. To the best of our knowledge, this is one of the first lines of research that uses a multi-round negotiation platform to investigate perceptions of anthropomorphism. We believe that natural interactions take place over multiple rounds/sessions, and it is therefore important to investigate perception differences through multi-round negotiations.

This paper is structured as follows. First, we introduce and explain the Object Negotiation Task, the platform used for both experiments described. Next, we outline an exploratory, behavioral experiment performed to examine the differences between interactions with a human-labeled agent and a computer-labeled agent. After which we discuss our fMRI experiment, using the same paradigm as the first, trying to identify differences in brain activity. Lastly, we discuss the implications of our results and future work.

## Objects Negotiation Task

The Objects Negotiation Task is a web-based multi-round negotiation task where a participant and a computer agent can take turns distributing objects (Dehghani, Carnevale, \& Gratch, 2014). The original version was designed for behav-
ioral data collection only, so in this paper, a modified version of this task was used for collection of both behavioral and brain data. Figure 1 shows the timeline of the modified version of this task. Some of the modifications made included an emotion-reporting phase and offer-review phase, which were added to separate collection of brain data between differing phases. In addition, a partner introduction phase was added, allowing participants to receive a notification specifying whether their partner type was another participant or the computer program before the negotiation began.

The sequence of the modified Objects Negotiation Task is as follows. When the task begins, the negotiation partner type is displayed. Specifically, in the human-labeled agent condition, the message shown to the participant is 'In this task, you will be negotiating with the other participant.' In a computer-labeled agent condition, the same message was shown but 'the other participant' was changed to 'a computer program'. Next, a 'connection establishment' message for the human condition and a 'program setup' message for the computer condition appear on screen, to persuade participants of their partner setting. Throughout the negotiation, the partner type is constantly included on screen so the participant clearly recognizes his/her partner type. The partner is labeled as 'the other participant' or 'the computer program.'

In the first negotiation round, items are positioned in the middle row, indicating that those items belong to neither player. The participant is asked to propose an initial offer by moving items into his/her own set of boxes (bottom row) or their partner's set of boxes (top row). Once the initial offer is made, the partner (agent) chooses an emotion pertaining to the offer which is then displayed to the participant. Available emotions include: happy, content, neutral, angry and sad. The partner only shows the predefined emotion for each round. After the emotion is displayed, the partner decides whether to accept or reject the offer. This decision is based on a pre-
defined offer value; when the payoffs of the predefined offer are more than the participant's current offer, the partner rejects, when the payoff is less, the partner accepts.

If the participant's offer is accepted, the items are distributed as proposed and the participant is notified. If the participant's offer is rejected, the partner then proposes a counteroffer. When the counteroffer is received, the participant has 5 -seconds for review. During this time, the participant can only observe; no items can be transferred. The review time was specifically introduced for optimal brain activation, as we wanted to record an active decision-making process. For the same reason, our analysis was focused on data collected during this review phase. After the review phase, the participant reports his/her emotion about the proposed offer by choosing from the following descriptive options: happy, content, neutral, angry, or sad. The participant also decides whether to accept or reject the offer. If the participant rejects the offer, a new round begins, and all phases are repeated. The negotiation can last for a maximum of six rounds. If no agreement is made in six rounds, neither party receives anything.

## Study 1: Online Experiment

We designed an online experiment to determine whether people perceive human-labeled agents differently than computerlabeled agents during interactions in our negotiation game, as well as to find behavioral differences between agent type in concession-making.
Negotiation Partners Two sets of strategies and two types of emotions were used for the partner agents. Agent strategies included tough and soft. A tough strategy starts with a greedy offer, and a soft strategy starts with a relatively generous offer. Figure 2 shows payoffs for the agent and the participant when the agent uses tough or soft strategies.

Agent emotions included anger and neutral (no emotion). Anger was chosen because it was found to be the most effective emotion in yielding concessions during negotiation tasks (Van Kleef, De Dreu, \& Manstead, 2004). For the anger condition, the agent displayed an angry face in rounds 2,4 , and 6 , and a neutral face in rounds 1,3 , and 5 . For the neutral condition, the agent reported a neutral face in every round.
Procedure 420 subjects ( 237 male and 183 female; mean age $=33.5$ ) living in the United States were recruited via Amazon Mechanical Turk (MTurk). Each participant was asked to read a hypothetical scenario in which they acted as a restaurant owner, and negotiated for fruit with another restaurant representative due to a fruit shortage as a result of a recent fire in a local market. Each subject was then told to negotiate with either a computer program or another (hypothetical) MTurk player. Regardless of type label, the negotiation partner was always a pre-programmed computer agent. After completing all negotiations, subjects were asked to fill out an anthropomorphism questionnaire (Bartneck, Kulić, Croft, \& Zoghbi, 2009) about their partner, as well as a demographic

Figure 2: Payoffs for agents and participants across both agent strategies.

Figure 3: Anthropomorphism Scores for human-labeled agents and computer-labeled agents. Higher score means the agent is perceived as more human-like. The error bar shows standard errors.
questionnaire. In the anthropomorphism questionnaire, participants rated their impression of their partner using a scale from 1 to 7 , where 7 means human-like and 1 means machinelike. Subjects were also given a simple attention-check question, implemented to make sure the participants were paying attention; it merely asked what type of partner they were assigned during the task. Each participant was compensated $\$ 1$.
Data Analysis We excluded subjects who had participated in our previous negotiation studies or failed to give the correct answer to the attention-check question. After exclusion, we had data from 329 subjects. Scores from each condition were calculated for the anthropomorphism questionnaire to verify whether participants perceived human-likeness differently between agents. In addition, we calculated concessions across partner type in each condition to analyze behavioral differences. Concession was calculated by subtracting payoffs of agreed offers from payoffs of initial offers. A three-way between-subjects analysis of variance (ANOVA) was used to find the interaction between partner type, partner strategy, and partner emotion during concession.
Results The anthropomorphism scores of the humanlabeled agents and the computer-labeled agents are shown in Figure 3. 1-way ANOVA results show that people consis-

Figure 4: Concessions to human-labeled agents and computer-labeled agents. The error bars show standard errors.
tently thought their partner to be more human-like when told their partner was a human player, no matter what the negotiation strategy $(\mathrm{F}(1,327)=14.09, p<0.001)$.

Concessions to human-labeled agents and computerlabeled agents during negotiations are shown in figure 4. ANOVA results show that there is a $2 \times 2 \times 2$ interaction between agent type (human/computer) $\times$ agent emotion (angry/neutral) $\times$ agent strategy (tough/soft) for concession $(\mathrm{F}(1,321)=3.387, p=0.066)$. We also ran a $2 \times 2$ ANOVA after dropping each strategy. A two-way interaction was found for tough strategy $(\mathrm{F}(1,164)=4.699, p=0.031)$.
Discussion Our findings from anthropomorphism scores suggest that there are perception differences in the interactions between human-labeled agents and computer-labeled agents. Also, our ANOVA results suggest that there is an interaction between agent type $\times$ agent emotion $\times$ agent strategy for concession. This indicates that not only are people's perceptions of the two agents distinct, but their behaviors also vary depending on agent type. To study whether these behavioral differences have neural correlates, we designed the following fMRI experiment. Because the largest concession differences were found in the tough conditions, implying the tough strategy was best suited to observe those differences in behavior, we mainly employed tough agents in the following experiment.

## Study 2: fMRI Experiment

We hypothesized that perceptual and behavioral differences could be captured in brain activity, especially in ToM related brain regions, as they were found to be correlated with human-likeness of physically existing human-like robots (Chaminade et al., 2007; Krach et al., 2008). Each subject performed the negotiation task with both types of agent in order to compare brain activity from human-labeled vs. computer-labeled agent interaction. To make interactions with human-labeled agents more realistic, we introduced a confederate into the study, so participants believed they would be competing against another human player.

Participants 20 healthy American subjects (10 male and 10 female), recruited via the University of Southern California online bulletin board, took part in this study. Subjects were 21.4 years old on average ( $\mathrm{SD}=2.58$ ). All participants were right-handed and had no history of neurological or psychiatric disorders.

Negotiation Partners Although we were only interested in tough agent type, we used two types of soft agents on top of four types of tough agents (human/computer-labeled $\times$ angry/neutral agents). This is modification was implemented because subjects participated in a series of consecutive negotiations, unlike our online experiment where each subject only played in a single negotiation. Including soft agents ensured that participants did not play with the same agent over and over again. Each subject negotiated with six types of agents. While every subject negotiated with four types of tough agents, 10 subjects ( 5 male and 5 female) negotiated with two types of emotion-neutral soft agents, while the remaining 10 subjects negotiated with two types of emotionangry soft agents. Agent order was randomized.

Procedure Each participant was greeted by an experimenter and introduced to the confederate as the competing player. The participant and the confederate were guided to a preparation room where they filled out an informed consent form, incidental findings form, and safety screening form. After forms were completed, the confederate was guided to a separate MRI room for "setting up". The participant was given the instructions and rules regarding the negotiation task, and played a trial negotiation against a computer program before starting the experiment. During the trial, a trackball mouse similar to one used in the scanner environment was provided, so that the participant became familiarized with it's operation. The participant was then guided to the actual MRI room and was told that while in the scanner he/she would run through three negotiation tasks with the participant in the other MRI room, and three negotiation tasks with the computer program. The task was back projected on a screen, seen through a mirror attached to the head coil, and operated a trackball mouse to navigate negotiations. In each task, a different set of negotiation items were used, and payoffs for these items varied with position, in order to give an impression that each negotiation was unique. Participants answered a shortened version of the anthropomorphism questionnaire at the completion of each round. After a maximum of six negotiation rounds, participants filled out a handedness and demographic questionnaire. Before leaving, subjects were debriefed and compensated $\$ 30$.
fMRI Data Acquisition fMRI scans were performed at the USC Dana \& David Dornsife Cognitive Neuroscience Imaging center. Images were acquired using a 3-Tesla Siemens PRISMA MRI scanner with a 20-channel matrix head coil. Two sets of high-resolution anatomical images were acquired for registration purposes. Six sets of echo-planar images (EPI), one set for each negotiation, were acquired continu-

Figure 5: Frontal medial cortex from Harvard-Oxford atlas (left) and overlaid accuracy map for all participants (right). A part of frontal medial cortex was included in the accuracy map (white dotted box).
ously with the following parameters: $\mathrm{TR}=2,000 \mathrm{~ms}, \mathrm{TE}=$ 25 ms , flip angle $=90^{\circ}, 64 \times 64$ matrix, one shot per repetition, in-plane resolution $3 \times 3 \mathrm{~mm}^{2}$, 41 transverse slices, each 3 mm thick, covering the whole brain. Total scan time for each participant was approximately 50 minutes.
Data Analysis We conducted a general linear model (GLM) analysis and then used the results as input for multivoxel pattern analysis (MVPA). GLM analysis was performed using FMRIB's Software Library (FSL) to locate brain regions activated during proposal review phases. As mentioned earlier, this phase was specifically targeted due to the likelihood of collecting data pertaining to decision making for subsequent negotiation rounds. For GLM analysis, data preprocessing steps included motion correction, brain extraction, spatial smoothing, slice timing correction, and high-pass temporal filtering. After completing data pre-processing, we modeled brain activity during proposal review phases using a double gamma hemodynamic response function. Data collection from all other time points were used as baseline. We then performed MVPA to find brain regions that illustrated different patterns across agent type. In MVPA, neural representations were decoded by applying pattern-classification algorithms on fMRI data (Norman et al., 2006). We used detrended and $z$-scored GLM analysis results as inputs for MVPA, and trained a linear Support Vector Machine (SVM) classifier using feature selection, introduced to improve classification performance by picking the most relevant features as inputs for the classifier (Guyon \& Elisseeff, 2003). Searchlight analysis (Kriegeskorte, Goebel, \& Bandettini, 2006) was used as the feature selection method to analyze contents multivariately at each location in the brain. We implemented a leave-one-participant-out cross validation as balance for MVPA. More details on fMRI data analysis can be found in (Kim, Gimbel, Litvinova, Kaplan, \& Dehghani, 2016), as the same analysis methods were used.

Results The right side of Figure 5 shows an overlaid accuracy map for all participants. Accuracy maps were acquired from the top $5 \%$ of all t -maps, which were generated using t-tests versus chance. Interestingly, medial prefrontal cortex, one of the ToM brain regions, was included in the accuracy map, suggesting that people indeed perceived the
human-labeled agent to have more human-like qualities.
MVPA, with searchlight as a feature selection method, revealed that agent type (human/computer) can be predicted based on brain activity during proposal-review phases. Prediction accuracy for agent type was $58.41 \%$, with a standard error $0.01 \%$, where chance level is $50 \%$. The improvement was found to have statistical significance (Two-tailed t-test: $p$ $<0.001$ ).

Discussion The results of Study 2 demonstrates that differences in how we perceive the 'humanness' of an agent can be captured using fMRI. Specifically, our results show that parts of the ToM neural correlates are activated in humanlabeled agent conditions, but not in computer-labeled agent conditions. This finding is consistent with previous studies that reported increased brain activity in ToM brain regions corresponding to human-likeness of interacting partners (Chaminade et al., 2007; Krach et al., 2008). Our MVPA analysis further revealed that these differences are great enough that classifiers can be trained that can reliably distinguish brain activity between the two types of agents.

## Overall Discussion

Our goal was to investigate differences in behavior and brain activity during human-agent negotiations. Focusing on partner type, we hypothesized that both parameters would be distinct when comparing computer-labeled and human-labeled interactions.

Results from our online experiment indicate that people perceive human-labeled agents more human-like than computer-labeled ones, even though both used parallel strategies and emotions. This suggests that people's attitudes towards computer partners are distinguishable from those towards human partners. Furthermore, a 3-way interaction between agent type $\times$ agent emotion $\times$ agent strategy was found for concession.

Results from our fMRI experiment suggest that brain patterns observed during interactions with human-labeled agents are different from ones with computer-labeled agents. More specifically, the medial prefrontal cortex, part of the ToMrelated neural structures, was found to be included in accuracy maps, indicating neural activity during interactions with human-labeled agents are distinct from ones with computerlabeled agents. This is in line with a previous finding, where the medial prefrontal cortex was found to be activated while playing rock-paper-scissors with a human player, but not activated when playing the same game with a known, pre-defined computer algorithm (Gallagher, Jack, Roepstorff, \& Frith, 2002). Using a negotiation paradigm, a more complicated task than rock-paper-scissors due to the inclusion of multiple decision-making rounds, we found that the same effect exists with differently labeled agents. Negotiations require a more substantial cognitive effort than a game like rock-paperscissors; there are a larger amount of possible actions to consider, an increased opportunities for loss, and a greater obligation to compete, or cooperate and come to some sort of
agreement. The negotiation tasks used in the aforementioned experiments are able to advantageously measure interactions that require high levels of cognitive energy, and are therefore more useful when attempting to explore human-robot interactions.

Our findings are also consistent with previous studies that found ToM-related neural structures to be more activated when interacting with agents that had more human-like characteristics, regardless of whether those agents happened to be robots or computer-generated characters (Chaminade et al., 2007; Krach et al., 2008). These findings imply perceptual variance between interactions with human-like and nonhuman-like agents, and leads us to believe that human participants do engage in greater mentalising efforts when faced with human-labeled or human-like robots.

In conclusion, we examined the relationship between negotiation partner type and behavioral and neural measures regarding individual's perceptions of human-agent interactions. Our study suggests that when either by labeling agents as other humans or as computer programs significantly impacts one's perception of the situation; this is ultimately demonstrated through negotiation behavior and brain activity. The results give us further insight into the counter-play between emotional and cognitive processes, leading us to believe that our emotions may have greater impact on decision making than which we are consciously aware. Ultimately, these results inform us that there is a noticeable and consistent difference between the perceptual and emotional reactions that humans have towards other humans when compared to those same reactions with computer agents. Further research needs to be executed to more thoroughly understand why these differences in interaction occur, but this study has illustrated that computers and technology do indeed impact the way humans interact with the world, and each other. This is important to consider as computers continue to be increasingly implemented in everyday life and society.

#### Abstract

Dyslexia is a common learning disability, but its core deficit is still under debate. The anchoring deficit hypothesis suggests that dyslexics' benefit from experimental stimuli statistics is impaired (e.g. Ahissar, 2007). In this study we asked whether dyslexia is also associated with reduced sensitivity to long-term statistics. Spans for lists of syllables were measured, and indeed, dyslexics benefited less than controls from syllabic frequency. However, dyslexics' benefit from sequence repetition was similar to controls'. In order to dissociate the impact of item familiarity from exposure unrelated factors, native English speakers performed the experiment. They were expected to benefit from repetition, but not from syllabic frequency (in Hebrew). Indeed, that was the case. These data suggest that benefits from long-term distributional statistics are impaired in dyslexia, whereas on-line benefits from sequence repetition are adequate. Moreover, our results suggest different underlying mechanisms for long-term distribution learning and short-term sequence learning.

# "Oops, I did it again." The impact of frequent behaviour on causal judgement 

Lara Kirfel (lara-christina.kirfel.15@ucl.ac.uk)<br>David Lagnado (d.lagnado@ucl.ac.uk)<br>Department of Experimental Psychology, UCL, 26 Bedford Way, London WC1E 6BT

#### Abstract

Current causal theories aim to incorporate the effect of statistical and prescriptive norms on causal judgements, stating that norm-violating actions are judged as more causal than norm-conforming ones. In this paper, we present two experiments that undermine this claim, showing that people attribute increased causality to agents who conform to the norm of frequent behaviour. Furthermore, we find that the time point at which a moral norm is introduced does not make a difference to causal attributions, but that the frequency of a norm violation further accentuates its causal rating. Because these findings present a challenge to current norm theories of causation, we argue for an extended counterfactual model of causal attribution.

Keywords: causal judgement; counterfactual reasoning, frequency; norms; moral judgement

## Introduction

Judgements about causal processes are a crucial skill to make sense of the word. While our ordinary concept of causation was long thought to be entirely objective in character, we know that factors that go beyond the causal facts of a situation, e.g. the moral status of an action, are hugely influential on how we think about the causality of an agent (Halpern \& Hitchcock, 2015; Hitchcock \& Knobe, 2009, Alicke, Rose \& Blome, 2011). For example, if two agents cause a negative outcome by jointly performing the same action, but only one of them is actually allowed to perform this action, people judge the agent who violated the rule as more of a cause (Knobe \& Fraser, 2008). A similar picture arises for the statistical properties of an action. Exceptional or atypical actions (Kahneman \& Miller, 1986), as well as actions with statistically unlikely outcomes (Kominsky et al., 2015) are judged more causal than typical actions or likely outcomes.

All these cases involve circumstances in which the factor that is viewed as a cause is 'abnormal': a person does something immoral, a person does something she usually does not do, or an action has a very unlikely outcome. It has therefore been suggested that our causal judgements are sensitive to 'normality', or 'norms', with the term norms encompassing a variety of norms like moral norms, social rules or statistical norms such frequent behaviour or the likelihood of an outcome. This view holds that normviolating actions, i.e. actions that deviate from norms or normal circumstances, are judged as more causal than normconforming ones (Hart \& Honoré, 1963; Hitchcock \& Knobe, 2009). The underlying assumption is that we assess a causal candidate in terms of its counterfactual relation for the
outcome (Gerstenberg \& Lagnado, 2010; Halpern \& Pearl, 2010) and that norms come into play concerning which counterfactuals we consider. Hence, when reasoning about the cause of an event, norms are thought to make normconforming counterfactuals more relevant (Hitchcock \& Knobe, 2009), more available (Kahneman \& Miller, 1986), more probable to be sampled (Icard \& Knobe, 2016) or to be ranked highest in the order of possible counterfactuals (Halpern \& Hitchcock, 2015).

Common to all these accounts is the idea that in a causal scenario with multiple causal candidates, we will single out the action or event that is norm-deviant, e.g. immoral or unlikely, because we have the tendency to counterfactually simulate an alternative scenario in which normality is in place and no norm is violated (Hitchcock \& Knobe, 2009; Kahneman \& Miller, 1986). In addition, it has been shown that the norm violation of one agent not only increases causal attribution, it can also reduce causal attribution to other, norm conforming agents, known as "causal superseding" (Kominsky et al., 2015). Although this account applies to normality and norms in a very broad sense, studies in causal attribution have mainly investigated the influence of violations of moral norms (Alicke, Rose \& Blome, 2011 Hitchcock \& Knobe, 2009; Knobe \& Fraser, 2008), statistical norms (Kahneman \& Miller, 1986; Kominsky et al., 2015) and norms of proper functioning (Hitchcock \& Knobe, 2009). We will subsume these theories under a general norm-framework of causal judgement.

In the causal cognition literature, frequent, repeated actions have often been considered as belonging to a special kind of statistical norms, so called 'agent-level' statistical norms or norms of 'typical behaviour'. According to the norm framework of causal judgement, actions that deviate from this norm, i.e. atypical actions that are rarely or almost never performed, are seen as more causal than actions that are performed frequently (Knobe \& Fraser, 2008). However, Sytsma and colleagues showed that these 'atypical', i.e. infrequent actions receive reduced instead of increased causal attribution (Roxborough \& Cumby 2014; Sytsma et al., 2012). The authors systematically varied the frequency and morality of actions in the 'pen case' scenario (Knobe \& Fraser, 2008). In this scenario, both a professor and an administrative assistant each take one of two available pens in the department office, with negative consequences. Sytsma et al. varied whether each agent frequently took pens from the office, and whether they were officially allowed to do so. While, as expected, they found that an agent was judged as more causal when violating the department policy, they also
found that an agent was attributed more causality when he frequently took pens rather than only once. This was even the case when there was no department policy prohibiting the use of pens (Sytsma et al., 2012).

By showing that an action that has been repeatedly performed previously receives higher rather than lower causal ratings, the authors provide evidence that agent-level frequent behaviour does not always follow the general schema attributed to the role of norms in causal reasoning. However, the influence of frequent behaviour on causal judgements in this particular case might not come as a surprise. The causal structure of the "pen case" scenario is sensitive towards the frequency of the actions - trivially, the more often a person takes pens, the more they contribute to the pens running out. This raises the question whether the frequency of a particular action, or non-action, also influences our judgement of its causal contribution in a causal structure where the frequency itself does not make a difference to the outcome. The causal situation in the pen case is cumulative: The more often the action is performed, the more likely the final outcome is to happen. However, let's imagine a case where at the end of each day the pen stock gets replenished to two pens. If only one of the agents repeatedly takes a pen on each day, then no problem occurs. But when both agents decide to take a pen on the same day, then there will be no pens left for emergency cases. This case represents a conjunctive causal structure - two actions are needed for the adverse outcome to occur. We were interested whether the frequency of an action still has an impact on our causal judgements in such a scenario:

1. Does the frequency of an action affect causal judgments in a conjunctive causal structure?

Norm-incorporating theories predict increased causal attribution to actions that violate moral norms, but make no prediction as to whether the frequency of the norm violation further accentuates its causal relevance. In terms of counterfactual dependence, if the joint actions of a frequent and a one-off moral norm violator lead to a negative outcome in a conjunctive causal structure, they are both equally causal - if either of them had not acted, the outcome would not have occurred (Halpern \& Pearl, 2010). Furthermore, they are both also 'equally abnormal', because both of them violated the norm in the situation of the final outcome. Current norm incorporating theories leave open whether we mentally undo only the final vs. all previous norm-violating actions in order to assess the causal relevance of a norm-violating agent. This motivated our second research question:
2. Is a frequent vs. one-off norm violation assigned a different amount of causality in a conjunctive causal structure?

Gershman et al. (2016) show that if a certain action leads to a negative outcome in a new context, e.g. the door at the new office breaks when you turn the doorknob clockwise, this action will be judged less blameworthy when it has been
a habitual action before, e.g. when the door knob at home runs clockwise. In fact, we can think of situations in which an action that has been frequently done before is suddenly not allowed anymore, for example smoking in bars after the UK smoking ban in 2007. This raises the question whether a norm-violating act that has been permissively performed before is judged less causal than a repeated norm violation:
3. How does a frequent norm violation compare to an action that has been done frequently, but violated a norm only once?

The two experiments in this paper aim to address these questions.

## Experiment 1

Experiment 1 examined the influence of the "frequency" and "morality" of an action on causal judgments in a conjunctive causal structure. Frequent and moral behavior were varied across the actions of one agent ('Agent 1') and held constant across actions of the other agent ('Agent 2'). In order to manipulate frequent behavior realistically, we used the time frame of a week in which information about the action of the agents is successively presented day by day. Additionally, we varied whether the official norm indicating which agent is allowed to perform the respective action is either introduced right at the beginning of the scenario, or just before the final outcome ("time point of moral norm"). By varying the time point at which the moral norm was introduced we could test actions that either frequently violate a norm, or violate the norm for the first time but have been frequently performed before.

## Methods

Participants 103 participants were recruited via Amazon Mechanical Turk ( $\$ 0.80$ for ca. 15 min ). Participants who answered more than four of the 32 manipulation check questions wrong were removed from the analysis, leaving 81 participants $($ male $=45$, female $=36$; mean age $=34.78$; $\mathrm{SD}=11.36$, age range $=19-74$ ).

Materials All conditions used variations of the same vignette. The scenario describes a week in a startup company, from Monday to Monday, with office days from Monday to Thursday. The company printer breaks as soon as it receives two printing orders at the same time [conjunctive causal structure with two actions], while individual printing does not make a causal difference. The participant acts as CEO with two co-workers, Agent 1 and Agent 2, whose names and gender are counterbalanced across scenarios.

[^368]Agent 1 either uses the printer frequently during the week ("frequent behaviour"), or never prints during the week ("infrequent behaviour"). Furthermore, there is a company policy that determines that Agent 1 and Agent 2 are either allowed to use the printer anytime they want, or only on selected days.

As the CEO of your startup, you officially rule that both Agent 1 and Agent 2 are allowed to use the printer whenever they want [Agent 1 is only allowed to print on Tuesdays and Thursdays, and Agent 2 only on Mondays and Wednesdays.]

By printing on e.g. a Monday, Agent 1 conforms to the company policy in case of the liberal printer policy ("moral norm conformation") or violates the company policy in case of the selective policy ("moral norm violation"). Combined with the frequency manipulation, Agent 1 therefore conforms to or violates the policy, and does so frequently or infrequently. In contrast, Agent 2 prints frequently during the week, and always only on the days on which she is allowed to print. Each day of the week is successively presented.

On Monday, $X$ uses the printer for printing the new flyer design.
On Tuesday, $X$ uses the printer for printing the program outline.
On Wednesday, $X$ uses the printer for the printing of the new logo.
On Thursday, $X$ uses the printer for printing out the schedule.
After the presentation of one week, i.e. the Monday after the start of the scenario, both agents simultaneously send printing orders to the printer and it crashes.

On the following Monday, you come into the office and the printer is broken. Both Agent 1 and Agent 2 have sent printing orders to the office printer today. This is bad because your start up currently does not have the budget to afford a new high quality colour printer.

The company policy is either introduced at the beginning of the scenario, as shown in the previous examples, or on Thursday, i.e. just before the final outcome ("time point of moral norm")

Design and Procedure The experiment was designed as 2 (Frequency) $\times 2$ (Moral Norm) x 2 (Time point of moral norm) within subject paradigm. Participants saw all eight variations of the scenario in a randomized order, and each office day was presented successively on a single slide. The participants then had to judge the causal contribution of both agents to the outcome on a 10-point causal rating scale ("To what extent did Agent X cause the outcome?": 0"- 'None at all'; "10"- 'Fully). Recent studies have highlighted that the term 'cause' in the test questions is ambiguous and can refer to both the causal mechanism and the agent's accountability (Samland et al., 2015). Therefore, we added a 7-point counterfactual relevance agreement scale ("If Agent X had not printed, the problem would not have occurred."; "1" 'Strongly disagree'; " 7 " - 'Strongly agree’) to directly test counterfactual reasoning. In addition, four manipulations check questions about the moral norm ("In the scenario you have just read, was Agent X allowed to print on Monday?") and the frequency of the agents' actions ("In the scenario you
have just read, did Agent X typically use the printer?') with the answer options ('yes', 'no') were given.

Figure 1. Experimental design with the norm introduced on beginning of the scenario (above) and on Thursday, i.e. at the end of the scenario (below).

## Results

Causal Rating | Agent 1 Causal ratings for Agent 1 were higher when they violated the moral norm ( $\mathrm{M}=6.35$; $\mathrm{SD}=2.43$ ) than when they conformed to it ( $\mathrm{M}=4.53$; $\mathrm{SD}=1.60), F(1,80)=67.71, p<.001, \eta_{p}^{2}=.46$. In contrast, when Agent 1 acted only once, they were judged as less causal ( $\mathrm{M}=4.80, \mathrm{SD}=2.46$ ) than when they performed a frequent behaviour $(\mathrm{M}=6.06, \mathrm{SD}=1.71), F(1,80)=25.08, p$ $<.001, \eta_{p}^{2}=.24$. The time point of the norm did not reveal any significant effects ( $\mathrm{p}=.83$ ).

Causal Rating | Agent 2 Agent 2 was seen as less causal when Agent 1 violated a moral norm ( $\mathrm{M}=3.61, \mathrm{SD}=2.33$ ) compared to when Agent 1 conformed to the norm ( $\mathrm{M}=5.40$, $\mathrm{SD}=1.78), F(1,80)=53.33, p<.001, \eta_{p}^{2}=.40$. Likewise, Agent 2 was seen as more causal when Agent 1 printed oneoff ( $\mathrm{M}=4.89, \mathrm{SD}=2.32$ ), compared to when Agent 1 printed frequently ( $\mathrm{M}=4.13, \mathrm{SD}=1.60$ ) , $F(1,80)=13.46, p<.001$, $\eta_{p}^{2}=.14$. The time point of the norm did not reveal any significant effects ( $\mathrm{p}=.16$ ).

Figure 2. Causal Rating. "M" indicates the moral norm and "F" the frequency of behaviour, with ' $\checkmark$ ' for 'conforming/frequent' and ' $\boldsymbol{X}$ ' for 'violating/one-off'. The error bars represent $\pm 1$ SE of the mean.

Counterfactual Relevance |Agent 1 The agreement ratings for the counterfactual relevance of Agent 1 were affected by both Agent 1's moral behaviour, $F(1,80)=21.60, p<.001$, $\boldsymbol{\eta}_{p}^{2}=.21$, and frequency of action, $F(1,80)=17.86, p<.001$, $\boldsymbol{\eta}_{\boldsymbol{p}}^{2}=.18$. The agreement for Agent 1 as relevant counterfactual was higher when they violated a moral norm ( $\mathrm{M}=5.20, \mathrm{SD}=1.47$ ) than when they did not $(\mathrm{M}=4.75$, $\mathrm{SD}=1.44$ ) and lower when they acted one-off ( $\mathrm{M}=4.69$, $\mathrm{SE}=1.63$ ) compared to when they acted frequently $(\mathrm{M}=5.26$, $\mathrm{SD}=1.32$ ).

Counterfactual Relevance | Agent 2 The violation of morality by Agent 1 decreased agreement with Agent 2 as counterfactually relevant (MD=-.45; SD=0.13), $F(1,80)=$ 12.67, $p<.001, \eta_{p}^{2}=.14$. Agent 2 was also seen less counterfactually relevant when Agent 1 acted frequently $(\mathrm{MD}=-.32 ; \mathrm{SD}=0.13), F(1,80)=12.67, p=.006, \boldsymbol{\eta}_{\boldsymbol{p}}^{2}=.14$

Moral Norm Violation A 2 (Frequency) $\times 2$ (Time point of moral norm) ANOVA for norm violating actions revealed a significant difference for the frequent norm violation ( $\mathrm{M}=7.09, \mathrm{SD}=1.24$ ), vs. infrequent norm violation ( $\mathrm{M}=5.62$, $\mathrm{SD}=1.36$ ) of Agent 1 on causal judgements, $F(1,80)=24.60$, $p<.001, \eta_{p}^{2}=.24$. A corresponding reverse rating was found for Agent 2 when Agent 1 violated the moral norm frequently $(\mathrm{M}=3.24, \mathrm{SD}=1.25)$ vs. once $(\mathrm{M}=3.99, \mathrm{SD}=1.33), F(1,80)=$ $8.43, p=.005, \eta_{p}^{2}=.09$. Counterfactual relevance ratings for Agent 1 were higher when Agent 1 frequently violated the norm ( $\mathrm{M}=5.49, \mathrm{SD}=.15$ ) vs. once once ( $\mathrm{M}=4.92, \mathrm{SD}=.20$ ), $F(1,80)=16.17, p<.001, \eta_{p}^{2}=.17$. Agent 2 was seen less counterfactually relevant when Agent 1 frequently violates the norm, compared to violating the norm once ( $\mathrm{MD}=-.47$, $\mathrm{SD}=.18), F(1,80)=7.23, p=.009, \eta_{p}^{2}=.08$.

Figure 3. Counterfactual relevance rating. " M " indicates the moral norm and " $F$ " the frequency of behaviour, with ' $\checkmark$ ' for 'conforming/frequent' and ' $X$ ' for 'violating/one-off'. The error bars represent $\pm 1 \mathrm{SE}$ of the mean.

## Discussion

Experiment 1 confirmed the effect of moral norms on causal attribution (Knobe \& Fraser, 2008), showing that an agent who violates a moral norm is judged as more causal and counterfactually relevant than a norm-conforming agent. We also found a reversed norm influence for agent-level statistical norms, with frequent behaviour being judged more instead of less causal than one-off actions. We found the same effects for counterfactual relevance ratings, showing that moral norm violations and frequent behaviour increase the extent to which an action is seen as counterfactually relevant to the outcome. An increase in causal attribution to Agent 1 due to norm violating and/or frequent behaviour was accompanied by a decrease in causal attribution to Agent 2, known as "causal superseding" (Kominsky et al., 2015). We did not find an interaction between the immoral norm behaviour and the time point at which the norm was introduced in the scenario. Hence, an action that has been violating the norm from the beginning is judged as causal as an action that has been frequently performed before, but only violated a norm after the new introduction of a moral norm.

Our finding that frequent behaviour increased causal attribution is consistent with Sytsma et al. (2012), but was surprising insofar as the causal structure of our scenario was designed to be causally insensitive to an individual action that occurs frequently, i.e. using the printer often. However, it might be argued that the influence of frequent vs. one-off actions in a conjunctive causal structure depends on the knowledge that both agents have about each other's behaviour. For example, when the agent who usually never uses the printer suddenly prints in a conjunctive causal structure, she might be seen as more causally responsible for the outcome if she is aware that the other agent frequently
prints. In addition, despite our attempt to implement a conjunctive causal structure, participants might have interpreted frequent behaviour in our scenario as gradually damaging the printer. In order to further investigate the role of knowledge, and accentuate the difference between a cumulative and conjunctive causal structure, we conducted a second experiment.

## Experiment 2

Experiment 2 examined the influence of frequent behavior in dependence of the underlying causal structure and state of knowledge of the agents.

## Methods

Participants 102 participants were recruited via Amazon Mechanical Turk ( $\$ 0.80$ for ca. 15 min ), and after removing participants who had more than four of the 32 check questions wrong, the data of 64 participants were analyzed ( male $=34$, female $=30$; mean age $=33.56 ; \mathrm{SD}=11.92$, age range $=21-74$ ).

Materials The same design as in Experiment 1 was used, except that the moral norm manipulation was removed by setting the moral status of all actions to "moral norm conforming" by a company policy that allowed the two agents to use the printer anytime. The frequency of the actions of Agent 1 was varied while holding the frequency of Agent 2 constant. Hence, either both of them frequently used the printer on different days during the week, or only Agent 2 used the printer. The underlying causal structure of the scenario was also varied by either containing a conjunctive causal structure (Experiment 1), or a cumulative causal structure, i.e. every action gradually increases the likelihood for the outcome to happen

The printer is quite worn out, and every printing order sent strains the printer system a bit more.

Finally, we varied whether the agents know about each other's behavior.

The printer management system does [does not] display the current user balance so that Agent 1 and Agent 2 know [do not know] who prints how much each day.

Design and Procedure The experiment was designed as a 2 (Frequency) $\times 2$ (Causal Structure) $\times 2$ (Knowledge) within Subject Design. The participants saw each of the eight scenarios in a randomized order, and answered two causal strength and counterfactual relevance questions, using the same scales as in Experiment 1. Following this, they were asked two manipulation check questions about the typical behavior ("In the scenario you have just read, did Agent X typically use the printer?") a knowledge manipulation question ("In the scenario you have just read, does the printer management system display the user balance?"), and a causal structure check question ("In the scenario you have just read, under which conditions does the printer crash?"), with the
options "Two or more printing orders at the same time" or "Overuse".

## Results

Causal Rating | Agent 1 Causal ratings for Agent 1 were generally higher when they acted frequently ( $\mathrm{M}=5.31$; $\mathrm{SD}=1.30$ than when they acted one-off ( $\mathrm{M}=2.90 ; \mathrm{SD}=1.89$ ), $F(1,63)=103.78, p<.001, \eta_{p}^{2}=.62$. However, the increase in causal contribution when Agent 1 used the printer frequently was greater in the cumulative causal structure than in the conjunctive causal structure, $F(1,63)=103.78, p=.001$, $\eta_{p}^{2}=.16$. No significant effect for knowledge was found ( $\mathrm{p}=.48$ ).

Causal Rating | Agent 2 Agent 2 was seen as less causal when Agent 1 acted frequently, ( $\mathrm{M}=5.32, \mathrm{SD}=1.30$ ), but more causal when Agent 1 performed a one-off action $(\mathrm{M}=6.93, \mathrm{SD}=1.90), F(1,63)=69.15, p<.001, \eta_{p}^{2}=.52$. The increase in causal attribution to Agent 2 when Agent 1 did not act frequently was greater in the cumulative than in the conjunctive causal structure, $F(1,63)=39.64, p<.001, \eta_{p}^{2}=$ .37. There was no significant effect for knowledge ( $p=.90$ ).

Figure 4. Causal Rating. " $F$ " indicates the frequency of behaviour, with ' 1 ' for 'frequent' and ' 0 ' for 'one-off'. The error bars represent $\pm 1 \mathrm{SE}$ of the mean.

Counterfactual Relevance Agent 1 was seen as more counterfactually relevant when they acted frequently ( $\mathrm{M}=4.86 ; \mathrm{SD}=.1 .33$ ) versus one-off $(\mathrm{M}=3.93 ; \mathrm{SE}=1.56), F(1$, 63) $=29.87, p<.001, \eta_{p}^{2}=.32$, and the increase in counterfactual relevance when acting frequently was greater in the cumulative structure, $\mathrm{F}(1,63)=6.90, p=.011, \eta_{p}^{2}=$ .10. Agent 2 is assigned less counterfactual relevance when Agent 1 acts frequently ( $\mathrm{MD}=-.56 ; \mathrm{SD}=.197, F(1,63)=$ $12.19, p=.02, \eta_{p}^{2}=.16$. There was no significant effect for the knowledge factor $(\mathrm{p}=.50)$.

Figure 5. Counterfactual Relevance Rating. "F" indicates the frequency of behaviour, with ' 1 ' for 'frequent' and ' 0 ' for 'one-off'. The error bars represent $\pm 1 \mathrm{SE}$ of the mean.

## Discussion

Experiment 2 confirmed the effect of frequent behavior on causal judgments. Frequent behavior was seen as more causal than one-off behavior, independent of the underlying causal structure. However, participants were aware that the change from frequent behaviour to a one-off action led to a greater reduction in causal contribution in the cumulative causal structure than in a conjunctive structure. The effect of frequent behaviour was independent of whether or not the agents knew about each other's behavior.

## General Discussion

Our two experiments found evidence for an increase in the causal attribution to an agent who acts in line with their frequent behaviour, even when the frequency of this behavior does not make a causal difference to the outcome. Our results present a challenge to the norm account of causal judgment, showing that a one-off action that deviates from frequent behavior is judged less instead of more causal for a negative outcome. Since the knowledge about the other agent's behavior did not make a difference to causal judgements, despite being crucial for estimating the outcome in a conjunctive causal structure, we rule out that people might have inferred bad intentions or foreseeability of the outcome from typical behavior (Lagnado \& Channon, 2008). Hence, we believe that the fact that people assign increased causality to a frequent, typical action goes against predictions of norm theories and shows the need for a new account of frequency of actions in causal attribution. Current counterfactual and structural equation models (Halpern \& Pearl, 2005; Chockler \& Halpern, 2014) fail to account for the asymmetry of causal attribution between a frequent vs. one-off actor in a conjunctive causal structure, given that previous behavior does not change the counterfactual dependency of the two actions in the actual situation.

We draw two conclusions from this. First, we argue for the need to include the previous history of actions of an agent
into counterfactual accounts of causal judgments. Second, we argue that an extension of current counterfactual theories is needed in order to capture the influence of frequency. One such extension could be probabilistic (Fenton-Glynn, 2016). While frequent behavior does not differ from one-off behavior in terms of single counterfactual dependencies, it does so probabilistically. If, in a counterfactual world, the other agent acts at a random time point in a conjunctive structure, the outcome is more likely to occur if I frequently perform the other action needed for the outcome. In contrast, it is less likely to occur if I act infrequently. The raised probability of the outcome due to my frequent behavior can even increase when we also vary whether the other agent acts frequently vs. one-off. As a result, we argue that in addition to counterfactually testing whether the undoing of an action makes a difference, we also need to test whether the variation of the frequency of the action would make difference to the likelihood of the outcome to occur.

Our results show that a frequent norm violation is judged more causal than a one-off moral norm violation. This is despite the fact that in the actual situation of the outcome, they are both equally counterfactually relevant, as well as equally. Hence, we think that current norm theories need to include the frequency of previous norm violations in order to fully capture the influence of moral norms on causal attributions. However, the time point at which the moral norm is introduced into the scenario does not change the way we assign causality to actions that violate this norm. To conclude, the influence of the frequency of an action proves to be a crucial factor in the attribution of causality, and calls for new theoretical frameworks of causation. We argue that this framework has to be probabilistic.

#### Abstract

We investigated how people would change and vary in accepting advice when the effectiveness of advice was unclear. In each trial, participants estimated a monthly rent of an apartment room based on the attribute list. Then, another estimate by a real-estate agent was given as advice. Participants made a final estimation, either by taking the advice fully, partially, or rejecting it totally. They repeated 48 estimations without feedback. The weight of advice index, representing how much each participant weighed a given advice, gradually decreased as the number of trials increased. Interestingly, the gradual reduction of acceptance was not observed in participants with high empathy and low depressive scores; they kept accepting advice even when the effectiveness of advice was unclear. These results suggest that the willingness of accepting and using advice depends on history of advice taking, the individual traits, and mood.

Keywords: decision making; advice taking; individual difference

## Introduction

When we cannot make a decision by ourselves, we frequently ask for advice. Assume you are about to purchase a house and have two candidate options. Both houses are similarly attractive but different in various aspects. You cannot decide which to buy. Here comes a friend and starts giving you a series of advice. Will you accept advice and, if so, how much will you use the advice for your final decision? Obviously, it depends. Generally, we do not know if advice is useful or not until the outcome of a decision comes out. However, under ambiguous situations with time constraints, we often need to decide whether we should accept advice. In the present study, we examined how people would change and vary in accepting advice when the effectiveness of advice is unclear. In particular, we were interested in whether advice taking would depend on history of experience of advice taking and individual traits and mood.

In general, people heed advice and adjust their estimate and/or judgment (Bonaccio \& Dalal, 2006; Yaniv, 2004b). However, this advice taking process is prone to various cognitive bias. For example, people tend to weight own judgment more even when they should take advice to improve their judgments (Yaniv, 2004a; Yaniv \& Kleinberger, 2000). One of the biasing factors is a
characteristic of advisor. For example, people follow advice more when their advisor is labeled as an expert by the experimenter (e.g, Meshi et al., 2001; Harvey \& Fischer, 1997), and when an advisor expresses great confidence in his/her advice (e.g., Sniezek \& van Swol, 2001).

Although the previous studies mainly focused on the characteristics of advisor, several studies showed that, the internal states of decision makers (e.g., emotion and confidence) also modulate advice taking behaviors (Cooper, 1991; Gino \& Schweitzer, 2008; Gino, Brooks, \& Schweitzer, 2012). For example, when anxiety is experimentally induced in participants, they show lower confidence and consequently a higher level of acceptance of advice (Gino et al., 2012). These previous findings suggest that there may be individual differences regarding advice taking. However, it is not clear how individual characteristics (i.e., emotion, personality, and interpersonal reactivity) would influence advice taking. Using three questionnaires of personality, emotion, and interpersonal reactivity, we examined individual variability of advice taking behaviors.

One of major motivation for acceptance of advice is to adjust and improve own judgments. Therefore, if the effectiveness of advice is unclear, the acceptance of advice will decrease over time. In the present study, we confirmed this tendency and then examined how the reduction of advice taking would vary across individuals.

## Method

## Participants

Fifty-four university students participated in the present study ( 18 females and 36 males). They gave written informed consent and were blind to the purpose of the study. Most of them lived in Tokyo and its vicinity and had some knowledge of rent in the Tokyo area.

## Price Estimation Task

Participants performed the price estimation task (Meshi et al., 2012), where they estimated rents of apartment rooms. Five attributes of each apartment room (room layout, area in square meters, distance form the nearest station, floor level, and building age) were presented on a computer monitor (Figure 1). Based on those set of information, participants estimated the monthly rent of each room (in Japanese yen).

After the initial estimation, another opinion, i.e., advice, on the rent of the room was given in one half of trials (advice condition). We instructed them, "Advice was derived from a real-estate agency who visited our laboratory to participate this experiment another day and judged the rental price for them on the same computer," but the price was an actual rent of the room around the Takadanobaba station, Sinjyuku, Tokyo. Then, participants were asked to decide whether they would consider changing their first estimation, if so how much. They reported the estimated price by adjusting the slide bar on the monitor with a computer mouse, and decided by clicking the mouse button. In the other half of trials, they did not receive any advice but still were asked whether or not they would like to change their opinions (no-advice condition). No feedback was given about their decision. Advice and no-advice conditions were randomly intermixed and presented 24 times, resulting in 48 trials for the whole session. The trials were divided into four sessions. The next session started after participants pressed the space bar; they were allowed to rest between trials.

Figure 1: Example of the trial flow of the price estimation task of the present study.

## Analysis

In the advice condition of the present task, we obtained two estimates for the rents: the fist estimate without advice and the second estimate after receiving advice. The difference between advice and the first estimate represents how much opinions are different between the participant and the advisor. The difference between the second rating and the first rating represents how much the participant changes his or her opinion. In order to examine how much each participant took into consideration or weighed the given advice, we calculated "Weight of Advice" index (WOA; Bonaccio \& Dalal, 2006).

$$
W O A=\frac{\text { Second estimate }- \text { First estimate }}{\text { Advice }- \text { First estimate }}
$$

For example, a participant's initial estimate was 1000 yen, and the advice was 2000 yen. Assume, after receiving the advice, the participant adjusts her estimate slightly higher, say, 1100 yen. Then, the weight of advice index would be calculated as 0.1 , indicating a small influence of advice. On the other hand, the participant may fully use the advice and adjust her estimate to 2000 yen. The calculated weight of advice index would then be 1 . It is theoretically possible that WOA is larger than 1 or takes a negative value. However, as such cases would represent behaviors different from normal advice taking or simple response errors, we excluded those data from the analyses (42 trials). Additionally, we also excluded the data from 89 trials whose first estimations were identical to the advice prices, or whose response time is 4 SD above the mean response time of all advice-taking trials. The resulted number of trials was 1165 .

## Questionnaires

In addition to WOA from each participant, to examine possible influences of participants' personality, mood, and interpersonal reactivity traits on the advice taking in the price estimation task, we used three questioners; Ten Item Personality Inventory (TIPI-J; Oshio, et al., 2012; Gosling, Rentfrow, \& Swann, 2003); Beck Depression Inventory (BDI; Beck et al., 1961), and Interpersonal reactivity index (IRI; Davis, 1980; 1983; 1996). These questionnaires are widely used to measure participants' personality, mood, and interpersonal reactivity traits in previous studies (e.g, Oshio et al., 2014). All participants were asked to answer those questionnaires.

## Results

In Figure 2, we plotted the difference between the first rating and advice, and the difference between the first and second ratings. The horizontal axis is the difference between the advice and the first estimate, representing how much opinions were different. The vertical axis is the difference between the second estimate and the first estimate, representing how much participants changed their estimates. Each dot represents a single trial. In this plot, two lines were apparent. One was a horizontal line at the 0 point of the vertical axis. These data points were from the trials where the participants did not change their estimates at all. Irrespective of the differences in opinions, they simply ignored the advice and did not change their estimates. The other was a diagonal line. The data points on the diagonal line were from the trials where the difference between the advice and the first estimate and the difference between the second estimate and the first rating estimate identical. That is, the participants fully accepted the advice. Then the data between these two lines represented the trials where the participants took the advice but adjusted their estimates partially.

To capture various advice taking behaviors, we calculated the Weight of Advice index (WOA). Figure 3 shows the frequency distribution of the WOA. The data at the WOA of zero correspond to the data on horizontal line in Figure 2, i.e., the participants did not take the advice at all. Out of the total trials of about 1165, 535 trials were this type. By contrast, the trials where the participants fully accepted the advice were at the WOA of 1 . These correspond to the diagonal line in Figure 2. 96 trials were this type. WOA values between 0 and 1 represent the trials where the participants partially accepted the advice. In total, advice was used $54 \%$ of trials. This acceptance ratio was similar to that observed in the previous study (Soll \& Larrick, 2009).

Figure 2: The difference between the second estimate and the first estimate as a function of the differences between advice and the first estimate.

Figure 3: Frequency distribution of the weight of advice (WOA) index.

## Variability of advice taking in time

Since the experiment contained 48 trials, we were able to examine how WOA would change as the experiment progressed. Figure 4 shows the averaged WOA scores from all the participants as a function of the trial number. We found that WOA, namely, the tendency to accept advice, gradually decreased over the course of the experiment $(r(48)$
$=-.524, p<.001)$. Then, we divided the trials into the first and second halves and found the significant difference of WOA scores between them $(t(1163)=2.70, p<.01)$, indicating that the participants followed the advice less in the second half than in the first half.
One may argue that the decrease in the acceptance of advice over time would be due to that the participants become better in the estimation task and could perform the task without advice in the second half. We did not provide feedback for their estimation. However, they repeatedly saw the rent estimation presented as advice, which were actual rents. In addition, the participants had some knowledge of rent in the Tokyo area. Thus, there was the possibility that participant's estimate would approach to the estimate presented as advice implicitly. To test such a possibility, we also calculated the difference between the advice and the first estimate as an index of the task performance (Figure 5). We did not find any improvement of the task performance as a function of trial number $(r(48)=.041, p=.786)$. Therefore, the decrease in WOA was not due to the better performance in the second half.

Figure 4: Averaged WOA scores as a function of the trial number. WOA decreased gradually as the number of trials increased. Error bars show the standard errors of the mean scores.

Figure 5: Averaged task performance scores (correct rent price, i.e., advice, minus the first estimate) as a function of the trial number. Error bars show the standard errors of the mean scores.

(mean WOA scores in Second half - mean WOA scores in First half)

Figure 6: Distribution of WOA changes of each participant. Positive values indicate that the participants accept the advice more in the latter half of the experiment (positive group), while negative values indicate that the participants accepted the advice less in the latter half of the experiment (non-positive group).

## Variability among individuals

The overall results suggested that, on average, the participants followed advice less in the second half than the first half of the task. However, this was not the case for all the participants; some participants did show larger WOA in the latter half. We calculated the change of WOA for each participant by subtracting WOA in the first half from WOA in the second half. Thus, a positive score would indicate that the participants tended to accept the advices in the second half. Figure 6 shows the distribution of WOA changes.

We divided the participants into the "positive-group" (WOA changes values were positive) and the "non-positive group" (WOA changes values were negative or equal to zero), and examined whether there would be any individual differences between the two groups of the participants. The questionnaires measured depressive state, big-five personality trait (Extraversion, Conscientiousness, Agreeableness, Openness to Experience, and Neuroticism), empathy for others (cognitive abilities on a Fantasy Scale (FS) and Perspective Taking (PT), and affective components through an Empathic Concern (EC) and Personal Distress (PD). We compared the scores of the questionnaires between the positive group and the non-positive group. Two participants were excluded from the analyses because significant parts of the questionnaires were incomplete. In total, the data from fifty-two participants were analyzed.

We found significant differences in depressive state $(t(50)$ $=2.30, p<.03$ ) and in perspective taking (PT) scores $(t(50)=-2.48, p<.02)$. The participants who showed the positive WOA changes had lower depression scores and higher perspective taking scores (Figure 7). These results suggest that individuals with less depression and higher perspective taking tend to keep taking the advice. There was

Figure 7: Averaged depression and perspective-taking scores for different WOA changes groups (non-positive and positive groups). Error bars show the standard errors of the mean scores.

Figure 8: The relationship between the depression and perspective-taking scores.
a significant negative correlation between the depression and the perspective taking scores $(r(52)=-.293, p<.05$; Figure 8). All the other scores did not show any significant difference.

## Discussion

In the present study, we examined how people would change and vary in accepting advice when the effectiveness of advice was not clear. We found that: (1) Participants took the advice less in the latter half of the experiment. (2) The decrease in WOA was not due to the change in task performance. (3) The decrease of WOA was pronounced in the participants with high depressive state and low perspective taking tendency of empathy. In other words, the participants with low depression and high empathy kept taking advice even when the effectiveness of advice was unclear. Our results suggest that the willingness of accepting and using advice changes with prior experience of advice taking and the individual traits and mood interact with the change in advice taking.

In about $54 \%$ of trials, the participants used advice either fully or partially, even though the usefulness of advice was not clear. This result suggests that it is difficult to ignore advice completely under uncertainty of usefulness of advice. Previous studies suggest that the major motivation of seeking advice is not only for accuracy in decision making but also for social reasons, for example sharing responsibility or to justify our decisions (Kennedy, Kleinmuntz, \& Peecher, 1997; Harvey \& Fischer, 1997). Our results might reflect this kind of social motivations in advice taking.

Since the participants were not sure about whether advice was useful or not in the present study, it was reasonable to assume that the acceptance of advice would reduce over time. However, this was not the case for all the participants; low depressive and high perspective taking participants kept taking advice. Also, there was the negative correlation between depressive scores and perspective taking scores. It has been reported that depression is associated with focused attention on the self rather than others (Ingram, 1990) and focusing increases the accruing periods and severity of depression (e.g., Just \& Alloy, 1997; Kuehner \& Weber, 1999; Nolen-Hoeksema, 2000; Nolen-Hoeksema, Parker, \& Larson, 1994). However, it still remains to be investigated how depressive mood and the ability of perspective taking influence and/or interact with advice taking behavior.

In the present study, we set the situation that advice was derived from a real-estate agency. There is the possibility that this information about advisor would help to increase the acceptance of advice even when the effectiveness of advice was not clear. A previous research showed that people valued expert advice than novice one when making decisions (e.g., Meshi et al., 2001). Therefore, the characteristics of an advisor have influences in advice taking, which include not only expertise but also how closely the advising person is related. In our daily-life, we often ask friends or family for advice, even though we can seek expert advice. Recent research suggests that advice would be accompanied by social and emotional support (i.e, regulating emotional distress), and decision makers prefer such emotional and social support when they make decisions (Horowitz et al., 2001; Dalal \& Bonaccio, 2010).

In the future research, it would also be interesting to examine the role of seeking or accepting advice derived from others that have close associations with them, such as friends or family.

In the present study, no feedback was provided, It is possible that providing feedback may affect the acceptance of advice over time. We found the decrease of WOA over time when the effectiveness of advice was uncertain. Providing feedback would make participants to explicitly adjust their estimates. In future research, it would be important to examine the effects of feedback on temporal variations for the acceptance of advice.

#### Abstract

The goal of the present study was to determine whether chronic post-stroke patients with motor aphasia have impaired inner speech abilities and whether they use inner speech in everyday life. To answer these questions, we recruited eight chronic post-stroke aphasic patients and 13 cognitively healthy adults, who underwent testing on a range of evaluative tests and four experiments specifically designed for the purposes of this study. The experimental results suggest that post-stroke patients with motor aphasia have impaired inner speech. However, patients' subjective reports indicate that they use various types of inner speech, despite the observed deficit. Taken together, our data suggest that impairment of certain aspects of inner speech may still allow a degree of use of other aspects of inner speech, emphasizing a need to extend research on inner speech in aphasia to the variety of its forms.

Keywords: aphasia; inner speech; anomia; working memory.

## Introduction

Inner speech has been traditionally recognized as an important component of human mental life, and in particular its role in the relationship between language and thought has been debated (Kinsbourne, 2000). The interest in inner speech has been renewed recently, partly due to new perspectives on how language contributes to consciousness and whether conscious thought is possible without inner speech (de Guerrero, 2005, Martínez-Manrique \& Vicente, 2010), and partly due to recent developments in speech production theories (e.g., Indefrey \& Levelt, 2004) that propose that inner speech is a stage in speech production that precedes articulation (Levelt, 1995). Inner speech is often defined as silently talking to oneself or speech-foroneself (Vygotsky, 1986), "the little voice in the head" (Perrone-Bertolloti et al., 2014), an internalized verbal thought that can be consciously explored (Marverl \& Desmond, 2012), "the subjective experience of language in the absence of overt and audible articulation" (Alderson-

Day \& Fernyhough, 2015, p. 931) or more generally as a form of mental imagery (Oppenheim \& Dell, 2008).

The unique cognitive status of inner speech is reflected in its pervasive role in a variety of functions. It is involved not only in language, but also in working memory (e.g., in subvocal rehearsal) (Paulesu et al., 1993; Baddeley \& Loggie, 1999), complex reasoning (Baldo et al., 2015), selfregulation (Vygotsky, 1986), meta-cognition (Bermúdez, 2003), and self-awareness (Morin, 2009; Morin \& Michaud, 2007). For example, impairment of inner speech has been associated with the impairment of global self-awareness, self-related memories and emotional awareness, along with impaired "sense of individuality" and corporeal awareness (Morin, 2009). It also contributes to auditory verbal hallucinations in schizophrenia (Frith, 1992). In addition to establishing that inner speech is implicated in a variety of cognitive functions in healthy and impaired brains, research so far has discerned various forms of inner speech, such as condensed, dialogic, self-referent, involving others (Alderson-Day \& Fernyhough, 2015), with the evidence indicating that these different forms of inner speech may require support of different brain areas (Alderson-Day et al., 2015).

However, investigating directly and objectively the highly subjective and elusive psychological processes that support inner speech represents a methodological challenge (Vygotsky, 1986; De Bleser \& Marshall, 2005). The attempts to determine the elusive nature of inner speech fall roughly into two types: the accounts that try to view inner speech in its entirety and emphasize its subjective character, and accounts that focus on a specific aspect of inner speech that can be objectively tested. Thus, the hypotheses generated by the first type of accounts cannot be objectively tested, and the explanations based on the second type of accounts do not exhaust the concept of inner speech.

As an example, Vygotsky's (1986) concept of inner speech is characterized by a highly subjective meaning, predicative nature, and a reduced syntactic form. In
contrast, an often studied proxy of inner speech in contemporary research is phonological representation of a word, which is tested via a person's ability to silently judge whether two words rhyme, whether one word is longer than the other, or whether two words are homophones (Levine et al., 1982; Feinberg et al., 1986). Making silent judgments in such tasks requires the use of inner speech.

Another way of distinguishing between the two types of approaches to studying inner speech is in terms of abstract and concrete inner speech, where the former refers to inner speech as relating language and thought, and the latter considers inner speech a stage in speech production, i.e., phonological and/or phonetic level of inner speech (Levelt, 1995).

One interesting and still not well explored issue pertains to inner speech abilities in persons with impaired overt speech due to brain damage, such as post-stroke patients with motor aphasia.

The available evidence suggests a great variability in inner speech abilities in persons with post-stroke aphasia, with patterns of partial as well as complete deficit in inner speech (Levine et al., 1982; Feinberg et al., 1986; LanglandHassan et al., 2015). Furthermore, the degree of inner speech deficit in these patients typically coincides with a degree of overt speech impairment, although cases of aphasia with discrepant overt-covert speech abilities were also reported (Geva et al., 2011a).

In the present study, we investigated inner speech abilities in chronic post-stroke patients with motor aphasia. The goal was to determine whether these patients had impaired inner speech abilities and how they used inner speech in everyday life. To answer these questions, we tested chronic poststroke aphasic patients on a variety of evaluative tests and four experiments specifically designed to assess their inner speech abilities.

## Methods

## Participants

Eight post-stroke aphasic speakers (two males) were recruited at a local rehabilitation center (Asociación de traumatismo cráneo-encefálico y daño cerebral adquirido de Álava, henceforth ATeCe). All patients were at the chronic stage, with more than one year post-onset time. They all had suffered a single stroke in the left hemisphere, affecting the prefrontal or fronto-temporal areas, except one person, who had a lesion in the left basal ganglia (A07). Seven patients had motor aphasia, while one person's aphasia was characterized as mixed aphasia (A02). This person's aphasia was of a predominantly motor type, with a strong anomic component it was labeled as "mixed" aphasia by the speech pathologist (C.L.) on the basis of multiple extensive tests, subjective observations and neurological reports. Severity of patients' aphasia ranged from moderate to severe. They were all right-handed before the illness, except one patient
who was left-handed (A03). They had no other significant neurological or psychiatric conditions.

Thirteen cognitively healthy adults for the control group (four males) were recruited from the community. The participants in the control group had no history of neurological or psychiatric disease, drug abuse, and at the time of testing they were not using any medications that could affect cognition.

All participants had normal hearing and normal or correct-to-normal vision.

## Evaluative measures

To obtain more general information on patients' cognitive abilities relevant for the present study, we administered the following evaluative measures: Montreal Cognitive Assessment (MoCA) (Nasreddine et al., 2005) to assess participants' general cognitive status, Boston Diagnostic Aphasia Examination (Goodglass \& Kaplan, 1983) - the Spanish version (García-Albea et al., 1996), Boston naming test (Kaplan et al., 1983), phonological discrimination test (Ardila et al., 1994), the Edinburgh handedness inventory (Oldfield, 1971), the Month ordering test (Almor et al., 2001) to test their verbal working memory, Raven's Progressive Color Matrices (Raven et al., 1990) to test their nonverbal intelligence, Beck depression inventory (Beck et al., 1961) to exclude severe depression, and the Varieties of Inner Speech Questionnaire (McCarthy-Jones \& Fernyhough, 2011) to obtain an insight into each patient's awareness of their use of different forms of inner speech in everyday life.

Unlike other types of inner speech questionnaires, the VISQ addresses important aspects of inner speech, such as condensation and dialogicality. The condensed form, which has by definition reduced syntax, and dialogic inner speech, which is exchange among different internalized perspectives, are of particular importance in studying inner speech of patients with motor speech disorders. Thus, the Questionnaire assesses four types of inner speech: dialogic, condensed, other people in inner speech, and evaluative/ motivational inner speech Examples of stimuli for each form are given in (1-4):
(1) My thinking in words is more like a dialog with myself rather than my own thoughts in a monologue. - Dialogic
(2) I think to myself in words using brief phrases and single words rather than full sentences. Condensed
(3) I hear other people's voice nagging me in my head. - Other people in inner speech
(4) I talk silently to myself telling myself to do things. - Evaluative/motivational inner speech (McCarthy-Jones \& Fernyhough, 2011).

Healthy controls (HCs) underwent MoCA and completed the Varieties of Inner Speech Questionnaire. All tests were administered in Spanish, which was the first language of all participants.

## Experimental measures

All participants were tested in four tasks, which require inner speech for correct completion: silent judgments of rhyming (experiment 1), syllable discrimination (experiment 2), identification of words in compounds (experiment 3) and identification of words in names for numbers (experiment 4).

Experiment 1: The rhyming task in our study required silent rhyming judgments of pairs of words associated with pairs of drawings. The silent rhyming judgments paradigm has been successfully used in previous studies on inner speech in other languages (Langland-Hassan et al., 2015). This paradigm is more appropriate for the Spanish language than the classical paradigm, in which rhyming of written words is judged, because judging whether Spanish written words rhyme can be done visually, on the basis of words' orthography and without evoking inner speech (e.g., avióncamión). There were 40 pairs of drawings in this experiment, with 20 pairs representing objects whose names rhyme in Spanish and 20 pairs representing objects whose names do not rhyme in Spanish. The drawings were selected from Snodgrass \& Vanderwart (1980), based on a standardization for Spanish (Sanfeliu \& Fernandez, 1996), considering name agreement, image agreement, familiarity, and visual complexity. The stimuli were created from the drawings with the highest ratings in Spanish-speakers.

Using the same pairs of words from this experiment, we tested participants' overt rhyming abilities at the end of experimental session. In this overt rhyming judgment task, the experimenter read aloud pairs of words and participants' task was to judge if the words within each pair rhymed.

Experiment 2: The syllable discrimination task required a silent discrimination of syllables in verbally presented words ( $\mathrm{n}=40$ ). The stimuli consisted of sets of randomized 2-syllable ( $\mathrm{n}=13$ ), 3-syllable ( $\mathrm{n}=15$ ), and 4 -syllable ( $\mathrm{n}=12$ ) highly frequent Spanish words, such as bueno. The experimenter read words and the participants were required to determine the number of syllables in each word.

Experiment 3: The following test required silently discerning words in compounds. The stimuli consisted of compounds ( $\mathrm{n}=20$ ) and simple words $(\mathrm{n}=20)$. Like in previous experiments, the stimuli included only highly frequent Spanish words, such as girasol and were presented in a randomized order. The experimenter read words and the participants were required to determine the number of words in each compound.

Experiment 4: The final test required silently discerning words in names for numbers. The stimuli ( $\mathrm{n}=20$ ) included trials that allowed 1, 2, 3, or 4 words to be discerned. For example, eight contains only one word, whereas in fifty-six two additional words can be discerned: fifty, six. The experimenter read number words and the participants were required to determine the number of words in each.

Except for the silent rhyming task, the stimuli in the experiments were presented verbally.

## Procedures

Before evaluation began, each participant signed informed consent. Prior to each experiment, participants completed two to four practice trials. They were instructed to avoid using strategies, moving the mouth or tongue, and to use inner speech in all tests. The experimenter would read the stimuli, except in Experiment 1 in which the stimuli were presented visually, and participants were required to respond as accurately as they could. There was no time limit for answers. Participants' responses for each experiment were recorded manually on a separate response form and later scored for accuracy. No feedback was provided during testing.

Testing was carried out individually with each participant in a quiet room, at ATeCe (patients) and at their homes (HCs). Each patient was assessed in 3 sessions. The first two sessions were devoted to evaluative measures (one session with the certified speech pathologist, C.L., one session with the neuropsychologist, E.U.G.) and the last session was devoted to the experiments. Each session lasted approximately 1 hour. HCs were tested in a single session.

The study was approved by the Basque Ethics Committee for Clinical Research as well as by the ethics committee of the University of the Basque Country. The study was conducted in accordance with the Helsinki Declaration guidelines on studies involving human subjects

## Statistical analyses

We performed Mann-Whitney test for group comparisons in experimental tasks and the modified -t-test (Crawford \& Howell, 1998) to compare performance in experimental tasks of the patient with mixed aphasia to the mean scores of the HCs group; the latter tests were one-tailed, as recommended (Crawford \& Howell, 1998), with $\alpha$ set at 05 . All statistical analyses were carried out in SPSS 22, except for the modified t-test which was performed using the SINGLIMS program (Crawford \& Howell, 1998).

## Results

The two groups did not differ considerably in age ( $\mathrm{t}(19)=-$ $1.433, \mathrm{p}=.168$ ) or in years of formal education ( $\mathrm{t}(19)=-$ $.560, \mathrm{p}=.582$ ). However, they differed in general cognitive status ( $\mathrm{t}(19)=-7.213, \mathrm{p}<.005$ ), with the aphasic group having achieved a mean score of $17.8( \pm 2.5)$ on MoCA and HCs having a mean of $25.1( \pm 2.1)$.

Each patient achieved $100 \%$ correct scores on the phoneme discrimination task. Their performance on Raven Progressive Color Matrices (RPCM) and verbal working memory (vWM) test varied, revealing different degrees of deficit in non-verbal intelligence and vWM capacity respectively across patients. The results of these tests are summarized in Figure 1.

Fig 1. Aphasic speakers' performance on RPCM and vWM.
Furthermore, patients' performance on the Varieties of Inner Speech Questionnaire revealed different degrees of use of the four types of inner speech (Fig. 2). The condensed inner speech featured prominently, while inner speech involving others was less present in their everyday spontaneous use of inner speech.

Fig 2. Aphasic speakers' use of four types of inner speech in everyday life.

Looking at the results from experimental measures, we found that, compared to HCs, the aphasic group performed considerably worse on both rhyming tests (silent and overt), and on the test of discrimination of syllables within words (Table 1).Their ability to discern numbers and words in compounds was comparable to that of HCs.

Table 1: Group differences across the experimental tasks.

|  | $U$ | $Z$ | $p$ |
| :--- | :--- | :--- | :--- |
| Silent ryyming | 4.500 | -3.475 | $.001^{*}$ |
| Overt rhyming | 1.500 | -3.701 | $.005^{*}$ |
| Syllables | 25.500 | -1.985 | $.047^{*}$ |
| Compounds | 32.000 | -1.513 | $.13 / .05^{*}$ |
| Numbers | 43.500 | -.631 | .53 |

However, since the modified $t$-test has shown that the person with mixed aphasia, A02, performed well in all tasks
relative to HCs (silent rhyming, $p=.16$; overt rhyming, $p$ $=.07$; syllables, $p=.33$; compounds, $p=.18$; numbers, $p$ $=.5$ ), we repeated analyses excluding this patient from the aphasic group.

The overall pattern of results remained unchanged, except that the $p$ value obtained in testing for differences in distinguishing words in compounds reached statistical significance ( $U=22.000, Z=-1.93, p=.05$ ). Thus, our experimental data indicate that the persons with motor aphasia had overall impaired inner speech, except when inner speech involved words for numbers.

## Discussion

The goal of the present study was to assess whether poststroke patients with motor aphasia have deficits in inner speech. To answer this question, we tested eight patients with chronic aphasia using four tests of inner speech, including the traditional tests such as silent rhyming judgments and syllable discrimination, together with the tests of word and number discrimination. The main finding of the present study is that post-stroke patients with motor aphasia have impaired inner speech. An additional, unexpected finding is their preserved ability to silently discern numbers in number words. The two findings are discussed in turn.

Since all the aphasic patients achieved $100 \%$ correct on the phoneme discrimination task (see Results), the deficit in silent rhyme judgments cannot be due to impaired ability for phonological discrimination. Instead of being solely due to inner speech impairment, the silent rhyme judgments impairment could be related to anomia, i.e. word finding difficulty which to some extent characterizes all types of aphasia (Benson \& Ardila, 1996). A deficit in retrieval of words referring to the presented images would preclude making judgments on whether a pair of words referring to a pair of drawings rhyme or not. Alternatively, a relatively high working memory load in the silent rhyming task could explain the deficit: the task requires interpreting pairs of drawings, keeping track of semantic information derived from the drawings, retrieving appropriate words, and maintaining the retrieved words in working memory, while judging whether the words rhyme.

Furthermore, the aphasic group had low scores in overt rhyme judgments, a task in which the experimenter read aloud pairs of words. Although this task imposes a smaller cognitive load compared to the silent rhyme judgment task, it still requires a certain amount of working memory capacity, a cognitive resource that appears to be deficient in the aphasic group (Fig. 1). Taken together, these results indicate that the aphasic group's deficit in judging rhymes both covertly and overtly may be due to the verbal working memory impairment. This explanation is compatible with the aphasic group's low scores on the subtests of MoCA related to language and/or memory for language, including repetition of sentences and verbal fluency. However, although limited vWM capacity may have affected silent
rhyming in the aphasic group, it does not explain their overall poor scores on inner speech tasks, involving also impaired discrimination of syllables in words and impaired discrimination of words in compounds. These scores indicate an impairment of inner speech, which could have been further exacerbated by an increased verbal WM load and anomia in the silent rhyming task.

The unexpected finding that the aphasic group was successful in discerning numbers in number words is not only interesting in itself, but it also has implications for the theories on number processing. It suggests that the aphasic speakers relied on a nonverbal, digital representation of numbers (e.g. "57") and not on spoken numerals representations ("fifty-seven"). This explanation is compatible with the proposals suggesting that number processing is mediated by modality-specific processes, e.g., verbal code vs. digits (Kadosh \& Walsh, 2009). While the neural substrates supporting the two types of processing differ, it remains unclear whether the differences pertain to these representations supporting inner speech as well.

Wernicke originally proposed that the left superior temporal gyrus (STG) supported auditory word-form recognition, monitoring of speech output generated by frontal regions as well as inner speech, while contemporary models suggest a functional distinction between the anterior STG, which supports auditory word-form recognition, and posterior STG, which regulates speech production, including inner speech (DeWitt \& Rauschecker, 2013). Neuroimaging studies have associated inner speech with a range of brain areas, including the left supramarginal gyrus, posterior STG, middle temporal gyrus and the inferior frontal gyrus (Paulesu et al., 1993; Indefrey \& Levelt, 2004; Geva et al., 2011b; Fama et al., 2017). A recent voxel-based lesion-symptom mapping study involving 40 lefthemisphere post-stroke patients indicates that inner speech, at the phonological access stage of speech production, is supported by the posterior STG and adjacent areas (Pillay et al., 2014), and that the left inferior frontal gyrus in fact supports working memory and control processes associated with inner speech. Our data appear to support this model, although we would interpret the working memory deficit in our aphasic group in terms of affected network connectivity (Kljajevic, 2014), because all the patients had deficient vWM , regardless of each case's specific site of lesion.

As pointed out in the Introduction, studying phonological word form as a proxy of inner speech provides only a part of the answer to the question of whether inner speech is impaired in motor aphasia. A quick look at the patients' subjective reports on their use of inner speech in everyday life (Fig. 2) suggests a rather complex picture. It suggests that, as in impaired overt speech - where some degree of communication may take place despite the deficit-, impairment of certain aspects of inner speech may still allow use of its other forms. It is not surprising that aphasic speakers in our study showed the most use of the condensed type of inner speech in everyday life. The condensed form is closest to the type of inner speech originally described by

Vygotsky (1986): compressed, and not necessarily resembling overt speech.

In conclusion, our data indicate a degree of inner speech impairment in post-stroke patients with motor aphasia, regardless of lesion distribution (frontal, fronto-temporal, deep grey matter structures). Like their overt speech, their inner speech appears to be affected by difficulties in word retrieval and reduced verbal WM capacity.

## Acknowledgments

This study was funded by a grant from IKERBASQUE, Basque Foundation for Science 111407EMDD (V.K.), IT769-13 (Basque Government) (A.V.) \& FFI2014-52196-P (Spanish MINECO) (A.V).

# The Impact of Population Structure on Models of Language Change 

Jordan Kodner<br>University of Pennsylvania, Philadelphia, Pennsylvania, United States<br>Christopher Cerezo Falco<br>University of Pennsylvania, Philadelphia, Pennsylvania, United States

#### Abstract

The dynamics of language evolution and learning in individuals have been extensively studied. Our knowledge of the transmission process in particular has been advanced by the iterated learning model. Additionally, work has been done in the area of population structure and social networks. However, less has been described about the interaction between individuallevel transmission and network structures. We present a general framework for representing transmission and learning algorithms within social networks. We demonstrate that population structure interacts with the transmission process to influence the dynamics of change. Taking network effects into account, studies on language evolution will capture a fuller picture of the phenomenon.

# Eye movements during reference production: Testing the effects of perceptual grouping on referential overspecification 

Ruud Koolen (r.m.f.koolen@uvt.nl)<br>Tilburg center for Cognition and Communication (TiCC), Tilburg University PO Box 90153, 5000 LE, The Netherlands<br>Yorick Fliervoet (yorick@fliervoet.com)<br>Tilburg center for Cognition and Communication (TiCC), Tilburg University<br>PO Box 90153, 5000 LE, The Netherlands

#### Abstract

When referring to a target object in a visual scene, speakers are assumed to consider certain distractor objects that are visible to be more relevant than others. However, previous research that has tested this assumption has mainly applied offline measures of visual attention, such as the occurrence of overspecification in speakers' target descriptions. Therefore, in the current study, we take both online (eye-tracking) and offline (overspecification) measures of attention, to study how perceptual grouping affects scene perception, and reference production. We manipulated three grouping principles: region of space, type similarity, and color similarity. For all three factors, we found effects, either on eye movements (region of space), overspecification (color similarity), or both (type similarity). The results for type similarity provide direct evidence for the close link between scene perception and reference production.

Keywords: Reference production; Perceptual grouping; Eyemovements; Overspecification; Visual scene perception.

## Introduction

Suppose you want to point out the marked object in Fig. 1 to a listener. To complete this task, you should produce a referring expression such as "the small bowl" or "the small green bowl", to distinguish the target object from the other objects that are present in the visual scene (the distractors). Although both above example expressions allow the listener to identify the target, the second one is overspecified: it contains a color attribute that is unnecessary for unique identification.

Figure 1: An example visual scene (Koolen et al., 2014)
From prior research (e.g., Pechmann, 1989; Koolen, Goudbeek, \& Krahmer, 2013; Rubio-Fernàndez, 2016), it is known that speakers overspecify their referring expressions very frequently. Why do they do so? We argue that at least one of the
answers to this question is to be found in visual scene perception, and explore to what extent certain objects in a scene are more likely to be perceived than others. For example, in Fig. 1, the plate on the sideboard might be overlooked because it is placed on a different surface than the target (i.e., sideboard rather than table), or because it has a different type (i.e., plate rather than bowl). In these cases, the distractor set would be limited to the large bowl, making a minimal description such as "the small bowl" likely to be uttered. On the other hand, if the plate on the sideboard catches attention anyway, for example because it has a different color than the target object, the perceived color variation may cause speakers to overspecify with color (Koolen et al., 2013).

Although there is growing awareness that scene perception and language production are indeed closely linked, previous research in this direction has generally taken indirect, offline measures of visual attention. Therefore, in the current paper, we combine online (eye-tracking) and offline (occurrence of overspecification) measures to search for structural relations between scene perception and attribute selection for referring expressions.

## Theoretical background

The starting point of our research is the assumption that in a reference production task, speakers do not regard all objects in a visual scene to be relevant distractors, but rather rely on a subset of distractor objects. More specifically, speakers are expected to only consider the distractors that are in their focus of attention (Beun \& Cremers, 1998). One can think of various factors that determine whether an object is perceived or not, such as its physical distance to the target (i.e., proximity). Given that proximity predicts that only objects that are close to the target referent are in the speaker's focus of attention, it can influence the composition of the distractor set for a visual scene (Clarke, Elsner, \& Rohde, 2013a).

Proximity is one of the Gestalt laws of perceptual grouping that were originally introduced by Wertheimer (1923), next to similarity, closure, continuation, and pragnanz. These laws are principles of perceptual organization that serve as heuristics: mental shortcuts for how we perceive the visual environment (Wagemans et al., 2012) and create meaningful groups of objects that we see around us (Thórisson, 1996). On top of the classical laws of grouping, Palmer (1992) defined another principle, common region of space, which holds that objects
that fall within an enclosing contour, such as a table surface, are usually perceived as a group as well.
This study will apply a manipulation of common region of space, as well as two manipulations of similarity: color similarity and type similarity. Previous research that directly tests how these principles influence reference production is scarce. For color similarity, we know that speakers overspecify more often when they perceive color variation in a scene than when all objects are of the same color (Koolen et al., 2013; RubioFernàndez, 2016). This effect of color variation interacts with type similarity: the proportion of overspecification is highest when there is at least one distractor object that shares its type with the target, but not its color (Koolen, Krahmer, \& Swerts, 2016). Also common region of space has been found to affect referential overspecification, as revealed by Koolen, Houben, Huntjens, and Krahmer (2014). In their experiment, Koolen et al. used scenes such as the one depicted in Fig. 1, displayed in both 2D and 3D. The target was always on the table, and mainly for the 3D scenes - speakers overspecified more often when a differently colored distractor was also on the table (in the same group as the target) rather than on the sideboard (in a different group), although the physical distance between the objects was the same in both scenarios.

Crucially, the above papers, as well as many others studies on reference production (e.g., Clarke et al., 2013a), have used indirect measures of visual attention, such as the occurrence of overspecification. This is problematic in studying how the distractors in a visual scene shape attribute selection. For example, although the experiment by Koolen et al. (2014) suggests that region of space affects overspecification, there is no direct evidence that this result is due to the way in which speakers might ignore distractors that are not in the same region as the target referent. Therefore, in the current research, we collect eye movements as a direct, online measure of visual attention, and combine these data with a more traditional, offline analysis of referential overspecification.

While eye-tracking methodologies are very commonly used to investigate language comprehension (e.g., Tanenhaus, Spivey, Eberhard, \& Sedivy, 1995), they are still rare in language production research, initially because speech movements can disrupt eye movement data (Pechmann, 1989; Griffin \& Davison, 2011). After some early studies that explored the effect of object fixations on order of mention (e.g., Griffin \& Bock, 2000; Meyer, Sleiderink, \& Levelt, 1998), some researchers recently started to apply eye-tracking to test the effects of perceptual and conceptual scene properties on rather open-ended descriptions (Coco \& Keller, 2012; 2015) and object naming (Clarke, Coco \& Keller, 2013b). However, none of this work has tested systematically how perceptual grouping affects attribute selection for reference production.

## Current study

To study how different manipulations of perceptual grouping affect reference production, we conducted an experiment in which speakers described target objects in visual scenes. The stimuli were taken from Koolen et al. (2014), for the sake of comparability. We recorded both the participants' speech as
well as their eye movements during the reference production task. Speech data were annotated for the occurrence of overspecification; i.e., if descriptions contained a redundant color attribute. This variable served as a replication of Koolen et al. (2014). New in our study are the eye-tracking data. Here, we analyzed the number of fixations on the distractor we manipulated, and the total gaze duration for that object.

For region of space, we hypothesize that if a distractor is in the same region of space as the target, it is viewed more often and longer than if the region of space is different, and that this will eventually lead to more overspecification. The same goes for type similarity, with more views, longer viewing time and more overspecification for a distractor of the same rather than a different type than the target. Lastly, for color similarity, we expect to find that a distractor most likely attracts attention if it has a different color than the target, resulting in more views, longer viewing times, and again more overspecification than for a distractor that shares its color with the target.

## Method

## Participants

Thirty-one participants ( 26 female, mean age: 21.6) took part in the experiment. The participants were gathered randomly at the campus of Tilburg University, and received a piece of candy as a reward. All participants were native speakers of Dutch, the language of the experiment.

## Materials

The stimulus material consisted of near-photorealistic visual scenes like the example scenes presented in Fig. 2 on the next page. As noted above, the scenes were taken from the related previous study by Koolen et al. (2014). They depicted a living room containing a dinner table and a sideboard, and some objects such as chairs for a more realistic look. The scenes were modeled and rendered using Maxon's Cinema 4D.

The table and the sideboard formed the two surfaces (i.e., regions of space) that were important for our manipulations, since these were the spaces where the target and its two distractors were positioned. The target object always occurred on the table, in the middle of the scene, together with a distractor close next to it (either left or right). This first distractor object always had the same type and color as the target object, but a different size. This way, the distractor ensured that size was always needed for a distinguishing description, and that mentioning color thus resulted in an overspecified referring expression. The scenes also had a second distractor object, by means of which our three manipulations of perceptual grouping were realized.
Firstly, there was a manipulation of perceptual grouping in the law of common region of space. This manipulation was operationalized by positioning the second distractor either in the same region of space as the target (i.e., on the table, see the left scenes of Fig. 2), or in a different region (i.e., on the sideboard, see the right pictures of Fig. 2). It is important to note that the physical distance between the target object and the second distractor was the same in both scenarios.

Fig. 2: Examples of critical trials in our experiment. The distractor shares its region of space with the target (i.e., the table) in the left scenes, and is in a different region (i.e., the sideboard) in the right scenes. The distractor has the same type as the target in the upper four pictures, and a different type in the lower four pictures. The distractor has the same color as the target in the first, second, fifth and sixth picture, and a different color in the third, fourth, seventh, and eighth picture.

Secondly, we had two manipulations of perceptual grouping related to the law of similarity. The first one varied the type of the distractor: this type could be the same as the target's type, or different. Example scenes can again be found in

Fig. 2, where the second distractor object (the plate) has a different type than the target object (the bowl) in the lower four trials, while all relevant objects are of the same type in the upper four trials. Another manipulation of similarity was
employed by varying the color of the second distractor: this color could again be the same as or different than the color of the target object (see again Fig. 2 for example scenes).

While Fig. 2 depicts all visual scenes that were created for the bowl, the same was done for three other types of targets: a plate, a mug and a cutting board. The scenes for these four object types were manipulated in all conditions, resulting in eight trials for each object type. Participants were thus presented with thirty-two (four $x$ eight) critical trails. In all trials, the target object could only be distinguished by mentioning type and size; if participants included color, it made the description overspecified.

Two measures were taken to avoid participants from using the same strategy for all critical trials. Firstly, we had thirtytwo filler trials. Although the scenes for these fillers had the same basic set-up as the critical trails, with all kinds of objects placed on the table and the sideboard, there were more objects present, which could all be the target for that scene. Furthermore, since all objects in the filler trials were white, participants were discouraged to use color when referring to the target here.

Secondly, to prevent participants from developing a viewing strategy, we created two versions of the experiment. For both versions, half of the visual scenes for the critical trials were mirrored. In version 1, this was done for the scenes in which the second distractor was in the same region of space as the target object, while in version 2, all the scenes in the different region of space condition were mirrored. Thus, by taking this measure, all participants saw half of the critical trails mirrored.

## Procedure

The experiment took place in a soundproof booth, located in the SensoMotoric Instruments lab at Tilburg University. The eye-tracking measurements were made with a SMI RED250 device, operated by the IviewX and the ExperimentCenter software-packages. The eye-tracker had a sampling rate of 250 HZ . We used the microphone of a webcam to record the descriptions of the participants; the camera was taped off for privacy reasons. The stimulus materials were displayed on a 22 inch P2210 Dell monitor, with the resolution set to 1680x 1050 pixels, with 90.05 pixels per square inch.

After entering the laboratory, participants signed a consent form, and read a first basic instruction stating that they were going to act as the speaker in a language production experiment. Participants were then seated in the soundproof booth, in front of the eye tracker, and their eyes were calibrated using a 9-point validation method. When the calibration was completed successfully, participants were invited to read a second instruction, which was more detailed than the first one, and stated that participants were going to produce oral descriptions of target objects in visual scenes in such a way that these objects could be distinguished from the remaining objects in the scene. It was emphasized that using location information in the descriptions (e.g., "the bowl on the left") was not allowed. After this second instruction, participants completed two practice trials, and had the possibility to ask
questions. Once the procedure was clear, the experimenter left the booth, and the experiment started.
All participants were shown a total of 64 stimuli ( 32 critical trails and 32 fillers) in a random order. The visual scenes were depicted in the middle of the screen, filling $70 \%$ of the available space; the remaining $30 \%$ consisted of a grey border surrounding the scenes. Before every trial, a screen with an ' X ' appeared somewhere in the $30 \%$ contour area. When this X had been fixated for one second, the next visual scene appeared automatically. When fixating the X did not work, participants could make the next scene appear manually by pressing spacebar. The position of the X was different for all trials: they appeared in a random position in the grey border, again to make sure that participants did not develop a viewing strategy. There were 1.6 times more X triggers on the top and bottom row than on the left and right side, in proportion to the $1680 \times 1050$ screen resolution. Once all 64 trials had been completed, participants were instructed to leave the booth. It took around 30 minutes to complete the experiment.

## Research design

The experiment had a $2 \times 2 \times 2$ design with three within-participants factors: region of space (same, different), type (same, different), and color (same, different). Three dependent variables were measured: the occurrence of color in the target descriptions; the gaze duration upon the manipulated distractor in milliseconds per trial per participant; and the number of times that the manipulated distractor was fixated per trial per participant.

## Data coding and preparation for analysis

All recorded object descriptions were transcribed and coded for the presence of color ( 0 or 1 ). For the eye-tracking data, we first checked for ill measurements, and excluded the data recorded for one participant from further analysis. We then assigned all fixations to either one out of four areas of interest (AOIs) we defined. There was one AOI for the target, one for the sideboard, one for the central part of the table, and one remainder area. The AOIs for the sideboard and the central part of the table represented the areas where the manipulated distractor could be placed. The remainder area was used for fixations that were not on the target or distractor objects that were present in the scenes. The AOIs where the manipulated distractor could occur were central to our analyses.
The coding process resulted in a separate path file for every participant. These path files were converted into a single file, and loaded into SPSS for statistical analysis. Although there was supposed to be data for 960 target descriptions ( 30 speakers times 32 trials), the data for 24 trials could not be analyzed because either the description or the eye movements were not recorded correctly. The final analysis thus contained data for 936 trials.
While the data for all 936 trials was used to analyze the redundant use of color, we created subsets of the data to analyze gaze duration and the number of fixations. For both variables, we only analyzed the cases where speakers fixated - and thus saw - the manipulated distractor. This was the case in 680 out
of 936 cases. For gaze duration, we then calculated for every trial the total amount of time that the participant looked at the manipulated distractor object, and standardized this score by calculating the $z$-score per trial per speaker. Only the scores in the range of $-3 \leq z \leq 3$ were included in the analysis, which means that scores for 13 cases were filtered out.

For the number of fixations, we created a similar subset of the data, but this time we calculated the number of times that speakers looked at the manipulated distractor for every trial. Again, the $z$-score was calculated, which led to the exclusion of 12 trials that were not part of the final analysis for this variable.

## Results

To test for significance, we performed a series of univariate ANOVA tests. We only report on interactions when they are significant. Given that we used subsets of the data in our statistical analyses, performing repeated measures tests was not possible due to empty cells.

## Results for redundant color use

In general, our speakers included a redundant color attribute in $64 \%$ of the descriptions. The first ANOVA was performed to test if redundant color use was affected by our manipulations of perceptual grouping.

The first factor that we expected to affect the redundant use of color was region of space. However, we did not find a significant effect here ( $F_{(1,927)}=.11$, n.s.) : speakers redundantly used color equally often when the manipulated distractor was in the same $(\mathrm{M}=.64, \mathrm{SE}=.02)$ or a different $(\mathrm{M}=.64, \mathrm{SE}=$ .02) region of space as compared to the target.
For our two manipulations of similarity, we did find effects on the redundant use of color. In these cases, the main effects of type similarity $\left(F_{(1,927)}=9.94, p<.01, \mathfrak{y}_{\mathrm{p}}^{2}=.011\right)$ and color similarity $\left(F_{(1,927)}=5.44, p<.05, \mathfrak{y}_{\mathrm{p}}^{2}=.006\right)$ were due to an increase in redundant color use when the manipulated distractor had the same type as the target, and a different color ( $\mathrm{M}=$ $.77, \mathrm{SE}=.03$ ). The other three cells were practically indistinguishable (same type - same color: $\mathrm{M}=.61, \mathrm{SE}=.03$; different type - same color: $\mathrm{M}=.60, \mathrm{SE}=.03$; different type different color: $\mathrm{M}=.59, \mathrm{SE}=.03$ ). This pattern resulted in a significant interaction between type similarity and color similarity $\left(F_{(1,927)}=7.47, p<.01, \mathfrak{y}_{\mathrm{p}}^{2}=.008\right)$.

## Results for gaze duration

The second ANOVA was run to analyze if our manipulations of grouping on the total amount of time that speakers looked at the manipulated distractor.

Firstly, there was a main effect of region of space on gaze duration $\left(F_{(1,651)}=215.5, p<.001, \mathfrak{y}_{\mathrm{p}}{ }^{2}=.249\right)$, showing that the distractor object was looked at significantly longer when it occurred in the same $(M=1812.7, S D=60.87)$ rather than a different $(M=466.7, S E=68.6)$ region of space than the target. A similar effect was found for the manipulation of type similarity $\left(F_{(1,651)}=5.06, p<.05, \mathfrak{y}_{\mathrm{p}}^{2}=.008\right)$. For this factor, we found that distractors that shared their type with the target
$(\mathrm{M}=1242.9, \mathrm{SE}=66.2)$ were looked at longer than distractors for which this was not the case $(\mathrm{M}=1036.5, \mathrm{SE}=63.5)$. The third factor, color similarity, did not affect gaze duration: although the distractor was looked at slightly longer when it had the same $(\mathrm{M}=1176.6, \mathrm{SE}=61.6)$ rather than a different $(\mathrm{M}=1102.8, \mathrm{SE}=67.9)$ color than the target, this difference was not significant $\left(F_{(1,651)}=.65\right.$, n.s. $)$.

## Results for number of fixations

The third dependent variable in our experiment was the number of fixations on the manipulated distractor. Again, there were effects of region of space and type similarity, but not of color similarity.
Firstly, when the distractor was in the same region of space as the target object, participants looked at this object significantly more often $(\mathrm{M}=2.04, \mathrm{SD}=.06)$ than when it occurred in a different region of space $(\mathrm{M}=1.56, \mathrm{SD}=.06) ; F_{(1,652)}=$ $33.37, p<.001, \mathfrak{y}_{\mathrm{p}}^{2}=.049$. Similarly, when the distractor was of the same type as the target object, it was fixated more often ( $\mathrm{M}=1.93, \mathrm{SD}=.06$ ) than when it had a different type $(\mathrm{M}=$ $1.67, \mathrm{SD}=.06$ ). Again, we found no effect of color similarity: the distractor's color (same: $\mathrm{M}=1.85, \mathrm{SE}=.06$; different: M $=1.76, \mathrm{SE}=.06$ ) did not influence the number of fixations $\left(F_{(1,652)}=1.15\right.$, n.s. $)$.

## Discussion

The goal of this research was to test how perceptual grouping affects reference production. We combined both online (eyetracking) and offline (occurrence of referential overspecification) measures of visual attention to study the extent to which grouping causes speakers to ignore certain distractors that are present in a visual scene, aiming to connect the observed scan patterns referential overspecification. We had three manipulations of grouping (i.e., common region of space, color similarity, and type similarity), all realized by varying the location and characteristics of one specific distractor object in the visual scenes that were presented to the participants.

The first manipulation that was present in our stimuli made the manipulated distractor object appear either in the same or a different region of space as compared to the target referent. In Koolen et al. (2014), this manipulation led to a significant effect of grouping on overspecification, with more redundant color attributes in the 'same group' condition rather than the 'different group' condition. In the current study, we could not replicate this result: the proportions of overspecification that we found were the same in both conditions. However, we did find effects of region of space in the eye-tracking data: when the distractor was in the same region as the target referent, it was viewed longer and more often than when it was in a different region. This way, region of space (Palmer, 1992) influences the extent to which certain distractors are considered in a reference production task.

The question remains why the patterns for common region of space that we observed in the eye-tracking data were not reflected in effects on overspecification with color, such as found by Koolen et al. (2014). To explain this issue, we refer to some practical differences between the two studies. Firstly,

Koolen et al. (2014) displayed the stimuli on a big television screen, while the current experiment used only $70 \%$ of a computer screen. Perhaps more important was that Koolen et al. found a convincing effect of common region of space for 3D visual scenes, but that the effect was small for 2D scenes. In the current study, only 2D scenes were used, due to the eyetracking paradigm. Given that our 2D scenes led to clear effects of region of space in the eye-tracking data, it would be interesting to test how this grouping principle affects language on variables other than overspecification, such as fluency and speech onset time.

For type similarity, the effect of the manipulation in the reference production data resonates the pattern in the eye-tracking data. When the distractor had the same type as the target, it was viewed longer and more often than when the type was different, and the proportion of overspecified references was higher. These results show direct evidence for the close link between visual scene perception and language production, in line with the few previous studies in this direction (e.g., Coco \& Keller, 2012; 2015; Griffin \& Bock, 2000). For color similarity, we found a significant interaction with type similarity for the speech data, with an increase in overspecification with color when the distractor had the same type as the target, and a different color. This interaction is a replication of Koolen et al. 2016). For the eye-tracking data, there were no significant effects or interactions with color similarity involved, presumably since color differences "pop out" of the scene (Treisman \& Gelade, 1980). As such, there is no strict need for speakers to fixate distractors (repeatedly) in order to perceive their different color.

Finally, we would like to discuss our decision to use subsets of the data for the eye-tracking analyses. In these subsets, we only included data for the trials where the speaker fixated the manipulated distractor object (or at least the AOI where it was occurred) at least once. Thanks to this approach, we could be certain that speakers were most likely aware of the existence of this object, which makes the observed effects of perceptual grouping even more valid: it excludes, for example, measurement errors that occur when speakers change their position in front of the eye-tracker. However, one can also argue that our approach was too strict, because in order to form a description of a target object, it is not necessary to scan all objects in the scene. In future analyses, we aim to refine our paradigm, also by distinguishing various time windows for every trial to test both the structural and temporal relations between scene perception and reference production.

## Acknowledgments

We thank Jan Huntjens and Eugène Houben (www.eyetractive.com) for developing the stimulus materials, and Rein Cozijn for his assistance in programming the experiment and analyzing the data.

# Modelling conceptual change as foraging for explanations on an epistemic landscape 

Ismo T Koponen (ismo.koponen@helsinki.fi)<br>Department of Physics, University of Helsinki, P.O. Box 64, FI-00014 Helsinki, Finland<br>Tommi Kokkonen (tommi.kokkonen@helsinki.fi)<br>Department of Physics, University of Helsinki, P.O. Box 64, FI-00014 Helsinki, Finland

#### Abstract

We discuss here conceptual change and the formation of robust learning outcomes from the viewpoint of complex dynamic systems, where students' conceptions are seen as context dependent and multifaceted structures which depend on the context of their application. According to this view the conceptual patterns (i.e. intuitive conceptions) may be robust in a certain situation but are not formed, at last not as robust ones, in another situation. The stability is then thought to arise dynamically in a variety of ways and not so much mirror rigid ontological categories or static intuitive conceptions. We use computational modelling in understanding the generic dynamic and emergent features of that phenomenon. The model shows how context dependence, described here through structure of epistemic landscape, leads to formation of context dependent robust states. The sharply defined nature of these states makes learning to appear as a progression of switches from state to another, given appearance of conceptual change as switch from one robust state to another.

Keywords: Conceptual change; concept learning; epistemic landscape; simulations

## Introduction

Learning scientific knowledge where learners initial, intuitive concepts gradually change towards more scientific ones is known as conceptual change. Conceptual change as an expression for such learning emphasizes the clear transition or even revolutionary-like transformation of learners knowledge during the learning process (Duit \& Treagust, 2003; Ozdemir \& Clark, 2007; Rusanen, 2014). The recently suggested complex dynamic systems view on conceptual change instead of such a picture views students' conceptions as multifaceted structures which depend on the context of their application. In the dynamic systems view the conceptual patterns (i.e. intuitive conceptions) may be robust in a certain situation but are not formed, at last not as robust ones, in another situation. The stability is then thought to arise dynamically in a variety of ways rather than mirroring rigid preconceptions or static intuitive conceptions (Brown, 2014; Gupta, Hammer, \& Redish, 2010; Koponen, 2013; Koponen \& Kokkonen, 2014). What we think as intuitive conceptions may be in fact so strongly dependent on context, instructional settings and individual learning history that such conceptions should be approached as emergent cognitive epiphenomena, which are situational and mirror partially the targeted scientific models forming the basis of the design of instructional settings. In what follows, we refer to such epiphenomenal conceptual structures simply as students explanatory schemes. In this study we discuss how the dynamic systemic view may change our ideas how conceptual change may accrue from emergent
robust learning outcomes. As a concrete example of learning we consider direct current (DC) electrical circuits and empirical results obtained in that context (Koponen \& Kokkonen, 2014; Kokkonen \& Mäntylä, 2017). In this case the target knowledge and learning situation can be modelled as learning a tiered structure of explanatory schemes, where students are expected to learn a simple set of concepts and relational schemes between the concepts. The model is highly simplified and idealized, but it shows how context dependence, described here through structure of epistemic landscape, leads to formation of context dependent robust learning outcomes. Due to sharply defined nature of these states, learning appears as a progression of switches from state to another, giving appearance of conceptual change as switch from one preexisting robust state to another, instead of gradual dynamic change.

## Empirical cases modelled

The research of learning DC-circuits has revealed that the students tend to use very similar types of explanatory schemes. Some researchers of conceptual change attribute these schemes to pre-existing ontological commitments, while some others see them more context dependent and possibly even artefacts of the empirical research setting (Brown, 2014; Gupta et al., 2010; Koponen, 2013; Koponen \& Kokkonen, 2014). Nevertheless, most empirical studies have revealed very similar collections of explanatory schemes although there are differences in details (see (Ozdemir \& Clark, 2007; Gupta et al., 2010; Koponen \& Kokkonen, 2014; Kokkonen \& Mäntylä, 2017) and references therein). The empirical data used here as starting point consists of three different contexts I-III (Koponen \& Kokkonen, 2014; Kokkonen \& Mäntylä, 2017):

- I: Light bulbs in series. Two variants (a single light bulb and two light bulbs) in terms of the brightness of the bulbs are compared. This comparison consists of events $e_{1}$ and $e_{2}$.
- II: Light bulbs in parallel. The first variant is again involves a single light bulb. The second variant involves two light bulbs in parallel. Comparisons yield events $e_{1}^{\prime}$ and $e_{2}^{\prime}$.
- III: Comparison of the brightness of light bulbs in series (I) and in parallel (II). In the first variant, participants compare the brightness of light bulbs in series, and parallel circuits
to the one-bulb case only. In the second variant, participants compare series and parallel cases to each other. This yields events $e_{1}^{\prime \prime}$ and $e_{2}^{\prime \prime}$.
All six different types of events are referred to as an event set $\varepsilon=e_{0}, e_{1}, e_{2}, e_{0}^{\prime}, e_{1}^{\prime}, e_{2}^{\prime}, e_{0}^{\prime \prime}, e_{1}^{\prime \prime}, e_{2}^{\prime \prime}$, with $e_{0}, e_{0}^{\prime}$ and $e_{0}^{\prime \prime}$ representing observations of the brightness of a single light bulb in each context (the brightest light bulb). This set thus describes (formally) the task and how it was sequenced and how students progressed from context to I to III. In what follows $\varepsilon$ is treated as exogenous variable describing the event set, scaled to range $\varepsilon \in[0,1]$ where 1 represent full set of events. Further details about the empirical setup, design and excerpts from the student interviews are reported elsewhere (Koponen \& Kokkonen, 2014; Kokkonen \& Mäntylä, 2017). When details are put aside, in all cases one finds similar types of explanatory schemes ,listed and characterised in Table I.

Table 1: The explanatory schemes $m_{k}$ inferred from the empirical studies (Koponen, 2013; Kokkonen \& Mäntylä, 2017).

| Model | Description |
| :--- | :--- |
| m 1 | The battery as a source of electricity <br> (current or voltage). |
| m 2 | m1+ components consume electricity <br> (current or voltage). |
| m 3 | $\mathrm{m} 2+$ voltage/current over components <br> creates/needs current/voltage. |
| m 4 | m3 refined as scheme based on Ohms law <br> + Kirchhoffs laws KI and KII. <br> m4+components consume electric <br> energy/power (Joule's law) |

Explanatory schemes $m_{1}$ and $m_{2}$ are well-known electric current-based intuitive explanatory schemes found in many empirical studies (Koponen \& Kokkonen, 2014; Kokkonen \& Mäntylä, 2017), while $m_{3}$ is partially correct explanation, which takes into account the role of components in determining the current. Finally, schemes $m_{4}$ and $m_{5}$ are complete and correct (scientific) schemes. The determination schemes D1 and D2 constraints (Kirchhoff's I and II laws, respectively) and D3 is relational scheme (Ohm's law) regulating the relationship between the pertinent concepts (voltage and current). A more detailed description of these cases and their representation are given elsewhere (Koponen \& Kokkonen, 2014; Kokkonen \& Mäntylä, 2017) and are not reproduced here. The structure of explanatory schemes can be schematically represented as in Fig. 1 as the generic tiered system, where more sophisticated explanatory schemes are at the highest tiers and the less sophisticated schemes at lower tiers can be seen as incomplete or partial versions of the higher tier explanatory schemes.

## The simulation model

The task we discuss here involves five explanatory schemes with ascending complexity and can thus be represented as

Figure 1: A Tiered system of five explanatory schemes. The different hierarchical levels consist of explanatory schemes $\mathrm{m} 1-\mathrm{m} 5$ of ascending level of complexity and expanding coverage of explanatory power. The symbols $C_{1}$ and $C_{2}$ are concepts (current and voltage) entering the models m1-m5.
a tiered structure shown in Fig. 1.The tiered system of explanatory schemes can be represented as an epistemic landscape, which is an abstract representation of the explanatory power of explanatory schemes. Such descriptions have been previously used in studies describing the cognitive and social effects of discovery and knowledge foraging (Weisberg \& Muldoon, 2009; McKenzie, Himmelreich, \& Thompson, 2015). Learning is then described as foraging for best expalining scheme in that landscape, based on utility guided probabilistic selection of the best explaining scheme.

## Epistemic landscape

A tiered system of explanatory schemes consists of schemes $m_{k}, k=1,2, \ldots, 5$, in which the hierarchical level $k$ is defined according to the complexity of the scheme. More complex schemes require greater proficiency from the user of the scheme, such as mathematical proficiency in deriving predictions from the scheme or making deductions based on it. The utility of a given scheme can be seen as a trade-off measure between the scheme's complexity and the amount of events which the learner needs to explain. The scheme $m_{1}$ is simple and, thus, its utility for a simple set of events is high, but decreases for many events to be explained. The scheme $m_{5}$ is the most complex one and requires great proficiency. Because it is complex to use, it has low utility in simple cases, but its utility increases with accumulation of events.

The system of explanatory schemes, as far as the explanatory power of schemes for given set of events is in focus, can be represented in idealized form of epistemic landscape. The epistemic landscape is a simplified description how increased information (in form of events) gives cues to select a given model, and on the other hand, it describes how much proficiency is required in using the model. There is at present
no detailed way to derive the epistemic landscape from the graph as described in Fig. 1 and the connection remains a qualitative one. With these restrictions, however, the epistemic landscape can be constructed by using utility functions $u_{k}(\varepsilon, \kappa)$, which describe the epistemic utility of schemes $m_{k}$. The detailed forms of the functions are, fortunately, not important here; it is enough that they can serve to describe the assumed generic features of the tiered system. Therefore, the mathematical description of the epistemic landscape adopted here is based on a set of suitably flexible functions. Convenient mathematical forms that are easy to use in simulations because the cumulative probability finction is invertible are provided by MinMax-distributions (Kumaraswamydistributions) (Jones, 2009) as given in Table 1. The epistemic landscape thus consists of five manifolds of which Fig. 2 show the schemes with the greatest utility in a given region.

Table 2: The utility functions $u_{k}(\varepsilon, \kappa)$ forming the epistemic landscape. The normalization factors $N_{1}-N_{5}$ are defined so that maximum value of each utility function is 1 . The functions $f_{n, m}(x)=x^{m}\left(1-x^{m-1}\right)^{n-m}$ are MinMax-distributions (Kuwaraswamy-distributions).

| State | Utility function |
| :--- | :--- |
| $m_{1}$ | $u_{1}(\varepsilon, \kappa)=N_{1} f_{n_{1}, m_{1}}(\varepsilon) f_{n_{1}^{\prime}, m_{1}^{\prime}}(\kappa)$ |
| $m_{2}$ | $N_{2}\left[a_{1} u_{1}(\varepsilon, \kappa)+a_{2} f_{n_{2}, m_{2}}(\varepsilon) f_{n_{2}^{\prime}, m_{2}^{\prime}}(\kappa)\right]$ |
| $m_{3}$ | $N_{3}\left[b_{1} u_{2}(\varepsilon, \kappa)+b_{2} f_{n_{3}, m_{3}}(\varepsilon) f_{n_{3}^{\prime}, m_{3}^{\prime}}(\kappa)\right]$ |
| $m_{4}$ | $N_{4}\left[c_{1} u_{3}(\varepsilon, \kappa)+c_{2} f_{n_{4}, m_{4}}(\varepsilon) f_{n_{4}^{\prime}, m_{4}^{\prime}}(\kappa)\right]$ |
| $m_{5}$ | $N_{5}\left[d_{1} u_{4}(\varepsilon, \kappa)+d_{2} f_{n_{5}, m_{5}}(\varepsilon) f_{n_{5}^{\prime}, m_{5}^{\prime}}(\kappa)\right]$ |

## Learning as foraging

The model of learning introduced here assumes that learning takes place as foraging for explanation schemes across the epistemic landscape. We assume that foraging is guided simply by the topography of the epistemic landscape, as a "hill climbing" (HC) in the direction of the steepest change of the gradient of the landscape (McKenzie et al., 2015; Weisberg \& Muldoon, 2009). When exogenous parameter $\varepsilon$ increases by $\delta \varepsilon$ (a new event or cue becomes available), the agent selects the most probable explanatory scheme from the neighborhood of its current state either by switching the state, "uphilling" by increasing the proficiency or, if more advantageous, "downhilling" by decreasing the proficiency. Proficiency is taken here as a skill-like property. A response to success and failure is modelled as logistic development (Steenbeck \& Van Geert, 2007; Van Geert, 2014) of learner's proficiency during the learning process in form

$$
\begin{equation*}
\kappa \leftarrow \kappa \pm \mu \kappa(1-\kappa) \tag{1}
\end{equation*}
$$

where $\mu$ is the effect of memory of success or failure. Here, success means that during foraging learner has upphilled, i.e. moved to direction of increased utility, failure, on the other hand, means that learner has downhilled, moved towards decreased utility.

Figure 2: The epistemic landscape corresponding to explanatory models from $m_{1}$ to $m_{5}$ as indicated in space spanned by events consisting of events $\varepsilon$ and learner's proficiency $\kappa$. The contours are shown for values $0.95,0.90,0.86,0.82,0.78$, $0.74,0.70,0.67,0.60,0.55,0.50$.

## Selection of explanatory scheme

The learners are assumed to select the best explanatory scheme $m_{k}$, one at a time, on basis how its utility compares to utilities of other schemes. The probability $P_{k}$ that scheme $m_{k}$ is selected is based on probabilistic decision theory (Laciana \& Oteiza-Aguirre, 2014; Yukalov \& Sornette, 2014) and is given as

$$
\begin{equation*}
P_{k}=\frac{u_{k} \exp \left[\beta u_{k}\right]}{\sum_{j \neq k} u_{j} \exp \left[\beta u_{j}\right]} \tag{2}
\end{equation*}
$$

where $\beta$ is parameter related to the confidence of choice, $\beta \ll$ 1 indicating low confidence (i.e. high noise or randomness) and $\beta \gg 1$ high confidence (i.e. low noise or randomness). In what follows, we use $\beta=5$ which represents high confidence.

## Implementation of simulations

The control (exogenous) variable is event $\varepsilon$. The output (endogenous) variables are the selected explanatory scheme $m_{k}$ and the learner's proficiency $\kappa$, which changes dynamically as a part of the learning process. The output variables depend on the parameters, which are the confidence $\beta$ and memory $\mu$.

The learning process as foraging across the epistemic landscape is simulated based on the probability of explanatory scheme selection $P_{k}$ in Eq. (2). At each instant when the value of $\varepsilon$ increases by $\delta \varepsilon$ (here $\delta \varepsilon=0.01$ ), it is decided whether: 1) the model switch happens, or 2) proficiency increases, decreases or remains unchanged. Both of these three
steps are characterised by a set of probabilities, and event selection is carried out by the roulette wheel -method (Lipowski \& Lipowska, 2012). In the roulette wheel -method a discrete set of $N$ possible events $k$ with probabilities $p_{k}$ are arranged with cumulative probability $\Phi_{k}=\sum_{i=1}^{k} p_{i} / \sum_{i=1}^{N} p_{i}$. The event $k$ is selected if random number $0<r<1$ falls in the slot $\Phi_{k-1}<r<\Phi_{k}$. In case 1) the probabilities $p_{k}$ are given by Eq. (5) and $p_{k}=P_{k}$ with $k=1,2,3$. In case 2 ) one has three probabilities $p_{1}=P_{k^{\prime}}(\varepsilon+\delta \varepsilon, \kappa)$, $p_{2}=P_{k^{\prime}}(\varepsilon+\delta \varepsilon, \kappa+\delta \kappa)$ and $p_{3}=P_{k^{\prime}}(\varepsilon+\delta \varepsilon, \kappa-\delta \kappa)$ for any given scheme $m_{k^{\prime}}$. All simulations are carried out for equally distributed set of all initial values of $\kappa$, for 100 steps with $\delta \varepsilon=0.01$ and $\delta \kappa=0.01$ in a mesh of $100 \times 100$ points and for 9000 repetitions.

## Results

The outcome of the simulations applied in case of learning the tiered theory structure is number density $n_{k}$ of choice of given scheme $m_{k}$ at given values of $\varepsilon$ and $\kappa$. The number density $n_{k}$ is related to likelihood that in an ensemble of students a given student holds the explanatory scheme $m_{k}$. In case a large set of students' explanatory schemes are collected in an empirical research the density $n_{k}$ would correspond the distribution of how different finding are classified in different categories, categories then roughly corresponding the peaks in the density distribution, while the slight differences in empirically found categories would corresponding the diffuse spread of seen in the density distribution. This association of empirical findings is not exact, of course, but provides a close enough interpretation of the density plots. Note that all density plots are shown as contour plots as in topographical maps.

The shift to hold or select more advanced schemes during the learning (or training sequence) when $\varepsilon$ increases from $\varepsilon=0$ (no events to be explained) to $\varepsilon=1$ (all events to be explained) is particularly clear when density $n_{k}$ of selected schemes in the $(\varepsilon, \kappa)$-space is examined. Such density distributions $n_{k}$ of preferred schemes are shown in Fig. 3 for strong ( $\mu=0.05$ ), intermediate ( $\mu=0.02$ ), and weak ( $\mu=0.01$ ) memory effects. Results are shown only for cases that initially have proficiencies $0.45<\kappa<0.55$ which represents a middle cohort of initial proficiencies, thus representing the assumed average student for which the learning task is designed. The results shown in Fig. 3 demonstrate how selection of given schemes $k$ accumulate to certain regions, different from but close to those regions where utilities (see Fig. 2) have peak values. These regions are shown as dark color in the figures, the darker the shade the higher the density. The dark regions where densities accumulate are the robust outcomes of learning. This behaviour is due to dynamic effects of foraging for best explanatory schemes in the epistemic landscape and how memory affects the development of proficiency.

The density distribution shows directly how likely a selection of given explanatory scheme is in comparison to other schemes. When the memory is weak $(\mu=0.01)$ the low-level schemes $m_{1}$ and $m_{2}$ are likely to be selected throughout the learning sequence. In addition, scheme $m_{3}$ is present through-
out the learning sequence because it is the most preferred initial scheme for mid-cohort learners. When memory increases from $\mu=0.01$ to 0.05 the dynamic evolution becomes more interesting. In the intermediate stage of learning (stage II) scheme $m_{4}$ begins to compete with $m_{3}$ and finally, in the end of the learning stage scheme $m_{5}$ is dominant. For the highest memory $\mu=0.05$ the development becomes very predictable. Schemes $m_{1}$ and $m_{2}$ are likely choices only at low proficiencies, and finally, in the end of the training sequence $\varepsilon_{i} 0.6$ the scheme $m_{5}$ is dominant. For high memory-effects and high confidence the robust learning outcomes are sharply defined, island- like and give expression of well-focused explanatory schemes with no overlap with other explanatory schemes. The overall picture is then that when new event becomes available, learner switches to better explaining schemes towards the end of the learning sequence. This is the successful learning path.

In high memory region, however, the polarization of learning outcomes happens; with increased preference of high level schemes $m_{5}$ also the preference for low level schemes $m_{1}$ and $m_{2}$ tend to increase. This is due to fact that success and failure affect in similar way and have equally strong memory-effect.; success feeds success but similarly also failure feeds failure. Of course, were the memory effect asymmetric, stronger memory effect for success than for failure, such polarization would disappear.

## Discussion and conclusions

In the complex systems view of conceptual change suggested here the formation of robust learning outcomes accrues from foraging on epistemic landscape, which represent the target knowledge as it is contained in the designed learning task. The interplay of learner's cognitive dynamics and the target knowledge as it appears in the design of the learning tasks leads to formation of stable and dense regions of preferred explanatory schemes in epistemic landscape. The origin of these robust states is on the learning dynamics and how it interacts with the context (structure of the learning task). In some cases, depending on the learner's proficiency and the development of the proficiency, learning outcomes may match the target knowledge, but in some other cases, may fall short of targeted outcomes. However, even those states, which do not match the targeted states, are robust, thus giving impression of pre-existing conceptual states of learner, as assumed in traditional conceptual change models. Accumulation of densities $n_{k}$ in certain regions are those areas, where empirical findings will be likely to associate the dynamically formed epiphenomenal robust state with a certain assumed misconception or pre-existing intuitive conception. If this interpretation is correct, the vision of conceptual change as switch between cognitively pre-existing static states to another needs to be revised and replaced by a more dynamic and fluid picture of dynamically formed robust but yet epiphenomenal states.

In the present study, the picture of conceptual change as

Figure 3: The effect of memory $\mu$ on explanatory scheme selection $n$ when events unfold (described as an increasing number of events $\varepsilon$ ). The cases with memory $\mu=0.01,0.02$ and 0.05 are shown. The range $\kappa \in[0.45,0.55]$ of initial proficiencies are considered (mid-cohort). The contours are shown for probabilities $P=0.80,0.70,0.50,0.25,0.15,0.10,0.05,0.02,0.01$, $0.0050,0.0025$. The number of repetitions for each of $100 \times 100$ data points is 9000 .
switch from intuitive conceptions to more scientific conceptions (or sometimes, to other intuitive conception) emerges as rapid but continuous dynamic development of one robust state to another state rather than as abrupt and discontinuous switch from one pre-existing static state to another. Moreover, such states are seen as epiphenomenal outcomes of interplay between learning dynamics and task design, rather than independent construct of mind, rooted in cognitively fundamental, e.g. substance-based ontological categories. The fact that for most of the training sequence there is little overlap between the different robust epiphenomenal states and periods of clearly continuous change are short, a picture of discontinuous switch from robust state to another is obvious. Superficially the course of events in the present model correspond the traditional view of conceptual change but the difference in interpretation of the underlying dynamics and nature of states in present view is fundamentally different from the traditional one; the present view strongly suggests that behind the observed behaviour is after all continuous learning dynamics and which, through designed epistemic landscape, is essentially context dependent.

In summary, the dynamic view provides fresh viewpoint on conceptual change and suggest new ways to conceptualise it. The results we have provided here are far from conclusive and are at best only suggestive, but we think that the view proposed here of learning outcomes as context dependent, dynamically robust but ultimately emergent epiphenomena deserves closer attention and prompts us to design very different empirical research settings. We expect that the main use of the abstract computational model as introduced here is on its potential uses in guiding attention in interdependencies of task structure and learning outcome, and in helping to focus on dynamic, time dependent features of conceptual change in empirical research settings.

#### Abstract

Individuals with autism spectrum disorders (ASD) are said to have deficits in "theory of mind." The present paper explores two main accounts of the mechanisms underlying these deficits. On one account, high-functioning adults with ASD struggle to infer others' mental states. On another account, they lack an ability to integrate those mental states into a coherent understanding of action. We tested these two accounts by making several modifications to the Faux Pas task - a commonly used advanced theory of mind taskincluding the presentation of explicit mental state information. Surprisingly, in contrast to previous work, individuals on the autism spectrum exhibited both intact integration and intact inference.

Keywords: Theory of mind; intentional action; autism spectrum disorder; mental state inference

## Autism and Theory of Mind: Belief and Action Understanding

Autism spectrum disorder (ASD) is a developmental disorder characterized by deficits in reciprocal social interaction and communication (DSM-V, American Psychiatric Association, 2013). In contrast to typically developing children, autistic children are widely described as having deficits in "Theory of Mind" (ToM), or the ability to represent the mental states of other people. Characteristic of these deficits have been ASD children's early failures to pass false belief tasks at the normative age of four years (Baron-Cohen, 1985). But by the time they reach adulthood, many high-functioning adults on the autism spectrum succeed at traditional false belief tasks (Bowler, 1992). Because ASD individuals require higher verbal ability than typically developing adults to pass such tasks, researchers have proposed that ASD individuals do so by using deliberate, conscious calculation (Happé, 1995) and by relying on specific features of language, such as complement syntax (Lind \& Bowler, 2009).

However, high-functioning autistic adults who pass classic ToM tasks persist in their social deficits (e.g., Klin, Jones, Schultz, \& Volkmar, 2003). Therefore, such tasks cannot be capturing these social deficits' core features.

Hence, autism researchers have developed more "advanced" ToM tasks to highlight the persistence of broader theory of mind deficits in more naturalistic settings. Although researchers have succeeded at demonstrating that individuals on the autism spectrum struggle with these novel tasks (Baron-Cohen, 1999; Zalla, Sav, Stopin, Ahade \& Leboyer, 2009), the precise mechanisms underlying these struggles have gone largely unexplored. The present paper explores these mechanisms by examining a modified version of one such task.

## The Faux Pas Task: Revealing Deficits in Adults with ASD

The "faux pas" task (Baron-Cohen, O'Riordan, \& Jones, 1999; Zalla et al., 2009) presents a context in which one character (the speaker) makes a statement that is unintentionally offensive to the listener because the speaker has a false belief. For example, in one story, Jane moves into a new apartment and purchases new curtains for the windows. When her best friend Lisa comes over, she says to Jane, "Oh, I hope you're going to get new curtains! These ones are awful!" Typically developing individuals recognize that Lisa's comment is offensive to Jane, but when asked why Lisa said that, infer that Lisa did not know the curtains were picked out by Jane herself. In contrast, while individuals with ASD can detect that something was "wrong" or "awkward" with Lisa's comment, they struggle to detect that Lisa made the comment unintentionally - that she had a false belief and made the statement out of a positive or neutral desire (e.g., to be helpful with decorating). The outcome is not just an unfortunate side effect of an otherwise fulfilled intention; the complete falsity of the agent's belief actually precludes the fulfillment of the speaker's desire. Unlike controls, adults with ASD demonstrated mixed success in detecting the character's false belief and positive desire. They sometimes acknowledged that the speaker had a positive desire but often failed to correctly infer the speaker's belief state. And in a small number of cases ( $10 \%$ of all responses), they even incorrectly attributed a negative intention to the speaker
(e.g., Lisa wants to insult Jill's taste in décor) (Zalla et al., 2009).

## The Faux Pas Task: What Does it Measure?

What explains the struggles that high-functioning individuals with ASD encounter on these tasks? The faux pas task has previously been described as a more naturalistic and more robust way than 'false belief' tasks of measuring mental state understanding. But understanding the mental states behind the kinds of actions presented in the Faux Pas task can be broken down into several distinct subtasks, outlined below and in Figure 1.
Conceptual integration First, achieving a holistic understanding of the depicted complex behavior requires an understanding of the concept of intentional action. This concept requires the social perceiver to grasp more than just individual mental state concepts of belief and desire: rather, it requires understanding how these individual concepts are integrated to support the understanding of an action as intentional. That is, an action is performed intentionally only if the agent had a desire for the action's outcome and a belief that her action would lead to (serve as a means to achieving) that particular outcome (Malle \& Knobe, 1997). In the present example, for instance, understanding what action was intentional (making a certain remark) and what outcomes were unintentional (the remark offended Jane) requires understanding both that Lisa had a false belief (that the curtains were bought by the previous owner) and that she wanted to be critical only of the previous owner, and that she therefore could not have offended Jane intentionally.
Mental state inference In addition to requiring participants to have a concept of intentional action, the faux pas task requires another capacity: the ability to infer the specific contents of the character's mental states. For example, it is not explicitly stated in the story that Lisa has a false belief about who bought the curtains or that she wanted to be critical of the previous owner; the social perceiver must infer this belief and this desire from the story. Further, there are at least two different mechanisms by which individuals with ASD could be failing to correctly infer the characters' mental states (see Figure 1). On the consensus account, the faux pas task is simply an "advanced" way of revealing enduring deficits in theory of mind - the ability to generate the contents of specific mental states, most particularly, belief - that are already revealed in simpler false belief tasks earlier in life. We refer to this account as the enduring "theory of mind" deficit account.

On an alternate account, however, individuals may struggle on the faux pas task not because they have an enduring deficit in generating the contents of mental states, but because the faux pas task contains an increase in complexity over traditional false belief tasks, thereby disallowing the use of familiar (linguistic) compensation strategies. For example, individuals with ASD may struggle on the faux pas task because this task presents stories in which it is necessary to make a rich suite of background
assumptions about the agent's social roles and context (e.g., the idea that friends normally do not insult their friends' curtains). Such a task does not allow for the use of simple rules (such as "perception leads to knowledge") to generate mental state contents; it instead requires social perceivers to draw productively on their general knowledge to produce accurate inferences. Since individuals with ASD also have documented deficits in this type of knowledge-based inferential generativity (Loth, Gómez, \& Happé, 2008), it is possible that struggles on the faux pas task are due to a general knowledge-based inference deficit, and not any deficit in theory of mind per se.

Figure 1. Capacities required for action understanding in the Faux Pas task.

## The Present Study: Which Hypothesis Explains Low Performance?

To distinguish between the mental state inference hypothesis and the conceptual integration (or intentional action understanding) hypothesis, we developed 8 novel vignettes based on the faux pas task (Zalla et al., 2009; Baron-Cohen at al., 1999) and created four conditions of varying information availability. In the "No Information" condition, we presented participants with no explicit mental state information, as in the original Faux Pas task. In three additional conditions, we presented them with either the character's belief only (Belief condition), the character's desire only (Desire condition), or both the character's belief and desire (Full Information condition). A sample story in the Full Information formulation follows. In the "No Information" condition, the underlined text would be omitted:
Clara is very short and dresses plainly. One day she goes to pick up her son James from school early for a medical appointment. Clara enters the school and spots James's teacher, Mrs. Hayes. Mrs. Hayes thinks that Clara is a student lost in the hallway. [Belief] Mrs. Hayes wants to help [Desire]. Before Clara can ask after James, whereabouts, Mrs. Hayes looks at Clara and says, "Have you lost your class, honey?"

Mental State Inference vs. Conceptual Integration By comparing stories in the three explicit mental state information conditions with the No Information condition, we can broadly distinguish between the inference and
integration hypotheses. If adults with ASD are capable of conceptually integrating mental state information for action understanding but are not capable of inferring this information, they should show improved performance in the presence of explicit mental state information over the "No Information" case. In contrast, if they are not capable of integrating mental state information for intentional action understanding, they should struggle to accurately interpret the meaning of the agents' actions as depicted in the stories even when mental state information is explicitly presented to them.

Two Mechanisms of Mental State Inference In addition to distinguishing broadly between mental state inference and conceptual integration, we also sought to distinguish two possible mechanisms of mental state inference deficit: the commonly cited theory of mind deficit and a nonspecific general knowledge deficit. In previous versions of the Faux Pas task, pieces of general knowledge (such as the fact that, in the above sample story, Clara probably appears to be younger than she really is) were not included in the story and instead had to be inferred - in addition to mental state information. Low performance on the task may thus have been a result of failed general knowledge inferences, not a result of failed ToM inferences. In the present task, we sought to mitigate this ambiguity by explicitly providing such background information in every condition (e.g., "Clara is very short and dresses plainly") and requiring participants to infer only the missing mental state information (e.g., that, in light of Clara's appearance, Mrs. Hayes falsely believed Clara to be a student). If participants continue to struggle to produce belief inferences in the No Information condition in spite of these additions of inference-ready background information, then we can be confident that the present faux pas stories indeed measure only mental state inference (or "theory of mind") capabilities, and not any additional abilities.

Conceptual Integration Apart from inference, by explicitly presenting mental state information, we can test ASD individuals' abilities to integrate this information in the service of intentional action understanding. To demonstrate integration capacity, individuals on the autism spectrum must go beyond understanding the fact that Lisa had a false belief. They must also show understanding of how her false belief is relevant to the action and its outcome: that it was because she had a false belief that she made the remark, and that the remark resulted in offense because of that false belief (Lisa didn't realize that it would lead to a negative outcome when she said it) (Figure 2). Similarly, understanding that Lisa had a positive desire is not sufficient for a full conceptual understanding of the action. In the presence of a positive desire, individuals with ASD must recognize that the action (utterance) still may have caused a negative outcome, even though the desire motivating it was a positive one. In summary, to show
integration capacity, individuals with ASD must be able to see how a story character's mental states relate to her action and its outcomes.

Most centrally, in the presence of both a belief and a desire (Full Information condition), the ability to correctly understand that the action is intended to be a positive one, was caused by the story character's false belief, and has a negative outcome, demonstrates intact integration capacities. In addition, the inclusion of conditions in which either a belief or a desire alone was presented allowed us to test integration abilities under somewhat more difficult conditions. ${ }^{1}$

Figure 2. Conceptual integration requires the social perceiver to recognize the relevance of the story character's mental states to the action's meaning and outcome.

## Study

## Procedure and Measures

We presented control and ASD participants with eight faux pas stories each: two of each in each of the four mental state information conditions (No Information, Belief only, Desire only, Full Information). Participants also received six control stories. Participants read each story and then answered several forced-choice and open-ended questions about the story (detailed below), which served both as measures of inference and integration depending on information condition: in the No Information condition, measures of belief understanding, explanations for the action, and description of the action were a measure of inferential abilities, and in the explicit mental state information condition, these same measures demonstrated participants' abilities to integrate provided mental states into a coherent understanding of action.

Participants 20 participants with Autism Spectrum Disorder (ASD), as confirmed on the ADOS-2 (Lord, Rutter, DiLavore, Risi, Gotham, \& Bishop, 2012), were recruited in partnership with the Rhode Island Consortium for Autism Research and Treatment (RI-CART), $M_{\text {Age }}=31.90$ years; 5 Female; mean score on Ravens Progressive Matrices, 9-item short form intelligence test (Bilker at al., 2012), $M=$ 45.94/60, $S D=8.0 .20$ typically developing controls were

[^369]recruited to match the ASD group on age, gender, and intelligence $\left(M_{\text {Age }}=30.35\right.$; 6 Female; $M_{\text {Ravens }}=49.75, S D=$ 14.29).

Interpretation of the Utterance After reading each story, participants were first prompted to describe the main character's utterance. They were instructed to "check all that apply" among four options: "It was awkward," "It was nice," "It was mean," and "It was neutral."

Belief Question Participants answered whether the character who made the utterance possessed a false belief (e.g., "Did Mrs. Hayes believe that Clara was James's mother?)

Explanation Question Participants then answered in a text box the "explanation" question, which simply asked, "Look back at what [character] said. Why did [s/he] say that?" These open-ended responses were content coded for explanatory quality. Two coders classified each response into a single numbered category, 0-3. To receive a perfect score of 3 , the participant had to give an explanation that directly stated or otherwise implied that the speaker's action was caused by that character's false belief. Incorrect responses, such as those that cited a negative intention on the part of the speaker, received a score of " 0 ".

## Results and Discussion

Interpretation of the Utterance To achieve a data reduction of the 32 cells represented (4 descriptors for each of 4 information conditions, rated by two different participant groups), responses for each of the four variables were first aggregated across each cell of the 2 (autism vs. control) X 4 (mental state information) design. Values on each variable were aggregated across participant group and information condition, yielding one variable for each descriptor, and entered into a principal components analysis. Two orthogonal components were extracted. Component loadings for each of the four variables are provided in Table 1.

Table 1. Principal components analysis of four utterance interpretation options results in two components

| Descriptor | Unintentional | Motive |
| :--- | :---: | :---: |
| Awkward | 0.65 | 0.33 |
| Nice | -0.48 | 0.35 |
| Mean | -0.32 | -0.61 |
| Neutral | -0.08 | 0.45 |

The two components can be best interpreted as capturing (1) whether the utterance was classified as awkwardly unintentional (awkward) vs. intentional (nice or mean) and (2) whether the motive behind the action was classified as nice (or neutral) vs. mean. Component scores for each participant were computed from linear combinations of the
four constituent variables, and ranged in value from -2 to 2 . A score close to +2 on the Unintentional component indicated that "awkward" was checked for both stories in that condition (and that the slight was therefore unintentional), while a score close to -2 indicated that the utterance in that story had instead been classified as intentional. On the Motive component, scores closer to +2 indicated less endorsement of the "mean" descriptor and more endorsement of the "nice" or "neutral" descriptors.

For this and subsequent measures, we performed two main analyses. To test the inference hypothesis, we compared the two participant groups with $t$ tests in the No Information condition only. To test the integration hypothesis, we performed ANOVAs on the four conditions for both participant groups. Of primary interest to the integration hypothesis were interactions between participant group (Autism vs. Control) and information condition (primarily, the three explicit information conditions vs. the No Information condition).

On the Unintentional component (Figure 3), controls recognized the utterance as "awkward" with greater frequency in the No Information condition than did ASD participants, $t(34.72)=2.04, p<.05$. In addition, there was an interaction between Autism and Information condition, but it did not reach significance, $F(1,38)=3.14, p=.08$. On the Motive component (Figure 4), there were no group differences in the No Information condition, nor were there significant main effects or interactions of information condition with participant group.

Figure 3: Unintentional Component
Implications for Inference Hypothesis Compared to control participants, ASD participants were less capable of recognizing that the speaker's utterance could be described as awkward. However, the two groups did not differ in any of the explicit mental state information conditions with respect to this recognition, suggesting that the noinformation difference may be spurious or not due to a deficit on the part of ASD participants. When assessing the possible motives of the speaker, ASD participants exhibited no difficulties identifying the positive desire (lack of 'mean' intent) underlying the speaker's utterance.

Implications for Integration Hypothesis In spite of some differences with controls in the No Information condition, ASD individuals performed similarly to controls in the presence of explicit mental state information, identifying the utterance's awkwardness with similar frequency and the story character's positive desire with similar frequency.

Figure 4: Motive Component
Belief Question Correct responses to the belief question were aggregated across the two stories comprising each of the four information conditions, yielding a score of 0 to 2 per condition (see Figure 5).

Figure 5: Belief Question
To examine the inference hypothesis, we compared performance of ASD participants ( $M=1.65$ stories correct) and Control participants $(M=1.80)$ in the No Information condition. There was no difference in performance, Welch's $t(36.88)=1.05, p=0.30$.

To test the integration hypothesis, we examined whether adding mental state information affected the accuracy of correctly recognizing the belief, again performing a 4 (Information condition) X 2 (Autism vs. Control) mixed ANOVA. There was a main effect of information condition: Participants as a whole exhibited improved performance in the presence of explicit mental state information (in the three explicit mental state information conditions) as compared to the No Information condition, $F(1,38)=4.36$, $p=.04$. No interactions between Autism and Information conditions reached significance.

Implications for Inference Hypothesis In our No Information condition, all general knowledge was made explicit, and ASD participants performed as well as controls. By contrast, in comparable no-information conditions, previous Faux pas studies did not make such background knowledge available and documented performance decrements for ASD participants. This pattern of results supports the hypothesis that previously documented inferential deficits may not be due to deficits in "theory of mind" per se, but may instead have been caused by the inability to draw inferences from general knowledge.

Implications for Integration Hypothesis Neither participants with ASD nor control participants performed at ceiling in the No Information condition, leaving room for improvement (and a demonstration of integration capacities) in the presence of explicit mental state information. Although there was a main effect of information condition, there was no difference between ASD and control participants. Thus, ASD participants appear to be as capable as control participants at integrating explicitly presented belief and desire information.

Explanation Question Once more, there was no difference between ASD and control participants in the No Information condition, Welch's $t(36.52)=.40, p=.70$. We also found no main effects or interactions involving the comparison between ASD and control participants across all four conditions (all $p$ s > 0.36). There were, however, significant main effects of information condition, with all participants providing higher-quality explanations when receiving explicit information about both mental states than in the No Information condition, $F(38)=3.71, p=.06$, and higherquality explanations when receiving explicit information about both a belief and desire than when receiving information about either one of these mental states alone, $F(38)=4.44, \mathrm{p}<.05$.

Implications ASD and control participants provided equally accurate explanations in all information conditions, including the most challenging one (where no explicit belief or desire information was provided). Moreover, like control participants, ASD participants improved their explanation quality in response to explicit mental state information, suggesting in particular that integration capacities held by control participants are also held by those with ASD. Thus, we may conclude once more that previously documented deficits for ASD individuals - in both inference and integration - may have been caused by other aspects of the task, such as the requirement of general knowledge recruitment.

## General Discussion

We considered two main hypotheses that could explain deficits for individuals with ASD in demanding theory of mind tasks such as the Faux Pas task. One suggests that individuals with autism struggle to generate the contents of mental states (inference), while the other suggests that they
struggle to integrate mental state information to reach a full understanding of action (integration). Both hypotheses fall short of explaining our data.

## Mental State Inference Deficits?

Contrary to previous studies of the Faux Pas task (Zalla et al. 2009, Baron Cohen et al., 1999) as well as other similar advanced theory of mind tasks (e.g., Happé, 1994), ASD participants in our study performed comparably to control participants, even when receiving no explicit mental state information. This performance spanned a number of measures, including correct inferences of the story character's false belief and positive desire. It appears that, in the presence of enriched background information to afford inferences from general knowledge, ASD participants more capably inferred mental states than they did in previous studies in which stimuli lacked such enriched background information. Although the present study did not directly compare background-enriched stories with unenriched stories, this finding is suggestive: previously documented deficits on advanced theory of mind tasks may depend on a suite of inferential capacities, of which mental state inference, per se, or "theory of mind," is only one, and perhaps a less influential one.

## Integration Deficits?

In addition to demonstrating intact inferential abilities in the presence of enriched background information, ASD participants in our study also demonstrated intact abilities to integrate provided mental state information into a coherent understanding of intentional action. Even in response to a challenging, open-ended question about the character's utterance- "Why did he say that?" -participants with ASD accurately linked mental states with action as well as controls did.

With the addition of (1) enriched background information and (2) explicit mental state information, high-functioning adults with ASD exhibited a remarkable ability to comprehend the meaning behind a story character's complex intentional action. This finding is notable in light of previous work suggesting that individuals with ASD struggle to reach the requisite mental state inferences (Baron Cohen et al. 1985, Happé 1994), and to integrate a character's mental states with her action's outcome to reach a full comprehension of that action (Moran, Young, Saxe, Lee, O'Young, Mavros, \& Gabrieli, 2011).

#### Abstract

Past choices can influence subsequent choices in employee selection. Previous approaches rather described similar sequential effects with feedback learning or the misperception of randomness. However, in the selection of job candidates also the accumulation of the moral impact of previous choices might influence subsequent choices. We investigated that question by making two major contributions to the literature. First, we developed an experimental paradigm for measuring sequential choices in employee selection and second, we implemented a widely applicable computational model, the Dependent Sequential Sampling Model, for explaining sequential effects in choices. By using this methodological approach, we uncovered sequential effects in employee selection. Participants ( $\mathrm{N}=600$ ) were especially motivated to compensate for morally dubious choices, with some participants showing consistent choice behavior if their previous choices had been morally virtuous. These results support the assumption of asymmetric compensation of morally dubious choices, sometimes referred to as the moral cleansing hypothesis.

Keywords: sequential sampling model; preferential choice; sequential decision making; employee selection.

## Theoretical Background

Ethical and moral aspect play a major role, when managers select new employees. In order to enable a fair employee selection procedure, every candidate is supposed to be evaluated only on her skills and accomplishments relevant for the position in question. This does not only involve the prohibition of any kind of discrimination, but also demands the evaluation of every candidate, independent of other candidates and contextual factors. However, interviewers deviate from such a fair evaluation procedure. Discrimination in the application process for jobs, e.g. based on gender and skin color, is common (Gregory, 2003; Bertrand \& Mullainathan, 2004; Pager, Western, \& Bonikowski, 2009). And instead of evaluating candidates independently, previous candidates on the same day influence the evaluation of later candidates (Simonsohn \& Gino, 2013). The present article tackles this problem. We will present a theory driven experimental method and computational model for investigating sequential effects in the employee selection and other areas. Our approach aims at first identifying sequential effects and second quantifying the individual degree and direction of the effects.

## Sequential Effects in Employee Selection

Many sequential effects in decision making and choices are explained with the "gamblers fallacy", the misperception of randomness (Ayton \& Fischer, 2004; Clotfelter \& Cook, 1993). However, if moral aspects are relevant for the choice, other factors contribute to the sequential effects as well. It is often assumed that the moral credentials of previous choices are accumulated and influence subsequent choices (e.g. Monin \& Miller, 2001; Tetlock, Kristel, Elson, Green, \& Lerner, 2000). This can well be illustrated in the employee selection. Given the common problem of discrimination in the job market (Gregory, 2003; Bertrand \& Mullainathan, 2004; Pager et al., 2009), it is of higher moral value to choose a person belonging to a group discriminated against than a person belonging to a favored group. This can lead to various potential sequential choice effects. If individuals made a series of choices for the same group, e.g the group not discriminated against, they tend to compensate these choices in the following (Conway \& Peetz, 2012; Jordan, Mullen, \& Murnighan, 2011; Sachdeva, Iliev, \& Medin, 2009). While some individuals simply balance morally dubious and morally good choices (Dhar, Huber, \& Khan, 2007; Dhar \& Simonson, 1999; Huber, Goldsmith, \& Mogilner, 2008), less symmetric compensating choice behavior is also possible. For example, especially after morally dubious choices, people feel the urge to compensate for these choices with a morally virtuous choice subsequently, referred to as cleansing (Tetlock et al., 2000). And also the complementary effect has been observed, referred to as licensing (e.g. Monin \& Miller, 2001). Nonetheless, even contrarily to the idea of compensation, consistent choice behavior is also possible (Gneezy, Imas, Nelson, Brown, \& Norton, 2011; Zhang, Cornwell, \& Higgins, 2014).

## Modeling Sequential Choice Effects

In most domains of real life choices and decisions, sequential effects have either been explained with models involving reinforcement learning (e.g. Kruschke, 1992; Gluck et al., 1988; Rieskamp \& Otto, 2006; Simão \& Todd, 2002; Stewart, Brown, \& Chater, 2002; Stewart \& Brown, 2004; Todd, 2007) or the effects are explained with the "gamblers fallacy" (Thaler \& Johnson, 1990; Novemsky \& Dhar, 2005; Chen,

Moskowitz, \& Shue, 2016; Ayton \& Fischer, 2004; Clotfelter \& Cook, 1993). However, these models do not explain asymmetries in compensating previous choices, which are in the moral literature sometimes referred to as moral licensing or moral cleansing, that even occur without explicit feedback. We will introduce a computational model in the following that can account for these effects. The model involves one parameter that indicates the individual degree and direction of sequential effects, it quantifies the tendency for compensation or consistency with previous choices.

## Method

In order to investigate sequential effects in the employee selection, we developed and applied the experimental paradigm "'The Sequential Employee Selection Task". In previous experiments on sequential effects in the job application process and other domains, the investigated choice often followed a different task, e.g. a rating task. Contrarily, participants in our experiment were faced with repeated choice tasks of the same format and in the same context.

After a series of choices between two candidates, who clearly differed in the qualification for the job (dominated trials), subjects were to choose between two equally qualified candidates (ambiguous trials). In some of the conditions candidates from a group discriminated against (discriminated group) dominated the previous trials, and in other conditions candidates from the complementary favored group (non-discriminated group) dominated these trials. The following ambiguous trials were the same between the conditions. Thus, different choice probabilities in these ambiguous trials indicated the influence of the previous trials.

If the choice probabilities in the ambiguous trials systematically differ between the conditions, there exist sequential effects in this task $\left(\mathrm{H}_{1}\right)$. If the probability to choose a candidate from the same, previously dominating, group is decreased, compensating choices are observed $\left(\mathrm{H}_{2}\right)$. If the probability increases, participants make consistent choices $\left(\mathrm{H}_{3}\right)$. If the compensation differs with regard to whether the discriminated or the non-discriminated group dominated the first trials, the compensation is asymmetric and the moral impact of the choices is accumulated. This finding would indicate sequential effects referred to as moral licensing $\left(\mathrm{H}_{2 \mathrm{a}}\right)$ or moral cleansing $\left(\mathrm{H}_{2 \mathrm{~b}}\right)$. If previous choices are compensated symmetrically, choices are balanced $\left(\mathrm{H}_{2 \mathrm{c}}\right)$. In order to estimate initial choice biases and the weights of the candidates' attributes, the manipulated sequences can further be compared to control conditions, in which only the ambiguous trials, the same as in the experimental conditions, were tested. As an additional add-on to previous studies, the sequential effects were not only tested in one single trial, but four ambiguous trials, enabling estimation of the individual degree of compensation.

## Participants

We recruited participants living in the U.S. through amazon's Mechanical Turk (Amazon, 2013). In order to avoid inatten-

Figure 1: Screenshot of one of the ambiguous trials in a condition with skin color as the salient category
tive participants or computer programs filling out the questions, we included an additional test page at the beginning. Of the 635 recruited participants $600(95 \%)$ passed that screening ( $47 \% \mathrm{f}$, mean age $=36.06$ ). Those participants received USD 1.50 for their participation in the 10 minutes experiment.

## Design and Procedure

The Sequential Employee Selection Task was manipulated on 2 factors between the subjects, resuming in 6 between-subject conditions. The sequential effects were investigated in four of these conditions differing with regard to the salient category, skin color vs. gender, and with regard to whether the candidates from the discriminated (female or black candidates) or the non-discriminated group (male or white candidates) dominated the first eight trials. In the two control conditions the baseline choice probabilities for candidates belonging to the respective groups were tested.

Participants were presented with a hypothetical recruiting scenario and asked to repeatedly choose the most suitable candidate out of two job applicants, see Figure 1 for an example. All candidates were described by three attributes on scales between 0-100: "leadership skills", "social competence", and "typing speed". The information was presented in an information board and a profile picture above this board. On top of it, a fictitious company name served as a title of the trial. The first two of the attributes were described as important in the initial instructions, whereas the third was described as a less important attribute for the position. The candidates' individual levels on the attributes are indicated by the numbers in the respective cells of the information board. The profile pictures above the table indicated the gender or the skin color of the candidates, depending on the condition. Pictures from the Chicago Face Database (Ma, Correll, \& Wittenbrink, 2015), only smiling faces, were used for the present experiment. Participants received no instructions with regard to the relevance of these personal characteristics and other features for the position, beyond the instructions on the three

Table 1: Illustration of the series of trials in the gender conditions. In the skin color conditions female faces are replaced with black male faces.

| Dominating group | Dominated trials |  |  |  | Ambiguous trials |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  | 1 | 2 | ... | 8 | 9 | 10 | 11 | 12 |
| Discr | $9>0^{7}$ |  |  |  | $9=0^{\prime}$ |  |  |  |
| Non-discr | $9<0^{7}$ |  |  |  | $9=0{ }^{\prime}$ |  |  |  |
| Control | - |  |  |  | $9=0^{\prime}$ |  |  |  |

Note. Discr/Non-discr $=$ female or black/male or white candidates dominate first 8 trials; Control $=$ only ambiguous trials; $[>,<,=]=$ better, worse, equally qualified.
attributes.

Each participant made twelve pairwise decisions in a row. The description of the task emphasized that the twelve candidate pairs applied for twelve different companies. Furthermore, showing fictitious company names at every decision stressed that each choice ought to be independent of the previous ones. The procedure of the experiment in the gender conditions is illustrated in Table 1. The choice pairs were constructed such that one of the two candidates was clearly superior on the two most important attributes (i.e. leadership skills and social competence) in the first eight pairs (= dominated trials), the two relevant attributes provided higher values for one candidate. Contrarily, the candidates in the last four pairs were equally well suited for the job (= ambiguous trials). In those trials, one of the relevant attributes had a higher value for one candidate, whereas the other attribute provided a higher value for the other candidate. The values of the third attribute were equal between the two. Thus, even when participants weighted all information for making a choice between the candidates, this weighted additive would lead to no preference for one candidate or the other. It was further controlled, that in two of these ambiguous trials the candidates from one group and in the remaining two trials the candidates from other group had a higher value on the first attribute. This procedure allows to control for the common use of a heuristic which places more weight on the first discriminating attribute (Take-the-best heuristic (TTB) Gigerenzer \& Goldstein, 1996). The order of the trials, within the dominated and the remaining ambiguous trials was randomized, and the position of the dominated candidates (left or right) was counterbalanced. However, the first of the ambiguous trials was fixed so that the the candidate from the discriminated group had a higher value on the first attribute in this trial. This was done in order to increase the contrast between the conditions. Subjects were randomly assigned to one of the conditions.

## Formalization of the Dependent Sequential Sampling Model

In order to explain sequential effects in choices it is assumed that some information of previous choices must be accumulated in memory and influence subsequent choices. As for modeling the evidence accumulation models within one trial (e.g. Busemeyer \& Townsend, 1993; Lee, 2004; Newell \& Lee, 2011), sequential sampling models might be used for modeling this accumulation process across trials as well.

In their simplest form, sequential sampling models assume that evidence in a given binary choice task is accumulated from a starting point across a fixed number of steps. After all fixed steps were made, this option with the highest accumulated evidence is chosen. For the purpose at hand, we adapted a similar sequential sampling model (Milosavljevic, Malmaud, \& Huth, 2010), for incorporating previous choices. The starting point of the evidence accumulation process usually represents only any previous bias for one of the options. In the present study, it was enlarged with incorporating previous choices as well. It was further considered 1) that the influence of previous choices decays exponentially with temporal distance and 2) that previous choices could potentially lead to compensation, confirmation or not influence subsequent choices. The latter, the direction and strength of the influence of previous choices, was governed by the compensationconsistency parameter $\kappa$.

Relying on a simple drift diffusion model (Milosavljevic et al., 2010) we assume that the evidence z in a binary decision task evolves according to the following equation across all time steps s:

$$
\begin{equation*}
z_{s}=z_{(s-1)}+\mu+\varepsilon_{s} \tag{1}
\end{equation*}
$$

The evidence which is added at every time step is defined by the speed of evidence accumulation $\mu$, representing the overall difference of the options' values in the trial $\mu=V_{A}-V_{B}$, and an error term $\varepsilon_{s} \sim N(0, .1)$. The values of the options V represent the sum of the option's attributes weighted with the attributes' weights w. If there is no previous bias nor any influence of previous choices, this evidence accumulation starts at 0 . For additionally indicating a systematic bias in a choice task $\beta$ is introduced. The parameter describes any initial response bias at the starting point $z_{0}$. In a similar vein $z_{0}$ can incorporate the influence of previous choices. We assume that the starting point in a given trial $\mathrm{t}, z_{0 t}$ is further influenced by $\rho=[-1,1]$ and a compensating-consistency parameter $\kappa$. The function $\rho$ incorporates the evidence for previous choices and the memory for it. It is determined as the inner product of a decay vector and the previous evidence. The decay vector determines that more recent trials have a greater impact. In line with previous research on memory, the memory further decreases as an exponential function. The impact of previous trials increases in those trials, in which the evidence was sparse.

$$
\begin{equation*}
\rho_{t}=\frac{1}{\left(V_{A t}-V_{B t}\right)} \cdot e^{- \text {decay }_{t}} \tag{2}
\end{equation*}
$$

As has been outlined in the introduction different hypotheses on the direction of the effect in sequential choices have been formulated. We incorporated these hypothesis in the compensation-consistency parameter $\kappa=[-1,1]^{1}$ which is multiplied with $\rho$ for determining the direction of the sequential effect. If $\kappa>0$, previous choices are compensated, if $\kappa<0$, individuals make consistent choices and if $\kappa=0$, previous choices do not influence the present choice. Following the starting point $z_{0}$ in trial t is defined as:

$$
\begin{equation*}
z_{0 t}=\beta-\kappa \times \rho_{t} \tag{3}
\end{equation*}
$$

Finally, a probit link is applied for predicting the choice probability in any trial $t$ based on the accumulated evidence from the starting point $z_{0 t}$ up to $z_{S t}$ in that trial.

$$
\begin{equation*}
P(A)_{t}=\phi\left(z_{S_{t}}, 0,1\right) \tag{4}
\end{equation*}
$$

Additionally we introduced a trembled hand error $\xi$ which indicates the probability to guess between the options.

$$
\begin{equation*}
P(A)_{t}=(1-\xi) \times \phi\left(z S_{t}, 0,1\right)+\xi \times .5 \tag{5}
\end{equation*}
$$

## Results

Figure 2: Probability to choose the minority candidate, as a function of the dominating group, and the position in the trial sequence (Trial Number). The choice probabilities of the dominated trials are averaged over the trials. The error bar represent $+/-1.96 \times S E$. The dashed line indicates guessing probability .5.

The dominating candidate was chosen on average in $94 \%$ of the dominated trials, indicating that the participants followed the instructions of the task very well. Figure 2 illustrate the choice probabilities of the candidates from the discriminated group. The data were collapsed over the categories skin color and gender, for reducing redundancy. As expected, we observed sequential effects in the task, because the probability to choose a female or black candidate in the ambiguous

[^370]trials, (Trial Number 9-10), differed between the conditions. The probability was decreased, compared to the other conditions, if the respective discriminated group had dominated the previous trials. The choice probabilities in the control condition serve as a reference for choice probabilities without sequential effects.

For explaining the observed sequential effects, the DSSM model was fitted to the data. The choice probabilities in the control conditions were used to inform the parameters of the DSSM model. The response bias parameter $\beta$ was fixed so that $\Phi(\beta, 0,1)$ corresponds to the averaged probability to choose a candidate from the discriminated group in the control conditions $(\mathrm{P}($ female $/$ black $)=.58)$. Likewise the decision weights were adapted for capturing the higher weight on the first attribute, by adapting the attributes weights w to the ratio of the choice probabilities, in accordance with the first attribute $\mathrm{P}($ female $/$ black $)=.78$, or not $\mathrm{P}($ female $/$ black $)=.38$, $\mathrm{w}=(2,1,0)$. The final model was fitted to the complete data set of the experimental conditions via grid search and minimizing logloss $\left(\log \operatorname{Loss}=-\frac{1}{n} \Sigma \log (\right.$ Likelihood $)$ ).

The best fitting parameters for the experimental conditions and the corresponding logLoss are illustrated in Table 2. The logLoss for a complete guessing model would be logLoss $=$ .69. In order to further validate the model we compared it via BIC to a complete Guessing and a Sequential Sampling Model SSM without dependencies between the trials. Across all participants, the DSSM provided a better fit than the guessing model and the SSM, $B I C_{D S S M}=1990, B I C_{S S M}=3423$, and $B I C_{\text {guess }}=6670$. The best fitting parameters indicate

Table 2: Best fitting parameters of $\kappa$ as a function of the conditions.

| Cat | Gender |  | Skin Color |  |
| :--- | :---: | :---: | :---: | :---: |
| Dom. <br> group | discr | non-discr | discr | non-discr |
| $\kappa$ | .08 | .48 | .12 | .56 |
| logLoss .25 | .31 | .29 | .29 |  |

Note $. \operatorname{logLoss}=$ mean negative $\log$ Likelihood
compensating choices in all conditions, however the compensation is higher in the conditions in which the candidates from the non-discriminating group dominated the first eight trials. In order to test the difference of $\kappa$ between the conditions, the best fitting parameters for $\kappa$ were additionally estimated on the individual level. This comparison revealed significant differences between the conditions in the gender condition $T(193.32)=-7.73, p<.001, \log (B F)^{2}>10$ and the skin color condition $T(164.09)=-8.99, p<.001, \log (B F)>$ 10. This indicates stronger compensation of morally dubious choices, than compensation of morally virtuous choices. There were large individual differences in the parameters, $\kappa$ $S D_{\text {discr }}=.69$ and $S D_{\text {nondiscr }}=.50$, and a considerable number of participants $\sim 30 \%$ applied extremely consistent choice

[^371]behavior in the condition in which candidates from the discriminated group dominated the first 8 trials.

To conclude, we observed sequential effects in the sequential employee selection task. In general, participants tended to compensate for previous choices, especially if these choices were morally dubious. If the previous choices were of high moral value, choosing the candidates from the group discriminated against, a large number of participants showed consistent choice behavior.

## Discussion

Present choices between job candidates are influenced by previous, unrelated, choices. Choosing a job candidate consistently from one group over the complementary group, defined by skin color or gender, decreased the probability to choose a candidate from the same group in subsequent trials. However, the sequential effects are not symmetric, because not all choices are equally compensated for. Thus, instead of balancing groups over a series of choices our data support the assumption of a stronger compensation for morally dubious choices, sometimes referred to as the moral cleansing hypothesis (Tetlock et al., 2000).

The mere existence of moral cleansing and moral licensing effects has been questioned recently via series of failed replications (Earp, Everett, Madva, \& Hamlin, 2014; Blanken, Van De Ven, Zeelenberg, \& Meijers, 2014). However, the experimental studies investigating these effects rarely observed multiple similar choices in a row. Those studies rather used different tasks, investigated behavioral intentions or used other experimental methods aiming at inducing a specific mindsets, in order to influence subsequent single choices. Furthermore, no computational model has been implemented for analyzing the data. We make two major contribution to this debate. First, we present an experimental paradigm for observing sequential effects in the employee selection and beyond. The task can easily be framed differently in order to test sequential effects in other contexts as well. Second, we formalized a computational model, the Dependent Sequential Sampling Model, for describing and explaining sequential choice effects and corresponding individual differences. Especially the individual estimates of $\kappa$ via the DSSM indicate large individual differences with regard to the compensation or confirmation of previous choices. While $\kappa$ on the group level indicated compensation also in the conditions which were dominated by candidates from the non-discriminating group, investigating individual estimates identified large individuals differences. Importantly, a meaningful number of participants showed actual consistent choice behavior (Zhang et al., 2014; Gneezy et al., 2011).

The DSSM relates to the well established application of accumulator models in choice tasks (Busemeyer \& Townsend, 1993; Lee, 2004; Newell \& Lee, 2011; Ratcliff, 1978). For the purpose at hand the model was used in a very simple version (Milosavljevic et al., 2010). A richer dataset, with within-subject manipulation of conditions and a larger num-
ber of sequential choices would further allow to increase the complexity of the model by estimating more parameters on the individual level, for example the individual initial decision bias. Nonetheless, the current simplicity is perfectly suited for the present research questions.

We provide strong evidence for compensation of morally choices in employee selection and the presented experimental and methodological approach further allows replicating our findings in other areas as well.

# The Influence of Prosody and Case Marking on Thematic Role Assignment in Ambiguous Action Scenes: Adults versus Children 

Julia Marina Kröger (jkroeger@cit-ec.uni-bielefeld.de)<br>Bielefeld University, Department of Linguistics, Germany<br>Katja Münster (katja.muenster@hu-berlin.de)<br>Pia Knoeferle (pia.knoeferle@hu-berlin.de)<br>Humboldt University Berlin, Department of German Language and Linguistics, Germany

#### Abstract

In two visual word eye tracking studies, we investigated the influence of prosody and case marking on children's and adults' thematic role assignment. We assigned an SVO/ OVS-biasing (vs. neutral) prosodic contour to unambiguously case marked German subject-verb-object (SVO) and object-verb-subject (OVS) sentences respectively. Scenes depicted ambiguous action events (e.g., donkey-paints->elephant-paints->cheetah) but case marking and prosody could, in principle, disambiguate. In adults, case marking but not prosody rapidly guided thematic role assignment. Children did not rely on case marking but exploited the biasing prosody to enhance their agent-first interpretation of the sentences. These results suggest that in scenes depicting fully ambiguous role relations, children's understanding of case marking at the age of five is not yet robust enough to enable thematic role assignment. Prosody did not overwrite the SVO preference, it rather enhanced it.

Keywords: Visual World Paradigm, eye movements; prosody; action scenes; age differences; language processing; thematic role assignment; case marking.

## Introduction

In rich contexts, listeners can rapidly exploit a range of different cues (e.g., prosody, non-linguistic information, case marking) during language comprehension. Such cues can, for instance, help them to efficiently identify the thematic roles of a sentence. Thematic roles distinguish the role an argument carries with regards to the predicate of the sentence (Carnie, 2002). Although children rapidly acquire language during the first years of their life, a full command of their native language takes, not surprisingly, time to develop. One aspect that is particularly challenging is the correct assignment of thematic roles. In German, for example, a transitive sentence typically includes a subject, a verb, and an object but speakers can arrange these constituents in more than one way, yielding, among others, subject-verb-object (SVO) or object-verbsubject (OVS) orders. To determine who is doing what to whom, comprehenders can rely on the case-marked determiners of the sentential noun phrases. Accusative case marks a sentence-initial noun phrase as the object (patient), and nominative case marks it as the subject (agent) of the sentence. But case marking can be
ambiguous in German (feminine and neuter nouns have the same form in the nominative / subject and the accusative / object case), resulting in temporary ambiguity as to who-does-what-to-whom. The resolution of this ambiguity can be difficult for children, not only because of their strong SVO word order bias. The following section describes a range of studies on how adults rapidly exploit visual, case, and prosodic cues for thematic role assignment while children sometimes struggle to exploit these cues.

## Visual Information

In rich contexts, non-linguistic information like the visual referential context, contrast between objects, depicted actions, or events can all rapidly influence the interpretation, syntactic structuring, and thematic role assignment of spoken utterances (e.g., Chambers, Magnuson, \& Tanenhaus, 2004; Knoeferle, Crocker, Sheepers \& Pickering, 2005; Sedivy et al., 1999; Tanenhaus et al., 1995). Tanenhaus and colleagues (1995) found that adults use referential context to disambiguate sentences (e.g., Put the apple on the towel in the box). The visual display contained either one or two referents (one referent: an apple on a towel, two referents: one apple on a towel and another apple on a napkin). Participants' gaze pattern suggested structural disambiguation in that they interpreted the towel as a destination (VP-analysis) for the apple in the one-referent context and as the location of the apple (NP modifier analysis) in the two-referent context (see Sedivy et al., 1999 for related effects of contrastive adjectives in establishing reference to objects).

Event relations depicted in the visual context can help listeners with anticipating thematic role relations. In Knoeferle et al. (2005), participants listened to locally ambiguous German SVO and OVS sentences (transl: 'the princess (agent/patient) washes/paints apparently the pirate (patient)/ the fencer (agent)'). The sentences did not provide information about who is the agent or the patient prior to disambiguation by case marking on the determiner of the second noun phrase. Scenes depicted the princess in both an agent and a patient role (the fencer was acting upon the princess while the princess was acting upon a pirate). During the verb ('washes / paints'), participants successfully anticipated the patient or the
agent role filler respectively in SVO and OVS sentences. Thus, the depicted event information resolved the ambiguity in the linguistic input.

Children, much like the adults, can rapidly exploit depicted actions to correctly identify thematic roles in German SVO and OVS sentences. Shortly after the verb had identified the action (and its associated role relations), the children anticipated the patient (vs. agent) in the scene for SVO sentences (Zhang \& Knoeferle, 2012) and the depicted agent (vs. patient) for OVS sentences (Münster, 2016; Zhang \& Knoeferle, 2012). However, children, unlike adults, did not exploit a referential context for disambiguating a VP-/NP-attachment ambiguity. When hearing Put the frog on the napkin... they interpreted the napkin as the frog's destination in both the one- and the two-referent context even though the latter biased towards a location interpretation (Trueswell et al., 1999). However, in the absence of real-time measures these results do not provide insight into children's online sentence processing.

## Case Marking

When it comes to linguistic information, case marking is believed to be a very strong cue for thematic role assignment with adult participants (e.g., Matzke, Mai, Nager, Rösseler \& Münte, 2002). However, studies in five-year old children report conflicting results. Dittmar et al., (2008), found that five-year-olds struggled to exploit case marking for thematic role assignment. The results of an act-out task revealed that children relied on (SVO) word order instead of case marking for interpreting ambiguous and unambiguous German SVO and OVS sentences. They interpreted the first noun phrase as the subject/agent even if it was case-marked as the object/patient of the sentence (agent-first/SVO bias). However, more recent evidence suggests that children at the age of four to five can rely on case marking for correct thematic role assignment in unambiguous German SVO and OVS sentences (e.g., Özge et al., 2015).

In Özge et al., (2015), information from the visual display likely supported the interpretation of the linguistic input. The scenes were created on the basis of world knowledge about who is the most likely agent and the most likely patient (typically the fox eats the hare and the hare eats the cabbage). The scenes thus showed animals (a hare, a fox, and a cabbage) between which stereotypical role relations exist, but they did not disambiguate who-does-what-to-whom (case marking did).

Even clearer effects of the visual context emerged in Zhang et al. (2012) and Münster (2016). Here, depicted actions (e.g., a bear painting a worm) disambiguated the role relations (only one animal performed the action mentioned in the linguistic input) but scenes did not depict stereotypical role relations; when the actions were absent, unambiguous case marking alone (i.e., in the absence of stereotypical role relations between bear and worm) was insufficient to disambiguate the role relations. Thus, the visual context seems to matter. By contrast, the effects of case marking alone on children's thematic role
assignment (i.e., when scenes do not support thematic role assignment through either stereotypical world knowledge associated with the characters or disambiguating action depictions) remain unclear.

## Prosody

Supra-sentential information can also be useful for establishing a link between the linguistic input and the visual world. Among others, prosody assigns focus to sentence constituents (e.g., via accentuation). Prosody can moreover rapidly disambiguate syntactic structure. In a visual world eye tracking study, participants rapidly exploited prosody to identify grammatical functions when the scene depicted role fillers such as a cat, a bird, and a dog, for which world knowledge implicated stereotypical thematic relations (e.g., cats chase birds and dogs chase cats, Weber et al, 2006). But the scenes did not otherwise disambiguate the upcoming thematic role relations. Feminine case marking (identical in nominative and accusative case) on the determiner of the first noun phrase created locally structurally ambiguous sentences: Die Katze (amb.) jagt womöglich den Vogel (acc/obj)/der Hund (nom/subj)- 'The cat (amb.) chases possibly the bird (obj/patient)/the dog (subj/agent)'. Biasing prosodic contours prompted listeners to make more anticipatory eye movements towards the agent (vs. patient) in the scene for ambiguous OVS sentences and towards the patient (vs. agent) in the scene for ambiguous SVO sentences. Prosody was the only information available for the correct anticipation of thematic roles prior to the disambiguating case marking on the second noun phrase; but at the same time, world knowledge associated with the scene may have provided a supportive background.

Children also exploited prosody for thematic role assignment (Grünloh et al., 2011). Two short videos showed thematic role relations in two orders, permitting a direct contrast of agent-patient and patient-agent events. However, prosodic effects (of an accentuated first noun phrase in OVS sentences) emerged only when case marking was also present. When case marking was absent (ambiguous OVS sentences) children relied on their (SVO) word order bias instead of prosody and thus interpreted the OVS sentences as agent-first sentences.

## The Present Research

This paper investigates the effects of prosody (biasing towards either the SVO or the OVS order as in Weber et al., 2006 vs. neutral) and case marking (SVO vs. OVS) in ambiguous action scenes. The actions were depicted but did not give away the specific role relations of the sentences (two characters performed identical actions and could both function as possible agents of the verb, Fig. 1, the elephant; the donkey, see Table 1 for sentences). Our scenes did not include stereotypical knowledge about who does what to whom. If a supportive context is necessary for children to exploit case marking, then we should see no effects of case marking on thematic role assignment in the present study (i.e., no anticipation of the agent / the
donkey in OVS but of the patient, the cheetah, in SVO and OVS sentences, Table 1 and Fig. 1, portraying an SVO bias). This prediction is based on the literature that revealed conflicting results regarding children's reliance on case marking (Dittmar et al., 2008; Özge et al., 2015). Alternatively, seeing event relations depicted could be helpful even if the characters perform identical actions (i.e., seeing a donkey as the patient in a painting event might help to integrate object case marking). If so, we should see effects of case marking.

If prosodic effects do not depend on a supportive scene context, then we should see effects of prosody on children's thematic role assignment and anticipation of role fillers in the scene. Alternatively, we may observe the effects of an SVO bias (more looks to the patient / the cheetah during the verb) independent of case marking and prosody in children.

Adults can rapidly use case marking for thematic role assignment (Matzke et al., 2002) and should thus anticipate the correct patient / agent depending on case marking. Prosody should also influence the timing and amount of anticipatory eye movements towards the target role filler during the time course of the sentence.

Participants further responded post-trial to questions about who-does-what-to-whom. Adults should answer these questions correctly in almost all cases since case marking was unambiguous (further effects of prosody may or may not emerge). For children, case-marking may affect the accuracy (reduced for OVS sentences). We also expected more correct responses for sentences assigned a biasing (vs. neutral) prosodic contour if children benefit from prosody for thematic role assignment.

## Experiments

Participants. 24 five-year old children (age range 4.5 to 5.10 years) and 24 young adult (mean age=25.5) monolingual (i.e., no acquisition of a second language before the age of 6) native speakers of German participated in this study. Children came from different kindergartens in the area of Bielefeld and the experiment was conducted at the kindergartens. Each child received a toy for participation. Young adults were students from Bielefeld University and were paid to participate. Participants had normal or corrected vision and hearing and all gave informed consent. The Bielefeld University ethics committee approved the experiments.
Materials. A linguistically trained female native speaker of German recorded 24 unambiguous transitive German subject-verb-object (SVO) and 24 unambiguous transitive German object-verb-subject (OVS) sentences. She was instructed to use the prosodic structure displayed in Table 1 for each sentence structure respectively. The sentences were all unambiguously case marked on the first noun phrase of the sentence. We emulated the prosodic contours reported by Weber et al. (2006) and these were either present or sentence intonation was even. In SVO sentences the main stress was on the verb ( $\mathrm{L}^{*}+\mathrm{H}$ accent on NP1, $\mathrm{H}^{*}$ accent on the verb) and in OVS sentences on the first noun phrase ( $\mathrm{L}+\mathrm{H}^{*}$ accent on NP1; Table 1).

Table 1. Overview of experimental conditions (ag=agent, pat=patient, subj=subject, obj=object).

| Sentence <br> Structure | Prosodic <br> Structure | Example <br> SVO <br> L*+H (NP1), <br> $\mathrm{H}^{*}$ (verb) |
| :--- | :--- | :--- |
| neutral | Der Elefant (subj/ag) <br> zeichnet sogleich den <br> Gepard (obj/pat). <br> The elephant (subj/ag) <br> draws immediately the <br> cheetah obj/pat). |  |
| OVS | Der Elefant (subj/ag) <br> zeichnet sogleich den <br> Gepard (obj/pat). <br> The elephant (subj/ag) <br> draws immediately the <br> cheetah obj/pat). |  |
| OVS | neutral | Den Elefanten (obj/pat) <br> zeichnet sogleich der <br> Esel (subj/ag). <br> The elephant (obj/pat) <br> draws immediately the <br> cheetah (subj/ag). |
| L+H*(NP1) | Den Elefanten (obj/pat) <br> zeichnet sogleich der <br> Esel (subj/ag). <br> The elephant (obj/pat) <br> draws immediately the <br> cheetah (subj/ag). |  |

For each of the 24 SVO and OVS sentences we created scenes depicting three clipart animal characters (Fig.1). The direction in which these characters were looking was the same for all three of them, either left or right. The middle character and one of the adjacent characters were depicted as performing the same action (e.g., for the verb 'draw', zeichnen, the two characters were depicted as holding a pencil on a canvas). The third character did not perform an action. Thus, the actions provided a context but did not permit comprehenders to unambiguously identify the correct thematic role relations upon hearing the verb.

The middle character was always role ambiguous because it could be the agent or the patient of the scene. We dub the other character depicted as performing an action the 'true agent' of the scene and the character not performing an action the 'true patient' of the scene. Each animal character filled both roles (that of a true agent and a true patient). The cheetah, for instance, is the true patient in the image shown in Figure 1. In a counterbalancing scene, the cheetah is the true agent. The elephant is depicted as drawing in the example scene (true agent); in a counterbalancing scene, the elephant is the true patient. Across all lists, each scene occurred once in each condition with all characters facing right and once
with all characters facing left. We added 8 fillers to the experiments. The number of filler was kept constant for the two experiments to maximize similarity in the materials across age groups. Post experiment questionnaires revealed no recognition of the experimental goal. After each trial participants were asked a comprehension question which was either presented in active or in passive voice (e.g., Who paints here? Or who is being painted here?). Prior to the actual experiment three practice trials familiarised the participants with the scenes and the task. The design of these items was identical to the experimental items. The sentences were structured either in SVO or OVS order and prosody was either biasing or neutral. All scenes were pre-tested with 20 five-year old children and the results confirmed that all depicted characters were correctly identified. Out of the 24 different depicted actions, only one was not correctly identified and was exchanged.

true agent ambiguous true patient
Figure 1. Example picture of a scene.
Procedure. Participants' eye movements were monitored with an Eyelink 1000 eye tracker with a sampling rate of 500 Hz Monocular, and an average accuracy of $0.5^{\circ}$ in the remote setup. Images were presented on a Dell laptop with a screen resolution of $1920 \times 1080$. Before starting the experiment, the experimenter manually calibrated the eye tracker using a five-dot calibration scheme. For each trial, the scene was presented for 2000 ms , followed by the auditory sentence. 1500 ms after sentence offset the question followed (Fig. 2). A drift correct point separated the trials to ensure calibration of the eye tracker and the same starting point for each trial. Participants first saw the practice trials. Next, the experimenter re-calibrated before starting the experiment. Each testing session lasted approximately 20 minutes.
Analysis. We defined two word regions for the analysis: verb and adverb (beginning of verb onset to adverb onset for the verb and beginning of adverb onset to NP2 onset for the adverb). These two regions were defined on the basis of the prosodic structure of the sentences. We focused on the verb region because this is where the prosodic structures can be distinguished. Whenever there is a main stress on the first noun phrase, the verb experiences a fall in stress. Otherwise the main stress is on the verb. We were further interested in the adverb region to examine post-verbal eye movements.

Visual input: 2000ms

Figure 2. Example for the time course of an experimental trial.

In the scenes, we defined two role fillers (the donkey, the true agent; the cheetah, the true patient) as areas of interest. The middle role filler was always mentioned at the beginning of each sentence and was thus not used for the analysis of anticipatory eye movements. We computed mean log-ratios of looks towards the agent and the patient of the scene (see Arai, van Gompel \& Sheepers, 2007; Carminati \& Knoeferle, 2013). Log-ratios are a relative measure that represents the looks towards one character over the other. On the basis of these mean log-ratios we conducted an Analysis of Variance (ANOVA) following a 2 (word order) x 2 (prosody) design by subject and by item for all word regions of the sentence (NP1, verb, adverb, NP2). All positive numbers in the log-ratios represent a preference of looking at the agent (vs. patient) in the scene and all negative numbers a preference towards the patient (vs. agent) in the scene. The postsentence questions show the number of correctly answered questions. We calculated percentages of correct answers of all possible answers and analysed the accuracy data using generalised linear mixed effects models (Bates, Mächler, \&Walker, 2015).
Eye movement results. The data for both age groups showed no significant effects of prosody in the verb and adverb regions (Figs 3 and 4). For the adults (only), the analyses revealed a main effect of word order for the verb and adverb (Fig. 3: adverb). The adults were more likely to inspect the patient (vs. agent) in SVO sentences (negative numbers) and the agent (vs. patient) in OVS sentences (positive numbers) during the adverb region (word order effect: $p<.001$ ).

The child data showed more looks towards the patient (vs. agent) in all four conditions (intercept $p<.05$ ). The preference to inspect the patient over the agent is only slightly higher in the biasing compared to the neutral prosody conditions (Fig. 4).
Accuracy Results. Adult's post-sentence answers revealed a high percentage of correct answers (99\%), with no difference between the conditions (Fig. 5). The child data revealed an overall accuracy of $71 \%$. The analyses revealed no clear difference between the two prosodic
conditions but a main effect of word order ( $p<.001$, Fig. $6)$.

## Discussion

We investigated children's and adults' thematic role assignment in unambiguously case marked German SVO and OVS sentences using scenes in which two role fillers performed identical actions. Thus, as participants heard the verb, it was unclear which of two events (one depicting the NP1 referent as the agent, the other depicting him as a patient) to rely on for anticipating upcoming role fillers. In brief, the scene did not disambiguate the thematic roles relations. But case marking and prosodic cues could, in principle, permit anticipatory thematic role assignment. We recorded participants' eye movements to the agent and patient in the scene while they inspected scenes and listened to related German SVO and OVS sentences (Table 1).
Previous research has reported effects of prosody on thematic role assignment in German children and adults (Grünloh et al., 2011; Weber at al., 2006). Unlike these previous findings, our results revealed no significant effect of prosody. Previous research further revealed that adults rapidly use case marking for thematic role assignment (Matzke et al., 2002). Results for children were, however, contradictory (Dittmar et al., 2008; Münster, 2016; Özge et al., 2016; Zhang \& Knoeferle, 2012). In line with previous findings, the adults in our study exploited case marking for real-time thematic role assignment. They directed more anticipatory looks towards the true patient (vs. agent) in SVO sentences and towards the true agent (vs. patient) in OVS sentences. Children, by contrast, did not exploit case marking for such visual anticipation. In both SVO and OVS sentences, they directed more anticipatory looks towards the true patient during the adverb. They thus seem to have interpreted OVS sentences as agent-first sentences, disregarding the unambiguous object case marking on the sentence-initial noun phrase.
In adults, the null effect of prosody might be explained by the fact that morpho-syntactic (case) information has stronger links to thematic role assignment than suprasentential information. Similar arguments have been made for prosodic marking and object color contrast (Sedivy et al., 1999). Sedivy et al. argued that color contrast effects enable a strongly contrastive interpretation already, eliminating further contrastive intonation effects. A similar argument might hold for case marking and prosody. Case marking in adults fully disambiguated thematic role assignment and prosody had no additional beneficial effects. Relatedly, adults in Grünloh et al. (2011, Exp. 1) failed to exploit prosody but used case marking for thematic role assignment.
Concerning the children, our prosody results differed from those by Grünloh and colleagues (2011) who reported that a contrastive OVS-biasing intonation in unambiguous sentences facilitated children's identification of patient-agent events. One reason for this might be that we used different scenes. In our study, participants saw one ambiguous scene that included both possible interpretations (e.g., true patient <-action ambiguous <-action true agent). In Grünloh and
colleagues (2011), by contrast, children selected one event picture from two adjacent ones (in which agent and patient roles appeared in reversed order, agent-patient vs. patient-agent). This direct contrast may have facilitated identifying the correct event by means of prosody (and case marking). In addition, in our scenes participants including children - inspected the NP1 referent when it was named. The verb then linked to a matching action of that referent and likely reaffirmed this was the correct agent. It is possible that the verb-action match and additional posture of the NP1 referent (facing the true patient), may have led children in particular to interpret an $\mathrm{L}+\mathrm{H}^{*}$ accent on NP1 as highlighting the NP1 as the agent rather than as the patient, even if case-marking indicated it was the object and patient.

In previous studies on children's use of case marking (Münster 2016; Özge et al., 2015; Zhang \& Knoeferle 2012), visual information likely provided a supportive background for exploiting case marking. Unlike prior research, our scenes did not constrain thematic role relations by means of stereotypical knowledge (Özge et al., 2016) or action depictions that - once the verb became available - permitted children to distinguish SVO and OVS sentences (Münster, 2016; Zhang \& Knoeferle, 2012). One of the reasons for why children in our study did not use case marking in real time might thus be the lack of supportive contextual information.

Children's comprehension mechanisms develop throughout the first years of their life. They learn from their immediate environment and from observing who interacts with whom. Perhaps they need an unambiguous visual background to exploit case for syntactic structuring. Without that, they fail to correctly interpret more demanding OVS sentences and fall back on default structures (e.g., SVO). Further research could examine when children start to abstract away from the visual display and begin to use case marking in an adult-like manner for syntactic structuring.

#### Abstract

How do we learn to think better, and what can we do to promote such metacognitive learning? Here, we propose that cognitive growth proceeds through metacognitive reinforcement learning. We apply this theory to model how people learn how far to plan ahead and test its predictions about the speed of metacognitive learning in two experiments. In the first experiment, we find that our model can discern a reward structure that promotes metacognitive reinforcement learning from one that hinders it. In the second experiment, we show that our model can be used to design a feedback mechanism that enhances metacognitive reinforcement learning in an environment that hinders learning. Our results suggest that modeling metacognitive learning is a promising step towards promoting cognitive growth.

Keywords: Decision-Making; Planning; Metacognitive Reinforcement Learning; Cognitive Training

## Introduction

One of the most remarkable aspects of the human mind is its ability to improve itself based on experience. Such learning occurs in a range of domains, from simple stimulus-response mappings, motor skills, and perceptual abilities, to problem solving, cognitive control, and learning itself (C. S. Green \& Bavelier, 2008; Bavelier, Green, Pouget, \& Schrater, 2012). Demonstrations of cognitive and brain plasticity have inspired cognitive training programs. The success of cognitive training has been mixed and the underlying learning mechanisms are not well understood (Owen et al., 2010; Anguera et al., 2013; Morrison \& Chein, 2011). Feedback is an important component of many effective cognitive training programs, but it remains unclear what makes some feedback structures more effective than others, and there is no principled method for designing optimal feedback structures.

To address these problems, we model cognitive plasticity as metacognitive reinforcement learning. This perspective allows us to translate methods for accelerating reinforcement learning in robots (Ng, Harada, \& Russell, 1999) into feedback structures for cognitive training in humans.

Here, we evaluate this approach in the domain of planning. As a first step, we developed a metacognitive reinforcement learning model of how people learn how many steps to plan ahead in sequential decision problems, and we test its predictions empirically. The results of our first experiment suggest that our model can discern which reward structures are more conducive to metacognitive learning. In our second experiment, we find that feedback structures designed based on our model can accelerate learning to plan.

We start by introducing the theory of reinforcement learning that our approach is based upon. The following two sections apply this theory to model the problem of deciding how to decide and the process by which people learn to do so. We then use this theory to motivate a novel computational method for designing feedback structures that promote cognitive plasticity and experimentally test the predictions of our theory. We close with a discussion of the implications of our results for cognitive training.

## Planning and reinforcement learning

A sequential decision problem can be modeled as a Markov decision process (MDP)

$$
\begin{equation*}
M=\left(S, \mathcal{A}, T, \gamma, r, P_{0}\right), \tag{1}
\end{equation*}
$$

where $\mathcal{S}$ is the set of states, $\mathcal{A}$ is the set of actions, $T\left(s, a, s^{\prime}\right)$ is the probability that the agent will transition from state $s$ to state $s^{\prime}$ if it takes action $a, 0 \leq \gamma \leq 1$ is the discount factor on future rewards, $r\left(s, a, s^{\prime}\right)$ is the reward generated by this transition, and $P_{0}$ is the probability distribution of the initial state $S_{0}$ (Sutton \& Barto, 1998). A policy $\pi: \mathcal{S} \mapsto \mathcal{A}$ specifies which action to take in each of the states. The expected sum of discounted rewards that a policy $\pi$ will generate in the MDP $M$ starting from a state $s$ is known as its value function

$$
\begin{equation*}
V_{M}^{\pi}(s)=\mathbb{E}\left[\sum_{t=0}^{\infty} \gamma^{t} \cdot r\left(S_{t}, \pi\left(S_{t}\right), S_{t+1}\right)\right] \tag{2}
\end{equation*}
$$

The optimal policy $\pi_{M}^{\star}$ maximizes the expected sum of discounted rewards, that is

$$
\begin{equation*}
\pi_{M}^{\star}=\arg \max _{\pi} \mathbb{E}\left[\sum_{t=0}^{\infty} \gamma^{\downarrow} \cdot r\left(S_{t}, \pi\left(S_{t}\right), S_{t+1}\right)\right] . \tag{3}
\end{equation*}
$$

Solving large planning problems is often intractable because the number of possible action sequences grows exponentially with the number of steps one plans ahead. When the state space $S$ is discrete and relatively small, dynamic programming can be used to find optimal plans in polynomial time (Littman, Dean, \& Kaelbling, 1995). But the highdimensional, continuous state spaces people have to plan with in real life are too large for these methods. Instead, people seem to rely on approximate planning strategies (Huys et al., 2015) and often decide primarily based on immediate
and proximal outcomes while neglecting the long-term consequences of their actions (Myerson \& Green, 1995). Despite its fallibility, looking only a few steps ahead can drastically simplify the planning problem, and this may often be a necessity for bounded agents with imperfect knowledge of the environment (Jiang, Kulesza, Singh, \& Lewis, 2015). Since cutting corners in the decision process is both necessary and problematic, good decision-making requires knowing when that is admissible and when it is not. Knowing how much to plan is therefore an important metacognitive skill to learn.

Previous work suggests that this metacognitive skill can be learned through trial and error (Lieder \& Griffiths, 2015). Learning through trial and error can be understood in terms of reinforcement learning (Sutton \& Barto, 1998). While certain reinforcement learning algorithms can, in principle, learn to solve arbitrarily complex problems, reinforcement learning can also be very slow-especially when rewards are sparse and the optimal policy is far from the learner's initial strategy. A common approach to remedy this problem is to give the algorithm pseudo-rewards for actions that do not achieve the goal but lead in the right direction ( Ng et al., 1999).While previous work has developed this idea to accelerate learning a direct mapping from states to actions, we will leverage it to accelerate learning to plan.

## Deciding how to decide

People can use many different decision strategies. This poses the problem of deciding how to decide (Boureau, SokolHessner, \& Daw, 2015). Previous research on meta-decisionmaking has focused on the arbitration between habits versus planning (Keramati, Dezfouli, \& Piray, 2011; Dolan \& Dayan, 2013). While this is an important meta-control problem, it is only one part of the puzzle because people are equipped with more than one goal-directed decisionmechanism. Hence, when the model-based system is in charge, it has to be determined how many steps it should plan ahead. Ideally, the chosen planning horizon should achieve the optimal tradeoff between expected decision quality versus decision time (Vul, Goodman, Griffiths, \& Tenenbaum, 2014) and mental effort (Shenhav et al., 2017).

Here, we make the simplifying assumption that people always choose the action that maximizes their sum of expected rewards over the next $h$ steps, for some value of $h$ that differs across decisions. A planning horizon of $h=1$ entails looking only at the immediate outcome of each action (myopic onestep planning) whereas a planning horizon larger than one entails solving a sequential decision problem to form a multistep plan. Under this assumption, the meta-decision problem is to select a planning horizon $h$ from a set $\mathcal{H}=\{1,2, \cdots$,$\} ,$ execute the plan, select a new planning horizon, and so on. More formally, this problem can be formalized as a metalevel MDP (Hay, Russell, Tolpin, \& Shimony, 2012). In our task, the meta-level MDP is

$$
\begin{equation*}
M_{\text {meta }}=\left(S_{\text {meta }}, \mathcal{H}, T_{\text {meta }}, r_{\text {meta }}\right) \tag{4}
\end{equation*}
$$

where the meta-level state $m \in \mathcal{S}_{\text {meta }}=\{0,1,2,3,4\}$ encodes
the number of remaining moves, and the meta-level action $h \in \mathcal{H}=\{1,2,3,4\}$ is the planning horizon used to make a decision. The meta-level reward function $r_{\text {meta }}$ integrates the cost of planning with the return of the resulting action:

$$
\begin{equation*}
r_{\text {meta }}\left(m_{k}, h_{k}\right)=-\operatorname{cost}\left(h_{k}\right)+\sum_{t=1}^{h} r\left(s_{t}, \operatorname{plan}_{t}^{\left(k, h_{k}\right)}\right) \tag{5}
\end{equation*}
$$

where $\operatorname{plan}_{t}^{(k, h)}$ is the $t^{\text {th }}$ action of the plan formed by looking $h$ steps ahead in the meta-level state $m_{k}$. The meta-decisionmaker receives this reward after the plan has been executed in its entirety. If the meta-decision-maker selects short planning horizons there can be multiple plan-act-reward-learn cycles within a single trial. The cost of planning $\operatorname{cost}\left(h_{k}\right)$ is determined by the branching factor $b$ of the decision tree according to

$$
\begin{equation*}
\operatorname{cost}\left(h_{k}\right)=\lambda \cdot b^{h_{k}} \cdot h_{k}, \tag{6}
\end{equation*}
$$

where $b^{h_{k}}$ is the number of plans, $h_{k}$ is the number of steps per plan, and $\lambda$ is the cost per planning step.*

## Metacognitive reinforcement learning

Solving the problem of deciding how to decide optimally is computationally intractable but the optimal solution can be approximated through learning (Russell \& Wefald, 1991). We propose that people use reinforcement learning (Sutton \& Barto, 1998) to approximate the optimal solution to the meta-decision problem formulated in Equation 4.

## Model

Our model of metacognitive reinforcement learning builds on the semi-gradient SARSA algorithm (Sutton \& Barto, 1998) that was develop to approximately solve MDPs with large or continuous state spaces. Specifically, we assume that people learn a linear approximation to the meta-level Q-function

$$
\begin{equation*}
Q_{\mathrm{meta}}\left(m_{k}, h_{k}\right) \approx \sum_{j=1}^{7} w_{j} \cdot f_{j}\left(m_{k}, h_{k}\right) \tag{7}
\end{equation*}
$$

whose features $\mathbf{f}$ comprise one indicator variable for each possible planning horizon $h\left(f_{1}=\mathbb{1}(h=1), \cdots, f_{4}=\mathbb{1}(h=4)\right)$, one indicator variable for whether or not the agent planned all $l$ steps until the end of the task $\left(f_{5}=\mathbb{1}(h=l)\right)$, the number of steps that were left unplanned $\left(f_{6}=\max \{0, l-h\}\right)$, and the number of steps the agent planned too far ( $f_{7}=$ $\max \{0, h-l\}$ ). The semi-gradient SARSA algorithm learns the weights of these features by gradient descent. To bring it closer to human performance, our model replaces its gradient descent updates by Bayesian learning. Concretely, the weights $\mathbf{w}$ are learned by Bayesian linear regression of the bootstrap estimate $\hat{Q}\left(m_{k}, h_{k}\right)$ of the meta-level value function onto the features $\mathbf{f}$. The bootstrap estimator

$$
\begin{equation*}
\hat{Q}\left(m_{k}, h_{k}\right)=r_{\text {meta }}\left(m_{k}, h_{k}\right)+\left\langle\mu_{t}, \mathbf{f}\left(m^{\prime}, h^{\prime}\right)\right\rangle \tag{8}
\end{equation*}
$$

[^372]is the sum of the immediate meta-level reward and the predicted value of the next meta-level state $m^{\prime}$. The predicted value of $m^{\prime}$ is the scalar product of the the posterior mean $\mu_{t}$ of the weights $\mathbf{w}$ given the observations from the first $t$ actions (where $t=\sum_{n=1}^{k} h_{n}$ ) and the features $\mathbf{f}\left(m^{\prime}, c^{\prime}\right)$ of $m^{\prime}$ and the planning horizon $h^{\prime}$ that will be selected in that state.

We assume that the prior on the feature weights reflects that it is beneficial to plan until the end $\left(P\left(f_{5}\right)=\mathcal{N}(\mu=1, \sigma=\right.$ $0.1)$ ), although planning is costly $\left(P\left(f_{1}\right)=P\left(f_{2}\right)=P\left(f_{3}\right)=\right.$ $P\left(f_{4}\right)=\mathcal{N}(\mu=-1, \sigma=0.1)$ ), and that planning too much is more costly than planning too little $\left(P\left(f_{7}\right)=\mathcal{N}(\mu=-1, \sigma=\right.$ $0.1)$ and $\left.P\left(f_{6}\right)=\mathcal{N}(\mu=0, \sigma=0.1)\right)$.

Given the posterior on the feature weights $\mathbf{w}$, the planning horizon $h$ is selected by Thompson sampling. Specifically, to make the $k^{\text {th }}$ meta-decision, a weight vector $\tilde{w}$ is sampled from the posterior distribution of the weights given the series of meta-level states, selected planning horizons, and resulting value estimates experienced so far. That is,

$$
\begin{equation*}
\tilde{w}_{k} \sim P\left(\mathbf{w} \mid \mathcal{E}_{k}\right) \tag{9}
\end{equation*}
$$

where the set $\mathscr{E}_{k}=\left\{e_{1}, \cdots, e_{k}\right\}$ contains the meta-decisionmaker's experience from the first $k$ meta-decisions; to be precise, each meta-level experience $e_{j} \in \mathcal{E}_{k}$ is a tuple $\left(m_{j}, h_{j}, \hat{Q}\left(m_{j}, c_{j} ; \mu_{j}\right)\right)$ containing a meta-level state, the computation selected in it, and the bootstrap estimates of its Qvalue. The sampled weight vector $\tilde{w}$ is then used to predict the Q-values of each possible planning horizon $h \in \mathcal{H}$ according to Equation 7. Finally, the planning horizon with the highest predicted Q-value is used for decision-making.

By proposing metacognitive reinforcement learning as a mechanism of cognitive plasticity, our model suggests that reward and feedback are critical for cognitive growth. Conceptualizing metacognitive reinforcement learning as a regression problem suggests that learning how to best think about a problem should require less practice the stronger the correlation between the features $\mathbf{f}(m, c)$ (i.e., the predictors) and the resulting reward net the cost of thinking (i.e., the criterion; Green, 1991). Here, we apply our model to predict how quickly people can learn that more planning leads to better results from the reward structure of the practice problems. According to the model, learning should be fastest when the reward increases deterministically with the planning horizon both within and across problems. By contrast, learning should be slower when this relationship is degraded by additional variability in the rewards that is unrelated to planning. The following experiments test this prediction and illustrate the model's utility for designing feedback structures that promote metacognitive learning.

## Experiment 1: Reward structures can help or hinder learning to plan

## Methods

We recruited 304 adult participants from Amazon Mechanical Turk. The task took about 25 minutes, and participants were paid $\$ 2.50$ plus a performance-dependent bonus of up to

## Round 1 of 13

Location: Smithsville Flight: 1 of 2 Earnings: \$0 Bonus: \$0

Figure 1: Screenshot of a problem from Experiment 1.
\$2.00. Participants played a series of flight planning games. The environment consisted of six different cities, each connected to two other cities (Figure 1). Participants began each trial at a given city, and were tasked with planning a specified number of flights. Each flight was associated with a known gain or loss of money, displayed onscreen. Thus, the participants' task was to plan a route that would maximize their earnings or minimize their losses, based on the number of planning steps required for that game.

The experiment comprised thirteen trials total: a sequence of three practice problems which required planning 2,3 , and 3 steps ahead, respectively, followed by ten 4 -step problems, with a break after trial eight. The order of the two 3-step problems was randomized, and the order of the ten 4-step problems was randomized across the last ten trials of the experiment. Participants were assigned randomly to one of two conditions: environments with reward structures designed to promote learning ("diagnostic rewards"), or environments with reward structures designed to hinder learning ("non-diagnostic rewards").

The problems of the diagnostic rewards condition were automatically generated to exhibit four characteristics:

1. For each $l$-step problem, planning $h<l$ steps ahead generates $l-h$ suboptimal moves. In other words, each myopic planner makes the maximum possible number of mistakes.
2. When the number of moves is $l$, then planning $l$ steps ahead yields a positive return, but planning $h<l$ steps ahead yields a negative return.
3. The return increases monotonically with the planning horizon from 1 to the total number of moves.
4. Each starting position occurs at least once.

The reward structures used for the non-diagnostic rewards condition were created by shifting the diagnostic reward structures so as to degrade the correlation between planning horizon and reward. Concretely, for half of the problems all rewards were shifted down such that no amount of planning could achieve a return better than $-\$ 10$. Since the original problems were such that the 1-step planner always performed worst, the shift was $\frac{-r_{1}+X}{l}$ where $r_{1}$ is the return of the 1 -step planner, $l$ is the number of steps in the planning problem, and $X$ is a random number between 10 and 20 that differed across problems $(X \sim \operatorname{Uniform}([10,20]))$. For the other half of the problems, all rewards were shifted up by $-\frac{r_{1}+X}{l}$ such that all planners achieve a return of at least $+\$ 10$. These reward structures make it extremely difficult for metacognitive reinforcement learning to discover that planning is valuable, because the random shifts greatly diminish the correlation between planning horizon and reward.

## Results

Both model simulations and human behavior demonstrated enhanced learning in environments with diagnostic rewards. Figure 2 shows the mean performance of the metacognitive reinforcement learning model, and the mean performance of human participants. Here, performance is measured as relative reward

$$
\begin{equation*}
R_{\text {rel }}=\left(R-R_{\min }\right) /\left(R_{\max }-R_{\min }\right), \tag{10}
\end{equation*}
$$

where $R$ is the total reward received during the trial, and $R_{\text {min }}$ and $R_{\max }$ are the highest and lowest possible total reward on that trial, respectively.

To measure the effects of condition and trial number on performance in human participants, we ran a repeatedmeasures ANOVA. This revealed a significant effect of both trial number $(F(9,2989)=3.44, p<0.001)$ and condition $(F(9,3029)=15.26, p<0.0001)$, such that participants improved over time, and participants with diagnostic feedback performed better than those without. To measure learning in each group, we ran a simple linear regression of the relative reward on the trial number. This revealed a significant regression equation for participants who received diagnostic rewards $(F(2,302)=11.28, p<0.01)$, with an $R^{2}$ of 0.59 , but not for participants who received non-diagnostic rewards $(F(2,302)=3.51, p>0.05)$, with an $R^{2}$ of 0.31 , suggesting that improvement in performance occurred with diagnostic rewards, but not without.

To analyze the frequency with which participants chose the optimal route, we performed a multinomial logistic regression of whether or not each participant chose the optimal route on trial number and group. This revealed significant effects of trial number $\left(p<10^{-6}\right)$ and group ( $p<0.0001$ ).

In addition, we found that participants interacting with a diagnostic reward structure learned to plan significantly further ahead than participants interacting with the non-diagnostic reward structure. When there were four steps left, the average planning horizon was 2.96 with diagnostic rewards compared to 2.65 with non-diagnostic rewards $(t(596)=2.94$,

Figure 2: Model predictions and human performance in Experiment 1. Error bars indicate the standard error of the mean. Model predictions were averaged over 500 simulations.
$p<0.01$ ). When the rewards were diagnostic of good planning, participants' choices in the first step of the 4 -step problems accorded $10.3 \%$ more frequently with 4 -step planning $(t(302)=3.57, p<0.001)$. For 3 remaining steps there was a significant increase in choices according with optimal 1-step $(p<0.01)$, 2-step ( $p<0.01$ ) and 4-step planning $(p<0.01)$. For 2 remaining steps, there was a significant increase in choices according with optimal 1-step planning ( $p<0.0001$ ) without a decrease in agreement with other planning horizons. Finally, on the last move participants' choices in the environment with diagnostic rewards corresponded $5.8 \%$ more frequently with optimal 1 -step planning $(t(302)=3.71, p<0.001)$, and significantly less frequently with 2-step and 3-step planning ( $p<0.01$ and $p<0.001$ ). In summary, diagnostic rewards led to better agreement between the planning horizon and the number of remaining steps.

## Experiment 2: Using feedback to promote learning to plan

When one has control over the reward structure of an environment, creating rewards tailored to faster learning may be feasible. However, often environmental rewards are fixed. In Experiment 2, we tested whether providing feedback may be an effective alternative approach to accelerating learning. When participants do not plan enough to find the optimal route, this could be because the time cost of planning an optimal route outweighs its benefits. To change that, we provided feedback in the form of timeout penalties for short-sighted decisions.

## Methods

We recruited 324 adult participants on Amazon Mechanical Turk. The task took about 30 minutes, and participants were paid $\$ 3.00$ plus a performance-dependent bonus of up to $\$ 2.00$. Participants played twenty trials of the flight planning game described above. These trials were divided into a training block and a testing block. The training block con-
sisted of six trials requiring 2-step planning, followed by ten trials requiring 3 -step planning. The testing block consisted of four additional 3-step trials. The order of the 2-step trials and the order of the 3 -step trials were randomized across subjects. Participants were randomly assigned to either the feedback condition or the control condition.

In the training block, participants in the feedback condition were told their apparent planning horizon at the end of every trial and penalized with a timeout that reflected the amount of planning they had eschewed. Concretely, we set the durations of the timeouts such that the cost of short-sighted decisions was proportional to the amount of necessary planning the participant had eschewed. Specifically, the forgone cost of planning was estimated by cost $=2^{l-\hat{h}}$, where $l$ is the number of moves for that trial, $\hat{h}$ is the participant's apparent planning horizon, and 2 is the branching factor since each step entailed a binary decision. The participant's planning horizon was estimated by the number of consecutive moves consistent with the optimal policy, beginning with the last move, followed by the second-to-last, etc. At the end of each trial of the first block, participants in the feedback group were penalized with a timeout delay for sub-optimal routes. The delay was calculated as $7 \cdot($ cost -1$)$ seconds. During this period, participants were unable to proceed to the next trial. If participants performed the optimal route, they were able to proceed immediately to the next trial.

The control group received no feedback and had to wait a fixed amount of time at the end of every trial in block 1 , regardless of their performance. This fixed period was set to 8 seconds, to match the mean timeout period for participants in the feedback group ( 7.9 seconds). Neither group received feedback or delays in the test block.

The planning problems presented in this experiment were created in two steps. In the first step, we created 2- and 3step problems with maximally diagnostic reward structures (according to the criteria used in Experiment 1) subject to the constraint that the first move with the highest immediate reward was optimal for exactly half of those problems. In the second step, we modified these problems so as to deteriorate the correlation between planning horizon and reward using the same method we employed to create the non-diagnostic reward structures used in Experiment 1.

## Model Predictions

We applied the metacognitive reinforcement learning model described above to the problem of learning how many steps one should plan ahead. We simulated a run of the experiment described above with 1000 participants in each condition. The simulations predicted a gradual increase in the relative return from the first 3-step problem to the last one (see Figure 3). With feedback, the relative return increased faster and reached a higher level than without feedback.

## Results

To quantify the effects of condition and trial number on performance (measured as relative reward), we ran a mixed-

Figure 3: Results of Experiment 2. The metacognitive RL model predicts that feedback accelerate learning to plan. Human behavior shows a similar pattern of results.
design repeated-measures ANOVA on participant performance during the 3 -step trials. This revealed a significant effect of feedback $(F(9,4521)=8.54, p<0.01)$ and trial number $(F(9,4521)=1.85, p<0.05)$ on relative reward. To measure learning in each group, we performed a simple linear regression of relative reward on trial number for the 3step trials in the training block (i.e., when participants in the feedback group received feedback). This revealed a significant regression equation for the feedback group $(F(2,322)=$ $5.28, p=0.05$ ), with an $R^{2}$ of 0.40 but not for the control group $(F(2,322)=1.57, p>0.05)$, with an $R^{2}$ of 0.16 . This suggests that participants who received feedback improved during the training block but the control group did not.

Feedback increased the model's average performance in both the training block and the transfer block. We next tested whether the enhanced learning of the feedback group during training resulted in better performance in the transfer block (trials 17-20) where they no longer received any feedback. A two-sample $t$-test revealed that the feedback group's advantage in the testing block was nearly significant $(t(1294)=1.53, p=0.063)$. Figure 3 compares our participants' performance to the model predictions.

As predicted by our model, a multinomial logistic regression of whether or not each participant chose the optimal route on trial number and feedback, revealed significant effects of trial number $(p<0.0001)$ and feedback ( $p<0.01$ ).

Feedback appeared to increase people's planning horizons: when there were two remaining moves, the choices of the feedback group accorded $4 \%$ less often with myopic choice $(t(1398)=-2.17, p<0.05), 7 \%$ more often with optimal 2step planning $(t(1398)=3.44, p<0.001)$, and $4 \%$ more often with optimal 3-step planning $(t(1398)=2.43, p<0.05)$.

## Discussion

In this article, we have introduced a computational model of how people learn to decide better. Its central idea is that
learning how to think can be understood as metacognitive reinforcement learning. Our model extends previous research on strategy selection learning (Lieder et al., 2014; Lieder \& Griffiths, 2015) by capturing that choosing cognitive operations is a sequential decision problem with potentially delayed rewards rather than a one-shot decision. The new model correctly predicted the effects of reward structure and feedback on learning to plan: Experiment 1 suggested that our model captures the effect of reward structures on the speed of metacognitive learning. We then applied our theory to design feedback for people's performance in environments whose reward structure is not diagnostic of good planning. Experiment 2 confirmed the model's prediction that this intervention would be effective.

Our results suggest two pragmatic approaches to promoting cognitive growth: first, designing reward structures that are diagnostic of the quality of reasoning, planning, and decision-making; second, providing feedback on the process by which a decision was made. In Experiment 2 we followed the latter approach by designing feedback based on the cost of planning; but other types of feedback may also be useful. If cognitive plasticity is based on model-free reinforcement learning as assumed by our theory, then its speed should critically depend on how well the feedback people receive upon performing cognitive operations reflects their value. Therefore, feedback structures that align immediate feedback with long-term value should be maximally effective at promoting cognitive plasticity and learning to make better decisions. Future experiments should test this hypothesis by designing feedback structures using the optimal gamification method introduced by Lieder and Griffiths (2016). Feedback designed using optimal gamification could be especially beneficial because the underlying method of reward shaping is designed to accelerate model-free reinforcement learning ( Ng et al., 1999). Critically, to promote learning how to decide, people should decide without any assistance and only receive feedback after their choice.

We hope that our theory of metacognitive reinforcement learning will be a step towards establishing a scientific foundation for designing feedback for cognitive training and other interventions for promoting cognitive growth. Future work will evaluate alternative forms of feedback, address the problem of transfer and retention, and design more effective training paradigms using tasks that are maximally diagnostic of how people think and decide.

# Thinking and Guessing: Bayesian and Empirical Models of How Humans Search 

Marta Kryven<br>University of Waterloo, Waterloo, Ontario, Canada<br>Tomer Ullman<br>Massachusetts Institute of Technology<br>William Cowan<br>University of Waterloo, Waterloo, Ontario, Canada<br>Josh Tenenbaum<br>Massachusetts Institute of Technology

#### Abstract

Searching natural environments, as for example, when foraging or looking for a landmark, combines reasoning under uncertainty, planning and visual search. Existing paradigms for studying search in humans focus on step-by-step information sampling, without examining advance planning. We propose and evaluate a Bayesian model of how people search in a naturalistic maze-solving task. The model encodes environment exploration as a sequential process of acquiring information modelled by a Partially Observable Markov Decision Process (POMDP), which maximises the information gained. We show that the search policy averaged across participants is optimal. Individual solutions, however, are highly variable and can be explained by two heuristics: thinking and guessing. Self-report and inference, a Gaussian Mixture Model over inverse POMDP, consistently assign most subjects to one style or the other. By analysing individual participants' decision times we show that individuals solve partial POMDPs and plan their search a limited number of steps in advance.

# The Puzzle of Conditionals with True Clauses: Against the Gricean Account 

Karolina Krzyżanowska (k.krzyzanowska@lmu.de)<br>Munich Center for Mathematical Philosophy \& Center for Advanced Studies, LMU Munich Geschwister-Scholl-Platz 1, 80539 Munich, Germany

#### Abstract

Indicative conditionals, that is sentences of the form "If $p$, then $q$," belong to the most puzzling phenomena of language. On the majority of accounts of indicative conditionals, the truth of $p$ and $q$ suffices for "If $p$, then $q$ " to be true or highly acceptable. Yet, many conditionals with true clauses, even if there is a meaningful connection between them, sound odd. The most common reaction to this phenomenon is to attribute the oddity of conditionals with true clauses to natural language pragmatics. We present an experimental study investigating how the presence or absence of a connection between the clauses affects the assertability of conditionals and conjunction expressing generic and specific kind of content. The results refute the standard pragmatic explanation.

Keywords: indicative conditionals; conjunctions; relevance; specific content; generic content; assertability

## Introduction

Indicative conditionals ${ }^{1}$ are sentences that we use to express hypothetical thoughts. They are central to our reasoning, planning, and problem solving. We entertain them when making everyday decisions ("If I add too much chilly to the curry, John will complain"), discussing public policies ("If we lower taxes, we will not have sufficient resources to fund social security benefits"), or doing science ("if we do not curb carbon output, sea levels will rise dangerously").

Conditionals are usually defined as sentences of the form "If $p$, then $q$," such as:
(1) If Dora studied physics, then she knows how to solve differential equations.

Intuitively, the antecedent of a conditional, $p$ ("Dora studied physics"), expresses a condition under which $q$, the consequent ("Dora knows how to solve differential equations"), occurs or from which it can be inferred. Assuming that it is true that Dora studied physics and that she knows how to solve differential equations, and given that a degree in physics is a good reason to believe that a person can solve differential equations, (1) is rendered true on any account that allows conditionals to be true or false at all, and highly acceptable on those accounts that deny conditionals their truth aptness (that is, accounts that do not view conditionals as statements that are 'true' or 'false,' in the same way that questions or commands are not true or false). But what if both $p$ and $q$ are true, yet there is no connection between them, that is, one cannot

[^373]infer $q$ from $p$ nor $p$ makes it more likely that $q$ ? Let us suppose that Dora can solve differential equations, and that she also plays basketball. The fact that Dora is a basketball player does not allow us to predict anything about Dora's mathematical skills. The two facts do not seem to be connected at all, yet on many prominent accounts of conditionals, the sentence
(2) is rendered true or, at least, highly acceptable:
(2) If Dora plays basketball, then she knows how to solve differential equations.

This is due to the fact that the majority of the prominent theories of conditionals validate the Principle of Conjunctive Sufficiency, often simply referred to as the Principle of Centering, which allows us to infer "If $p$, then $q$ " from the conjunction of $p$ and $q$.

Centering has recently attracted attention in psychology of reasoning (Cruz et al. 2016), because this is an inference rule that distinguishes between some of the most popular philosophical and psychological accounts of conditionals, such as the Mental Models Theory (Johnson-Laird \& Byrne 2002) and the suppositional theory (Adams 1975; Edgington 1995; Evans \& Over 2004; Cruz et al. 2016), on the one hand, and the 'inferentialist' approach on which a connection between a conditional's antecedent and its consequent belongs to the literal, semantic meaning of a conditional, on the other hand. This connection may be defined in different ways, for instance, as a whole variety of inferential relations (Krzyżanowska et al. 2013, 2014) or in terms of probabilistic relevance (Skovgaard-Olsen et al. 2016b,a), but on no 'inferentialist' account of conditionals will a sentence like (2) be acceptable unless one can show that there is some kind of relationship between basketball and maths.

This is not to say that proponents of the 'centering' theories do not find sentences like (2) strange. They do, but assume that the oddity of missing-link conditionals can be explained in terms of pragmatics, that is, the aspect of language that allows speakers to infer the intended meaning of linguistic expressions even where it is different than what is literally said. For instance, "Some students passed the exam" pragmatically implicates that not all of them passed, although, from a purely logical point of view, it is consistent with "All students passed the exam" (Bott \& Noveck 2004). Along these lines, (Over et al. 2007, p. 92) make the following observation. Anyone who takes the natural-language conditional to
be probabilistic-its meaning exhausted by the Equation, i.e. $\operatorname{Pr}$ ("If $p, q$ ") $=\operatorname{Pr}(q \mid p)$-can argue that:
the use of a conditional pragmatically suggests, in certain ordinary contexts, that $p$ raises the probability of $q$ or that $p$ causes $q$.

A similar take on the connection between $p$ and $q$ can be found in the Mental Models literature. On this account, a language user interprets an assertion by constructing mental models (Johnson-Laird \& Byrne 2002, p. 653). On the most recent version of Mental Models Theory, the core meaning of a natural language conditional refers to a set of possibilities equivalent to the material interpretation of a conditional (p. 665). However, what kind of possibilities a language user envisages when interpreting a sentence is susceptible to the processes of semantic and pragmatic modulations. In particular:
modulation can establish an indefinite number of different temporal, spatial, and coreferential relations between the antecedent and consequent of a conditional. (Johnson-Laird \& Byrne 2002, p. 660)

But what kind of pragmatic mechanisms are responsible for the oddity of missing-link conditionals? The most famous pragmatic explanation of why some conditionals, and especially those that are true due to the truth of their consequents, appear odd was proposed by Grice (1989). He argued that:

To say that " $p \supset q$ " is to say something logically weaker than to deny that $p$ or to assert that $q$, and is thus less informative; to make a less informative rather than a more informative statement is to offend against the first maxim of Quantity, provided that the more informative statement, if made, would be of interest. There is a general presumption that in the case of " $p \supset q$," a more informative statement would be of interest (Grice 1989, p.61).

On this account, a sentence such as (2) is simply unassertable in a context in which its antecedent and consequent are known to be true, because a stronger statement, namely "Dora knows how to solve differential equations" is available and should have been asserted instead. Note, however, that even if an appeal to the maxim of Quantity explains why sentences like (2) are not felicitous things to say, it does not illuminate the fact that speakers seem to interpret conditionals as if their clauses were somehow connected. Moreover, it also does not allow us to distinguish between sentences such as (2) and those conditionals with true clauses that are, intuitively, perfectly fine, like (1).

Both (1) and (2) consist of a true antecedent and true consequent. The only difference between them is that there is an inferential connection between doing physics and possessing certain mathematical skills, whereas playing basketball, as far as we know, has no bearing on the latter at all. The truth of
$p$ and $q$ is clearly not enough for a conditional to be a reasonable thing to say or to accept, but neither does it suffice to render a conditional unassertable at all.

## Connecting antecedents and consequents

In the case of what we will label in the following as a TT conditional, that is, a conditional whose antecedent and consequent are (known to be) true, the connection between the clauses cannot be translated directly into 'possibilities' in the way envisaged by Mental Models Theory, or into the notion of the probabilistic relevance, understood in terms of the $\Delta p$ rule, if the conditional probability, $\operatorname{Pr}(q \mid p)$, is understood as the ratio of $\operatorname{Pr}(q \wedge p)$ to $\operatorname{Pr}(p)$ (Over et al. 2007; Oberauer et al. 2007; Skovgaard-Olsen et al. 2016b). On this widespread probabilistic approach, $p$ is said to be positively relevant for $q$ if $\Delta p>0$, where $\Delta p$ is defined as a difference between $\operatorname{Pr}(q \mid p)$ and $\operatorname{Pr}(q \mid \neg p)$. However, when both $p$ and $q$ are known to be true, $\operatorname{Pr}(p)=\operatorname{Pr}(q)=\operatorname{Pr}(q \mid p)=1$, whereas $\operatorname{Pr}(q \mid \neg p)$ is undetermined since $\operatorname{Pr}(\neg p)=0$, and hence $\Delta p$ cannot be calculated. Another, related, measure of probabilistic relevance is the difference between $\operatorname{Pr}(q \mid p)$ and $\operatorname{Pr}(q)$ (cf. Skovgaard-Olsen et al. 2016a). $\operatorname{Pr}(q \mid p)>\operatorname{Pr}(q)$ ensures that the antecedent has a probability-raising effect on the consequent. However, when both $p$ and $q$ are known to be true, $\operatorname{Pr}(q)=\operatorname{Pr}(q \mid p)$. In that case, $p$ is probabilistically irrelevant for $q$ just because $\operatorname{Pr}(q)$ cannot be raised any higher. Yet, as the example (1) illustrates, the clauses of a TT conditional may seem connected anyway, hence probabilistic relevance defined in this way is insufficient to capture the intuition behind that connection. By the same token, Johnson-Laird and Byrne's (2002) suggestion that the core meaning of the conditional is that the "antecedent describes a possibility, at least in part, and the consequent can occur in this possibility." ( p . 650), is of no help with TT conditionals, as true states of affairs are necessarily 'possible,' so that the notion of possibility is insufficient to distinguish between 2 and 1.

Some of these problems can be avoided when conditional probability, rather than unconditional probability, is treated as the primitive notion, and thus $\operatorname{Pr}(q \mid p)$ is not calculated from $\operatorname{Pr}(p \wedge q)$ and $\operatorname{Pr}(p)$ (e.g. Popper 1959; de Finetti 1970/1990). One may also consider a counterfactual notion of relevance, that is, e.g., $\Delta p$ calculated as if $p$ was not known to be true. ${ }^{2}$ In our experimental design, we assume an intuitive, pre-theoretic notion of the connection, which does not depend on any particular operationalisation of the notion of relevance.

## What antecedents and consequents are about

In order to understand the semantics and pragmatics of conditionals, one should arguably turn to the way conditionals are actually used in everyday language. Linguists have sought to provide extensive overviews of different types of conditionals

[^374]Jenny enters the room of her 14 year old son, Tom, to persuade him to clean up his room a bit. She even offers him her help. While sorting through the papers on Tom's desk, Jenny notices a math test with an " $F$ " on it, which, apparently, Tom has concealed from her. Tom notices what his mother found and decides to divert her attention to something else.

Tom: "Oh, look, my plant has dried up completely."
Jenny: "Did you water it at all?"
Tom: "Well, no..."
In this context, would it make sense for Jenny to say the following?

Figure 1: Example vignette used in the experiment.
(see, e.g, Declerck \& Reed 2001, for a comprehensive corpus based analysis). Such overviews reveal that conditionals can be characterised and classified in many different ways. Consideration of those differences suggests that the broad category of 'indicative conditional' (as in, 'in the indicative mood' as opposed to the 'subjunctive mood', e.g., I would, I could, etc.) which is the theoretical focus of the majority of psychological and philosophical work is far too broad. The way a conditional is interpreted and evaluated may be affected by the kind of content expressed by its clauses, even where the content is broadly 'indicative'. Among others, the content of a clause may be specific, that is, the clause can be about a specific object (a token) known to all participants of the conversation, e.g. "this book," or generic, concerning a type of an object, e.g. "a book." Consequently, we can distinguish between generic and specific conditionals:

## Generic (type):

(3) If a book is hardcover, it is expensive.

Specific (token):
(4) If this book is hardcover, it is expensive.

As noted by Declerck \& Reed (2001, p. 2), the unacceptability of conditionals with true antecedents:
is due to the fact that a speaker cannot process a fact as a supposition, except in 'inferential' conditionals, i.e., in conditionals expressing a conclusion $Q$ that is drawn from a premise $P$.
We investigate whether there is a difference in how people process generic and specific content, and consequently, if the two types of content may have an effect on people's assertability judgements. Additionally, we hypothesise that the presence or absence of an inferential connection may make the
conditional assertable, even if the antecedent is true and hence difficult to process as a supposition.

## The present experiment

We investigated whether people's assertability judgements depend on what a conditional is about. More specifically, we were interested in two factors that may be expected to affect people's evaluations of a conditional: the presence of an inferential connection between antecedent and consequent, and the kind of content the conditional expresses. We compared how people evaluate conditionals with how then evaluate conjunctions consisting of the same true clauses, such as:

Conditional: If you didn't water your plant, you failed your math test.
Conjunction: You didn't water your plant and you failed your math test.
Our test followed a $2 \times 2 \times 2$ factorial design. Sentence type (conditionals vs. conjunctions) was manipulated within subjects. Type of content (generic: type vs. specific: token) and the inferential connection (presence: C+ vs. absence: C-) were manipulated between subject. These are examples of conditionals belonging to each of the resulting four groups:

Token C+ If you didn't water your plant, it dried up.
Token C- If you didn't water your plant, you failed your math test.
Type C+ If you don't water a plant, it dries up
Type C- If you don't water a plant, you fail math tests.
Finally, we asked participants to evaluate the extent to which given sentences are reasonable things to utter in given contexts by means of two different questions:

Assertability: "In this context, to what extent would it be natural for X to assert the following sentences?"

Sensibleness: "In this context, would it make sense for X to say the following?"

## Methods

## Participants

244 individuals participated in the online survey on the MTurk platform (https://www.mturk.com/). We removed four participants who did not complete the survey and three participant whose reported first language was not English. Of the remaining 237 participants, 115 were female. The mean age of the participants was 33.97 (range 18-63). All participants received a small remuneration for their time and effort.

## Materials and procedure

Each participant has been randomly assigned to one of the four groups: Type C+, Type C-, Token C+, Token C-. Participants in each group were presented with 8 blocks, one at a time. The order of presentation was randomised. Each block contained a vignette consisting of a conversational context followed by two sentences: a conditional and a conjunction, presented in randomised order. There were four types of vignettes. Each participant saw each vignette twice: once followed by the question about the "assertability" of the two sentences, and once followed by the question about their "sensibleness." Figure 1 shows an example Token-C- item used in the experiment.

## Results

The data on 'sensibleness' mirrored exactly the pattern of responses to the 'assertability' question. Therefore, for brevity's sake, we report only the analysis of the latter question, the descriptive statistics for which are reported in Table 1 , below.

Table 1: Descriptive statistics for 'assertability.'

|  |  | Type |  | Token |  |
| :--- | ---: | ---: | :---: | :---: | :---: |
|  |  | C+ | C- | C + | C- |
| Conditionals | mean | 5.51 | 2.52 | 3.92 | 1.48 |
|  | sd | 0.94 | 1.08 | 1.35 | 0.74 |
| Conjunctions | mean | 3.79 | 4.59 | 5.98 | 6.04 |
|  | sd | 1.48 | 1.30 | 0.79 | 1.01 |

As figure 2 suggests, the absence of an inferential connection makes both type and token TT conditionals unassertable, although the presence of connection does not seem to be enough to make a token conditional assertable. By contrast, the presence or absence of a connection has little effect on the assertability of token conjunctions. When there is no connection at all, conjunctions are judged to be more assertable than conditionals. At the same time, while token $\mathrm{C}+$ conjunctions seem to be more assertable than token $\mathrm{C}+$ conditionals, type $\mathrm{C}+$ conjunctions are less assertable than type $\mathrm{C}+$ conditionals.

We performed analyses in R (R Core Team, 2016) using functions from Wilcox (2016) and the WRS2 package
(Mair, Schoenbrodt, \& Wilcox 2016). The robust analyses used $20 \%$ trimmed means. This difference between type and token is confirmed by significant 2-way interaction in a robust mixed ANOVA ('bwtrim' function) between the variables type/token and conditional/conjunction, both with an inferential connection $(\mathrm{C}+)(Q=111.74, p<.001)$ and without (C-) $(Q=68.11, p<.001)$. We thus conducted further statistical analyses separately for token and type materials.
Token A robust mixed ANOVA produced significant main effects of Sentence Type, $Q=485.34, p<.001$, and Connection, $Q=83.94, p<.001$, and a significant interaction, $Q=$ $77.98, p<.001$. Simple-effects analyses comprise robust t -tests. We compared the effect of sentence type separately for items with and without a connection using robust pairedsamples t-tests (the yuend function). When there was a connection, conjunctions were rated on average 2.11 higher than conditionals; this difference was significant, $t(26)=8.66$, $p<.001, r=.89$. When there was no connection, conjunctions were rated on average 4.94 higher than conditionals; this difference was significant, $t(35)=23.83, p<.001, r=.94$. We explored the effect of the connection for each type of sentence, using robust independent-samples t -tests (the 'yuen' function). For conditionals, ratings were on average 2.67 higher with a connection than without; this difference was significant, $t(43.78)=12.25, p<.001, r=.90$. For conjunctions, ratings were on average .16 higher without a connection than with; this difference was not significant, $t(57.79)=.80$, $p=.43, r=.11 .^{3}$

In sum, the token data showed that conjunctions were rated consistently higher than conditionals. Conditionals were rated higher with a connection; conjunctions nonsignificantly higher without one.

Type A robust mixed ANOVA produced a non-significant main effect of Sentence Type, $Q=1.79, p=.19$. The main effect of Connection was significant, $Q=40.21, p<.001$, as was the interaction, $Q=134.85, p<.001$. As above, simple effects of sentence type comprised robust paired-sample t -tests. With a connection, conditionals were rated on average 1.79 higher than conjunctions; this difference was significant, $t(35)=6.46, p<.001, r=.83$. Without a connection, conjunctions were rated on average 2.28 higher than conditionals; this difference was significant, $t(35)=9.20, p<.001$, $r=.87$. As above, simple effects of connection comprised robust independent-samples $t$-tests. For conditionals, ratings were on average 3.15 higher with a connection than without; this difference was significant, $t(65.41)=14.98, p<.001$, $r=.90$. For conjunctions, ratings were on average .92 higher without a connection than with one; this difference was significant, $t(68.26)=3.20, p=.002, r=.10$.

In sum, the type data showed that, when there was a connection, conditionals were rated higher than conjunctions. When there was no connection, conjunctions were rated

[^375]

Figure 2: Distribution of the responses to the 'assertability' question.
higher than conditionals. For conditionals, items with a connection were rated higher than items without; for conjunctions, the opposite was the case.

## Discussion

Our data clearly show that knowing that $p$ and $q$ are true is not sufficient for "If $p, q$ " to be assertable. The presence of an inferential connection between $p$ and $q$ is not sufficient either, yet it is necessary for a conditional to be assertable. However, the presence of a connection does not seem to affect the assertability of conjunctions in a similar way. In fact, conjunctions in which conjunct are inferentially connected tend to be rated lower than those without a connection. Our findings pose a problem for all theories of conditionals that treat the intuition that conditionals are about connections solely as a pragmatic aspect of their meaning. Our results undermine the standard pragmatic account of the oddity of missing link conditionals. On this account, asserting a TT conditional is a violation of the Maxim of Quantity, because when both $p$ and $q$ are known to be true, one is justified in asserting a stronger, more informative statement. That is, one should assert the conjunction of $p$ and $q$. As our data clearly show, when an inferential connection is present, generic conditionals are more
assertable than generic conjunctions which cannot be reconciled with the standard, Gricean account.

A Gricean explanation of these findings can follow two different paths: One can reject the most fundamental principles of Gricean pragmatics by denying that informativeness guides people's assertability judgements. Another, less costly, option is to rethink the semantics of conditionals and accept the possibility that the connection between antecedents and consequents is an important part of their meaning. On the latter approach, the connection should be taken as an additional piece of information conveyed by a conditional, but not by a conjunction. Our findings suggest that we need an account that renders conditionals more informative than conjunctions (on their standard, truth-functional interpretation). ${ }^{4}$ Neither Mental Models nor the suppositional account of conditional can follow the latter path, however. Johnson-Laird \& Byrne (2002, p. 651) deny that a relation between $p$ and $q$ is part of the core meaning of a conditional: the logic of a conditional on this interpretation is essentially the logic of

[^376]material implication. Although Johnson-Laird \& Byrne admit that content of the clauses of a conditional (semantic modulation) and contextual factors (pragmatic modulation) influence the interpretation of a conditional, the only thing that these mechanisms do is constrain the set of possibilities a speaker envisages when interpreting a sentence. On Mental Models theory, when $p$ and $q$ are known to be true, the interpretation of a conditional and the interpretation of a conjunction do not seem to be distinguishable at all. Apart from vague appeals at 'pragmatic modulations,' Mental Model theory has no way to explain our findings.

The data are no less problematic for the suppositional account. First of all, as observed earlier, none of the standard probabilistic measures of relevance is applicable when both clauses of a conditional are known to be true, if conditional probability is understood in accordance with Kolmogorov's axioms. Second, even if we grant the supporters of the probabilistic interpretation of a conditional that the relevance of $p$ for $q$, however it is formalised, is pragmatically implicated, this account does not have the means to explain the discrepancy between type and token TT conditionals.

Token conditionals are sentences such as "If you didn't water your plant, it dried up" or "If this book is hardcover, it is expensive." Although a hard cover $(p)$ is a good evidence that the book costs a lot $(q)$, i.e., one can infer $q$ from $p$ together with some general knowledge about the world, the conditional sounds strange to many respondents. In the same context, a generic conditional "If a book is hardcover, it is expensive" is evaluated as assertable. This discrepancy might be due to the fact that the specific antecedent, which refers to a particular book that is directly available to conversational partners, is considered a fact and hence, as suggested by Declerck \& Reed (2001, p. 2), is more difficult to process as a supposition from which one is to make an inference (cf. Elder \& Jaszczolt 2016 on the notion of remoteness). By contrast, the generic antecedent "a book is hardcover" requires an additional inferential step to be evaluated as true (if something is true about this book in front of us, it is also true about $a$ book), hence the evidence for the truth of the antecedent can be considered inferential and not direct.

Most fundamentally, however, our results suggest that an adequate account of the conditional and of reasoning with conditionals will have to engage more seriously with the circumstances in which conditionals can and cannot be used in everyday language.

# Cascading effect of context and competition on novel word learning 

Sarah C. Kucker (kuckers@uwosh.edu)<br>Aaron Bagley (baglea45@uwosh.edu)<br>The University of Wisconsin Oshkosh; Department of Psychology<br>800 Algoma Blvd; Oshkosh, WI 54901 USA

#### Abstract

Learning, especially in the case of language acquisition, is not an isolated process; there is ever-present competition between words and objects in the world. Such competition is known to play a critical role in learning. Namely, the amount and variability of competing items during word learning have been shown to change learning trajectories in young children learning new words. However, very little work has examined the interaction of competition amount, competition variability, and task demands in adults. The current study assesses adults' ability to map new word-referent pairs in varying amounts of competition and competitor variability. In addition, the effect of mapping context on retention was assessed. Results suggest that retention is weak in some cases and importantly, there are cascading effects of competitor variability in mapping on later retention of new words. Results are discussed in light of associative learning mechanisms and the implications of competition for learning.

Keywords: word learning; fast mapping; context; competition

## Introduction

Word learning always occurs in a context. New words are encountered in a conversation, new objects are alongside others on a shelf, and word-referent pairs are embedded in fleeting moments. Often, the referent for a word is not immediately clear. It is precisely this complexity and ambiguity that has puzzled researchers for decades - how do individuals, and young children in particular, correctly map a novel word to its referent amidst dozens of possible objects in the world around them? The last few decades of research have subsequently resulted in multiple pathways by which children overcome the problem of referential ambiguity to acquire new words and add them to their lexicon. We know that children appear to use their prior knowledge of objects (e.g. mutual exclusivity; Markman \& Wachtel, 1988), novelty (e.g. N3C; Mervis \& Bertrand, 1994), and social cues (Akhtar, Carpenter, \& Tomasello, 1996) to eliminate competitors and focus on the target. We know that the number of competitors present (Zosh, Brinster, \& Halberda, 2013) and the context in which objects are encountered (Horst, 2013) matter. And we know that as a child's vocabulary grows, so too does their performance in word learning tasks (Bion, Borovsky, \& Fernald, 2013). There has also been parallel research on how both adults (Alt \& Gutman, 2009; Greve, Cooper, \& Henson, 2014; Halberda, 2006; Warren \& Duff, 2014) and robots (Morse et al., 2015; Twomey, Morse, Cangelosi, \& Horst, 2016) acquire new words.

Most recently, there has been a further push to view word learning as a process that unfolds over multiple timescales instead of a one-shot learning episode (Kucker, McMurray, \& Samuelson, 2015). The initial mapping between a new word and its referent happens in real-time. This is an in-themoment process of comprehending "Where's the wif?" or "Get the dax." However, this initial association between the word and referent is often weak and transient. Over time and repetitions the word-referent association becomes honed and strengthened, partially by reinforcing the correct links but also by pruning away incorrect associations (McMurray, Horst, \& Samuelson, 2012). Regardless if it is children, adults, or robots, word learning requires real-time responses to interact with slower associative mechanisms. Successful long-term learning thus depends partially on the context in which the word-referent pair was initially encoded as well as the context in which it is stored and retrieved.

## Competition in Mapping

Across all work on word learning, there is one factor that is consistent - competition. Competition occurs between objects present in the world, between words in the lexicon, and between former knowledge and new. At times there exists a lot of competition, while at other times the competition is limited. Sometimes, the competing items that may be present are relevant and helpful (e.g. learning about forks while in the kitchen), and sometimes the competitors and context are not. In addition, the initial context in which a word is mapped to its referent can vary widely not just between people or words, but even across occurrences of a single word. That is, the word fork may be heard primarily in the kitchen, but occasionally could be used while outside. This competition and its variability have cascading effects on retrieval and retention of newly learned information.

One of the classic tests of word learning is Carey and Bartlett's (1978) study of "fast-mapping". Here, preschool children were presented with a novel word while in a classroom, surrounded by multiple people and objects and tested on their ability to accurately "Get the chromium tray, not the blue one". This referent selection task has been used for decades to test not just an individual's ability to map words and referents in ambiguous scenes, but also retain newly mapped word-referent pairs until a later time.

A critical part of the classic referent selection task is the presence of competition - in order to get the chromium tray, children had to decide against the blue tray and not pick up a cup or spoon. In many variations of the task, there is obviously competition between multiple items that may be present (e.g. tray vs. cup). Other versions of the task
highlight the competition between known items and novel (e.g. blue vs. chromium). And others try to eliminate direct competition by directly naming a single item. Regardless of the number or type of competitors, both children and adults are easily able to map a novel word to a novel referent in-the-moment (Horst, Scott, \& Pollard, 2009; Warren \& Duff, 2014; Greve, et al., 2014), becoming increasingly successful over development (Bion, Borovsky, \& Fernald, 2013). However, real-time eye-tracking behavior does suggest there are differences in mapping due to competition. For instance, when children and adults are presented with both a known and a novel object and hear a novel word, they reliably look to the competing known items before settling on the novel referent (Halberda, 2006). In addition, there is evidence that explicit selection of a competitor (in error) can still lead to later learning (Fitneva \& Christiansen, 2011). Thus, the simple presence of competitors can change even subtle selection behaviors and cognitive processing.

Furthermore, other work suggests that the details about how many competitors or the variability of the competitors also shift real-time processing, which has cascading effects on long-term learning. First, work with children suggests that the number of competitors present during mapping has a direct negative correlation on performance - fewer items seem to help mapping (Axelsson, Churchley, \& Horst, 2012), but more competitors benefit long-term learning (Zosh, et al., 2013). And, computational models of referent selection and retention propose that though more competition during mapping requires more cognitive processing, it also results in more opportunities for pruning away spurious word-referent links, thus allowing more honing in a single trial (McMurray, et al., 2012). This subsequently boosts retention (McMurray, Zhao, Kucker, \& Samuelson, 2013). In a recent study of adult word learning, encoding new words with competitors resulted in almost immediate lexical competition between the new word and known word. However, learning that occurred in an isolated, direct-naming context did not (Coutanche \& ThompsonSchill, 2014). Competitive initial learning also led to broader semantic networks days later. Taken together, the amount of competition influences real-time processing and has cascading effects on long-term retention.

In addition to the amount of competition present, the type of competition may also play a role. Specifically, the relevance and variability of competing known foil items interacts with new word-referent pairs. Recent work has demonstrated that young children often learn new words better when couched in a known context, such as when drawn from a category of objects they are familiar with (Borovsky, Ellis, Evans, \& Elman, 2016), or when an item is physically located in a related scene (Meints, Plunkett, Harris, \& Dimmock, 2004). It is also clear that both children and adults pay attention to competitors even if they are not the target. In some cases, children implicitly extract some minor representation or memory for competitors such that they are more likely to look at them later (Wojick, 2013). In other cases, adults recall semantic information about the
novel target, acquired while the target was presented in various scenarios (Alt \& Gutman, 2009). In addition, context diversity is more predictive of word knowledge in adults (and vocabulary acquisition in children) than simple frequency of occurrence (Adelman, Brown, \& Quesada, 2006; Hills, Maouene, Riordan, \& Smith, 2010). Put together, this suggest that the composition of, and specifically the relationship between, the competitors might matter not just for mapping, but also for retention.

## Competition in Retention

Generally, adults are considered to be good at learning new words, performing well above chance on laboratory tasks (Greve, et al., 2014). However, we also know that an individual's ability to retain newly learned words is reliant on a number of factors, such as the length of delay (Vlach \& Sandhofer, 2012; McGregor, 2014) and phonological neighbors (Tamminen \& Gaskell, 2008). Work with children has suggested that retention is also partially dependent on the number of competitors present during mapping (Zosh, et al., 2013), and the types of cues present during encoding (Capone \& McGregor, 2005). Furthermore, most work showing good retention with adults has thus far primarily used relatively easy task - pulling the target out of a three-item array. Thus, though adults are expected to be good at learning new words, it is likely that competition can still play a role. A recent study by Dautriche and Chemla (2014) found context effects in crosssituational learning where consistent repetition of competitors over the course of multiple blocks led to improvements in memory for both the broader context group and target. Learning here was tested through forcechoice selection of the target from four-item array. In another study, Warren and Duff (2014) tested retention after a zero competitor/ ostensive (direct) naming condition as well as a two-item referent selection condition. Critically, they looked at retention with both a three-alternative forcedchoice recognition test (3AFC) and free recall (recalling word-forms from test). Overall, typically developing adults selected the referent on the 3AFC test well above chance, near $65 \%$ correct, for both conditions. However, free recall varied between the mapping contexts - accuracy was higher for words learned directly without competitors than those with competition during mapping. That is, though context may influence initial encoding, the method for tapping retention is critical in assessing the robustness of the newly acquired word-referent pair.

Despite the lack of work on competition effects on the retention of new words, the evidence suggests that the associative learning processes of adults, like children, are highly variable and occur incrementally over multiple timescales (Kucker, et al., 2015). Such associative processing occurs over the lifespan and critically, some propose that the complex networks in which new words are learned are also linked with advances in other areas of cognition (Roembke, Wasserman, \& McMurray, 2016). Thus, the process of learning a single new word has
important implications for broader theories of associative learning and cognition.

## Current Study

Competition is widely accepted as highly relevant for word learning, but there is still much debate about how much competition is optimal and what effects initial competition has on long-term learning. Both the number and variability of competitors has been studied in word learning of young children (though with mixed results); much less work has been conducted in adults despite the fact that adults too, continue to learn new associations. In addition, the question of how adults learn simple associations (such as words) is at the crux of many computational models of learning and information processing (e.g. Regier, 2005; McMurray, et al., 2012). Thus, there is a gap in understanding both how an adult's real time processing changes across contexts and the impact the contexts have on their retention of new wordreferent associations. The current study fills this gap by combining word learning methods from work with children with the adult literature to test the impact of competition (amount and variability) on in-moment mapping, and the cascading effects mapping context has on retention. Furthermore, learning is assessed with two different methods to tap both weak associations that may be recognized in an array but not recalled as well as robust associations that can be easily recalled without cues.

## Methods

## Participants

A total of 149 adults participated. All individuals were monolingual English speakers and provided informed consent before participating. Individuals were recruited either through a current college course (receiving course credit), or through Amazon's MTurk (receiving \$1.75).

## Stimuli

Individuals saw a randomly selected subset of known and novel words and objects over the course of the experiment. Known items were drawn from pools of prototypical toys (book, ball, drum, block), kitchen utensils/tools (fork, spoon, bowl, cup), vehicles (car, boat, airplane, bike), clothing (shoe, hat, belt, purse), or furniture (chair, bed, lamp, clock). All images were previously normed by a separate set of adults to elicit their respective labels and be obvious members of their category. Novel items were drawn from a pool of unique items typically used in child word learning studies. These items were judged in prior studies to be highly unfamiliar and not easily named by most adults (Horst \& Hout, 2016). Novel words were legal words in English but had few or no known orthographic neighbors.

Table 1. Mapping conditions

| Condition | \# of <br> Comp <br> etitors | "Which is the cheem?" |
| :--- | :--- | :--- |
| OD none | 0 |  |

and all completed the entire study on-line in a single sitting. Conditions varied in the number of competitors present during initial mapping and the variability of competitors present (Table 1). The number of competitors varied from zero to four with the to-be-learned novel object present alongside no other items (ostensive definition trial; OD none), paired with two distinct known competitors ( 3 total items, alternative forced-choice trial; 3AFC), or paired with four distinct known competitors (5AFC) on each trial. Competitors also differed in their variability - competitor items were either variable, drawn from distinct known categories (vary), or clustered and drawn from the same category (same).

Each condition began with a mapping phase in which participants were initially exposed to novel word-referent pairs, followed by a retention phase in which they were tested on their memory for the word-referent pairs from mapping. During the mapping phase, participants were instructed to pay attention to a series of word-referent pairs presented on the screen. One each trial, a novel printed word was presented along with an image of a novel object. In the OD none ( 0 competitions) condition, no other items were present on the screen. In the 3 and 5 item conditions ( 3 AFC , 5AFC), 2 or 4 images of known items were respectively presented alongside the novel item. Items were presented equally spaced in a horizontal row with location randomized across trials. In each case, the participant had to click on the correct referent before proceeding to the next trial. Novel word-referent pairs were presented at least once (in the case of OD none) and no more than three times (for most AFC versions) over the course of all training trials (referred to as Novel Mapping trials). The 3AFC and 5AFC conditions also included filler/catch trials in which participants were asked to select one of the known items (referred to as Known Mapping trials). These were included both as catch trials and to draw the participants attention to the competitors in order to increase encoding of them. There were between 12 and 16 total mapping trials and each participant was trained on 4-5 novel words.

Immediately following the mapping phase, participants were tested for their comprehension and retention of the novel word-referent pairs. This was done via two methods free response recall and forces-choice (multiple choice) recognition. The free response retention trials asked participants to describe the referent for each of the novel words from mapping/training (e.g. "Describe the cheem"). Though prior work has asked participants to recall the wordform (thus testing phonological memory), here we ask for a description of the item to tap semantic-conceptual memory and thus allow a tighter connection to what is tested in the forced-choice trials. In addition, one current hypothesis is the semantic relationship (not names) between stimuli matters. In the forced-choice trials, participants were given one of the novel words from mapping and asked to select the correct referent from an array of all multiple novel objects from mapping. Words and objects for all phases were counter-balanced across conditions and participants.

## Results

Average percent correct for each participant on Known Mapping trials, Novel Mapping trials, Forced Choice (recognition) Retention, and Free Recall Retention were scored. Both Mapping trials and the Forced Choice Retention were calculated as percent of trials an individual correctly chose the target. Free Recall response was scored by 2-3 independent, blind coders who calculated a binomial score for each answer. If the written description was specific enough to uniquely identify the target object from the array of novels, it received a score of one. However, if the description was either too vague to refer to a single specific item or if it described a foil object, it received a score of zero. This coding scheme thus gave participants credit for a variety of responses (e.g. an overall description or a single unique feature) as it eliminated possible referents systematically based on the information given. For instance, if the participant responded "the blue flat thing", and there was only one novel item presented that was blue (and it was the correct answer), they would receive a one. If, however, a participant responded with "the round one", and multiple novel objects were spherical, then they would receive a score of zero. Only scores of one were counted as correct in calculating overall performance. All coding was conducted as a consensus of scores across two blind coders with additional 1-2 coders settling all discrepancies. Responses that required more than four coders to come to a consensus were thrown out.

First, performance on mapping across all conditions was analyzed. Each condition was compared against chance and each trial type was analyzed with a two-way ANOVA of performance on Number of Competitors (3AFC vs. 5AFC) by Competitor Type (vary vs. same). Unsurprisingly, adults are very good at the Known item filler trials on all conditions, selecting the known target item at nearly ceiling levels (see Figure 1). As suspected, there was no difference between conditions on these trials (Known Mapping; $\mathrm{F}(1,149)=.806, p=.493, \mathfrak{\eta}^{2}=.016$ ). Adults were also well

Figure 1. Performance on mapping and retention
above chance in all conditions at selecting the novel target (Novel Mapping). However, there was a main effect Type of Competitors, $\mathrm{F}(1,178)=9.027, p=.003, \eta^{2}=.048$, with adults performing significantly better when the competing items varied than when competitors were from the same category. There was no effect of competitor amount. This suggests that despite a very robust lexicon and a clear ability to find the referent when asked, adults real-time mapping of novel words may be influenced by subtle changes in the type of items present, regardless of the number of items.

Performance on retention was then analyzed. Most subjects were asked both a free recall retention question followed by a forced-choice recognition test. Due to a programming error, 29 subjects in the 3AFC same condition only answered the forced-choice test and 24 subjects in the 3 varies condition were asked the forced-choice first followed by free recall. ${ }^{1}$ In addition to testing performance against chance, a repeated measures ANOVA of Retention Test Type (forced-choice vs. free recall) on Number of Competitors (3AFC vs. 5AFC) by Competitor Type (vary vs. same) was run. First, adults were well above chance in all conditions on the forced-choice retention, though importantly, not at ceiling. Chance in both cases was set at $20 \%$ as presumably, adults were recalling one of the five just-learned items. On free recall, however, performance was much more mixed with performance in the vary conditions at or near chance, 3AFC: $\mathfrak{t}(45)=1.401, p=.168$; 5AFC: $\mathrm{t}(28)=2.042, p=.051$. In addition, there was a significant ANOVA of Retention for Type of Retention, Number of Competitors and Competitor Type, $\mathrm{F}(1,216)=5.865, \quad p=.016, \quad \eta^{2}=.026$, with a significant Competitor Type main effect, $\mathrm{F}(1,216)=13.286, p<.001$, $\mathrm{y}^{2}=.058$, and Test Type by Competitor Type interaction, $\mathrm{F}(1,199)=5.655, p=.018, \mathrm{n}^{2}=.028$. Thus, the variability of the context matters for mapping and has cascading effects on retention, especially when a more rigorous test of recall is used.

[^377]
## Discussion

Overall, the results show a unique pattern of responding for both in-the-moment mapping as well as retention. Though the type of competitors appears to matter overall for Novel Mapping, its effect on retention is confounded by the type of test, showing differential affects for forced-choice vs. free response retention. This could mean that the processes that support real time processing may not be the same mechanisms driving retention. Alternatively, it could suggest that associative learning is a complicated interaction of multiple factors and tasks and there are different ways of tapping knowledge to reveal those processes in different ways. That is, a free response retention test has no other items present. Thus, in order to respond, an individual has to have a robust memory to retrieve, but also may grasp onto any cues they can, such as vague memories from when they initially learned the word (Coutanche \& Thompson-Schill, 2014). Initial context that had more helpful cues (similar, same competitor condition) would give more relevant aids to retrieval, thus boosting performance.

Not only does the type of test matter, but subtle shifts in learning that are not always apparent with one test can be revealed with another. Specifically, the different retention tests give hints to the strength of the word-referent associations formed. Forced choice retention tests show only a slight effect of competitor variability, however, free recall for those exact same items is influenced in a different way by the variability of competitors from the previous mapping trials - variable competitors are equivalent to the Ostensive Naming, zero competitors condition on forcedchoice retention, (though lower than same competitor condition) but at chance when tested with free recall (at which point all other conditions are above chance).

These results also speak to the nature of the underlying association. During mapping, the initial association is weak, fragile, and likely has many spurious connections. More competitors, especially competitors that are vastly different and unique, take longer to process, and thus initial mapping is less successful. In some prior cases, these "harder" initial encoding scenarios have led to more robust learning because they require more processing (Vlach \& Sandhofer, 2014). If we only test learning through a forced choice recognition test, that is precisely what we see - above chance learning across the board. However, the free response retention reveals that the variable groups (the same groups who were relatively poorer on Novel Mapping) are at chance for recalling the word-referent link. This suggests that the wordreferent link that is being built during mapping has clearly been encoded and withstands weak tests of its viability, but has a long way to go before it is fully integrated into the lexicon.

At its core, word learning is a form of associative learning. As such, the results of the current study may suggest that domain-general associative mechanisms are influenced by the context and competition. Importantly, associations are constantly in flux and robust links are not guaranteed, even in supposedly "easy" cases of learning.

That means that the imperfect retention seen in the current study is not evidence for a lack of learning, but rather as an in-progress process which will continue to be strengthened over time. The type of competitive mechanism employed in these associative learning situations is not just beneficial for a single moment as demonstrated here, but likely also beneficial for the $2^{\text {nd }}, 3^{\text {rd }}, 4^{\text {th }}$ and all future encounters of the word (Benitez, Yurovsky, \& Smith, 2016; Dautriche \& Chemla, 2014; Yurovsky \& Yu, \& Smith, 2013). That is, learning is reliant not just on one-to-one links, but rather is couched within a larger network which has a direct influence on the development of a single association, which in turn may alter learning future associations.

As a whole, the current study examines two critical elements to associative learning -1 ) how does the amount and variability of context shape real-time processing, and 2) how does the amount and variability of the competitors shape the refinement of those associations over time. Results suggest that there is not a single pathway to mapping or retaining, but rather, like most cognitive processes, it is a complicated interaction.

#### Abstract

Explaining how intelligent systems come to embody knowledge of deductive concepts through inductive learning is a fundamental challenge of both cognitive science and artificial intelligence. We address this challenge by exploring how a deep reinforcement learning agent, occupying a setting similar to those encountered by early-stage mathematical concept learners, comes to represent ideas such as rotation and translation. We first train a Dueling Deep Q-Network on a shape sorting task requiring implicit knowledge of geometric properties, then we query this network with classification and preference selection tasks. We demonstrate that scalar reinforcement provides sufficient signal to learn representations of shape categories. After training, the model shows a preference for more symmetric shapes, which it can sort more quickly than less symmetric shapes, supporting the view symmetry preferences may be acquired from goal-directed experience.

## Introduction

Mathematical concepts are formally definable and may be deduced from of axioms. In contrast, most human mental representations, such as visual categories and language concepts, resist precise definitions and only come to be known after considerable inductive experience. Similarly, deep neural networks have achieved human-level or state-of-the-art performance on tasks such as object recognition (He, Zhang, Ren, \& Sun, 2016), game playing (Mnih et al., 2015; Silver et al., 2016), and speech generation (van den Oord et al., 2016) by learning distributed (rather than symbolic) representations through inductive (rather than deductive) training. The empirical success of human learners and artificial neural networks contrasts sharply with the description of mathematical concepts as abstract, formal, and universal ideals.

A growing literature argues that the developmental details of embodied agents are not mere nuisance variables associated with the learning and deployment of mathematical concepts, but are necessary tools in facilitating cognition. For instance, some work suggests that the use of hand gestures aids learning by grounding the meaning of abstract principles such as continuity and magnitude in the willful motions of the body (Goldin-Meadow, Cook, \& Mitchell, 2009; Marghetis \& Núnez, 2013; Marghetis, Núñez, \& Bergen, 2014). The tuning of low-level responses of the visual system has also been associated with algebraic expertise. Marghetis, Landy, and Goldstone (2016) argue that a process of "regimented perception", implemented by object-based attention,

Figure 1: The top panels show example frames from the shape sorting environment. The blue cursor indicates grabbing, and the green cursor is not grabbing. The bottom panel shows examples of each shape in isolation: Hexagon (Hex.), Equilateral Triangle (E. Tri.), Trapezoid (Trap.), Square, and Right Triangle (R. Tri.).
lets viewers parse algebraic notation in such a way that makes salient its hierarchical structure, thus offloading much of the work of calculation from high-level cognition to perception. Taken together, this work suggests that for all its formality, mathematics is still an evolutionarily recent phenomenon, and in its comprehension, one marshals bodily and neural resources adapted for other purposes.

This account dovetails nicely with the Parallel Distributed Processing approach (Rogers \& McClelland, 2014), or more recently, advances in deep learning. Just as embodied cognition challenges the primacy of symbolic representations in mental processes, deep learning has been used to overcome a number of problems once thought solvable only through the manipulation of compositional tokens or formal logic. For example, the "Differentiable Neural Computer" of Graves et al. (2016) can answer queries involving textual and hierarchical reasoning, relying solely on a learned, neural memory device. Furthermore, these models learn "end-to-end", adjusting connection strengths between stimulus-facing neurons based on error signals propagated down from higher level de-
cisions (Mnih et al., 2015), much as Marghetis et al. (2016) argue that pursuing algebraic skills re-tunes the visual system. Despite these connections to the embodied approach in mathematical cognition, we are not aware of major work exploring how deep neural networks capture mathematical, and in particular geometric intuitions through a goal-driven, learning process of perception and actuation.

This paper provides a proof of concept and an exploratory analysis. We demonstrate that a domain-agnostic learning algorithm is able to represent geometric concepts that are only implicitly coded in its training task's structure. In particular, we develop a simulated shape sorting toy similar to those enjoyed by young children. Such a learning environment tasks an agent to carry out sequences of actions that require knowledge about some geometric properties (whether implicit or explicit) to maximize reward. We train an agent to expertise in this task, then evaluate its learned behavior and representation of shape categories.

Our primary contribution has been to show that reinforcement learning (RL) is sufficient to train a convolutional neural network agent to perform a shape sorting task expertly. This training leads to the development of shape-specific representations at the top convolutional layer, which feeds into network layers that compute value. We also found that our model exhibited a preference for objects with higher orders of symmetry, supporting the view that experience, rather than an innate symmetry bias, may be the basis for similar similarity preferences in both human infant and primate studies (Bornstein, Ferdinandsen, Gross, 1981; McMahon Olson, 2007). We also make available the source code for the pixels-to-actions shape-sorting task described in this paper.

## Approach

Our goal is to demonstrate that deep learning may provide a computational paradigm for building on psychological theory and generating new hypotheses about geometric concept acquisition. Blocks worlds have previously been used to study and model intuitive physics (Hamrick, Battaglia, \& Tenenbaum, 2011; Zhang, Wu, Zhang, Freeman, \& Tenenbaum, 2016). Although such environments feature a finite set of discrete entities adhering to rules of interaction, their broad properties and questions of investigation tend to differ. For instance, these environments simulate physical properties, like velocity. In contrast, we seek to understand abstract properties, such as shape and symmetry, and we thus introduce an environment with few physical constraints. As such, the experimental setup can be decomposed into an environment and learning agent, which we represent with a neural network.

## Environment

During the initial training stage of our neural network, the model interacts with a simulated shape sorting toy (see Figure 1), which may be interpreted as a finite horizon Markov Decision Process (MDP) with deterministic transitions and high-dimensional states (Kochenderfer \& Reynolds, 2015).

Environment interactions are divided into trials, which consist of at most 500 timesteps. At timestep $t$, the environment emits an image $s_{t} \in \mathbb{R}^{84 \times 84}$ depicting some combination of two types of objects: blocks and holes. Every object in $s_{t}$ is characterized by an orientation and a position vector, which remain fixed for holes, but are subject to change for blocks. Each object is also characterized by a convex, 2D shape drawn from the set $X$, which includes squares, trapezoids, equilateral triangles, right triangles, and hexagons. Once a shape is chosen for an object, it is held constant throughout the course of a trial. The image $s_{t}$ also includes a cursor used by an agent to manipulate the position and orientation of blocks.

The initial frame $s_{0}$ includes three blocks whose shape assignments $X_{b}$ are drawn uniformly with replacement from $X$ with randomized positions and orientations. Four holes with random orientations are also given shape assignments $X_{h}$ drawn without replacement from $X$. A constraint $X_{b} \subset X_{h}$ ensures that no block will be generated without a corresponding hole. The positions for holes are also randomized at the beginning of each trial, but only drawn from four possible, equidistant locations. This second constraint ensures that holes never overlap. In contrast, blocks may overlap (sometimes completely) but are manipulable, and can be disentangled by an agent.

Given $s_{t}$, an agent responds with action $a_{t}$ in $\mathcal{A}$, which includes: up, down, left, right movements, toggle grab, rotate clockwise or counterclockwise, or wait. Rotations are $30^{\circ}$ and a single cardinal movement covers $10 \%$ of the height or width of $s_{t}$. If the grab is active, blocks will "stick" to the cursor, changing position and orientation with the cursor. If the grab is inactive, movement and rotation actions do not influence the blocks.

The environment uses a reward function that assigns a small reward when the cursor grabs a block $r_{1}=0.001$, a small penalty $-r_{1}$ when the cursor contacts the border of the screen, a large reward $r_{2}=1.0$ when the cursor fits a block to a corresponding hole or completes a trial. A fit occurs when the cursor "releases" a block over a hole, and the block's vertex set is contained by the hole's vertex set. If a fit occurs, the block disappears and will not return for the rest of the trial.

## Agent

We desire a model of a learning agent that is (1) Deep, or capable of expressing multiple, hierarchical representations that could feasibly embody geometric invariants, given raw pixels, (2) Psychologically plausible, or sufficiently similar to animal decision making to suggest research directions for cognitive science, and (3) Powerful enough to solve the nontrivial MDP described in the previous section. The Deep QNetwork (DQN) (Mnih et al., 2015) is an attractive option that can accommodate these considerations.

DQN has attained state-of-the-art results on similar tasks that include discrete action spaces and high-dimensional state spaces. Sharing many architectural properties with convolutional neural networks, it learns a succession of hidden rep-

Figure 2: The Dueling Deep-Q Network architecture and the dimensionality of each layer. Boxed layers are involved in representation, output layers are involved in actuation. Dotted lines denote scalar-vector broadcasting that merge value and advantage streams. We use the same filter sizes and strides as Wang et al. (2016)
resentations that can be visualized and interpreted as an abstraction hierarchy (Zeiler \& Fergus, 2014). Furthermore, DQN features some desiderata as a model of animal decision making. A prioritized replay pool has been compared to hippocampal learning mechanisms (McClelland, McNaughton, \& O'Reilly, 1995), and the architecture is trained using temporal difference (TD) learning, which has been shown to underpin some forms of animal learning (Shah, 2012).

TD learning is here accomplished by minimizing the adaptive loss function

$$
\begin{equation*}
L_{i}\left(\theta_{i}\right)=\mathbb{E}_{\left(s, a, r, s^{\prime}\right) \sim D}\left[\left(y_{i}-Q\left(s, a ; \theta_{i}\right)\right)^{2}\right] \tag{1}
\end{equation*}
$$

with target value

$$
\begin{equation*}
y_{i}=r+\underset{a^{\prime}}{\gamma \max ^{\prime}} Q\left(s^{\prime}, a^{\prime} ; \theta_{i}^{-}\right) \tag{2}
\end{equation*}
$$

State-action-reward sequences ( $s, a, r, s^{\prime}$ ) observed during environment interactions are drawn from a replay buffer $D$ and used as training samples. $Q\left(s, a ; \theta_{i}\right)$ represents the sum of discounted future rewards if action $a$ is taken from state $s$ and is estimated at epoch $i$ by a DQN parameterized by $\theta_{i}$. Updating the model using estimates from a target network parameterized by $\theta_{i}{ }^{-}$has been shown to improve the stability of training (Mnih et al., 2015; Wang et al., 2016). A policy can then be induced from the DQN by selecting actions maximizing $Q\left(s, a ; \theta_{i}\right)$ with probability $\varepsilon$ and otherwise selecting exploratory, random actions.

In this work, $Q\left(s, a ; \theta_{i}\right)$ is represented by a Dueling Deep Q-Network (DDQN) which is subject to the same TD learning paradigm as DQN, but features a different architecture (Wang et al., 2016), shown in Figure 2. ${ }^{1}$ DDQN follows its convolutional layers with two disjoint, fully-connected streams that represent the scalar value of a state $V(s)$ and the advantage $A(s, a)=Q(s, a)-V(s)$ of a state-action pair

[^378]separately. These representations are merged with the broadcasting rule
\[

$$
\begin{array}{r}
Q(s, a ; \theta, \alpha, \beta)= \\
V(s ; \theta, \beta)+A(s, a ; \theta, \alpha)-\frac{1}{|\mathcal{A}|} \sum_{a^{\prime}} A\left(s, a^{\prime} ; \theta, \alpha\right) \tag{3}
\end{array}
$$
\]

where $\theta, \alpha$, and $\beta$ parameterize the convolutional, advantage, and value sub-networks respectively. DDQN has been shown to improve the state-of-the-art beyond the performance of DQN and has some favorable properties as a neurobiological model, as it extends to deep neural networks the advantage learning paradigm, which has been shown to correlate with striatal neural activity during instrumental learning tasks (O’Doherty et al., 2004).

## Learned Behavior

We trained our agent to complete the shape sorting task over the course of one week on a single GeForce GTX 980 graphics processing unit. It completed approximately 480,000 trials consisting of at most 500 timesteps each. After training, the agent completed two experimental tasks consisting of 50,000 trials. Although the agent trained using $\varepsilon$-greedy exploration with $\varepsilon=0.1$, testing tasks were performed using a pure greedy policy. On both experimental tasks, we found that the agent adopted the strategy of performing translation actions early in the trial, followed by rotation actions once the block was in place over the correct hole.

Single Block Performance. One block per trial was drawn from $X_{b}$ and initialized at a random position with four holes from which to choose. The agent's cursor was initialized at the center of the screen. Each trial ended when the agent fit the block to the appropriate hole, attempted to fit the block to an incorrect hole, or exceeded 500 timesteps. Incorrect fits and time outs together accounted for less than $4 \%$ of the total number of trials, with the vast majority of failed trials resulting from time outs.

Table 1 demonstrates the agent's efficiency at the task on the trials it successfully completed, in addition to the estimated value computed by the network upon first grabbing a block. Although the agent performed nearly optimally on all shapes, we found that the network assigned higher estimated value for shapes with greater symmetry (which also corresponds the minimum number of steps needed to fit the block to a hole). However, although the right triangle and trapezoid share the same symmetry order, the trapezoid is assigned slightly higher value.

Shape Preference. Observing that our model estimated higher value for some shapes over others, we tested to see whether the agent demonstrated preferences in a twoalternative forced choice. In this experiment, two blocks belonging to different shape categories were generated and placed equidistantly to corresponding holes. Trials terminated when the agent selected a "winner" by releasing a held

Table 1: Agent's performance on single-block trials, including value estimated by layer Val., and average number of steps needed to complete the trial against average number of steps actually taken by the agent, per each shape category.

| Shape | Value | Min. Steps | Act. Steps | Ratio |
| :--- | :--- | :--- | :--- | :--- |
| Hex. | 0.70 | $10.74 \pm(3.7)$ | $11.83 \pm(4.0)$ | 0.91 |
| Square | 0.67 | $11.37 \pm(3.8)$ | $12.57 \pm(4.1)$ | 0.91 |
| E. Tri. | 0.64 | $11.76 \pm(3.9)$ | $12.90 \pm(4.1)$ | 0.91 |
| Trap. | 0.57 | $13.73 \pm(4.2)$ | $15.06 \pm(4.7)$ | 0.91 |
| R. Tri. | 0.55 | $13.66 \pm(4.2)$ | $15.38 \pm(4.8)$ | 0.89 |

Figure 3: Each cell displays the fraction of choices between two shapes in which the shape on the $x$-axis was chosen. Marginal probabilities of choosing a given shape are shown above.
block over a corresponding hole. We observed a slight bias such that the policy selected the block appearing on the right hand side of the screen $58.65 \%$ of the time, but controlled for this effect by randomizing block position each trial.

The results shown in Figure 3 accord with the findings from the single block experiment. Blocks appear to be preferred on the basis of the number of steps needed to achieve a fit, which is in turn determined by their symmetry order. However, the trapezoid is again preferred to the right triangle, despite the fact that both blocks are equally symmetric. We explore a possible explanation for this result in the next section.

## Learned Representations

To gain insight on the agent's elicited behavior, we treat the network as a feature extractor and use classification techniques to explore how it internally represents shape categories in different layers. Within the context of computational neuroscience, linear classifiers have been used to decode information about categorical stimuli from neural responses (Naselaris, Kay, Nishimoto, \& Gallant, 2011). We adopt a
similar approach. Intuitively, because neural networks are universal function approximators (Hornik, Stinchcombe, \& White, 1989), the activation vectors of a well-tuned network corresponding to different categories should be discriminable up to a linear transformation. As such, we assess the classification accuracy of a Support Vector Machine (SVM) trained on encodings from different layers of the DDQN.

Our SVM implementation comes from the open source library, scikit-learn (Buitinck et al., 2013) and makes use of a linear kernel $K\left(x, x^{\prime}\right)=x^{\top} x^{\prime}$. Multiway classification is achieved using a "one-versus-all" scheme, such that for $n$ classes, $n$ separate binary classifiers are trained to discriminate its corresponding class from examples belonging to other categories. The final classification is made by the model that makes its predictions with the largest margin.

## Dataset

One might argue that shape representations in the network depend heavily on scene context. For example, when a scene contains multiple blocks, it may not be useful to encode any information about shape identity until the cursor has taken hold of a single block, as only then must it make a decision contingent on the identity of the shape. To test this hypothesis, we also repeat the discrimination experiment for conditions involving an absent cursor, and conditions in which the cursor is visibly grabbing the block.

We generated our training and validation image sets by enumerating all the possible positions and orientations for a single block, subject to the environment's translation and rotation step sizes, and excluding duplicate shape orientations resulting from symmetry. Each combination was used to produce a set of 100 unique examples by randomly permuting the background holes. The resulting data set consisted of 81,000 images, which we shuffled and partitioned into training and validation sets using a $25-75$ split. The data sets including a cursor were generated by the same process.

Each frame $s_{i}$ was replicated four times, producing an $84 \times 84 \times 4$ tensor, which was then encoded as an activation vector $z_{i}{ }^{j}$ at the $j$ th layer of the DDQN. Because the size of the layers differ greatly, we use principal component analysis (PCA) to enforce that all activation vectors have 300 dimensions. To establish a classification baseline, we repeat the same analysis on encodings produced by an untrained, randomly initialized neural network with the same architecture. We do not standardize encodings prior to classification or dimensionality reduction, as all input variables are ReLU-gated activations and are thus measured on the same scale.

## Results

Results shown in Figure 4 support the view that shape information is scene dependent, albeit slightly. At the level of Conv3 and beyond, classification accuracy was consistently greater by about $3 \%$ when the cursor was grabbing the block. Figure 5 visualizes the activation vectors in both conditions, and suggests that the categories become better separated during a grab. Interestingly, these results contradict the view

Figure 4: Average validation accuracy of the SVM. The top plot shows accuracy per encoding layer, with baseline accuracy on encodings produced by a DDQN with random weights. The bottom plot shows classification confusion on the "Grabbing" condition at Conv3 in the trained network.
that shape information plays a major role in the directions of greatest variance in higher layers. Whereas the classifiers achieve above $70 \%$ accuracy on frames encoded by Conv3, upstream encodings from $A d v$. and Val., were discriminable only about $45 \%$ of the time, dropping even below Convl and Conv2.
The most significant misclassifications are shown to be between the equilateral triangle and trapezoid, whereas the most easily discriminable shapes were the hexagon and square. These misclassifications may explain the preference for trapezoid blocks over right triangles, despite their similar orders of symmetry, as the network seems to "confuse" trapezoids with the easier triangle shape, whereas the right triangle is easy to classify as a difficult block.

## Conclusions

Learning mechanisms and computational principles underlying mathematical cognition are not well understood. However, deep neural networks provide opportunities for exploring this direction of inquiry. We hypothesized that reinforcement learning, which incorporates active probing of an environment, serves as a sufficient training signal for learning many geometric properties embodied implicitly in an interactive shape sorting task.

Figure 5: A sample of 2,500 encodings extracted from Conv3. Linear Discriminant Analysis was used to project the 300dimensional vectors onto a subspace in which the classes are well-separated. The separation is more clear when the cursor is grabbing the block.

On a representational level, we showed that shape identity can be recovered from the network's hidden layers using linear classifiers and that this information is more strongly encoded in later convolutional layers than in the final hidden layers needed to valuate states and possible actions. Recent work suggests an analogy between the hierarchical structure of convolutional neural networks and the hierarchical structure of the visual system (Yamins et al., 2014). If this analogy is to be taken seriously, we should predict that despite their simplicity, geometric forms may find representation in later visual areas when tied to one's goals, as when playing with a shape sorter or interpreting mathematical diagrams on an exam.

On a behavioral level, we found also that a preference for symmetric blocks emerged as a consequence of their ease of fitting. Past work indicates that a preference for symmetric shapes exists among both monkeys (McMahon \& Olson, 2007) and human beings, but emerges only later in development (Bornstein, Ferdinandsen, \& Gross, 1981). Bornstein et al. (1981) in particular suggest that this preference, which favors vertical over horizonal symmetry, arises not from the information redundancy present in such figures, but from their adaptive value. Symmetrical figures tend to be animate, and can thus act as adversaries or allies in an organism's pursuit of goals. In our domain as well, we found that a block's degree of symmetry influences a learning agent's discounted sum of expected rewards. This result further supports the adaptive view of symmetry preference over the redundancy view, and implies a number of testable predictions for future work.

Follow up studies should investigate whether children trained to play with shape sorters prefer different blocks on the basis of their symmetry properties, and if so, if this preference can be modulated by increasing the stakes of the task, whether by providing greater rewards or less time to react. Further simulation work should also explore the relationship
between symmetry and visual similarity. Despite both being completely asymmetric, we found that trapezoids were strongly preferred to right triangles, as they are visually closer to equilateral triangles. An experiment in which "adversarial" shapes attempt to look easier to fit than they really are may demonstrate how the constraints of perception (imposed by the visual similarity between blocks) and the constraints of actuation (imposed by the reward signal, or task) must be mutually satisfied in embodied, geometric concept acquisition.

#### Abstract

We propose causal agency models for representing and reasoning about ethical dilemmas. We find that ethical dilemmas, although they appear similar on the surface, differ in their formal structure. Based on their structural properties, as identified by the causal agency models, we cluster a set of dilemmas in Type 1 and Type 2 dilemmas. We observe that for Type 1 dilemmas but not for Type 2 dilemmas a utilitarian action does not dominate the possibility of refraining from action thereby constituting a conflict. Hence, we hypothesize, based on the model, that Type 1 dilemmas are perceived as more difficult than Type 2 dilemmas by human reasoners. A behavioral study where participants rated the difficulty of dilemmas supports the models' predictions.

## Introduction

Currently, we experience a hot debate on moral reasoning and artificial intelligence (AI). In one respect, the discussion is about how to apply AI technology morally. In another respect, there is a requirement to enable AI technology itself to make moral decisions. Fields of application are self-driving cars (Bonnefon, Shariff, \& Rahwan, 2016), robots navigating in social environments (Lindner, 2015), and even robots that give moral advice (Lindner \& Bentzen, 2017). As a consequence, new research areas such as machine ethics (Allen, Wallach, \& Smit, 2006) and moral human-robot interaction (Malle, Scheutz, Arnold, Voiklis, \& Cusimano, 2015) arise.

To address the requirement for autonomous moral decision making, we recently introduced a software library for modeling hybrid ethical reasoning agents (short: HERA) ${ }^{1}$ (Lindner \& Bentzen, 2017). The goal of the HERA project is to provide theoretically well-founded and practically usable logicbased machine ethics tools for implementation in artificial moral agents such as (social) robots and software bots. To align human moral reasoning with moral reasoning by machines, our development of formal models and algorithms is informed by moral psychology and moral philosophy. We aim for the integration of various theories about human moral development, moral reasoning, and ethics.

There are several approaches to explain human moral reasoning. Kohlberg (1984), whose approach is based on Piaget's "genetic epistemology" claimed that individuals are passing through six invariant and universal stages in the development of moral reasoning. Reaching the next stage rep-

[^379]resents a qualitative advance in the ability to make consistent and differentiated judgments concerning moral norms and principles. Conversely, the theory of moral reasoning advocated by Mikhail (2007) assumes that there is moral grammar triggering certain moral judgments. He hypothesizes two rules for the grammar: the norm prohibiting intentional battery as a means, and the norm of double effect valuating battery as side effect. The research by Greene, Sommerville, Nystrom, Darley, and Cohen (2001); Haidt (2001) claims a prevalence of emotionally based moral intuition. Greene and Haidt (2002) are moving away from moral reasoning tending towards moral judgments caused by immediate affective intuitions and emotions. Greene et al. (2001) advanced the dual process model of moral judgment. They assume competitive moral subsystems in the brain resp. moral reasoning that is influenced by the mutual interaction and competition between two distinct psychological systems: (1) the emotional, intuitive, deontological judgment system and (2) the rational, calculated, utilitarian judgment system.

Throughout the literature, various hypothetical moral dilemmas are used to investigate questions concerning human morality, moral reasoning and moral judgments. We will make use of four dilemmas:

1. Runaway Trolley Dilemma A runaway trolley is about to run over and kill five people. If a bystander throws a switch then the trolley will turn onto a sidetrack, where it will kill only one person.
2. Pregnancy Dilemma A pregnant woman is about to give birth to her triplets. If the doctors treat the woman then her triplets will live, but she will die. Otherwise, the triplets will die, but the life of the pregnant women will be saved.
3. Boat Dilemma A boat is about to sink because of overweight. If the crew is told to throw the biggest person into the sea then the boat will not sink and the other three passengers will be saved (but the big person will die).
4. Hijacked Airplane Dilemma An airplane was hijacked by terrorists, and the terrorists threaten to crash the airplane against a populated area on the ground. If the military shoots the airplane the passengers will die but the airplane will crash in a deserted area thus not harming anyone else.

Several ways of classifying dilemmas and different moral reasoners have been proposed: Greene, Nystrom, Engell,

Darley, and Cohen (2004) differentiate between personal dilemmas and impersonal dilemmas. Among subjects, commonly more deontological judgments are produced with personal dilemmas, while impersonal dilemmas commonly produce consequentialist judgments (Moll \& de Oliveira-Souza, 2007). Crockett (2013) proposes a model-based system for consequentialist reasoning: The reasoner evaluates the best outcome of an action by starting from the current action and searching through a decision tree. In the model-free evaluation, which is associated with deontological reasoning, the forward searching is not activated. Shou and Song (2015) found that most of their subjects, irrespective of whether they chose a deontological decision or a consequentialist decision, evaluated consequences when information about outcome probabilities was provided. Wiegmann and Waldmann (2014) propose that the moral dilemmas' underlying causal structure supports moral intuition and thus is an important factor for the moral judgments humans make.

Thus, we observe that research has been focused on the effects of content and structure of moral dilemmas on human moral judgments. Our research focus is on moral complexity and adds evidence for how structural properties of moral dilemmas affect their perceived difficulty. The paper is structured as follows: First, we introduce causal agency models as a tool for representing moral dilemmas in terms of causes and utilities. Second, we define ethical principles within this framework. Third, the four aforementioned moral dilemmas are modeled using causal agency models. Based on structural commonalities and differences of these models, we distinguish two dilemma types, which we term Type 1 and Type 2 dilemmas. We hypothesize that Type 1 dilemmas are more difficult to solve for humans than Type 2 dilemmas. Fourth, we present an empirical study which shows that our model predicts human ratings about the perceived difficulty for the two types of moral dilemmas.

## Causal Agency Models

Ethical principles can be modeled as specifications of moral permissibility in causal agency models. Causal agency models are extensions of causal models that are used for counterfactual reasoning about causality, responsibility, blame, and related concepts (Halpern, 2016). In our HERA framework, an ethical principle is represented as a logical formula whose truth determines which actions are permissible according to the principle and which are not. Actions and their consequences are modeled as directed acyclic graphs showing causal influence. At the root of the graph will be actions and other independent variables influencing consequences further down the graph. Boolean structural equations capture all the information about the causal relationship between variables. For instance, to model that the trolley from the Runway Trolley Dilemma will turn onto a sidetrack when the bystander throws the switch, we may write the boolean structural equation turn $:=$ throw. The boolean variable turn will be true in the model whenever the boolean variable throw is true in the
model. The set of boolean structural equations in a model is called a causal mechanism. The truth assignment of the root node of the graph is called a world or an option. Formally, we define causal agency models as follows:

## Definition 1 (Causal Agency Models)

A (boolean) causal agency model, $M$, is a tuple $\langle U=A \cup$ $B, C, F, u, W\rangle$, where, $A=\left\{a_{1}, \ldots, a_{m}\right\}$ is a nonempty finite set of propositional variables called the actions. $B=\left\{b_{1}, \ldots, b_{k}\right\}$ is a (possibly empty) finite set of propositional variables called the background variables. Together the actions and background variables are the exogenous variables as defined above. $C=\left\{c_{1}, \ldots, c_{n}\right\}$ is a finite (possibly empty) set of propositional variables called the endogenous variables. $F$ is a causal mechanism explained above. $u:$ literals $\rightarrow \mathbb{Z}$ is a utility function assigning an integer value to each literal. W is a set of boolean interpretations of $(A \cup B)$.

We assume some familiarity on the part of the reader with classical propositional logic (and $(\wedge)$, or $(\vee)$, not $(\neg)$, and so on) and of truth functional semantics. A formula containing variables such as $\left(c_{1} \wedge a_{1}\right)$, is intended to mean that consequence $c_{1}$ and action $a_{1}$ both obtain. We write $M, w_{i}=$ $\left(c_{1} \wedge a_{1}\right)$ for $\left(c_{1} \wedge a_{1}\right)$ is true with option $w_{i}$ (or at world $\left.w_{i}\right)$ in the model $M$. Apart from propositional formulas we need simple arithmetic formulas expressing the utility of literals. We write $u\left(v_{i}\right)=z$, for an integer $z$, with the intended meaning that the utility of $v_{i}$ is $z$, similarly we write $u\left(v_{i}\right) \geq u\left(v_{j}\right)$ for the utility of $v_{i}$ is equal to or greater than the utility of $v_{j}$. We extend the utility function to conjunctions of literals by addition of the utilities of the conjuncts. The utility of other formulas (e.g., disjunctions) is undefined.

## Ethical Principles

Causal agency models play the role of representations of situations involving moral decisions. We now define ethical principles according to which moral permissibility of actions can be assessed based on the actions' consequences. For the following discussion, the principle of act-utilitarianism and the notion of Pareto dominance are of particular importance.

The utilitarian principle focuses on consequences of actions. It states that an agent ought to perform the action among the available alternatives with the overall maximal utility. We adopt an act-utilitarian interpretation which does not distinguish between doing and allowing, i.e., the causal structure of the situation is not taken into account. Thus the action which the agent ought to perform is the one which leads to the best possible situation, i.e., the highest utility, regardless of what the agent causes and intends.

## Definition 2 (Utilitarian Permissibility)

Let $w_{0}, \ldots, w_{n}$ be the available options, and $\operatorname{cons}_{w_{i}}=$ $\left\{c \mid M, w_{i} \models c\right\}$ be the set of consequences and their negations that obtain with these options. An option $w_{p}$ is permissible according to the utilitarian principle if and only if none of its alternatives yield more overall utility, i.e., $M, w_{i}=$ $u\left(\bigwedge \operatorname{cons}_{w_{p}}\right) \geq u\left(\bigwedge\right.$ cons $\left._{w_{i}}\right)$ holds for all $w_{w_{i}}$.

The utilitarian principle allows that an action brings about some bad consequences if it at the same time brings about more good consequences. For instance, it allows sacrificing some people if this sacrifice serves the good of many people. As an alternative to utilitarian permissibility we introduce the principle of Pareto permissibility. To this end, we first define the notion of Pareto dominance, which allows us to conclude that some action brings about a negative outcome in some respect, although it may be the optimal action from an utilitarian point of view. An option $w_{a}$ dominates another option $w_{b}$ if and only if $w_{a}$ is no worse in any aspect compared to $w_{b}$, and $w_{a}$ improves at least one aspect of $w_{b}$ either by making more good consequences obtain or less bad consequences obtain. Thus the agent does not change the world for the worse and will change it for the better by choosing the dominant action instead of the dominated one.

## Definition 3 (Pareto Dominance)

Let $w_{0}, w_{1}$ be two available options, let cons ${ }_{w_{i}}^{\text {good }}=$ $\left\{c \mid M, w_{i} \models c \wedge u(c)>0\right\}$ be the set of good consequences of option $w_{i}$, cons $\overline{w_{i}} \overline{\text { good }}=\left\{c \mid M, w_{i} \models \neg c \wedge u(c)>0\right\}$ the set of good consequences that does not obtain in option $w_{i}$, and cons $_{w_{i}}^{\text {bad }}=\left\{c \mid M, w_{i} \models c \wedge u(c) \leq 0\right\}$ the bad consequences of option $w_{i}$. Option $w_{0}$ dominant option $w_{1}$ if and only if the following conditions hold: 1) $w_{0}$ shares all the good consequences with $w_{1}\left(M, w_{0} \models \bigwedge\right.$ cons $\left._{w_{1}}^{\text {good }}\right)$, 2) $w_{0}$ either has at least one good consequence that does not hold in $w_{1}$, or $w_{1}$ has at least one bad consequence that does not hold in $w_{0}\left(M, w_{0} \models \bigvee \operatorname{cons}_{w_{1}}^{\overline{\text { good }}}\right.$ or $\left.M, w_{0} \models \neg \bigwedge \operatorname{cons}_{w_{1}}^{\text {bad }}\right)$, and 3) all the bad consequences of $w_{0}$ are also bad consequences of $w_{1}$ $\left(M, w_{1} \models \bigwedge\right.$ cons $\left._{w_{0}}^{b a d}\right)$.

Based on Pareto dominance, Pareto permissibility is defined. Pareto permissibility permits options not dominated by other options. Pareto permissibility can thus be understood as a principle of moral rationality: If there is an option that is better in all aspects compared to an alternative, then the only rational choice is to choose the better one. It would be irrational (and thus impermissible) to choose the worse alternative.

## Definition 4 (Pareto Permissibility)

Let $w_{1}, \ldots, w_{n}$ be the set of options available to an agent. Option $w_{i}$ is permissible according to the Pareto principle if and only if it is not dominated by some option $w_{j}$.

As will become apparent below, utilitarian permissibility and Pareto permissibility predict the same set of permissible actions for some dilemmas and different sets of permissible actions for other dilemmas. Generally, actions permissible from the utilitarian point of view are also permissible from the Pareto point of view. But the converse does not hold: For some dilemmas, the set of actions permitted by each principle differ. In those cases of disagreement the moral reasoner has to solve a conflict.

## Models of Moral Dilemmas

In this section, the four dilemmas presented in the introduction are modeled within the framework of causal agency mod-
els. Commonalities and differences are discussed both with respect to representation and ethical reasoning.

## Representations

Consider the Runaway Trolley dilemma (cf., p.1). We model this situation from the perspective of the bystander, who faces the decision to either throw the switch or to refrain from doing so. Let $a_{1}$ be the action variable representing the action of throwing the switch, and $a_{2}$ be the action variable representing refraining from throwing the switch. The consequence variable $c_{1}$ represents that the one person on the other track dies, and the consequence variable $c_{2}$ represents that the five persons on the current track die. The causal mechanism is expressed by structural equation in the following way: The structural equation $c_{1}:=a_{1}$ states that throwing the switch brings about the death of the one person on the other track, and the structural equation $c_{2}:=\neg a_{1}$ states that not throwing the switch will bring about the death of the other five persons. We assign utilities $u\left(c_{1}\right)=-1$ and $u\left(c_{2}\right)=-5$ to the consequences reflecting the number of deaths. For the lucky case that $c_{1}$ or $c_{2}$ do not obtain, we assume positive consequences, viz., $u\left(\neg c_{1}\right)=1$ and $u\left(\neg c_{2}\right)=5$. (One could argue that it is also appropriate to set $u\left(\neg c_{1}\right)=u\left(\neg c_{2}\right)=0$, because survival does not improve the persons' current state of being alive. On the other hand, to escape from danger intuitively bears positive utility. We consider this question as another empirical question that is out of the scope of this paper. For now it is important to note our findings do not depend on this choice.)

We consider now the Pregnancy dilemma and model the situation from the perspective of the doctor, wo faces the decision to either treat the woman or to refrain from doing so. Thus, we are assuming two actions $a_{1}$, treating the woman, and $a_{2}$, refraining from treating the woman. Moreover, we introduce consequence $c_{1}$ representing that the woman dies, and consequence $c_{2}$ representing that the triplets die. The structural equations are $c_{1}:=a_{1}$ and $c_{2}:=\neg a_{1}$. The utilities are set in accordance with the number of dying individuals: $u\left(c_{1}\right)=-1$ and $u\left(c_{2}\right)=-3$. As with the first dilemma, we assume that not dying yields positive utility, and hence we set $u\left(\neg c_{1}\right)=1$ and $u\left(\neg c_{2}\right)=3$.

Note that the Pregnancy dilemma is structurally isomorphic to the Runaway dilemma, i.e., the dilemmas can be mapped to each other. The only difference is the number of deaths in case of inaction (3 versus 5). Hence, we do not expect big differences regarding the complexity of reasoning about these dilemmas.

The Boat dilemma is modeled from the perspective of the crew, that has to decide whether to throw the biggest person into the sea. We assume two actions $a_{1}$, throwing the biggest person into the sea, and $a_{2}$, refraining from doing so. In contrast to the two previous dilemmas, it would be incorrect to model this dilemma as a choice between the one dying because of performing $a_{1}$ and the other three dying because of refraining from action. Instead, the model has to capture that the biggest person will die in both cases, viz., either because of being thrown into the sea or by drowning together with his
colleagues because of the sinking ship. To represent this situation appropriately, we assume three consequences: the ship sinks $\left(c_{1}\right)$, the biggest person dies $\left(c_{2}\right)$, and the three other passengers die ( $c_{3}$ ). The structural equations are $c_{1}:=\neg a_{1}$ (the ship will sink if the biggest person is not thrown into the see), $c_{2}:=a_{1} \vee c_{1}$ (the biggest person will die if she is thrown into the sea or if the ship sinks), and $c_{3}:=c_{1}$ (the three other passengers will die if the ship sinks). The utilities again reflect the number of deaths: $u\left(c_{2}\right)=-1$ and $u\left(c_{3}\right)=-3$, and as with the other two principles we assume that $u\left(\neg c_{2}\right)=1$ and $u\left(\neg c_{3}\right)=3$.

The Hijacked Airplane dilemma again is isomorphic to the Boat dilemma. It can thus be modeled accordingly: $a_{1}$ refers to the action of shooting the airplane, and $a_{2}$ to refraining from doing so. Consequence $c_{1}$ represents the airplane crashing, $c_{2}$ represents the death of the passengers, and $c_{3}$ corresponds to the death of people on the ground. The utilities can be set to any values such that $u\left(c_{2}\right)>u\left(c_{3}\right)$.

## Ethical Reasoning

The ethical principles "utilitarian permissibility" and "Pareto permissibility" defined above can now be applied to the outlined models of the four moral dilemmas. The first observation is that according to utilitarian permissibility taking action $\left(a_{1}\right)$ is permissible and refraining from action $\left(a_{2}\right)$ is impermissible in all four dilemmas, i.e., it is obligatory to throw the switch, to treat the woman, to throw the biggest crew member into the sea, and to shoot the hijacked airplane. This is rather easy to see by considering the sums of the utilities. E.g., throwing the switch in the Runaway Trolley dilemma yields utility $u\left(c_{1} \wedge \neg c_{2}\right)=-1+5=4$ whereas not throwing the switch yields $u\left(\neg c_{1} \wedge c_{2}\right)=1-5=-4$.

For the Runaway Trolley dilemma and the Pregnancy dilemma, performing action $a_{1}$ does not dominate refraining from action $\left(a_{2}\right)$ according to the definition of Pareto dominance. To see this, note that cons ${ }_{w_{a_{2}}}^{\text {good }}=\left\{\neg c_{1}\right\}$ (i.e., the good thing about not throwing the switch is that the one person will not die, and the good thing about not treating the woman is that the woman will not die) but $M, w_{a_{1}} \not \vDash \neg c_{1}$ (i.e., the one person will die in case of throwing the switch, and the woman will die in case of treatment). Conversely, using exactly the same argument refraining from action does not dominate acting. Thus, no matter how one decides someone will be harmed who will not be harmed under the alternative option. Because no action is dominated by the other, both the actions are permissible according to Pareto permissibility.

For the Boat dilemma and the Hijacked Airplane dilemma, performing action $a_{1}$ is the only Pareto permissible choice. The reason is that drowning the biggest person and shooting the airplane dominate the respective alternatives. Note that $w_{a_{1}}$ dominates $w_{a_{2}}$ according to the definition of Pareto dominance: First, observe that $\operatorname{cons}_{w_{a_{2}}}^{\text {good }}=\emptyset$ (i.e., refraining from action yields no positive consequences), $\operatorname{cons}_{w_{w_{2}}}^{\overline{g o o d}}=$ $\left\{\neg c_{2}, \neg c_{3}\right\}$ (i.e., when refraining from action none of the positive consequences hold), and $\operatorname{cons}_{w_{a_{1}}}^{b a d}=\left\{c_{2}\right\}$ (i.e., the nega-
tive consequence of $a_{1}$ is that the biggest person dies resp. the passenger die). Second, verify that indeed $M, w_{a_{1}} \models \top$ (satisfying condition 1 of the definition of Pareto dominance, all the good consequences of refraining are also good consequences of throwing, viz., there are none), $M, w_{a_{1}} \models \neg c_{2} \vee$ $\neg c_{3}$ (satisfying condition 2 of the definition of Pareto dominance, throwing (shooting) yields one of the good consequences not yielded by refraining, viz., $\neg c_{3}$ ), and $M, w_{a_{2}} \models c_{2}$ (satisfying condition 3 of the definition of Pareto dominance, the bad consequences of throwing (shooting) is also a bad consequence of refraining).

To sum up, for the isomorphic pair Runway Trolley dilemma and Pregnancy dilemma, both taking action and refraining are Pareto permissible but only the former is permitted by the utilitarian principle. Thus, the two principles are in conflict. For the isomorphic pair Boat dilemma and Hijacked Airplane dilemma, the two principles agree on only permitting taking action.

## Type 1 and Type 2 Dilemmas

Our formal investigations suggest that the moral dilemmas we are considering can be classified based on their formal properties. All the considered dilemmas are constituted by the choice between a big sacrifice as a consequence of inaction or a smaller sacrifice as a consequence of action. However, in case of the Runaway Trolley and the Pregnancy dilemma, the sets of negatively affected people are disjoint, whereas in case of the Boat dilemma and the Hijacked Airplane dilemma, the set of negatively affected people as a consequence of action is a subset of the set of negatively affected people as a consequence of inaction. This analysis yields that putting other people in danger by saving some raises moral conflicts, whereas saving a subset of people in danger does less so.

We take this difference to be a justification for subsuming dilemmas of the Runaway Trolley and Pregnancy dilemma type under Type 1 dilemmas, and dilemmas of the Boat and Hijacked Airplane type under Type 2 dilemmas. We conjecture that the utilitarian choice does Pareto dominate the alternative option in case of Type 2 dilemmas whereas it does not in Type 1 dilemmas. Thus, for Type 1 dilemmas, ethical principles predict different sets of permissible actions, and hence there is a conflict to resolve which is not present for Type 2 dilemmas. We therefore hypothesize that Type 2 dilemmas are easier to solve for humans, and we present a study which confirms our hypothesis.

## Hypotheses

The above theoretical analysis predicts that Type 2 dilemmas-due to the absence of a moral conflict-are easier to solve than Type 1 dilemmas. These considerations lead to two testable hypotheses:

- Hypothesis 1: Type 1 dilemmas such as the Pregnancy and the Runaway Trolley dilemma are rated as equally difficult.
- Hypothesis 2: Type 2 dilemmas such as the Boat dilemma
and Hijacked Airplane dilemma are rated as significantly easier to solve than Type 1 dilemmas.

Both hypotheses can be formally justified: The Type 1 dilemmas Pregnancy and Runaway Trolley are isomorphic, i.e., each one can be mapped to the other conserving the structure of the problem. Hypothesis 2 is justified for Type 2 dilemmas, as the utilitarian optimum dominates the possibility of refraining from action. This does not hold for Type 1 dilemmas. These hypotheses are investigated in the next section experimentally.

## Experiment

We report the second part of an experiment that focuses on rating the difficulty of moral dilemmas.

## Methods

Participants Participants were recruited on the online platform Amazon Mechanical Turk and received a monetary compensation for their participation. A total of 60 participants $(f=33)$ completed the study $\left(M_{\text {age }}=40.7, S D_{\text {age }}=\right.$ $8.86, \min _{\text {age }}=21, \max _{\text {age }}=70$ ). $33 \%$ of the participants reported to have finished high school or college, $12 \%$ stated to have an associate degree, $32 \%$ reported to have a bachelor degree while $23 \%$ stated to have a master or a higher academic degree.

Procedure, Design and Materials After the introduction to the setting participants received three problems. Each problem consisted of brief descriptions of two moral dilemas (c.f., Bucciarelli, Khemlani, \& Johnson-Laird, 2008), both presented at the same time on the left or the right part of the screen. Participant had to decide which of these two moral decision situations was more difficult to make, given that they should aim for saving lifes. More precisely, the participants had to decide between the Pregnancy and Runaway Trolley Dilemma, the Pregnancy and Boat Dilemma, and the Runaway Trolley and Boat Dilemma. Hence, participants were making a binary decision that was encoded in a dichotomous variable. After selecting the more difficult scenario the participants had to rate the perceived difficulty on a scale from 0 (hardly more difficult) to 100 (extremely more difficult) using a slider. This value was encoded in a second variable.

## Results

The frequencies of selections for the moral dilemma decision tasks can be found in Fig. 1. In the first problem the same number of participants rated either the Pregnancy Dilemma or the Trolley Problem to be the more difficult one. In the second problem 38 participants decided the Pregnancy Dilemma to be the more difficult decision scenario while 22 participants chose the Boat Dilemma. In the third problem 44 participants opted for the Trolley Dilemma and 16 for the Boat Dilemma. A two-tailed binomial test was used to compare the frequencies for the dichotomous variable.

As predicted, no reliable difference in the evaluation of the difficulty of the moral dilemmas Pregnancy and Runaway

Figure 1: Frequencies in the evaluation of the moral dilemma difficulty between two tasks $(* \leq .05, * * * \leq .001)$.

Table 1: Mean values for the participants rating of the difficulty to find a decision in the selected scenario.

|  | Mean $_{\text {difficulty }}$ |  |  |
| :--- | :--- | :--- | :--- |
| Decision Task | PW | RT | OB |
| PW-RT | $M=72.37$ | $M=60.23$ |  |
|  | $S D=28.37$ | $S D=32.40$ |  |
| PW-OB | $M=58.32$ |  | $M=51.05$ |
|  | $S D=32.48$ |  | $S D=37.22$ |
| RT-OB |  | $M=50.07$ | $M=43.94$ |
|  |  | $S D=32.99$ | $S D=32.91$ |

Note: PW: Pregnant Woman scenario; RT: Runaway Trolley scenario; OB: Overweight Boat scenario

Trolley can be found (exact binomial test, two-sided, n.s., $n=60$ ). There is a significant difference in the evaluation of the moral dilemmas Pregnancy and Overweight Boat (exact binomial test, two-sided, $p \leq .05, n=60$ ) and a significant difference in the evaluation of the moral dilemmas Runaway Trolley and Overweight Boat (exact binomial test, twosided, $p \leq .001, n=60$ ). Once more, Fig. 1 illustrates the differences of difficulty per decision task. The mean values of the participant's rating of their personal difficulty to find a decision in the previously selected scenario are shown in Table 1. Subsequent two-tailed t-tests showed no significant differences between the mean values $M_{P W}$ and $M_{R T}$ (decision task PW-RT), $M_{P W}$ and $M_{O B}$ (decision task PW-OB), and also not for $M_{R T}$ and $M_{O B}$ (decision task RT-OB) concerning their rating of the subjective difficulty.

## Discussion

As our theory predicted moral dilemmas can systematically differ in their perceived difficulty: When asking about the Pregnancy and Runaway Trolley dilemmas, as hypothesized, no significant difference in the relative difficulty rating could be identified. We explain this by the dilemmas' same complexity of the formal structure requiring a similar cognitive
effort. However, the questions concerning the decision difficulties between the ethical scenarios Pregnancy and Overweight Boat or the Runaway Trolley and Overweight Boat resulted in reliable differences in the evaluation of the difficulty of the moral decision situation. In both cases the Boat Dilemma was selected reliably less often. These results support our theory of a different formal structure implying a different cognitive effort and therefore a lower complexity of the Boat Dilemma.

Once the participants have selected the moral dilemma they perceived to be more difficult (the dichotomous decision), their subsequent rating of the difficulty in the interval from 0 to a 100 is statistically equal in comparison to the rating of the participants who chose the other dilemma confirming the result. Overall, there is a tendency towards a lower decision difficulty in the Boat Dilemma.

## General Discussion

The formally predicted distinction between Type 1 and Type 2 moral dilemmas have been empirically supported. Our results support the theoretical assumption that less the dilemma's content but the formal structure and the associated cognitive effort is a predicting factor affecting people's rating of a dilemmas' difficulty. We recall that a main difference between moral dilemmas of Type 1 and Type 2 are either based on action that the utilitarian choice does not or does Pareto dominate the alternative choices. This connects the presented formalism with ethical principles and a decision theoretic interpretation. For Type 1 dilemmas, ethical principles predict different sets of permissible actions, and hence there is a conflict to resolve which is not present for Type 2 dilemmas. The absence of such a conflict appear at least on the problems' surface to be easier to solve due to the lower cognitive effort they require. Further investigations ought to contain a replication of the results with balanced materials and higher sample sizes. In addition applying qualitative research such as interviews or thinking aloud techniques may give deeper insight in the complex human decision-making process particularly in morally difficult decision situations. This would offer additional insights about the motives, thoughts, and concepts people have when they have to solve tasks about moral principles and can provide the reasons for their decisions. By applying a qualitative content analysis of the different causal structure of dilemmas may improve the detection and categorization of the objective, systematic, and formal features of the dilemma's content. These categories in turn can be validated by an assignment of dilemmas as a possible task in a further experiment. Having a formal theory at hand allows to systematically analyze the implications of the objectives, concepts, and features relevant for moral decision making. Our formalism is able to distinguish between moral dilemmas and-at least for the reported cases-predict a perceived subjective difference between human raters.

# Communicative efficiency in language production and learning: Optional plural marking 

Chigusa Kurumada<br>ckuruma2@ur.rochester.edu<br>Department of Brain and Cognitive Sciences, Meliora Hall University of Rochester

Scott Grimm<br>scott.grimm@rochester.edu<br>Department of Linguistics, Lattimore Hall<br>University of Rochester

#### Abstract

Recent work suggests that language production exhibits a bias towards efficient information transmission. Speakers tend to provide more linguistic signal for meaning elements that are difficult to recover while reducing contextually inferrable (more frequent, probable, or expected) elements. This tradeoff has been hypothesized to shape grammatical systems over generations, contributing to cross-linguistic patterns. We put this idea to an empirical test using miniature artificial language learning over variable input. Two experiments were conducted to demonstrate that the inferrability of plurality information inversely predicts the likelihood of overt plural marking, as would be expected if learners prefer communicatively efficient systems. The results were obtained even with input frequency counts of the plural marker counteracting the bias, and thus provide strong support for a critical role of inferrability of meaning in language learning, production, as well as in typologically attested variations.

Keywords: language production, artificial language learning, optional morphology, plural marking, communicative efficiency

## Introduction

Speakers face a multitude of constraints when encoding their intended message as an actual utterance. On the one hand, speakers want to encode their meaning in a way that guarantees communicative success-it must be understood by the interlocutor. At the same time, speakers need to cope with difficulties associated with utterance planning and articulation. As researchers have shown, speakers regularly do this, e.g. by choosing shorter forms and/or elements that are readily retrieved and formulated (see, inter alia, Ferreira \& Dell, 2000; MacDonald, 2013).

A body of psycholinguistic work sees this negotiation between communicative success and effort minimization as a guiding principle of the computational system underlying language production and comprehension. Specifically, it is expected that there is an efficiency-based trade-off between the amount of information encoded and the amount of linguistic signal expended by the speaker. (e.g., Aylett \& Turk, 2004; Levy \& Jaeger, 2007; Buz, Tanenhaus, \& Jaeger, 2016). Communicative efficiency is predicted to be maximized when the speaker preferentially encodes components of meanings that are otherwise less likely to be inferred by the listener given prior expectations.

Against this backdrop, we consider the possible role of communicative efficiency in the organization of grammatical number marking. Grammatical number systems often have "markedness" contrasts between a default, uncoded value, and a value explicitly coded, e.g. through morphology. Typically, the singular value is uncoded while the plural value
is coded, as in $d o g$ vs. dogs. One question we will ask is if a plural value for a referent is likely to be inferred, will a speaker encode it? While it has been long observed that languages have preferences for what information is coded in default forms as opposed to explicitly coded (e.g., Greenberg, 1966), the causes underlying these preferences have remained obscure. The design of our study allows us to take a step towards distinguishing what sort of information forms the basis for these preferences. In particular, we investigate whether the active ingredient is the predictability of linguistic forms, i.e. frequency of occurrence of some element in produced language, or if predictability is related to the meaning.

## A case study: Optional plural marking

Unlike in English, grammatical encoding of plural meaning (e.g., dog vs. dogs) can be optional in some languages. Optional Plural Marking (OPM) is not uncommon crosslinguistically (e.g., Yucatec Maya (Butler, Bohnemeyer, \& Jaeger, 2017)) and has been investigated in linguistic work on grammatical systems (see Corbett (2000) and Haspelmath (2013) for general discussion). Yet, the mechanisms that predict when speakers would use (or would not use) the marker are not well understood.

A class of proposals, elaborated for number marking more generally, grounds the encoding of number values in conceptual properties related to entities (Prasada, Ferenz, \& Haskell, 2002; Wisniewski, Lamb, \& Middleton, 2003). This viewpoint suggests that singular (or plural) values might be more conceptually consonant for some entity types than for others. For instance, entities that are typically conceptualized as individuals (e.g., large animals) tend to be referenced in language as singular, rather than plural. For these entities, their occurrence in plural is limited, and therefore, plural coding is the unexpected or "marked" value. Conversely, for entities that are often conceptualized as collectives (e.g., small insects), plural coding is the expected or "unmarked" value. In sum, on this view formal (morphological) markedness corresponds to conceptual markedness.

When combined with a framework such as the communicative efficiency hypothesis, this "markedness" of plural meaning can predict biases seen in language production. Put simply, learning and production is guided by a consideration to communicate the plural meaning most efficiently. That is, learners should prefer systems in which markedness of plural meaning is inversely correlated with the production of plural marking. In relation to OPM, accounts based in communicative efficiency predict that when learners of an OPM language
refer to multiples of individualized items (e.g., large animals), they should be more likely to produce plural marking, compared to when referring to multiples of collective items (e.g., small insects).

Preliminary support for the conceptual markedness account comes from repeated observations across a number of studies on typologically-diverse languages which possess a singulative/collective morphology (e.g., Arensen (1998) on Murle, Mifsud (1996) on Maltese, Stolz (2001) on Welsh, see (Grimm, 2012) for discussion). In these languages, referents that are likely to be conceptualized and manipulated as collectives (e.g., fruits, grains, vegetables) or as a group/mass of individuals tend to be expressed with lexical items that have a plural meaning by default (e.g., psy "peas" in Welsh) and only through an additional singulative suffix can singletons be designated (e.g., psy-en "pea").

A difficulty arises, however, in determining "markedness" of plural meaning based on token counts of plural forms in a corpus. Haspelmath and Karjus (2017), for instance, collected token counts of singular vs. plural forms of a word (e.g., psy-en and psy) to argue that frequency asymmetries can predict the asymmetrical plural marking system such that the more frequent meaning (singular/plural) is often encoded in a simpler form. However, in this approach, one can only infer the frequency of meaning (e.g., How often does one talk about pea(s) as singular or plural?) based on the frequency of form (e.g., How often does one use a singular or plural form for pea(s)?). In other words, there is no simple way of dissociating predictions of the communicative efficiency account from an account based on form frequency: speakers may be simply reproducing the patterns heard in the input (e.g., They are more likely to hear psy than psy-en when they see peas and are faithfully representing the pattern in their own production).

To address this problem, we present two production experiments using an artificial language learning paradigm. Learners acquire 12 novel nouns and one novel verb to produce simple intransitive sentences with the Subject-Verb word order. As we describe below, the novel lexicon consists of two classes of referents: six Individuals and six Collectives that depict fictitious animals and insects, respectively. In the input, they were visually presented as either singletons or multiples at varying rates: Individuals are more likely to be singletons whereas Collectives are more likely to be multiples. Referents are optionally (stochastically) plural-marked and the probability of occurrence of the marker was constant across Individuals and Collectives.

This setup pinpoints an instance where frequency (inferrability) of meaning can be examined independent of frequency of forms. For instance, Individuals are less likely to appear as multiples compared to Collectives. This makes the plural meaning less inferrable for Individuals than for Collectives without the overt marking. Therefore, conceptual-markedness based accounts would predict that learners should be more likely to use the plural marker with

## a) singletons

b)multiples

Experiment 1

Experiment 2

Figure 1: Sample images of visual stimuli in Experiments 1 and 2.
the Individuals rather than Collectives. Critically, this bias is not predictable based purely on the frequency of forms. Notice that, given the fact that Collectives are more likely to appear as multiples, a larger proportion of token counts of Collectives appear with the plural marker than Individuals. If learners are simply reproducing the patterns observed in the input, they should produce the optional plural marker more with Collectives than with Individuals.

Results from this investigation may help to bridge the gap between the factors shaping sentence production in language processing and those that are shaping typological patterns. It has long been observed that the lexicon and grammar of languages across the world tend to exhibit many properties that would be expected if language was shaped by communicative pressures (e.g., Zipf (1949); Plotkin and Nowak (2000), also precisely those predicted by accounts of communicatively efficient language production Piantadosi, Tily, and Gibson (2011); Jaeger (2013)). Recent work on learning biases during (miniature artificial) language acquisition has also found similar biases to be active during artificial language learning (e.g., Culbertson, Smolensky, \& Legendre, 2012; Fedzechkina, Newport, \& Jaeger, 2016; Smith \& Wonnacott, 2010). Fedzechkina et al. (2012) found that native speakers of American English, when learning a miniature language with an optional case marking morphology, restructure the input and condition the uses of the marker on factors such as Animacy. This is in line with patterns observed in existing optional (or more categorical) case-marking languages, suggesting a tight link between observations in lab-based studies and typological pattern found in existing languages (e.g., Aissen, 2003; Kurumada \& Jaeger, 2015).

Figure 2: Schematic illustration of the flow of the experiment and proportions of singleton and multiple visual prompts.

## Experiment 1

We employ a miniature artificial language learning paradigm modifying Fedzechkina, Jaeger, and Newport (2012). Participants first learn 12 nouns and then learn to produce intransitive sentences in response to video clip prompts. We manipulated visual features of the referents (e.g., size, group size, movements) as well as the probability with which Individuals (animals) and Collectives (insects) appear as singletons and multiples, respectively. If optional number-marking is affected by a preference for communicative efficiency, speakers should be more likely to produce responses with a pluralmarker for Individual (animal) compared to Collective (insect) referents.

## Methods

Participants 48 native speakers of American English at University of Rochester participated in this study. They received $\$ 10$ for their participation.

## The language

Lexicon We constructed 12 nonce nouns. Six of them denote large animal characters and the other six denote small insect characters (e.g., Fig.1). To ensure that results did not include spurious phonological effects, we created two versions of character-noun combinations. All of the nouns were 1-2 syllables obeying English phonotactics (e.g, norg, velmick, zamper). When characters were presented as multiples, the noun was optionally suffixed with the plural-marker ( $-k a$ ) $2 / 3$ of the time.

We included only one verb - glim - meaning "moving up and down." In constructed sentences, the verb followed a noun, constituting a SV (intransitive) word order (e.g., Velmick-ka glim).

## Procedure

There were five phases in this experiment (Fig. 2). Participants went through phases (1) - (3) for six of the 12 noun types (three animals and three insects) and then repeated the same procedure to learn the other six words.
(1) Word exposure ( $\mathbf{1 2}$ characters $* 2=24$ trials total): During word exposure, participants were presented with pictures of each of the characters. Participants were instructed to repeat the names of the characters aloud. In this phase, all the characters were presented as singletons. An animal was depicted approximately three times as large as an insect.
(2) Word learning game ( 12 characters * $4=48$ trials total): The initial word presentation was followed by a word learning phase where participants were presented with four pictures (4 Alternative-Forced-Choice task) and asked to choose the correct match for the noun provided (48 trials total). Feedback was provided after each trial. In this phase, Individuals and Collectives were presented as singletons and multiples at different rates. Individuals occurred $75 \%$ of the time as a singleton (i.e., one animal, Fig. 1a), and $25 \%$ as multiples (Fig. 1b). Collectives had the inverse distribution (25\% singleton, $75 \%$ multiples). Both Individual (animal) nouns and Collective (insect) nouns were followed by the pluralmarker (ka) $2 / 3$ of the time when occurring as multiples.
(3) Word production ( 12 characters * $1=12$ trials total): Participants were shown 12 characters (singleton) one by one and asked to name each of them.
(4) Sentence comprehension ( $\mathbf{1 2}$ characters $* 4=48$ trials total): During the sentence comprehension phase, participants viewed short clips and heard their descriptions in the novel language. Participants were asked to repeat the sentences out loud. As in the word learning phase, Individuals and Collectives occurred as singletons $75 \%$ and $25 \%$ of the time, respectively, and they were followed by the pluralmarker (ka) $2 / 3$ of the time when occurring as multiples. Consequently, participants heard the animal and insect nouns with
ka 10 times and 30 times, respectively, by the end of this phase (Fig. 2). Importantly, this means that input frequency biases against the prediction of communicative-efficiency: the input in our experiment(s) provides more instances of training for plural-marked Collectives than Individuals.
(5) Sentence production ( 12 characters $* 2=24$ trials total): In the final test (sentence production) phase, participants saw silent videos of singletons and multiples and had to produce intransitive descriptions. In this phase, visual images for the multiples had three instances of the characters both for animals and insects. This was done to ensure that participants use -ka to signal plurality rather than the particular number of instances (two for animals and ten for insects) seen in the exposure input.

## Scoring

In the 4AFC comprehension test, participants' responses were scored as "correct" if they matched the intended referent. Following the standard used in similar studies (e.g., Fedzechkina et al. (2012)), we a priori decided to exclude participants who failed to achieve mean accuracy of $65 \%$ from all analyses.

We transcribed the production obtained in (5) and annotated if participants produced a given noun correctly and if a noun was produced with $k a$ or not. In the comprehension test, participants responses were scored as "correct" if it matched the provided input, while subtle phonological variations (e.g., velmick pronounced as belmick) were ignored.

## Results and Discussion

Comprehension Accuracy To ensure that participants had achieved a sufficient level of accuracy in identifying referents, we first measured their performance in the 4AFC word learning game. The average rate of correct response was $93.9 \%$ (animals, $93 \%$; insects, $94 \%$ ) and all the subject means were well above the pre-determined cut-off rate of $65 \%$. The mean accuracy of the word production phase (3) was above $85 \%$. This suggests that the task was feasible and the lexicon was acquired reasonably well before participants performed the production task.

Plural Marker Use in Production We excluded six (12.5\%) of the participants who failed to produce $50 \%$ of the sentences in the final sentence production phase. This was done to ensure that the data analyzed are produced by those who have mastered the language at a more or less sufficient level. All the results we report below remain unchanged, however, when we include all the participants. We then further removed $116(13 \%)$ sentences that included wrong nouns such as a different character's name or a noun that did not belong to the learned lexicon. The final dataset included 42 subjects and 773 sentences.

Proportions of participants' plural marker use in Experiment 1 are illustrated in Fig. 3. To analyzed the data, we used a mixed effect logit model in R, predicting the use of the optional plural marker. We included the noun classes (Individuals (animals) vs. Collectives (insects)) and visual prompts
(singleton vs. multiples) as fixed effects and participants and items as random effects. The model included the maximal random effects structure justified by the data based on model comparison (Jaeger, 2008). There was an expected significant main effect of visual prompts such that participants were more likely to produce the optional plural marker $k a$ for multiples ( $p<.001$ ). Critically, the interaction between the noun class and the visual prompts was also significant ( $p<.03$ ): learners (inversely) conditioned plural production on plural inferability. They did so despite the fact that they were exposed to three times as many instances of $-k a$ with the Collectives (insects) compared to the Individuals (animals).

## Experiment 2

What is driving the observed difference between Individuals and Collectives? Under our hypothesis, it is at least partially due to the expectation that animals are less likely to be represented with the plural meaning, and hence the meaning is less inferrable (and conversely for insects). In Experiment 1, however, it is not clear if the inferrability of the plural meaning (the conditional probability of multiples given the referent) is learned within the experiment or it is carried over from participants' prior semantic knowledge that insects are more likely to occur, and be referred to, as multiples.

To separate these two factors, in Experiment 2, we used the lexical items from Experiment 1 while associating them with novel geometrical shapes to minimize effects of prior semantic knowledge. If participants exhibit the same asymmetric use of the plural marker for Individuals and Collectives, that will yield support for the idea that the inferability is likely extrapolated in this experiment.

## Participants

52 native speakers of American English at University of Rochester participated in this study. They received $\$ 10$ for their participation.

## The language

The lexicon was identical to that used in Experiment 1. The only difference is that the visual images consisted of 12 geometrical shapes with no commonly known names. To equate the visual features of the referents (e.g., size, spacial distributions, complexity of visual scenes), we created two classes of referents (Fig. 1). Individuals consisted of six relatively large geometrical shapes spatially distributed in a manner similar to how the animals were presented in Experiment 1. On the other hand, Collectives consisted of six smaller shapes that replace the insects in Experiment 1.

## Procedure

The same as Experiment 1.

## Results and Discussion

Comprehension Accuracy The mean accuracy in the 4AFC task was $86 \%$ (Animals, 89\%; Insects, 83\%), suggesting that the word learning was slightly more difficult in Experiment

Figure 3: Proportions of plural marker use by conditions. Dots present by-participant averages (White $=$ singleton visual prompt; Black $=$ multiple visual prompt). Error-bars show 95\% Confidence Intervals. Dotted line indicates the input ratio of the $-k a$ marking for the multiples.

2 compared to Experiment 1, presumably due to the overall unfamiliarity with the geometrical shapes. One subject could not achieve the cut off rate of $65 \%$ and was removed from the analysis. The mean accuracy in the word production phase (3) was $80 \%$.

Plural Marker Use in Production We excluded ten (19.2\%) of the participants who failed to produce $50 \%$ of the sentences in the final sentence production phase. As in Experiment 1 , all the results we report below remain unchanged with the complete set of data. We then further removed 151 ( $15.5 \%$ ) sentences that included wrong nouns. The final dataset included 42 subjects and 823 sentences.

Proportions of participants' plural marker use in Experiment 2 are illustrated in Fig. 4. We constructed a combined model with the noun classes (Individuals vs. Collectives), visual prompts (singleton vs. multiples), and experiments as fixed effects and participants and items as random effects. As in Experiment 1, we found a significant main effect of visual prompts (= more $k a$ use for multiples) $(p<.001)$ and an interaction between the noun class and the visual prompts ( $p<.002$ ), indicating an inverse conditioning of $-k a$ production on plural inferrability. Importantly, there was no significant effect of the experiments. This suggests that the plural predictability is not necessarily tied to participants' prior knowledge of the semantic classes (animals vs. insects) and is learnable with respect to new classes of referents.

## General Discussion

Our results suggest that native speakers of American English prefer to produce an NP without overt marking of plurality when the meaning is more inferrable given the noun classes (e.g., animals vs. insects). The effect was present even with the nonce noun classes, when their within-experiment

Figure 4: Proportions of plural marker use by conditions. Dots present by-participant averages (White $=$ singleton visual prompt; Black $=$ multiple visual prompt). Error-bars show 95\% Confidence Intervals. Dotted line indicates the input ratio of the $-k a$ marking for the multiples.
statistics, as well as visual features of referents (size, spacial arrangements, and movement patterns), support differential plural predictability. We thus argue that learners have implicit knowledge of the relative inferrability of plural meaning (e.g., How often do you describe animals/insects as singletons vs. multiples?), and this knowledge supports the learning of morphological systems of a novel language. Critically, English does not have the optional plural marking (OPM) system. Still, when native speakers of English are exposed to an OPM language with no bias to mark plurality for low-inferrability items, they end up producing more plural marking for less inferrable items.

The current results constitute strong support for the view that language production is optimized to maximize the efficiency of information transmission (Levy \& Jaeger, 2007, Jaeger, 2013). The asymmetrical uses (and non-uses) of $k a$ cannot be accounted for in terms of availability of an upcoming linguistic element or other sources of speaker-internal production or planning difficulties (Ferreira \& Dell, 2000; MacDonald, 2013), since all the sentences were produced with the same verb and no participant failed to learn the verb.

It is an open question how learners compute the plural predictability. In the current experiment, we provided multiple cues to noun classes beyond the statistics of singleton vs. multiples. For instance, Individuals were always depicted larger in size than Collectives. In the sentence comprehension and production phases, each instance of Individuals moved independently while Collectives always showed a group motion. Future studies can manipulate these cues separately to delve into effects of spacio-temporal distributions of referents on conceptualization of noun classes and their plural inferrability.

Lastly, this study has broad implications for understand-
ing typologically attested morpho-syntactic variation. It has long been hypothesized that conceptual markedness plays a guiding role in grammaticalization of morpho-syntactic elements. The current experimental paradigm using an artificial language allows us to dissociate the effects of input in terms of the predictability of forms (e.g., How often do you hear a particular noun with $-k a$ ?) and the predictability/inferability of meaning (e.g., How likely is it that a given referent is described as a singleton vs. multiples?), making it possible to test a multitude of hypotheses put forward about effects of meaning-based predictability. For instance, it has been observed that functionally paired objects (e.g., glasses, chopsticks, a set of pillars) and body-parts (e.g., eyes, ears, hands) are often conceptualized as plural by default, and hence likely encoded without any additional plural marking morphology (Haspelmath \& Karjus, 2017). We can directly test this hypothesis in the current paradigm using objects that differ in their likelihood of appearing in pairs.

In summary, the inferrability of plurality information guides learners to restructure the input they receive, as would be expected if language users are biased towards communicatively efficient systems. Our results thus illuminate the critical role of distributional information of meanings on language learning, production, and typological variation across languages.

#### Abstract

Many common tasks require or are made more efficient by coordinating with others. In this paper we investigate the coordination dynamics of a joint action pick-and-place task in order to identify the behavioral dynamics that underlie the emergence of human coordination. More precisely, we introduce a task dynamics approach for modeling multi-agent interaction in a continuous pick-and-place task where two agents must decide to work together or alone to move an object from one location to another. Our aims in the current paper are to identify and model (1) the relevant affordance dynamics that underlie the selection of the different action modes required by the task and (2) the trajectory dynamics of each actor's hand movements when moving to grasp, relocate, or pass the object. We demonstrate that the emergence of successful coordination can be characterized in terms of behavioral dynamics models which may have applications for artificial agent design.

## Introduction

Often, everyday tasks can be accomplished more quickly and efficiently when individuals work together and coordinate their actions to accomplish task goals. However, increasing the number of individuals engaged in a task constructively increases the complexity of the task by expanding the degrees of freedom and interactions that define the task action space. Computational approaches to dealing with the increased complexity of joint action tasks largely focus on reducing complexity by identifying representational or neural structures that support successful joint action (Graf, SchützBosbach, \& Prinz, 2009; Rizzolatti \& Craighero, 2004; Sebanz \& Knoblich, 2009). Equally important, however, is understanding what aspects of successful multiagent coordination naturally emerge from the physical and informational dynamics of a given task context (Richardson \& Kallen, 2016; Richardson, Marsh, \& Schmidt, 2010; Richardson et al., 2015). The aim of the current project was to identify these task dynamics for a simple joint action pick-and-place task. Of particular interest, was the degree to which the complex patterns of interpersonal movement coordination and action (affordance) selection that emerge could be
captured by extending a low dimensional behavioral dynamics (Warren, 2006) model of individual environmental route navigation (Fajen \& Warren 2003) and pick-and-place behavior (Lamb et al., under review, Washburn, et al. 2015). Because the pick-and-place behaviors exhibited by the proposed low dimensional model emerge from the physical and informational dynamics of a given task context, the proposed model may be developed as a simple artificial agent system that can interact with human co-actors. An artificial agent system based on the model would be able to interact with human co-actors in the task without access to a coactor's cognitive states, i.e. without a theory of mind.

## Methods

## Participants

20 University of Cincinnati students (aged 18 to 28 years) were recruited to participate in the experiment. Participants received credit as a part of a class requirement for an undergraduate Psychology course. All participants provided written consent prior to completing the study, with the procedures and methodology employed reviewed and approved by the University of Cincinnati Institutional Review Board.

## Materials and Apparatus

An illustration of the experimental task setup is provided in Figure 1. Participants stood at a $1.65 \mathrm{~m} \times 0.89 \mathrm{~m} \times 0.995 \mathrm{~m}$ table in a laboratory room and completed a joint action pick-and-place task in a virtual environment. The virtual environment consisted of a room similar to the laboratory room and a table that was isomorphic in size and location to the table in the laboratory room. The virtual environment was displayed to each participant using Oculus Rift DK2 virtual reality headset (Oculus VR, Irvine, California). The physical table acted as a solid surface limiting the participants' movements within the virtual environment and creating a surface on which the participants could move a hand-held wireless Polhemus Latus motion-sensor (Polhemus Ltd, Vermont, USA) that tracked their right hand movements within the virtual environment at 96 Hz . The participants'
head movements were also tracked using Oculus Rift DK2 head tracking system.

The virtual environment, task objects, and task controllers were designed using the Unity 3D game engine (version 5.2.0; Unity Technologies, San Francisco, California) and Sketchup 2015 (Tremble Navigation Technologies, Sunnyvale, California). The maximum display latency between the participants' real-world movements and their movements in the virtual environment was 33 ms . The experimental task states were continuously recorded at 70 Hz .

As indicated in Figure 1, Participant locations were identified in terms of the "A" side or the "B" side of the table, where the body of the participant on the A side of the table (participant A ) is nearer to the center of the appearance range than the body of the participant on the B side (participant B). Participant A was positioned on the A side of the table, standing half way between the middle of the table and the pickup location. Participant B was positioned such that their right shoulder was directly across the table from the right shoulder of participant A (see Figure 1).

Within the virtual environment, the participants were represented as identical virtual avatars modeled after a crash

Figure 1: Illustration of experimental setup. At the beginning of each trial a virtual disc would appear on the left side of the table within the appearance range. Disc color indicated target location for that trial. The targets squares ( $\mathrm{M}=$ magenta, $\mathrm{Y}=$ yellow, $\mathrm{G}=$ green, $\mathrm{B}=\mathrm{Blue}, \mathrm{R}=$ red $)$ were always visible on the right side of the table. test dummy with a height of 1.8 m . Both the participants' right hands were represented by a semi-transparent blue sphere at the end of the dummy's right wrist in order to simplify interaction with the task environment. An inverse kinematics
controller (model and controller supplied by Root Motion, Tartu, Estonia) driven by the Polhemus motion sensor movements and the head movements of the participants controlled the right arm and body movements of the participants' virtual avatar, respectively. The resulting arm and body movements were not identical to the real world arm and body movements of the participants, but were close enough to render any differences between the real and virtual body postures of the participants unnoticeable or not functionally relevant.

## Experimental Task

The experimental task required participants to work together to move virtual disc objects (henceforth disc) that appeared on one end of a virtual tabletop to one of five evenly spaced target locations on the other end of the table (see Figure 1). The target location for a given trial was indicated by the color of the disc. A trial involved successfully moving a disc to the correct target location. Target colors and locations did not change during the task. However, discs appeared in random locations along the $y$ table axis within the middle third of the table (appearance range). Participants completed 2 blocks of 150 trials, 30 trials for each target color. Target colors were randomly presented.

The participants were instructed to pick up the disc when it appeared and attempt to move it to the target location. Either participant could pick up the disc, but they were instructed not talk or gesture to one another during the task. A pickup occurred when a participant's sphere came in contact with the disc. When picked up, the disc moved with the participant's sphere until it reached the target or the participant passed the disc. The participants were informed that if the target was either too far away or uncomfortable to reach, they could pass it to the other participant. A pass involved picking up the disc and then releasing it somewhere on the table by lifting their hand from the table. To complete a pass, the other participant would pick up the disc and move it to the target. A trial was completed when the disc reached the correct target.

## Procedure

Participants were told that the experiment was investigating the dynamics of joint action pick-and-place behavior and that they would be completing a simple pick-and-place task with one another. The participants were then embedded within the virtual environment using the HMD and viewing height and sensor calibration was performed. Task instructions were then provided to the participants and after participants indicated that they understood the task procedure and goal, they were given an opportunity to complete 2 practice blocks. The first practice block consisted of 12 trials where the disc always appeared in the center of the appearance region and indicated the middle (green) target. Each participant took 6 turns picking up the disc and either passed it or took it to the target. The second practice block involved 20 trials, 4 trials for each target location. In this practice block, the pickup location was randomly assigned within the appearance range on each trial.

As mentioned above, experimental trials were broken up into 2 blocks of 150 trials. After the first experimental block participants switched sides of the table, i.e. the participant on side A moved to side B and the participant on side B moved to side A. Participants switched HMDs and moved to the other side of the lab room table to effect this switch. Experimental blocks lasted between 10 and 15 minutes.

## Results

In order to model the emergence of successful joint action during the current pick-and-place task, the analysis was directed towards answering two general questions. First, what task variables determined the participants' decision to pickup and/or or pass. In other words, what were the affordance (action opportunity; Gibson, 1979) based action selection dynamics that characterized pickup and pass behavior? Second, what were the trajectory dynamics of the participant's hand movements when moving to grasp, relocate, or pass the disc within a two-dimensional task space. Below we consider each of these questions in turn.

## Decisions

For the pick-and-place task investigated here there were two affordance based action selection decisions that we examined. First, participants had to decide whether or not to pick up the disc when it appeared. In order to understand the basis for this decision we applied the C4.5 decision tree algorithm (Quinlan, 1993) using a 10 fold cross validation to participant pick decisions ( $n=2998$ ) in order to create a decision tree with a minimum node size of 50 instances. This analysis revealed that the only attributes used to build the tree were the current location of each actor's hand to the disc, with the resulting decision tree able to correctly predict $87 \%$ of the pick decisions. Attributes that were considered for each participant included: hand's current distance to the disc, hand's current distance to target, disc location, and target location. These attributes were not considered relevant to modeling the decision behavior if it was not included in the decision tree produced by the C 4.5 method or if its exclusion resulted in a change in predictive success of $<3 \%$.

The C4.5 decision tree algorithm was also applied using a 10 fold cross validation to a data set of 2998 passing decisions in order to create a decision tree with a minimum node size of 50 instances. When the only attribute used to build the tree was the distance of the resting location of one of actor's hand to the disc the resulting decision tree was able to correctly predict $79 \%$ of the pickup decisions. Resting hand location for each side was defined as a position 0.15 m from the edge of the table directly in front of the participant's right shoulder. The same set of attributes considered for the pickup decision were considered for the pass decision, with the addition of the previous pass decision. None of these other attributes

[^380]significantly increased pass prediction beyond that predicted by actor resting location alone.

Figure 2: Heat-maps of example participant (top) and model simulation (bottom) trajectories during the experimental task.

## Movements

An example of the complete set of participant pair trajectories are illustrated in figure 2 (top) as a heat map. This heat map plot was created by dividing the table into $125 \times 108$ grid and for each trial, the number of times a participant's location was recorded in a given grid cell was tallied to create a histogram of trajectory locations in table coordinates. A greyscale value was assigned to each cell from a scale of 64 shades. All participants exhibited a qualitatively similar sideways "spaghetti monster" heat-map, with concentrations of trajectories (brighter areas), corresponding to discs (far left side of heat-map plot), pass/rest locations (top and bottom left of center on the heat-map plot), and target locations (5 distinct points across the right of the heat map plot). Because of the number of subtask trajectories, trajectory heat maps provide a relatively straightforward tool for comparing qualitative similarities between both human participants and between human data and simulation data. ${ }^{1}$

Participant trajectories tended to curve slightly away from straight-line trajectories. This may be due to the fact that after completing a subtask goal participants employed a simple strategy of heading in the general direction of the next subtask goal instead of taking an initial heading defined by the straight-line angle from their current location to the goal location.

Participant subtask movements exhibited a bell shaped velocity profile with the peak velocity occurring around half
way through the trajectory. Across all subtask trajectories, the average peak velocity was $1.231 \mathrm{~m} / \mathrm{s}(\mathrm{Mdn}=1.252 \mathrm{~m} / \mathrm{s}, \mathrm{Q} 1=$ $0.924 \mathrm{~m} / \mathrm{s}, \mathrm{Q} 3=1.373 \mathrm{~m} / \mathrm{s}$ ) and the peak velocity occurred on average around $57 \%$ ( $\mathrm{SD}=15 \%$ ) of any given subtask trajectory. For the 14 subtask trajectories examined, average peak velocity for each subtask trajectory was significantly correlated, $r(14)=0.89, p<0.001$, with the average straightline distance of each subtask trajectory. Shorter trajectories had lower average peak velocities than longer trajectories.

In order to identify where participant's passed the disc on pass trials, cluster analysis was conducted, using the K-means cluster analysis algorithm, which finds cluster centers that minimize the sum of squared error (SSE) for a given number of clusters, k. We analyzed the release/pass locations to determine whether these locations typically clustered around 1,2 , or 3 cluster centroids. The optimal number of clusters was defined as the value of $k$ such that the difference of the SSE for a reference distribution, determined by Monte Carlo sampling of a reference distribution, was greatest compared to the other values of $k$. For each pair, separate evaluations were run for each side of the table. For side A, when a participant on side $A$ passed at least once during the experiment ( $n=8$ pairs), the optimal number of clusters was 1 for all passes on this side of the table. Likewise, when a participant on side $B$ passed at least once during the experiment ( $n=9$ pairs), the optimal number of clusters was 1 for most pairs $(n=7)$. When a participant on side A passed during the experiment $(n=8)$, the passes clustered around an average $(x, y)$ table location of $(0.24 \mathrm{~m}, 0.62 \mathrm{~m})$. When a participant on B side of the table passed ( $n=9$ ), the passes clustered around an average $(x, y)$ table location of $(0.33 \mathrm{~m}$, 0.18 m ).

## Model

The current study had two overall aims. The first aim was to identify the behavioral dynamics that underlie a continuous joint action pick-and-place task, in which two participants had to move objects from one tabletop location to another either alone or by passing the object to another co-actor. Our second aim was to develop a behavioral dynamics model that can characterize the joint action behaviors and choices (pickup or not; pass or not) of the participants engaged in during the joint action pick-and-place task. With respect to this aim we developed a model of both the participant's movement in the task space and their decisions to both pick up the object when it appears on a given trial and to pass the object.

## Movement Dynamics

In order to model the dynamics of each participant's, henceforth agent, hand movements throughout the task, a task specific parameterization of the Fajen and Warran model of human locomotory navigation was employed (Fajen \& Warren, 2003, 2004, 2007; Warren \& Fajen, 2008). This model has also been extended to model single actor pick and place behavior (Lamb et al., under review). In the current context, the model characterizes a heading direction or
angle, $\varphi_{i}$, of an agent's hand or end-effector (where each agent is indexed by $i$ ) during each task trial was defined by

$$
\begin{equation*}
\ddot{\varphi}_{i}=-b_{g_{i}} \dot{\varphi}_{i}-k_{g_{i}}\left(\varphi_{i}-\theta_{g_{i}}\right)\left(e^{-c_{1} d g_{i}}+c_{2}\right) \tag{1}
\end{equation*}
$$

where $\dot{\varphi}_{i}$, and $\ddot{\varphi}_{i}$, correspond to the velocity and acceleration of the agent's end-effector heading angle, respectively, and $b$ and $k$ are damping and spring/stiffness terms, such that $-b_{g_{i}} \dot{\varphi}_{A_{i}}$ acts as a friction force on turning rate, and the function $-k_{g_{i}}\left(\varphi_{i}-\theta_{g_{i}}\right)$ operates to minimize the difference between the current heading angle, $\varphi_{i}$, and the angle $\theta_{g_{i}}$, of the corresponding subtask goal/target location (i.e., the pickup location for pickup movements, the release/pass location for passing movements, and the target/drop-off location for target movements). The distance of the agent $i$ 's end effector to the current goal location is defined by $d_{g_{i}}$. The presence of the factor $\left(e^{-c_{1} d g_{i}}+c_{2}\right)$ in the second addend of the right-hand side introduces an exponentially decaying function characterized by a constant offset parameter $c_{2}$ and an exponential decay rate, which is a function of the constant parameter $c_{1}$ and the Euclidean distance, $d_{\mathrm{g}}$, between an agent's current hand location and the current goal location. The parameter $c_{2}$ ensures that the rate of change in heading direction never goes to zero (Fajen \& Warren, 2003). Note that the parameters $\theta_{g_{i}}$ and $d_{g_{i}}$ change continuously as the position of the agent's hand/end-effector moves through the task space.

Finally, in order for to capture the non-constant velocity profile observed in participants, $v_{i}$ is introduced to characterize the movement velocity of the agent's endeffector (hand). $v_{i}$ is defined by means of the additional $2^{\text {nd }}$ order differential equation

$$
\begin{equation*}
\ddot{v}_{i}=-b_{v_{i}} \dot{v}_{i}-k_{v_{i}}\left(v_{i}-C_{v_{i}}\left(1-e^{-d_{g_{i}}}\right)\right) \tag{2}
\end{equation*}
$$

where $b_{v_{i}}$ and $k_{v_{i}}$ act as damping and stiffness terms on the rate of change of $v_{i}$, which increases and decreases as a function of the target (goal) distance, $d_{g_{i}}$. When the agent's end-effector or hand is far away from the target location (1-$\left.e^{-d g_{i}}\right) \approx 1$ and $v_{A}$ increases. As the distance to the goal location decreases, however, $\left(1-e^{-d g_{i}}\right)$ approaches zero and $v_{i}$ decreases accordingly. $C_{v_{i}}$ is a constant parameter that specifies the maximum velocity in $\mathrm{m} / \mathrm{s}$, such that the same equation can be used for a wide range of different movement distances, with differential peak velocities resulting for shorter and longer distances (see Lamb et al., under review for more details on this velocity function).

## Action Selection Dynamics

In the experimental task there are two task defined choices. First, one of the agents must choose to pick up the task object while the other agent chooses to stay out of the way. Second, once an object is picked up, the agent with the object must decide to either take the object to the goal location or pass it to their co-actor. In both cases, the decision can be
characterized as a selection between action modes or affordances, i.e. pick up the object or wait and take the object to goal or pass. Moreover, previous research using a nonrandom pick-and-place task paradigm suggests that recent action modes may affect the current action mode selection (Lamb et al., Under Review). As a result, in the current context the action mode selection dynamics may be captured by

$$
\begin{equation*}
\dot{x}_{l}=-\alpha_{j_{i}}+x_{i}-x_{i}^{3} \tag{4}
\end{equation*}
$$

where $x_{i}$ represents the state variable for action section (i.e., affordance mode) of the previous action selection process and $\dot{x}_{l}$ is the action selection state variable for the current trial. $\alpha_{j_{i}}$ corresponds to the specific subtask action mode and agentnormalized E/A ratio where the decision to pick up an object can be defined for Agent 1 by

$$
\begin{equation*}
\alpha_{s_{1}}=\left(\sigma_{s_{1}}-\frac{d_{g_{s_{1}}}}{R_{1}}\right) \delta_{s_{1}}-\left(\sigma_{s_{2}}-\frac{d_{g_{s_{2}}}}{R_{2}}\right) \delta_{s_{2}} \tag{5}
\end{equation*}
$$

and for Agent 2 by

$$
\begin{equation*}
\alpha_{s_{2}}=\left(\sigma_{s_{2}}-\frac{d_{g_{s_{2}}}}{R_{2}}\right) \delta_{s_{2}}-\left(\sigma_{s_{1}}-\frac{d_{g_{s_{1}}}}{R_{1}}\right) \delta_{s_{1}} \tag{6}
\end{equation*}
$$

where $d_{g_{s_{i}}}$ is the distance from current location of the $i^{\text {th }}$ agent's end effector to the disc's location. Similarly, the decision to pass was defined by

$$
\begin{equation*}
\alpha_{p_{i}}=\left(\sigma_{p_{i}}-\frac{d_{g_{p_{i}}}}{R_{i}}\right) \delta_{p_{i}} \tag{7}
\end{equation*}
$$

$d_{g_{p_{i}}}$ is the distance of the agent's resting end-effector (hand) location to the target location, and $R_{i}$ is a measure of the agent's maximal preferred reach. In both equations equation, $\sigma_{j_{i}}$ and $\delta_{j_{i}}$ are constant scaling factors. In Eq. 5, 6, and 7, $d$ is a subtask action mode parameter that identifies the state of the subtask action relevant environmental property.

## Model Simulation

To determine whether systems defined by the movement trajectory dynamics (Eq. 1 and 2) and the action selection dynamics (Eq. 4, 5, 6, and 7) of the current model could complete the task independently complete the current pick-and-place task, a MATLAB (2016a) simulation was conducted. A flow diagram illustrating the structure of the simulation is provided in Figure 3. The simulated environment consisted of a $1.5 \mathrm{~m} \times 0.89 \mathrm{~m}$ rectangular space matching the experimental table's dimensions. The simulation target and disc locations were initialized in the same manner as in the experimental task. 10 different simulation sequences were conducted, with each simulation sequence consisting of 400 trials. Each simulation sequence
was initialized with the same pickup/target order used for a participant pair. The passing location centers corresponded to the observed passing location centers for each participant pair. Cluster centers corresponding to each participant pair were used to initialize the simulation sequence based on that pair's appearance/target order. Experimentally observed within pair variability in pass locations was likely due to the many complex interactions from which this passing behavior emerges (Holden, 2002; 2005; Stephen \& Mirman, 2010). However, in our simulations this variability is produced by a sequence of random values generated from a lognormal distribution that were added to the passing location centers in order to produce a pass location distribution that was similar to the experimentally observed data.

For each action selection the pickup and passing solutions to parameter equations, action selection dynamics, Eq. 4, were integrated for 1500 steps using the MATLAB ODE45 function with the end state of the integration used to drive the pickup and pass decisions (and return to rest position). The output state of the action selection equation was stored as an input for integration of the action selection equation in the next trial ( $x=0$ for the first trial in a sequence). Heading angles were initialized in the cardinal direction of the next subtask goal, e.g. pick up to target trajectories initialized with a heading angle of $0^{\circ}$ heading directly to the right side of the table. Random noise was added to the initial angle from a uniform distribution with $\mathrm{min} / \mathrm{max}$ values of $\pm 17^{\circ}$. The movement dynamics, Eq. 1 and 2, were integrated for each subtask movement using the Euler integration (. 01 time step), with integration terminated when the model location was within 4 cm of the target location. Random noise was added to the model heading direction, $\varphi_{i}$, at each time step of the integration using a uniform distribution with $\mathrm{min} / \mathrm{max}$ values of to $\pm 1.14^{\circ}$.

Figure 3: Structure of simulation. Eq. 1 and 2 are implemented in the upper loop and Eq. 4 through 7 are implemented in the lower goal selection loop.
An example simulation run is illustrated by the bottom heat-map in Figure 2. For all simulation runs, the simulation agents successfully completed the pick-and-place task within the task constraints. All simulation agent trajectories
remained within the task space and subtask trajectories were within the same regions as those produced by human participants. Simulation agent trajectories exhibited less variability as can be seen in figure 2, though the importance of this variability for a human co-actor engaged in the task is something that will require further research. To the extent that it is relevant, this variability may be replicated in an artificial agent implementation of the model by the addition of noise terms, through coupling to the human agent, and possibly by noise introduced by the agent's hardware instantiation (e.g. motor variability in a robotic system).

The simulation agents were also able to spontaneously select between picking up the object or not and between passing the object or completing the task alone in a manner similar to the real participants. For pickup trajectories it is notable that pickup decisions may be made and changed as co-actors move or do not move throughout the task space. If both simulation co-actors are roughly the same distance the pickup location at the beginning of a trial, noise and velocity profile variations still results in just one agent picking up the object. If a simulation agent picked up an object, that agent always passed for the farthest target and often did for the second farthest, with the decision to pass for this target fluctuating due to previous pass decisions and noise in the system, matching experimentally observed participant behaviors.

## Conclusions

The current model is useful for providing insight into how complex movement and decision dynamics might emerge from a system given relatively simple information structures. Notably, the model does not assume the need to understand or predict co-actor intentions or beliefs. This makes the model an ideal candidate for implementation in an artificial agent system that can interact in real-time with human coactors but does not have access to sophisticated sensory or computational systems for interpreting high level cognitive states. We are currently in the process of implementing a version of this model in virtual and robotic systems to test with human co-actors in order to validate the capabilities of behavioral dynamics models applied in this way.

#### Abstract

When a neural network is trained on multiple analogous tasks, previous research has shown that it will often generate representations that reflect the analogy. This may explain the value of multi-task training, and also may underlie the power of human analogical reasoning - awareness of analogies may emerge naturally from gradient-based learning in neural networks. We explore this issue by generalizing linear analysis techniques to explore two sets of analogous tasks, show that analogical structure is commonly extracted, and address some potential implications.

Keywords: neural networks; structure learning; representation; analogy; transfer;

## Introduction

Analogical transfer is often considered an essential component of "what makes us smart" (Gentner, 2003). However, there is a tension in the literature - Detterman (1993) has declared that "signifient transfer is probably rare and accounts for very little human behavior." Yet other authors have found that in some cases analogical transfer between superficially dissimilar systems can be so natural that it may not even require explicit awareness of the analogy (Day \& Goldstone, 2011). How can we reconcile these viewpoints?

One feature that often separates the researchers with these opposing viewpoints is the type of tasks and transfer they consider. When Detterman (1993) says that the manipulations necessary to show transfer have "the subtlety of [a] baseball bat", he cites work like that of Gick \& Holyoak (1980) which shows the difficulty of rapidly making an explicit mapping between two superficially disparate domains to explicitly solve a problem. By contrast, the Day \& Goldstone (2011) experiments show transfer when participants learn about a system by interacting with it over a longer period of time, and then transfer is measured implicitly on an analogous system. We believe that this distinction between fast-explicit analogical transfer and slower-potentially-implicit analogical transfer may explain much of the disagreement in the literature. (See also Bransford \& Schwartz (1999).)

Previous work has shown that neural networks can provide a good model for "slow" analogical transfer in domains as broad as artificial grammar learning (Dienes et al., 1999) and verbal analogies Kollias \& McClelland (2013). In particular, one line of work shows that neural networks are capable of extracting analogous structure from knowledge domains
that are completely non-overlapping in their inputs and outputs (Hinton, 1986; Rogers \& McClelland, 2008). In other words, if you train a neural network to solve two identical tasks, using separate sets of inputs and outputs but sharing the hidden units, in some cases it will generate representations that reflect the analogy (i.e. analogous items will generate more similar patterns of activity in the hidden units than non-analogous items) (Rogers \& McClelland, 2008). This can lead to the ability to correctly make analogical inferences about items not explicitly taught (Hinton, 1986). This extraction of shared structure sets neural networks apart from simple forms of statistical pattern recognition (Rogers \& McClelland, 2008) such as linear data analysis techniques like PCA.

Furthermore, recent work has shown that neural networks can show benefits of training on multiple tasks (Dong et al., 2015; Rusu et al., 2015, e.g.). Even a small amount of learning on distinct but related tasks has been shown to improve performance. For example, training a natural language translation system on image captioning and autoencoding improves translation performance (Luong et al., 2016). Learning on numerous language translation pairs can even give generalization without further training to unseen language pairs (Johnson et al., 2016). We suggest that these benefits may be due to neural networks ability to extract shared structure. Because human experience is filled with distinct tasks that share common elements (language, various perceptual modalities, etc.) understanding the way that structure is learned across tasks may be essential to understanding human intelligence and building better artificial intelligence systems.

However, we have little understanding of how, why, or when neural networks are able to extract structural analogies from their training data. Here, we describe a preliminary investigation into this question, and in the process describe a new approach to analyzing neural network representations that may yield more general insights. We begin with a very simple instantiation of a task with analogous structure.

## A Simple Task

In the original work of Hinton (1986), a neural network was taught to answer queries about the structure of two perfectly analogous family trees (one English and one Italian, see fig. 5), and was shown to generate representations that extract the analogy, in the sense that analogous people from differ-
ent families are represented similarly. Here, we pare this task down to its barest essentials: two perfectly analogous domains with separate inputs and ouputs. For our task, the inputs can be thought of as the set of letters $\{R, L, \rho, \lambda\}$, and the outputs as $\{P, D, S, \pi, \delta, \sigma\}$. The task can be seen as mapping an input letter onto the letters that it can follow (e.g. "R" can follow "D" as in "draw," but cannot follow "S"), where there is an analogy between the Latin and Greek letters. See below for the input-output (I/O) mapping:

|  | $P$ | $D$ | $S$ | $\pi$ | $\delta$ | $\sigma$ |
| :--- | :---: | :---: | :---: | :---: | :---: | :---: |
| $R$ | 1 | 1 | 0 | 0 | 0 | 0 |
| $L$ | 1 | 0 | 1 | 0 | 0 | 0 |
| $\rho$ | 0 | 0 | 0 | 1 | 1 | 0 |
| $\lambda$ | 0 | 0 | 0 | 1 | 0 | 1 |

When and how does a neural network extract the analogous structure across the domains in this simple task?

## Methods: Linear Networks?

There have been recent developments in the theory of linear neural networks which show that the process of learning is entirely driven by the Singular Value Decomposition (SVD) of the input-output correlation matrix (Saxe et al., 2013). The SVD can be seen as breaking the structure of the task into individual "modes" - linear structures in the dataset, somewhat like components in PCA. Specifically, a mode consists of an input pattern (which can be interpreted in this case as the input letters the mode responds to), a singular value (which roughly corresponds to the amount of variance explained by this mode), and an output mode (the output letters produced by the given pattern on the inputs). For example, see Fig. 1 for the SVD of the I/O mapping for the letter task above.

This decomposition tells us more about the task structure the network is using. There are three modes in the SVD. The first (left output mode/top input mode) represents the difference between the Latin and Greek letters, so it is positive for the Greek inputs and negative for the Latin outputs, and is positive for the Greek outputs and negative for the Latin outputs. The next two components represent the distinctions between the letters R and L , and the letters $\rho$ and $\lambda$, respectively. Saxe et al. (2013) showed these results have implications for the learning of non-linear networks as well, so linear neural networks can be a more tractable place to analyzee learning dynamics. In addition, using the I/O SVD allows the discovery of representational components which are distributed across units, so it is more general than simply examining what aspects of the task individual hidden units represent, or examining the weight matrices directly. Thus one might hope to answer our questions in a linear framework.

However, linear networks cannot represent analogous structure from non-overlapping inputs and outputs at convergence. With non-overlapping inputs and outputs, the I/O correlation matrix is block diagonal, and the SVD modes will thus occur within blocks (this is why in Fig. 1 the modes showing separation between the letters in each domain have
no input or output weights to the other domain). ${ }^{1}$ Thus, since the final representational components that a linear network learns are precisely the components of the SVD (Saxe et al., 2013), there will be no sharing of structure across domains.

Furthermore, the optimal rank $k$ approximation to a matrix is to take the top $k$ components from the SVD (Mirsky, 1960). If a linear network's hidden layers are restricted to rank lower than that of the I/O correlation matrix, detail within the domains will be lost. Thus a linear neural network cannot solve the task perfectly if any of its hidden layers has a number of units smaller than the rank of the I/O correlation matrix. By contrast, a non-linear network can exploit the analogy between the domains to find more parsimonious solutions. Is there a way to leverage linear insights in the non-linear case?

## Methods: A Linearized Approach

As we shall see, while a linear network cannot extract the analogous structure from the task, inserting a single nonlinearity after the output layer can allow it to do so. In the case that the non-linearity is a sigmoid, this essentially reduces the problem to logistic regression; here we will use rectified linear units in our analysis because their structure makes the output patterns more intuitively interpretable. Once this almost-linear network has solved the problem, consider its outputs immediately prior to the non-linearity. These are produced by the linear part of the network, and together with the non-linearity suffice to produce the desired outputs. We can use these to turn the problem into a linearly analyzable one - simply treat these pre-nonlinearity outputs as outputs of a linear network. Then the problem becomes susceptible to the types of linear analyses discussed above.

Thus we trained a neural network with a single hidden layer (4 units) and a single non-linearity (a rectifier at the output layer) to solve this task. See fig. 3 for a diagram of the network. No biases were used, weights were initialized uniformly between 0 and 0.1 , all training was done by Stochastic Gradient Descent (i.e. in each epoch the data are presented one at a time in a random order, and the weights are updated after each data point) with $\eta=0.01$ for 500 epochs.

## Results

The solution that the nonlinear network discovers the majority of the time (about $75 \%$ ) is to output the same pattern on both sets of output units, but offset the "incorrect" domain sufficiently negative so that it is hidden by the rectified, thus the task that the linear portion of the network is effectively performing at convergence is:

|  | $P$ | $D$ | $S$ | $\pi$ | $\delta$ | $\sigma$ |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| $R$ | 1 | 1 | 0 | 0 | 0 | -1 |
| $L$ | 1 | 0 | 1 | 0 | -1 | 0 |
| $\rho$ | 0 | 0 | -1 | 1 | 1 | 0 |
| $\lambda$ | 0 | -1 | 0 | 1 | 0 | 1 |

[^381](Note that the network can actually map the first element of one domain onto either element of the other. We discuss the solution shown here one for clarity, the other just shuffles some rows and columns.)

The SVD of this linearized mapping shows a rank 2 solution (see fig. 2). The first component is similar to the first component of the regular SVD, in that it reflects the separation of the domains, but the second component collapses the other two components of the linear SVD. In other words, the analogy has been learned - the network is using the parallels between the two tasks to reach a more parsimonious solution. It is able to incorporate the analogy into its computations by allowing both the sets of outputs to vary, and simply suppressing the outputs from the "wrong" domain for its current task.

Because this solution is rank 2, a non-linear network with two hidden units should be able to solve the task, whereas a linear network will require three. We have verified these results empirically for this task. Thus the ability of a non-linear neural network to extract common structure from multiple tasks can allow it to find more parsimonious (i.e. lower-rank) solutions. We would like to highlight this point: the representation of the analogy in the SVD is not purely epiphenomenal - it makes a more parsimonious solution possible.

## Evolution of the I/O Mappings

When a non-linear network has only two hidden units, it must extract the analogy to be able to solve the task, but with more hidden units there are a variety of solutions that could potentially emerge (such as just learning the mapping of each input to its output pattern independently). However, our network extracted shared structure on about $75 \%$ of the runs we conducted (as measured by more than $20 \%$ score on the crossprojection metric described below). What drives this fairly consistent extraction of analogy? In this section we consider the evolution of the outputs over the course of learning.

The output structure of the network goes through a fairly consistent progression, which we will describe qualitatively at various key stages (the exact values depend on the initialization, so the matrices here are approximations to within about $\pm 0.1$ ). The outputs begin as small positive numbers, approximately 0 (because the weights are initialized uniformly between 0 and 0.1 ). Next, the network captures the base rate activations of each output unit, around epoch 75. (Note that this is already accounted for in the SVD, because the output variables are centered before computing the SVD).

$$
\text { base rates }=\left[\begin{array}{cccccc}
0.5 & 0.25 & 0.25 & 0.5 & 0.25 & 0.25 \\
\vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\
0.5 & 0.25 & 0.25 & 0.5 & 0.25 & 0.25
\end{array}\right]
$$

Then the network captures the existence of the two domains but not the structure within them (around epoch 140). This corresponds to the first component of either SVD. Up to this point, a linear network follows a similar learning trajectory.

$$
\text { base rates by domain }=\left[\begin{array}{cccccc}
1 & 0.5 & 0.5 & 0 & 0 & 0 \\
1 & 0.5 & 0.5 & 0 & 0 & 0 \\
0 & 0 & 0 & 1 & 0.5 & 0.5 \\
0 & 0 & 0 & 1 & 0.5 & 0.5
\end{array}\right]
$$

Finally it learns the internal structure of the domains (they are not learned at exactly the same time, which is learned first depends on the initilization). Around epoch 400 it has solved the task completely, with some sort of offset structure in the non-linear case, or without in the linear case:

$$
\text { solution with offsets }=\left[\begin{array}{cccccc}
1 & 1 & 0 & 0 & 0 & -1 \\
1 & 0 & 1 & 0 & -1 & 0 \\
0 & 0 & -1 & 1 & 1 & 0 \\
0 & -1 & 0 & 1 & 0 & 1
\end{array}\right]
$$

For most of the learning process, the networks are extracting similar structure, so one might expect that even the linear network would show some representation of the analogy at intermediate stages of learning. Indeed, once the base rates by domain are learned, both the linear and non-linear networks begin to extract the analogy between the domains. See fig. 4 for a plot of how much each domain's input mode projects to the other domain's output mode, i.e. "cross-talk" between the domains. This is a simple measure of the extent to which the network is extracting shared structure. However, while both networks develop some representation of the analogy initially, this activity extinguishes rapidly in the linear network, while it persists in the non-linear network.

Why do both networks show some representation of the analogy initially? We will analyze this in the linear case. At the stage when the base rates by domain have been learned, adding a little bit of shared structure actually reduces meansquared error (MSE). If the network moves from the base rates by domain pattern to the pattern shown below, the small increase in MSE from the $\pm 0.1$ values is more than offset by the decrease from splitting the 0.5 values into 0.4 and 0.6.

$$
\left[\begin{array}{cccccc}
1 & 0.6 & 0.4 & 0 & 0.1 & -0.1 \\
1 & 0.4 & 0.6 & 0 & -0.1 & 0.1 \\
0 & 0.1 & -0.1 & 1 & 0.6 & 0.4 \\
0 & -0.1 & 0.1 & 1 & 0.4 & 0.6
\end{array}\right]
$$

Indeed, suppose there is a hidden unit which responds differentially within the domains (as they all will to some extent because of the random initialization). The updates of the output weights for this unit will point in the direction of analogy extraction once the base rates by domain have been learned. See below for the output error, hidden unit activity, and corresponding weight updates in the case that the hidden unit responds positively to the first element of each domain, and negatively to the other. ${ }^{2}$ (Note that the output weight updates for a hidden unit are proportional to the product of the output error and the hidden unit's activation.)

[^382]

Figure 2: SVD of linearized I/O correlation matrix (colors are scaled to show qualitative features, red $=+$, white $=0$, blue $=-$ ). Note how Fig. 2a becomes Fig. 1a if the negative values are hidden by a nonlinearity.

Figure 3: Simple task network, showing a sample propagation of an input through the network with the single non-linearity at the output. (Circles represent inputs or fully connected units, squares represent non-linearities.)

Figure 4: I/O SVD component cross-projection (dot product between output mode of an SVD component and the response of the network to the other domain's input mode)

Figure 5: Family trees from Hinton (1986), (reproduced with permission).

Figure 6: Family tree task network (Circles represent inputs or fully connected units, squares represent non-linearities. Ellipses denote units omitted from the diagram - the hidden layer and all input and output groups had 12 units apiece.)

| output error |  |  |  |  | unit | unit output weight updates |  |  |  |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| 0 | + | - | 0 | 0 | 0 | + | 0 | + | - | 0 | 0 | 0 |
| 0 | - | + | 0 | 0 | 0 | - | 0 | + | - | 0 | 0 | 0 |
| 0 | 0 | 0 | 0 | + | - | + | 0 | 0 | 0 | 0 | + | - |
| 0 | 0 | 0 | 0 | - | + | - | 0 | 0 | 0 | 0 | + | - |
| net output weight update: |  |  |  |  | 0 | + | - | 0 | + | - |  |  |

Summing these updates captures the analogy between the domains. The network will exploit this analogy to reduce error, even if it must eventually discard it in the linear case.

## Reanalyzing Hinton's Family Tree Example

Next, we briefly turn our attention to the example of Hinton (1986). Hinton's task involves learning two isomorphic family trees, one English and one Italian (see fig. 5). This structure is taught implicitly by presenting a person (e.g. "Jennifer") and a relationship (e.g. "Father"), and training the network to produce the correct target person ("Andrew" in this case). There are 52 such relationships per family.

## Methods

Hinton used the same inputs for type of relationship for both families. To highlight the extraction of analogous structure we separated these into distinct input banks (these could be thought of as the English and Italian words for different relations, e.g. "uncle" vs. "zio" ). We also reduced his network down from 3 hidden layers to a single hidden layer with 12 units. Unlike the simple problem above, this problem is not linearly separable, so we included a non-linearity at the hidden layer as well as the output (see fig. 6). We trained this network by SGD with $\eta=0.005$ for 1000 epochs.

In a task which requires multiple non-linearities, we cannot perform as simple an analysis as in the earlier task. However, by definition each layer of the network has only a single nonlinearity, and so we can perform an analysis like the above on each layer. In this way we can understand something about the computations that layer is performing. However, the interpretation will not be as simple as above.

This difficulty is compounded by the complexity of the structure being learned in each family. In the simple problem above it was possible to "eyeball" the structure extraction, but here the structure is too rich. There are a variety of possible ways the families can be mapped onto one another (e.g. flipping the tree left to right and swapping all genders), and it's possible that the networks are extracting overlapping structure from several of these analogies. In this setting, how can we examine whether the network is learning the analogy?

As a first test of this, we looked for representation of the analogy in the input modes of the first layer SVD. To do this, we computed the dot product of each mode's weights for one family with that mode's weights for the other family, and then tested how significant this similarity was by comparing it to the null distribution generated nonparametrically by randomly permuting the columns of the input mode matrix 1000 times and computing the same dot product for each one.

We denoted a mode as showing significant extraction of the analogy if it showed a stronger similarity between the weights for the two families' inputs than $95 \%$ of its permutations did. We repeated this analysis across 100 network initilizations.

## Results

We found a great deal of analogous structure was extracted. The runs had a median of 4 modes showing significant analogous structure extraction, and all the runs had at least one significant mode (for comparison, if 5\% of the modes showed significant results by chance, we would still expect $54 \%$ of the runs to yield no significant results). To account for the symmetry of the tree under flipping, we repeated the same analysis after permuting the second family's input columns appropriately. Since the network has no way to distinguish the "regular" mapping from this "flipped" mapping during learning, we would expect to see a similar frequency of significant modes for each, and indeed the distributions are similar. Furthermore, the runs had a median of 6 modes showing significant extraction of either the regular or flipped mapping, and in all of the runs it had extracted 3 or more components that significantly represent one analogy or the other (if we assume 5\% false positives, we would expect results this extreme in only $0.01 \%$ and $3 \%$ of the runs, respectively). See fig. 7 . The frequency of analogy extraction suggests this may be a central feature of how neural networks solve tasks.

Although we have focused on broad analogies between the families here, we would like to note that analyzing the SVDs can give more detail. In some cases modes reflect an analogy only in the "person" inputs, or only in the "relationship" inputs. Within a family, analyzing the SVD modes can outline the structure the network is extracting, e.g. modes often appear which represent the gender of the target of a relationship like "mother". We have omitted these analyses due to length constraints.

## Disussion

We have outlined a new technique for analyzing neural network representations and their learning dynamics: analyzing the SVD of the "linearized" mapping at each layer (i.e. the mapping from the inputs to the pre-nonlinearity activity). This allows us to bring the power of linear analyses to bear on the rich phenomena that occur only in non-linear networks.

Using this technique, we have explored how a simple neural network can extract the analogy between simple tasks with non-overlapping inputs and outputs. We showed that, while a linear network cannot represent analogies, a single nonlinearity at the output layer can allow the network to represent the analogy, and that this structure emerges naturally (even in a linear network) from gradient descent once the base rates by domain have been learned. A linear network must discard this analogy to reach its optimal solution, but a non-linear network is able to retain it by simply offsetting the outputs to a sufficiently negative value, and does so the majority of the time in our results. Here we used rectifiers, but the same general solution is achievable with other nonlinearities.

Figure 7: How many of the input modes from the SVD showed significant projection onto the regular or flipped analogies (with null distribution for comparison)

We then broadened our approach to explore the family tree task originally proposed in Hinton (1986). Because this task is not linearly separable, we created a general network with two nonlinear layers, and applied our analysis to each layer. We found evidence of a great deal of extraction of two possible analogies between the families in the network (either the intended isomorphism between the family trees, or one in which one family tree was flipped left-to-right and genderreversed), and that networks seemed generally to be discovering elements of both analogies. Indeed, representation of the analogies seemed even more common than on the simpler task. On the simple task $25 \%$ of the networks showed no evidence of common structure extraction, but on the family tree task every network extracted at least three input modes that projected significantly onto one of the analogies.

These results suggest that sensitivity to analogy may be a natural feature of gradient based learning in nonlinear neural networks. This may underlie many of the "slow" analogical transfer effects we highlighted in the introduction. Furthermore, this may be a part of why learning multiple tasks facilitates more rapid learning and better performance in machine learning systems, and it may have important implications for cognition. The power and generality of human cognition may result from extracting common structure from the diverse but deeply related tasks we engage in throughout our lives.

## Future Directions

1. In our analysis we analyzed the input modes of the first layer and the output modes of the second layer. In the future it will be important to explore modes that map into and out of the hidden layer, and what they imply about the representations at the hidden layer. This would also allow us to apply this analysis to deep networks.
2. Learning representations that reflect analogies may provide amortized inference about potential analogical structure in the world. Can this support explicit analogical reasoning?

Keywords: category adjustment models; emotion memory; emotion perception; face perception; individual differences; Bayesian modeling

#### Abstract

When participants view and then reproduce simple objects that vary along a continuous dimension such as length or shade, or when they view images of faces that vary in emotional expression, their estimates tend to be biased toward the average value of the presented objects, a phenomenon that has been modeled as the result of a Bayesian combination of prior category knowledge with an imprecise memory trace (Corbin, Crawford \& Vavra, 2017; Huttenlocher, Hedges \& Vevea, 2000). Whereas previous work described a general cognitive strategy based on data aggregated across participants, here we examined individual differences in strategy. Thirty-six participants viewed and reproduced 496 morphed face stimuli that ranged from angry to happy. We found substantial variation in the bias patterns participants produced. Individuals' estimates were well fit by a model that posited attraction toward three categories, one at the happy end of the range, one at the angry end, and one that captured the entire range of presented stimuli, and by allowing the weight given to each category to vary by participant.

## Introduction

Memories are never pure. Memory of an object is determined not only by that individual object, but also by the set, or category, to which it belongs. Specifically, items tend to be remembered as being more like the typical (average) item in a set than they actually were. For example, Huttenlocher, Hedges and Vevea (2000) had participants view and immediately reproduce individual items that varied along a continuous dimension such as length, width, or shade. They manipulated the presented distribution of lengths, widths, and shades and found that estimates were biased toward the central value of the distribution shown. They proposed the bias is a byproduct of a Bayesian combination of a noisy, unbiased memory trace of the stimulus with a prior distribution that reflects the presented stimuli. Related Bayesian accounts have been developed to
account for bias in time perception (Jazayeri \& Shadlen, 2010), hue judgments (Olkkonen, McCarthy, \& Allred, 2014), and estimates of the sizes of familiar fruits and vegetables (Hemmer \& Steyvers, 2009). Here we extend this earlier work in two important ways. First, we apply this explanation to rich, socially relevant stimuli: faces that vary in emotional expression. Second, we model individual differences in how people rely on category knowledge when remembering facial expressions.

It is an open question whether memory for facial expressions can be characterized by the same principles that have been used to explain memory for length of a line. Facial expressions are socially meaningful and visually complex stimuli with which people have extensive prior experience, and unlike many other objects, faces are processed holistically (e.g., Maurer, Le Grand, \& Mondloch, 2002). Compared to simple geometric objects, it is more difficult to assess visual memory of real faces. One approach is to use morphing software to create gradations of faces that vary along a dimension of interest. By morphing pictures of the same actor making angry, neutral, and happy faces, we can create a continuum of emotional expression to be used in memory tasks like the immediate reproduction procedure described above. These morphed continua allow researchers to assess the degree to which a particular face is remembered as having an expression that is more or less happy or angry than it actually was.

Few studies have used face morphs to examine bias in memory for individual facial expressions (but see Haberman, Brady \& Alvarez, 2015; Haberman \& Whitney, 2009 for related work). In a study designed to examine the central tendency bias in face memory, Corbin, Crawford and Vavra (2017) ran several experiments in which participants viewed faces one at a time and, after each one, estimated its expression by adjusting a response morph. Estimates were consistently biased toward the central value of the stimulus distribution, whether it ranged from very sad to neutral, very happy to neutral, or moderately happy to moderately sad. Furthermore, the degree of this central tendency bias

Figure 1: Example stimuli. Shown are the original angry neutral, and happy faces used to generate the stimulus morphs as well as morphed images between angry and neutral and between neutral and happy.
increased with longer retention intervals between stimulus and response. Bayesian models predict such an effect because, as the trace memory distribution becomes noisier (i.e., more variable), the Bayesian combination of trace memory and category knowledge will give more weight to the category knowledge (see also Huttenlocher et al., 2000; Crawford, Huttenlocher \& Engebretson, 2000).

The Corbin et al. (2017) work was designed to allow for group-level conclusions and not for modeling of data from individual participants. This is typical of cognitive psychology, which usually characterizes the cognitive processing of a presumably generic, modal human mind without examining the variation between individuals. However, as we have noted elsewhere (Crawford, Landy \& Presson, 2014; Crawford, Landy \& Salthouse, 2016), that can lead to conclusions about aggregate tendencies that do not reflect the behavior or cognitive processing of any single individual. In fact, little is known about how people differ in their use of stimulus distributions to inform estimates of individuals. Building on the Corbin et al. findings, here we use Bayesian hierarchical modeling to examine both aggregate bias patterns and bias patterns at the level of individual participant. This approach allows us to estimate how each individual combines different category structures to arrive at estimates.

Emotional faces vary in physical dimensions such as mouth shape and brow orientation, as well as in affective significance, which can be processed automatically and unconsciously (e.g., Axelrod, Bar, \& Rees, 2015; Vuilleumier, 2005). A continuum of emotional expression is necessarily bound up with physical feature variations and we do not attempt to tease these apart. Instead, we capitalize on previous work (Corbin et al., 2017; Haberman et al, 2015, Haberman et al., 2019) showing that the continuum created by morphing emotional faces produces results that mirror those found in studies using simple dimensions such as size, color, or shade. This work suggests that, when shown a set of faces that vary on a morphed expression continuum, people are sensitive to the central tendency of the set along that dimension.

## Experiment

## Method

Participants Thirty-six (11 male) students from the undergraduate participant pool at the University of Richmond received course credit for participating.

Materials Images were from the NimStim face stimulus set ${ }^{1}$, a database of photographs of young adults depicting various emotional expressions. Sixteen models ( 8 male, 8 female) were chosen and the closed-mouth angry, neutral, and happy expressions of each were used to create the stimuli. Because in some cases, changes in hair position led to distracting artifacts in the morphed sets, we edited the initial images to maintain consistent hair placement. Using FantaMorph software (Abrosoft, 2002), each model's expressions were morphed from angriest to neutral to happiest, creating a set of 41 evenly distributed expressions that changed in $5 \%$ increments.

Procedure Each trial started with a crosshair at the center of the screen for 830 ms followed by a centrally presented single image frame taken from the morphed sets of faces and shown for 500 ms . The faces presented for study ranged from an angry expression (face \#5) to happy (\#35) and did not include the five most extreme images from either end of the continuum. After a blank screen ( 66 ms ), a response face of the same model was shown in the upper left hand corner of the screen. Participants were instructed to "use the right and left arrow keys to change the expression of the face to match the expression of the previous photograph." Pressing the right arrow key made the expression cycle through the entire morph (images $0-40$ ), cycling from happy to neutral to angry (or vice versa). Pressing the left arrow key cycled in the opposite direction. In a between subjects

[^383]manipulation, participants were randomly assigned so that the starting frame of the response morph was always the angriest face ( $\# 0$ ) or always the happiest face (\#40). Participants estimated each of the 31 facial expressions for each of the 16 models, for a total of 496 randomly ordered trials.

## Modeling

We modeled this data using a hierarchical Bayesian approach, simultaneously modeling individuals and group averages (see Figure 2). We assumed that each person was affected by a weighted combination of three potential biases: an overall inward bias toward the central category prototype ( $N$ ), and two attractive biases toward postulated extreme categories, representing the endpoints of happiness $(H)$ and anger ( $A$ ). We assumed equal variance for each category, and a logistic categorization boundary. Each category had a separate 'weight' $(W)$, which allowed the model to treat responses as the result of any number of categories from 0-3; best-fitting models uniformly predicted three categories (see Figure 5).

Explanations of bias are usually rooted in principles of Bayesian estimation: biasing responses toward a prior expectation reduces error (e.g., Feldman, Griffiths, \& Morgan, 2009; Huttenlocher et al., 2000). In this initial analysis, we simply assumed that each category attracted responses toward its center. This structure captures the relationships most often studied in category-based adjustment experiments, but abstracts away from the relationship between variability and category use-components of the model which have previously met with some predictive success (Crawford et al, 2016), but which were to the side of our primary concerns in this initial analysis

Model predictions were unbounded, but actual responses were bounded between an extreme happy face (valued as 1), on one end of the scale, and an extreme angry face (-1). To handle this, we assumed that when participants retrieved a face beyond the edges of the scale, they would select the most extreme face available.

Figure 2: Graphical model diagram of the Bayesian model. Rij is the response to stimulus j presented to subject i . The mean response is the sum of the stimulus value, sij, and three sources of bias, corresponding to the angry (A), neutral (N), and happy (H) prototypes. Each prototype has a weight (W) and a location (L). The category weights were potentially asymmetric, depending on the valence of the initial response slider (that is, whether the response face (f) was set to maximally angry ( -1 ) or maximally happy (1). The model only shows the first layer of fits: all top-level distributions were governed by population-level hyper parameters (see Table 1), which employed weak priors. In all cases, we assumed unbounded parameters to be normally distributed, and positive unbounded parameters to be gamma.

Figure 3: Aggregate and Individual Model Fits: (Left panel) Mean bias in response along with predictions averaged across participants. Errors reflect standard errors. (Right panel) Model fits for each individual participant. Use of all three categories is substantial, but starting side of the response strongly impacted the relative strength of these categories.

Figure 4: Individual model fits and data. Each dot is the bias in response to that stimulus, averaged across all times that participant viewed that expression. Each panel represents responses from one participant. Although different participants show quite different behaviors, the model treats each as a variation around a common theme of inward bias toward three weighted prototypes.

## Results

Aggregated and individual response patterns are plotted in Figures 3 and 4. As can be seen, there was a strong pattern, overall, of attraction toward the center of the distribution. However, this was tempered by strong outward trends among most individuals. These outward biases tended to be moderately strong, roughly comparable in size to the bias toward the center, and in some cases dominating it. Figure 3 shows the aggregated model fits across participants; Figure 4 the individual fits.

Parameters fit hierarchically are listed in Table 1 and include the weights attributed to each category and the locations of each category.

The magnitude of the individual differences in weights can be characterized by the posterior deviation parameters ( $\sigma$ ) governing weights. The $95 \%$ Highest Density Intervals for these excluded 0 (see Table 1), indicating that individuals differed in the weight given to these parameters (gamma shape parameters of roughly $<1$ correspond to high density around 0 ), and that these differences were not well explained by sampling noise.

Table 1: Priors and posteriors of population parameters. The $\mu$ values on the locations indicate mean locations of the categories, while the weight parameters have shape and rate values.

| Parameter | Population Prior | 95\% HDI |
| :---: | :---: | :---: |
| $W_{A}$ | $\Gamma$ (shape, rate) shape $\sim \Gamma(1,0.005)$ rate $\sim \Gamma(1,0.005)$ | $\begin{aligned} & \text { shape: }[11,168] \\ & \text { rate: }[6,92] \\ & \text { mean: }[1.6,2.4] \end{aligned}$ |
| $W_{N}$ | $\Gamma$ (shape, rate) <br> shape $\sim \Gamma(1,0.005)$ <br> rate $\sim \Gamma(1,0.005)$ | shape: $[39,196]$ rate: [42,175] mean: [.85,1.2] |
| $W_{H}$ | $\Gamma$ (shape, rate) shape $\sim \Gamma(1,0.005)$ rate $\sim \Gamma(1,0.005)$ | shape: 120,235$]$ rate: [57,124] mean: [1.6,2.6] |
| $L_{A}$ | $\begin{aligned} & N(\mu, \tau) \\ & \mu \sim N(-1,80) \\ & \tau \sim \Gamma(1,200) \end{aligned}$ | $\begin{aligned} & \mu:[-1.3,-1.15] \\ & \tau:[.2,2640] \end{aligned}$ |
| $L_{N}$ | $\begin{aligned} & N(\mu, \tau) \\ & \mu \sim N(0,80) \\ & \tau \sim \Gamma(1,200) \end{aligned}$ | $\begin{aligned} & \mu:[-0.06,-0.002] \\ & \tau:[68,560] \end{aligned}$ |
| $L_{H}$ | $\begin{aligned} & N(\mu, \tau) \\ & \mu \sim N(1,80) \\ & \tau \sim \Gamma(1,200) \end{aligned}$ | $\begin{aligned} & \mu:[1.225,1.325] \\ & \tau:[52,2040] \end{aligned}$ |
| tau | $\Gamma$ (shape, rate) <br> shape $\sim \Gamma(3,1)$ <br> rate $\sim \Gamma(3,1)$ | $\begin{aligned} & \text { shape: }[3600 \text {, } \\ & \text { 10000] } \\ & \text { rate: }[240,520] \end{aligned}$ |
| $\beta$ (side bias) | $\begin{aligned} & N(\mu, \tau) \\ & \mu \sim N(0,80) \\ & \tau \sim \Gamma(5,0.1) \end{aligned}$ | $\begin{aligned} & \mu:[0.01,0.02] \\ & \tau:[4,800,28800] \end{aligned}$ |

Figure 5: Simplex plot of the relative weights accorded to each category. A dot reflects a mean individual. Red indicates starting values on the happy side, blue on the angry side. Although in principle, the total weight could vary, in practice each individual showed a mean weight between 3.3 and 3.5 , making simplex plots a useful visualization of the three values.

One factor had a strong apparent impact on the weight given to the left and right categories: the starting location of the response. To quantify this effect, we modeled the left and right weights as symmetric, except for a mean shift determined by an individual splitting parameter. This splitting parameter was fit to individuals; the posterior fits are shown in Figure 5. The results suggest a moderate impact of start location on category weight, such that people more heavily weighted the category represented in the starting value.

## Discussion

Building on earlier work on inductive category effects on memory, we assume that estimates of an individual object combine an inexact memory trace of the object with knowledge of the set to which it belongs (e.g., Huttenlocher et al., 2000), producing estimates that are biased toward category prototypes. Such central tendency effects have been shown in studies using immediate reproduction tasks with simple stimuli that vary on one or two dimensions, such as size and shade (e.g., Crawford et al., 2001). Extending this work to more complex and socially relevant stimuli, Corbin et al. (2017) found that estimates of emotional expressions are also biased toward the center of the presented range of expressions, suggesting that participants used an inductively formed category to adjust estimate of faces.

Here we further examined the kinds of category structures involved in face memory and the degree to which individuals differed in their use of these structures.

As in previous work, estimates generally were biased toward the presented distribution's center (here a neutral expression). In addition, we found substantial variability between participants such that most participants were not well described by a model that treated estimates as resulting from adjustment toward a single, centrally located category. Good model fits at the participant level were achieved by positing that estimates could be adjusted toward two additional categories (centered on angry and happy values) and by allowing category weights to vary by participant. We note that this threecategory model reflects the structure that was used to generate the stimuli: pictures of faces that actors made when told to show happy, angry and neutral expressions.

Some of the difference in how participants weighted the different categories could be accounted for by the starting value of the response face, which was randomly assigned between subjects. On average, greater weight was given to the category that aligned with the starting position (either $100 \%$ happy or $100 \%$ angry). The effect of the starting value was not linear across the stimulus range, as would be expected by inadequate adjustment away from an anchor. Instead it appears that the starting value encouraged participants to rely more heavily on the closest emotion category. Although studies of inductive category learning typically focus on the distribution of test objects, this result suggests that response objects may also contribute to the category structure used during estimation.

It is common to analyze group-level data and describe the collective's average behavior, but this approach can miss meaningful variation in cognitive strategies used by individuals. Modeling responses at the individual level reveals similarities across participants as well as some systematic differences. From the current study, it is not known why people adopt the strategies that they do. The model's success in capturing the different data patterns produced by individuals makes it a valuable framework for future studies of how differences in cognitive, social, and affective processing may influence the reliance on categories when remembering emotional faces. The variation in bias that we observed suggests that models pitched at the level of group averages are likely to mislead us away from the best interpretations.

#### Abstract

Studies of unconscious plagiarism have reported that people mistakenly include a partner's responses when trying to recall their own (recall-own task) and include own responses when trying to recall their partner's (recall-partner task). In a simulation, we tested if participants' memory performance at test, including source errors, can be explained by participants simply guessing items that come easily to mind. We show that guessing alone cannot account for the pattern of data participants show at test. Modifying the simulation by including memory for self-generated items allows us to replicate the pattern of responding in the recall-own but not the recall-partner task, even when we assume that participants in the recall-partner task strategically withhold more fluent items from report. This suggests that judgements of items' memory strength alone cannot explain performance in the unconscious plagiarism paradigm.

Keywords: source memory; free recall; unconscious plagiarism

## Background

In the standard unconscious plagiarism (or cryptomnesia) experiment (Brown \& Murphy, 1989), participants in groups take turns to generate solutions for a task. Following a delay participants are asked to complete a recall and/or a generatenew task. In the recall task, participants are asked to selectively recall the solutions they generated themselves, avoiding those generated by others in the group. In the generatenew task, participants are asked to generate novel solutions to the task, avoiding both previously self- and other-generated ones. Plagiarism errors (or source errors in the recall-own and generate-new task) are now solutions generated by other members of the group that participants falsely claim to have generated themselves, with plagiarism typically at abovechance rates for both the recall-own and generate-new task (Brown \& Murphy, 1989). More recently, Hollins, Lange, Berry, and Dennis (2016) showed that source errors in recall tasks are not limited to the recall-own task, but also occur during the recall of partner-generated items in the recall-partner task. Rather than participants being biased to simply claim ideas as their own, it appears that participants are simply confused about the source of the ideas they retrieve from memory (Hollins, Lange, Dennis, \& Longmore, 2015; Perfect, Field, \& Jones, 2009).

While source errors are typically treated as an instance of false memories, an alternative account is that they constitute accidental errors that occur by chance (Brown \& Murphy,

1989; Tenpenny, Keriazakos, Lew, \& Phelan, 1998). In the study phase, participants are asked to take turns generating responses to cues, such as category exemplars. Without further instruction to generate typical or atypical exemplars, it is likely that participants will first generate responses that are readily available to them, i.e. typical exemplars in the category. This would be in line with participants employing a fluency heuristic (Jacoby, Woloshyn, \& Kelley, 1989).

Brown and Murphy (1989) tested this non-memorial guessing account. They presented participants with the test phase of an unconscious plagiarism experiment without a preceding study phase. When treating this generation at test as recall from a study phase that participants did not participate in, participants still committed "source errors" to a high degree. This seems to suggest that reporting items based on fluency or the frequency or typicality of items could be responsible for source errors.

Critically, Brown and Murphy (1989) focused only on source errors, and only on source errors in the recall-own task. In the present paper, we adapted the unconscious plagiarism and anti-plagiarism paradigm as used in Hollins et al. (2015, 2016) for actions. We constructed guessing simulations that builds on Brown and Murphy but attempts to simulate performance across all task measures in both retrieval tasks. If source errors are in part the result of chance performance, the same would have to be true for the correct retrieval and the generation of novel items at test.

We constructed a base guessing model that samples, ignorant to study phase and task, from the possible items per category cue, with sampling weighted by the frequency or typicality of those items. In subsequent simulations, we modified this base guessing simulation by manipulating the number of items per cue available to participants at test, the memory for self-generated and partner-generated items, and the orientation towards self-generated or partner-generated items at test given the retrieval task.

## Experimental work

Unconscious plagiarism has been exclusively studied with verbalizable stimuli (for reviews see Perfect \& Stark, 2008; Gingerich \& Sullivan, 2013). We adapted the unconscious plagiarism paradigm with two retrieval tasks to motor actions to produce observed data. In this experiment, we asked par-
ticipants to take turns performing and observed actions with a partner in the study phase. In the test phase, participants then were asked to recall performed actions (equivalent to the Recall-own task for verbal material) or asked to recall observed actions (equivalent to the Recall-partner task).

## Method

Participants 40 members of the public participated for payment of $£ 12$. Three participants did not attend all sessions and their data were excluded from the analysis.

Procedure Participants were asked to attend two sessions in total, a day apart. For the first session, participants were paired and asked to take turns generating and acting out shapes with any part of their body or combinations of body parts. They were shown 15 shape cues $(=$, A, C, F, H, I, J, K, $\mathrm{L}, \mathrm{O}, \mathrm{P}, \mathrm{T}, \mathrm{V}, \mathrm{X}, \triangle)$ in total. Participants were cued with a printed label of each shape. Members of the pair took turns generating actions for each cue, interleaving performing and observing actions such that performing an action in response to a cue was followed by observing the other person perform an action in response to the same cue. Each participant generated a total of 4 actions per cue, resulting in 60 performed and 60 observed actions overall. Participants were told to observe their partners during partner-generation to avoid duplicating exemplars that had already been created for a cue. Participants observed their partner perform actions under a secondary task load for two-thirds of the shape cues. The assignment of shape cues to secondary task conditions was counterbalanced across participants. The focus of the present paper is on the control condition only, i.e. the one-third of actions participants performed and observed without secondary load, for the purposes of simulating guessing performance.

Participants returned the next day individually for a memory test. They were instructed to retrieve and re-perform either the actions they had generated themselves (Recall performed) or those they had observed their partner perform (Recall observed) the previous day. They were cued with the shape labels, and asked to re-perform as many actions as they could remember for each shape (free report). They were asked to avoid performing actions that did not comply with their retrieval task.

Preprocessing of observed data In the study phase, participants could commit two types of errors: self-plagiarism, that is repeating an item they had already generated for a particular cue, and other-plagiarism, repeating an item their partner had already generated for a cue. In the control condition, participants self-plagiarised on average 5.13\% ( $\mathrm{SD}=5.75 \%$ ) of items and plagiarised $9.73 \% ~(\mathrm{SD}=6.25 \%$ ) of partner-generated items. Items that both participants had generated at study for a cue were removed from analysis, since the source of the item, if retrieved, would be ambiguous.

## Results

Participants' mean performance in both retrieval tasks is shown by the bars in the figures in this paper. Correct source
retrieval was higher in the Recall performed than the Recall observed task, $t(34.80)=2.75, p=.009$. There was no evidence for source errors or intrusion errors being committed more frequently in one than the other retrieval task, $t(31.86)=1.29, p=.21$ and $t(35)=.04, p=.97$.

## Simulating frequency-based guessing

## Base guessing simulation

In the base frequency-based guessing simulation we extended the idea of a test phase without prior study phase tested by (Brown \& Murphy, 1989). We used a Monte Carlo procedure to simulate how many correct responses, source errors and intrusion errors participants would make if they were guessing and had just generated potential actions for each shape "on the fly" during the test phase, rather than genuinely retrieving them from what they had previously either seen or performed. We simulated the test phase of the experiment for each participant and each shape separately to take into account differences between individual participants, differing frequency profiles for the different shapes, and the typicality of individual items.

As a first step of the simulation process, we determined frequency norms for the different actions generated for each of the 15 shapes used in the experiment. We took into account all possible shapes all participants had generated across the experiment. Some actions were produced more frequently than others across participants, resulting in a frequency profile for each shape. Both self-plagiarised and partner-plagiarised items at study were included in the creation of these frequency profiles. For each shape, we converted these frequency profiles of the different actions into probability distributions, reflecting the relative probability that a particular action was produced for a given shape. For each shape, the probabilities across the shape cue summed to 1 to represent all possible actions for the shape.

We used these distributions as the basis for participants' guessing. Partner-plagiarised items were excluded from the distribution prior to guessing to match the analysis of the observed data. For each participant we sampled the number of items from each shape distribution that participants reported at test for that particular shape (excluding the partnerplagiarised items again). The sampling was weighted by the relative probability of the items, to implement that guessing was not random but biased by the frequency or typicality and therefore fluency of items. This sampling was done without replacement to match the experimental procedure of only retrieving an item once. Items were sampled sequentially, with the distribution re-normed after each draw. We repeated this for every participant, and ran the simulation over 500 iterations for stable estimates.

In addition to the items participants reported at test (correct responses, source errors, novel items), we now also have the same measures if participants were only guessing at test.

Figure 1 shows the results of the base guessing simulation (the full-length distribution indicated by the stars) relative to
the observed data. In both retrieval tasks, mere guessing may approximate the number of source errors but cannot account for the number of correct responses and intrusion errors. It is therefore unlikely that performance in this paradigm occurs simply because highly-frequent items are generated both at study and test, regardless of an influence of memory.

In the next section, we will modify this base guessing simulation by manipulating first the length of the frequency distribution, and then introducing memory and meta-cognition into the frequency-based guessing.

## Modifying the base guessing simulation

In the base guessing simulation we assume that participants' responses are based entirely on the overall frequency (or typicality) of items. This assumption leads to the following conditions for guessing: a) each participant has the entirety of each shape distribution available to them at retrieval, b) memory encoding in the study phase does not affect the frequency of items (i.e., there is no effect of memory) and c) participants' responding does not change with the instruction to retrieve items from one or the other source. In the next three steps, we therefore simulated the influences of the length of the distribution, memory effects and retrieval task orientation on participants' guessing. Strictly speaking, only the first modification still represents participants only guessing, i.e., responding without memory. The second modification introduces an effect of memory and the final modification an effect of metacognitive choices made at retrieval.

Length of the distributions In the base guessing distribution, the simulated participants sample their guesses from all possible ways a particular shape was produced in the experiment. This assumes that each participant has access to all possible ways a shape can be represented with the body that were produced throughout the experiment - this is a strong assumption that may inflate the number of novel items relative to items generated at study. It is more likely that each participant has only a subset of items for each shape cue available to draw on. In the first modification of the base guessing simulation, we therefore simulated the pattern of performance in the task if participants guess from frequency distributions for each shape that are a shorter, i.e., include fewer possible actions.

Table 1: Average number of items in the guessing distributions with shortened tails

|  | Number of items per cue |  |  |
| :--- | :--- | :--- | :--- |
| Length | Mean $(\mathrm{SD})$ | Max | Min |
| Full | $23.66(4.68)$ | 33 | 16 |
| 0.9 | $12.30(3.19)$ | 19 | 5 |
| 0.8 | $8.18(2.20)$ | 13 | 2 |
| 0.7 | $5.59(1.26)$ | 8 | 1 |
| 0.6 | $3.78(0.88)$ | 6 | 1 |

The probabilities associated with the items in the base

Figure 1: Observed data in bars (correct responses, source errors, intrusion errors) with $95 \%$ confidence intervals and data predicted by participants guessing with distributions of varying length relative to the full distribution (points)
guessing simulation sum to 1 , from most frequent items at higher probabilities to least frequent items with lower probabilities. We created shorter distributions by successively shortening the tail of each shape distribution, i.e., removing the least frequent items. This resulted in distributions representing the top $90 \%, 80 \%, 70 \%$ and $60 \%$ of items generated for each shape across participants in the study phase. The sampling procedure was otherwise identical to the one described above.

Table 1 shows the average number of items, as well as maximum and minimum number of items, that could be sampled across shapes for the different lengths of distributions. For the shorter distributions, in some cases the total number of guesses to be sampled was longer than the distribution to sample from. In those cases, the total possible number of items, i.e. all items in the shortened distribution, was sampled as a guess in lieu of the total number of responses participants in fact made in that case.

Figure 1 shows participants’ observed performance (bars) and simulated performance (points and lines) in both the Recall performed and Recall observed task. The stars indicate the sampling based on the full-length distributions for each shape, the remaining points the proportionally shorter distributions (relative to the full-length distribution). Comparing the simulated performance across the different lengths of the distribution shows that with shorter distributions, the number of novel items that are sampled during guessing decreases. There is only a minimal effect on the number of correct responses and source errors that are sampled.

While guessing even based on shorter distributions does not approximate performance in the Recall performed task, guessing based on drastically shortened distributions comes close to replicating the pattern of responding in the Recall observed task. Though note that the radically shortened dis-
tributions do not contain many items available for guessing. Naturally, these very short distributions not only contain only a minimum of novel items (hence the decrease in the sampled novel responses), they also do not contain many items participants generated in the study phase and hence do not drastically increase correct and source error responses.

Performance in the Recall-performed task (the original unconscious plagiarism paradigm) cannot be only the result of frequency-based guessing at test. In the Recall observed task, this type of guessing could potentially account for the pattern of responding. In the next step, we modified the distribution further by adding memory for items that were generated at study.
Memory after generation Pure guessing, here implemented by sampling based on the overall frequency or typicality of items, does not fully approximate performance in the memory test and therefore is not an explanation for unconscious plagiarism performance (when both correct responses and intrusions are considered alongside the number of source errors). In the next step, we tested if adding an effect of memory to the model by boosting the probability of items that were generated by participants could account for the pattern of data observed in the experiment.

We used the full-length distribution (rather than shortened distributions). We implemented memory for items by adding a second probability term to all items participants generated themselves (but not to items participants observed their partners perform - we added this modification in the final simulation). The additional probability terms for self-generated items were 0 (the base guessing simulation), $0.1,0.2,0.3,0.4$ and 0.5 . The final shape distributions were re-normed so all probabilities summed to 1 after this memory probability term was added to the prior probability of each item. Beyond the memory boost, the sampling procedure was identical to the one described in the previous simulations.

Figure 2 shows the observed data (bars) and the predicted responses based on the guessing simulation with memory boost. The memory boost results in good approximation of performance in the Recall performed task (even with the fulllength distribution used for guessing). This suggests that participants in the Recall performed task may simply successfully employ a fluency heuristic (Jacoby et al., 1989) by reporting items that are strongly represented at test by a combination of their base typicality and some memory.

In the Recall observed task, increasing the likelihood of generated (here: source error items) to be guessed leads to grave misfits of the pattern of data observed in the experiment. If participants were still simply reporting the most fluent exemplars at test, regardless of the task, the number of source errors (self-generated items with higher memory), should be higher than the number of correct responses (observed actions). This is clearly not what participants in the experiment are doing.

In the final modification, we therefore introduced a metacognitive modification to the simulation that has partici-

Figure 2: Observed data in bars (correct responses, source errors, intrusion errors) with $95 \%$ confidence interval and data predicted by participants guessing with self-generated items' probability to be sampled boosted by varying probabilities.
pants orient their report towards their retrieval task, i.e., deliberately withholding fluent items in the Recall observed task.

Orienting towards retrieval task Both the manipulation of the length of the distribution and boosting memory for self-generated items assumed that participants use a fluency heuristic in the test phase of an unconscious plagiarism task. Regardless of the the task instruction to retrieve self-generated or other-generated (here: observed) items, the fluency heuristic assumes that participants will base their responding entirely on what comes to mind at test. This means items associated with higher probabilities will be reported more readily, regardless of the retrieval task.

In a more nuanced approach, it is feasible that participants are able to regulate the memories they report (Marsh \& Bower, 1993; Hollins et al., 2016). In this case, participants in the Recall observed task could be able to withhold items that first come to mind from report if they assume that better memory/higher fluency would be indicative of self-generation and hence represents a source error. This type of source monitoring is based entirely on monitoring the memory strength of items, rather than any source features.

In the simulation, we implemented a task orientation by sampling double the total number of items a participant reported from each shape distribution. For the Recall performed task, we then used the top half of the sampled items as items guessed in the simulation. In the Recall observed task, we discarded the first few guesses (this is participants withholding items from report) and instead used the bottom half of guesses, the relatively less frequent items. The remainder of the simulation was identical to previous simulations, with sampling based on the full-length distribution.

Figure 3 shows the results for the frequency-based guessing if self-generated items are boosted in memory and participants in the Recall observed task withhold these items.

Figure 3: Observed data in bars (correct responses, source errors, intrusion errors) with $95 \%$ confidence intervals and data predicted by participants guessing with self-generated items' probability to be sampled boosted by varying probabilities.

The results for the Recall performed task are naturally equivalent to the simulation without retrieval task orientation, since in both cases the most frequent items are reported. For the Recall observed task, the simulated participants are now less likely to now report source errors, i.e. they successfully withhold those items. Rather than this boosting the correct retrieval (items they observed their partner perform), this modification only increases the number of novel items. Even with an orientation towards weaker items, a frequency-based guessing procedure with memory for self-generated items does not account for the observed pattern of data in the Recall observed task.

Remember, we implemented only increased memory for self-generated but not for observed items. It is possible that even small increases in memory for observed items could explain the correct responses in the Recall-observed task. In a final step modification, we therefore manipulated memory for observed actions. We sampled from distributions slightly limited in length ( 0.9 distribution from the length modification) and boosted memory for self-generated actions by 0.3 (the boost that most closely matches the pattern of responding in the Recall performed task). We boosted memory for observed actions by a probability term of $0,0.3 / 4,0.3 / 3,0.3 / 2$ and 0.3 , using the assumption that memory for self-generated items is not likely to be lower than memory for observed actions.

Figure 4 shows the results of the simulation and the observed data. Boosting memory for observed actions does not lead to a closer approximation of the data in the Recall performed task, in part because the effects of the shortened distribution and memory for observed actions both limit retrieval of novel items and increase retrieval of observed actions.

In the Recall observed task, with additional memory for observed actions, the number of correct responses observed in the experiment cannot be replicated. This may not be sur-

Figure 4: Observed data in bars (correct responses, source errors, intrusion errors) wit $95 \%$ confidence intervals and data predicted by participants guessing with self-generated items' probability to be sampled boosted by varying probabilities.
prising given the implementation of the task orientation in the simulation. We implemented participants' orientation towards observed actions in the Recall observed task as a withholding of the first few sampled items, in spirit of participants' performance being based on fluency and the interpretation of fluency alone. Increasing the probability of observed items now makes it more likely for those items to be sampled first, and therefore withheld. In other words, to replicate the pattern of observed data using a frequency-based sampling approach, memory for observed actions has to be lower than memory for self-generated actions, with the items participants observed needing to be of higher strength than novel items that were not generated. In the simulations, we did not achieve this balance. It is not clear if memory strength alone is sufficient to explain performance in the Recall observed task.

## Discussion

We adapted the extended unconscious plagiarism paradigm (Hollins et al., 2016, 2015) to motor actions. Participants took turns generating and observing actions in the study phase, and were asked to retrieve actions they performed themselves or actions they observed their partner perform in the test phase. We simulated performance in the task to test if guessing alone can account for the pattern of data we observed.

We simulated the experiment to test if frequency-based guessing can account for the observed results. This account is a variation of a fluency or memory strength account of unconscious plagiarism (Marsh \& Bower, 1993; Hoffman, 1997; Jacoby et al., 1989) and proposes that memory retrieval in the unconscious plagiarism paradigm is guided by the overall memory strength or availability of items at test. Items with higher memory strength are more likely to come to mind and hence be reported at test. We have shown that this approach
with modifications of length, memory and task orientation provides a reasonable description of the data in the Recall performed task. Notably, it does less well in accounting for the data in the Recall observed task.

Given the framework of this kind of memory strength account, the main difference between the retrieval tasks is that participants will do better to report highly-frequent items in one case (Recall performed task) and better to withhold them in another case (Recall observed task). In the Recall observed task, participants ideally report items of some memory strength. In our simulations we were not able to replicate that participants, in fact, are able to make correct responses in the Recall observed task that exceed source errors and intrusion errors.

While responding based on memory strength alone could explain performance in the Recall performed task, it is not sufficient to explain performance in the Recall observed task (for a similar conclusion using a signal detection approach, see Hollins et al., 2016).

There are two possibilities. Participants in the Recall observed task may simply be guessing. In particular if they can only generate very few items (or only very few items beyond self-generated items they remember and are potentially withholding from report), guessing without any memory boost may account for performance in the task. We showed that with very short distributions, performance in the task was approximated. Arguably, the shortest distributions that came closest in matching the pattern afford unrealistically few items to participants in the test phase.

Alternatively, performance in the unconscious plagiarism (and anti-plagiarism paradigm) may not be only based on the overall strength (fluency, familiarity or item memory) of items. In line with the source monitoring framework (Johnson, Hashtroudi, \& Lindsay, 1993) used to explain monitoring failures in other false memory paradigms, participants may judge source memory on a dimension separate to the overall memory strength. While memory strength alone may not allow participants to distinguish very typical items that were not generated from atypical items they observed, retrieving source features from the memory of the observed actions (visual, cognitive, affective, etc.) would allow them to report the observed action over the novel action when asked to do so by the task.

In conclusion, plagiarism errors are not simply the result of participants guessing and reporting typical exemplars at study and at test. While performance when asked to retrieve self-generated items may be explained by participants simply using overall memory strength to guide their responding, performance when asked to retrieve partner-generated items cannot. A source memory account that assumes that participants consider qualitative features of their memory alongside the overall memory strength would be more parsimonious in accounting for performance in both retrieval tasks.

#### Abstract

The transformational theory of similarity suggests that when judging similarity, people are sensitive to the number of transformation operations needed to make two compared representations match. Although this theory has been influential, little is known about how transformations are learned and to what extent learned transformations affect similarity judgments. This paper presents two experiments addressing these questions, in which people learned categories defined by a transformation. In Experiment 1, when the transformations were directly visible, people had no trouble learning and applied their knowledge to similarity and categorization judgments involving previously unseen items. In Experiment 2, the task required transformations to be inferred rather than observed. People were still able to learn the categories, but in this more difficult case ratings were less strongly affected by training. Overall, this work suggests that newly learned transformations can impact similarity judgments but the salience of the transformation has a large impact on transfer.

Keywords: similarity; category learning; transformational similarity

## Introduction

Calculating similarities is a core process in cognition (Medin, Goldstone, \& Gentner, 1993) and plays a central role in categorization (Nosofsky, 1984). However, there is considerable debate about the fundamental building blocks for computing the similarity between objects that contain structured properties (Markman \& Gentner, 1993; Hahn, Chater, \& Richardson, 2003). One proposed basis for similarity is the transformational distance between items (Imai, 1977), which holds that the similarity between two objects is proportional to the number of steps required to transform one object into the other. Several papers outline the theoretical foundations of the approach (Chater \& Vitányi, 2003; Chater \& Hahn, 1997; Bennett, Gács, Li, Vitányi, \& Zurek, 1998), the empirical evidence for it (Hahn et al., 2003; Hodgetts, Hahn, \& Chater, 2009; Hahn, 2014), and the arguments against it (Larkey \& Markman, 2005; Müller, van Rooij, \& Wareham, 2009; Grimm, Rein, \& Markman, 2012).

Transformation distances are sensitive to the primitive transformations available, but it is unclear how people might determine the relevant set (Grimm et al., 2012). Some transformations may be innate, but Müller et al. (2009) argue that for computational tractability, transformations must be organized in relatively small domain-specific sets. This suggests
that where domain structure is learned, the relevant transformations for comparisons in that domain must also be learned.

We interpret the transformational approach as predicting a strong link between transformation learning and similarity judgments: learning a new transformation that directly connects two items should reduce the transformation distance between the items and thus increase the similarity between them. However, relatively little is known about how quickly transformations can be learned or how much new transformations impact similarity. The most relevant evidence comes from Hahn, Close, and Graf (2009), who found that people shown morphs from A to B rated similarity higher in the observed morph direction than the reverse direction. These results suggest that people are able to learn transformations over short timescales, and that there may be some impact on similarity. We extend this line of work using a transfer task, where test items are novel but instantiate the trained transformation. We manipulate whether transformations are directly observed or inferred, and separate measures of learning success from those of similarity judgment change.

## Experiment 1

Can people learn categories that are defined by a novel transformation, and do they apply this transformation to novel categorization and similarity judgments? Experiment 1 addresses these questions with a training task designed to maximize the salience of a transformation relationship linking objects that belong to the same category. This is accomplished by showing the transformation after each categorization judgment during training. After training, we compare category membership and similarity judgments for a common set of previously unseen test items, contrasting responses from participants who were trained on different transformations.

Our results suggest that people learned the transformations and that this learning influenced subsequent categorization and similarity judgments. Items related by the newly-learned transformation were rated as more similar and more likely to belong to the same category. Items related by a novel transformation sharing some higher-level properties with the trained one were also rated as more similar and more likely to belong to the same category, although to a lesser extent.

Figure 1: The two transformations used during the training phase of Experiment 1. In the movement training people learned a non-rigid clockwise rotation transformation (top row), whereas in the COLOR TRAINING condition they learned a color swapping rule (bottom row). For both, the image on the left shows how that transformation was defined, and the image on the right gives an example on a particular stimulus. In this figure we use textures to display the four possibilities for each cell. The actual stimuli were presented in color, with the four possible values being red, green, yellow and blue.

## Method

Participants Four hundred and forty-four participants were recruited via Amazon Mechanical Turk and paid US\$0.75. $62 \%$ were male, with ages ranging from 18 to 67 (mean: 33.3). Three hundred and eleven participants were from the USA, 120 were from India, and 13 were from other countries. Forty-seven were excluded from all analyses: 12 for self-reported color-blindness and 35 for failing to pass check questions during the test phase of the experiment.

The experiment used two different pre-defined exclusion criteria, one based on training phase responses and one based on test phase responses. For the training phase, if any participant took more than 40 trials to learn any category that participant's data would be excluded. No participants were excluded on this basis. For the test phase, we also excluded any participant who gave an average similarity/categorization rating of less than 6 (out of 7) to the test trials with identical stimuli: 35 people were removed on this basis. One hundred and eighty six people were assigned to an IDENTITY condition in which the transformation to be learned was the identity transformation (i.e., no change). These participants easily learned the categories but were at floor for all generalization questions. Their results are not analyzed further.

Procedure The experiment consisted of six training phases and a test phase. Within each training phase, participants were trained on a new category of objects until their accuracy reached criterion. In the test phase, participants were asked to make categorization or similarity judgments of novel stimuli. All stimuli in the experiment consisted of $3 \times 3$ grids of colored cells, where each cell was a single color: red, yellow, blue or green (see the right panel of Figure 1). The stimuli were approximately 200 pixels wide on each side.

In each training phase, participants were shown a 'base' stimulus and told that it belonged to a category (e.g., wugs).

Two items were displayed underneath with the question "Which of these is also a wug?" Participants were instructed to respond by clicking on the button located below their choice and were given feedback based on their choice. After an incorrect selection, the message "Sorry, try again" appeared and participants had to click the correct stimulus to proceed. After a correct selection, the message "Correct" appeared and an animation was presented morphing the base stimulus into the correct one. The next trial would then begin with the newly transformed item as the new target stimulus. For each category (e.g., wugs) this process continued until either the participant made four correct choices in a row or 40 trials had elapsed, at which point the experiment moved on to the next category (e.g., philbixes).

The set of stimuli in each category was determined by the base pattern and the transformation (shown in Figure 1). Each of the six training categories began with a unique 'base pattern' that was the same for all participants, and on each subsequent trial category members were generated by one application of the transformation. For participants in the COLOR TRAINING condition ( $\mathrm{n}=114$ ), the transformation from one item in the category to the next was a color-swapping rule in which cells that were colored red became green, green became red, blue became yellow, and yellow became blue. In the MOVEMENT TRAINING condition ( $\mathrm{n}=144$ ), the transformation that defined the set of items in the category was a non-rigid clockwise rotation of the cells in the grid. Applying this transformation caused the colors around the outside of the grid to shift one cell forward.

The test phase consisted of 20 test trials in which participants were asked to make judgments about pairs of novel stimuli that never appeared during training. The stimuli could be related to each other in one of six ways: identical $(\mathrm{n}=2)$, no simple relation ( $n=2$ ), related by the trained movement ( $n=4$ ) or trained color ( $n=4$ ) transformations, or related by the novel movement ( $n=4$ ) or novel color ( $n=4$ ) transformations. The

Figure 2: Effect of transformation training. The $y$-axis reflects the difference in responses given due to training condition, contrasting ratings given when test items do not match the training condition (NO MATCH) as compared to when they are related to the training, either as an exact MATCH or as a similar but novel NEAR MATCH. Thus, values above zero indicate effective training (in the case of MATCH) and generalization (in the case of NEAR MATCH). The left panel shows Experiment 1, which made the transformations explicit. In it, people learned and generalized the transformations for both categorization (light bars) and similarity (dark bars) questions, although the magnitude was smaller for similarity. The right panel shows Experiment 2, in which the transformations were less salient. In that case, learning and generalization were evident for categorization questions, but these were much larger than for similarity. Error bars express $95 \%$ credible intervals for a Bayesian t-test.
basis for these relations were not equally available to all participants: test items instantiating color transformations were unrelated for people given the movement training, and vice versa, manipulating the relation of the test items to the training while keeping the items themselves constant. The identical and no simple relation trials were of the same form as the test trials but only used for attention-check exclusions and not analyzed further. The novel movement transformation consisted of shifting all cells in the grid down by one row and moving the bottom row to the top. The novel color transformation swapped red with blue and green with yellow.

The order of test trials was randomized. Half the participants in each condition were asked to make CATEGORIZATION judgments by rating how likely it is that the two stimuli "have the same name" from "Not at all" to "Extremely" on a seven point scale. The other half were asked to rate the SIMILARITY of the two stimuli on a seven point scale.

In summary, there were two training conditions, each using a different transformation. There were four critical types of test item (excluding attention checks). The critical property of interest was the relationship between the test item and the training condition: did the test reflect the same or similar transformation as the training? The same items had different status for different participants depending on the training they saw: test items were considered to be MATCH trials when the two stimuli being compared were related by an application of the trained transformation, NEAR MATCH trials when
the test stimuli were related by a transformation similar but not identical to the trained one, and NO MATCH when the test stimuli were not related to the training. Thus, for a person who received COLOR TRAINING, a test item involving that same color transformation would be a MATCH, one involving the novel color transformation would be a NEAR MATCH, and the two movement-related test items would be NO MATCH. None of the test items were previously seen in training.

## Results

We first wish to establish whether the training phases were of comparable difficulty. We therefore looked at both how fast people reached the mastery criterion as well as the exclusion rates between conditions. People reached the criterion of four correct responses in a row in an average of 6.3 trials in the MOVEMENT TRAINING condition, and 5.8 in COLOR TRAINING, with $95 \%$ of all categories learned in eight trials or less. Participant inclusion rates were also comparable across conditions, at $86.0 \%$ and $87.5 \%$, as was average accuracy over all trials ( $85 \%$ and $88 \%$ in the MOVEMENT and COLOR training respectively). This suggests that people learned to effectively distinguish category members from foils and that both transformations were similarly difficult.

To test the impact of training on people's ratings, we examined the degree to which their responses were different on the MATCH and NEAR MATCH test items from the NO MATCH baseline. NO MATCH baseline ratings for test items related

Similarity Judgments

| Test item relationship | Test item average | NO MATCH item average | Difference | BF |
| :--- | ---: | ---: | ---: | ---: |
| MATCH items | $3.61(1.71)$ | $2.49(2.00)$ | 1.13 | $>1000$ |
| NEAR MATCH items | $3.14(1.71)$ | $2.58(1.91)$ | 0.569 | $>1000$ |

CATEGORIZATION Judgments

| Test item relationship | Test item average | NO MATCH item average | Difference | BF |
| :--- | ---: | ---: | ---: | ---: |
| MATCH items | $4.17(1.76)$ | $1.46(1.83)$ | 2.71 | $>1000$ |
| NEAR MATCH items | $3.15(2.11)$ | $1.7(1.922)$ | 1.45 | $>1000$ |

Table 1: Descriptive statistics and hypothesis tests for Experiment 1. For each of the MATCH and NEAR MATCH items (first column), we show the average responses for each (second column) compared to the NO MATCH baseline on the same items (third column). We performed a Bayesian $t$-test on the difference between these (fourth column) and found that in all cases there was a strong effect of training (fifth column).
by a COLOR transformation came from participants exposed to MOVEMENT TRAINING, baseline ratings for test items related by a MOVEMENT transformation came from participants exposed to COLOR TRAINING. In both cases the stimuli involved in the MATCH and contrasting NO MATCH groups were physically identical, likewise for NEAR MATCH items and their corresponding NO MATCH group. The left panel of Figure 2 illustrates these differences due to training experience. For instance, the MATCH bar reflects the difference between responses for the same item in the MATCH and NO MATCH conditions (thus, a value higher than zero indicates that the transformation training had an effect). Similarly, the NEAR MATCH bar reflects the difference between responses for the same item in the NEAR MATCH and NO MATCH conditions (thus, a value higher than zero indicates some generalization of training to a similar transformation).

Table 1 shows the absolute responses for the items of interest (i.e., the MATCH or NEAR MATCH items, in the second column) and the unrelated NO MATCH items in the third column. We used a Bayesian t-test (Morey, Rouder, \& Jamil, 2014; Rouder, Speckman, Sun, Morey, \& Iverson, 2009) to quantify the difference between them (fourth column), yielding a Bayes factor associated with the size of that different (fifth column). There was a strong ( $B F>1000: 1$ ) effect of training for both the categorization and similarity judgments. However, these two types of judgment were impacted to different extents. For instance, the overall difference in item ratings between training conditions was between 1.07 and 1.33 larger ( $95 \%$ credible interval) for categorization judgments than similarity judgments.

Similarly, both MATCH and NEAR MATCH test item ratings differed strongly due to training ( $B F>10^{3}: 1$ ), but to different extents. For instance, the difference due to training was between 0.67 and 0.93 rating points larger for MATCH as opposed to NEAR MATCH transformations. This suggests that people were less likely to generalize their responses as strongly to similar but not identical transformations.

## Conclusion

The results of Experiment 1 show that learning categories that are defined by a transformation can lead people to produce consistently different patterns of judgments for novel items.

Test items that were connected either by a learned transformation or a similar transformation were reliably rated higher. This increase in rating was found for similarity judgments as well as judgments about category membership.

This pattern of results is consistent with the predictions of the transformational account of perceptual similarity (Hahn et al., 2003). Furthermore, it suggests that by learning categories that are related by a transformation people can infer the transformation and apply it to novel items and categories.

That said, it is unclear to what extent the training in Experiment 1 is reflective of real-world transformation learning. In the experiment, objects were shown transforming into each other repeatedly; but in the real world, many transformations that define categories occur at a time scale that people cannot directly observe (e.g. seasons, aging, etc.). Experiment 2 aimed to test if the explicit presentation of the transformation was necessary to elicit quick learning and generalization of transformations.

## Experiment 2

Experiment 1 provides "in principle" evidence that people are capable of learning rich knowledge about classes of stimulus transformations and the categories to which they are applicable. However, the structure of our task made learning as easy as possible: during the training phase participants were explicitly shown the transformation at the end of every trial. When learning new categories in real life it is more typical for people to encounter a variety of exemplars. For example, when learning the transformations involved in the aging of human faces, people observe many faces at different ages, but do not directly observe the aging process. It is thus unclear how generalizable these results are.

This issue is particularly important for evaluating the transformational account of similarity. With a few notable exceptions, such as rotation, the majority of transformations plausibly involved in comparisons are unobservable. Experiment 2 addresses the question of how easily learnable transformations when they are more implicit. By increasing the difficulty of the task, this manipulation also allowed us to examine the extent to which variation in ease of transformation learning is reflected in similarity.

## Method

Participants Two hundred and fifty-two participants were recruited via Amazon Mechanical Turk and paid US\$1. $60 \%$ were male, with ages ranging from 19 to 67 (mean: 34.7). Two hundred and forty-seven participants were from the USA, with the remainder from India, South America, and the UK. Fifty-three were excluded from all analyses: 2 for self-reported color-blindness, 12 for not completing the experiment, and 39 for failing exclusion criteria.

The experiment used two different predefined exclusion criteria, one based on training phase responses and one based on test phase responses. For the training phase, if any participant took more than 30 trials to learn two of the last three categories that participant's data would be excluded (this number was arrived at based on pilot data). Twelve participants were excluded on this basis. For the test phase, any participant who gave an average similarity/categorization rating of less than 6 (out of 7) to the identical trials were excluded: Twenty-seven people were removed on this basis. Ninetyfive participants were in a COLOR TRAINING condition and 92 were in a movement training condition. Sixty-five participants were in an Identity condition and their results are not analyzed further.

## Procedure

As in Experiment 1, this experiment consisted of six training phases and a test phase. Within each training phase, a new category of objects was learned until a mastery criterion was reached. In the test phase, participants were asked to make categorization and similarity judgments of novel stimuli. However, a number of aspects of the experiment differed from Experiment 1.

Based on pilot testing of category learning, the stimuli were simplified by adding the constraint that each stimulus contained at least six cells that shared the same color. Furthermore, the COLOR TRAINING transformation was modified to increase the number of possible stimuli within the categories. Instead of changing all colors (red to green, green to red, yellow to blue, and blue to yellow) as a single transformation, this was broken into two transformations. A single transformation consisted of either swapping the colors of red and green, or swapping yellow and blue. This doubled the number of stimuli in each condition in the COLOR TRAINING condition to more closely match the number in the mOVEment training condition.

The structure of the training trials also differed from Experiment 1 . On each trial participants were shown two stimuli and asked if both items belonged in the category. There was always at least one category member displayed. In half the trials, the other stimulus was also in the category and related by one application of the transformation being trained. In the other half, the other stimulus was not in the category. After participants responded yes or no they were given feedback indicating if they were correct, but unlike in Experiment 1 they did not observe the actual transformation.

Participants proceeded to the next category when they were correct on 8 of 10 trials. Consecutive sets of six trials were constrained to contain three 'yes' and three 'no' trials (in shuffled order), meaning participants reaching criterion answered both 'yes' and 'no' correctly. The test phase was largely similar to Experiment 1 except that the UNRELATED trials were removed and trials were grouped into four blocks, with order of presentation randomized within each block to avoid runs of similar test items.

## Results

The results indicate that difficulty was higher than Experiment 1 , but comparable across conditions. People reached the accuracy criterion in an average of 14.12 trials in COLOR training and 13.8 trials in movement training. Inclusion rates were comparable between conditions at $74 \%$ and $80 \%$ respectively.

As in Experiment 1, we were interested in whether responses to test items were different based on whether the transformation involved was a MATCH, NEAR MATCH, or NO match to the trained transformation. The right panel of Figure 2 shows the differences in responses, analogous to the same analysis in Experiment 1, with the associated Bayesian t-test results shown in Table 2. In all cases we find strong evidence that participants' ratings for the same items were higher when they had a MATCH or NEAR MATCH relationship to training as opposed to NO match status ( $B F>49: 1$ at minimum). This suggests that training was effective and people were capable of learning the transformations even if they were not explicitly shown.

That said, the size of the difference depended on question type. Category learning showed a much larger effect: the difference was between 1.09 and 1.31 points larger ( $95 \%$ credible interval) for categorization questions than similarity ones. Unlike in Experiment 1, match and near match status were not strongly differentiated: the difference involving MATCH status items as opposed to NEAR MATCH status items plausibly included zero (with a $95 \%$ CI between -0.01 and $0.21)$.

## General Discussion

The results from Experiment 1 showed that people are capable of learning a novel transformation, recognizing that this transformation is relevant to determining category membership, and applying the learned transformation when assessing similarity between items belonging to novel categories. This finding is consistent with the learning effect seen in Hahn et al. (2009), but extends previous results in showing systematic generalization across related transformations.

Experiment 2 echoes these results and further finds that the effect is not limited to training in which people see objects transforming; seeing labeled category members can induce a change in judgments. However, there are two notable differences from Experiment 1. First, as the transformations become less prominent during training, they seem to have less impact on subsequent judgments, particularly for similarity.

|  | SimILARITY Judgments <br> Test item relationship |  |  |  | Test item average |
| :--- | ---: | ---: | ---: | ---: | ---: |
| NO MATCH item average | Difference | BF |  |  |  |
| MATCH items | $3.56(1.6)$ | $2.98(1.75)$ | 0.58 | $>1000$ |  |
| NEAR MATCH items | $2.66(1.53)$ | $2.31(1.62)$ | 0.35 | 49 |  |
|  |  |  |  |  |  |
|  |  | CATEGORIZATION Judgments |  |  |  |
| Test item relationship | Test item average | NO MATCH item average | Difference | BF |  |
| MATCH items | $3.72(1.85)$ | $2.14(2.15)$ | 1.57 | $>1000$ |  |
| NEAR MATCH items | $2.93(1.98)$ | $1.35(1.82)$ | 1.58 | $>1000$ |  |

Table 2: Descriptive statistics and hypothesis tests for Experiment 2. For each of the match and NEAR MATCH items (first column), we show the average responses for each (second column) compared to the NO мATCH baseline on the same items (third column). We performed a Bayesian $t$-test on the difference between these (fourth column) and found that in all cases there was a strong effect of training (fifth column).

Second, the novel and trained transformations were less well differentiated.

The attenuation of the training effects seems likely to be a result of task difficulty, with people less inclined to shift their judgments based on training that was less clear. However the lack of differentiation between trained and novel but similar transformations is harder to interpret. Possibly participants formed an incomplete representation of the transformation which was applicable to both near and exact matches to training, but the form of this representation is unclear. People's success in distinguishing targets from foils at training suggests they did not simply track which features remain invariant (e.g., noting in the MOVEMENT TRAINING condition that colors are preserved and in the COLOR TRAINING condition that configurations are preserved).

In terms of the predictions of transformational similarity, our results are somewhat mixed. It is clear that people learn transformations relevant to a new domain quickly, and that such transformations can be applied to categorization and similarity judgment. However, the pattern of generalization between exact matches and near-matches would seem to require some kind of graded availability of transformations based on family resemblances between them, complicating the computation of transformation distances.

Transformations as features are common in natural categories, for example growth and aging or characteristic movement. Despite this, their role in similarity judgments over structured representations remains unclear. Taking as a starting point predictions implied by tractability constraints on the transformational account of similarity, the two studies presented here examine the conditions under which transformation learning might influence similarity and categorization. Our results show that people can learn transformations quickly and use them in subsequent similarity and categorization judgments. However, productive use of the transformations depends to some extent on the ease with which the transformation was learned, and in both easy and difficult learning conditions involves generalization across related transformations.

# Preschoolers and Infants Calibrate Persistence from Adult Models 

Julia Leonard<br>Massachusetts Institute of Technology, Cambridge, MA, USA<br>Max Kleiman-Weiner<br>Massachusetts Institute of Technology, Cambridge, Massachusetts, USA<br>Yuna Lee<br>Massachusetts Institute of Technology, Cambridge, Massachusetts, USA<br>Josh Tenenbaum<br>Massachusetts Institute of Technology<br>Laura Schulz<br>Massachusetts Institute of Technology

#### Abstract

Perseverance, above and beyond IQ, predicts academic outcomes in school age children, however, little is known about what factors affect persistence in early childhood. Here, we propose a formal Bayesian model of how children might learn how to calibrate effort from observing adult models and then explore this idea behaviorally across two experiments in children and infants. Results from Experiment 1 show that preschoolers persist more after watching an adult persist, but only if the adult is successful at reaching their goal. Experiment 2 and a pre-registered replication extend these findings, showing that even infants use adult models to modulate their persistence, and can generalize this inference to novel situations. These results suggest that both preschoolers and infants are sensitive to adult persistence and use it to calibrate their own effort in far-reaching ways.

# You can take a noun out of syntax...: Syntactic similarity effects in lexical priming 

Nicholas A. Lester (nlester@umail.ucsb.edu)<br>Department of Linguistics, University of California, Santa Barbara, USA

Laurie B. Feldman (Ifeldman@albany.edu)<br>Haskins Laboratories, New Haven, CT, \& Department of Psychology, State University of New York, Albany, NY, USA

Fermín Moscoso del Prado Martín (fmoscoso@linguistics.ucsb.edu)<br>Department of Linguistics, University of California, Santa Barbara, CA, USA

#### Abstract

Usage-based theories of syntax predict that words and syntactic constructions are probabilistically interconnected. If this is true, then words that occur in similar distributions of syntactic constructions should prime each other. These effects should be fine-grained; even small differences between the syntactic distributions of pairs of words of the same grammatical category should cause variation in priming. Prior research from production suggests that this prediction should hold even in tasks without any syntactic requirement. In this study, we introduce a measure of the similarity between the syntactic contexts in which two nouns occur. We show that this similarity measure significantly predicts visual lexical decision priming magnitudes between pairs of nouns. This finding is consistent with the predictions of usage-based theories where fine-grained similarity of syntactic usages between prime-target pairs affects decision latencies, over and above any effects attributable to semantic similarity.

Keywords: syntax; priming; usage-based linguistics; visual lexical decision; information theory

## Background

Lexical priming experiments have a long history in psycholinguistic research. Though the bulk of this research has focused on semantic and orthographic effects, some studies have considered the role of syntax (henceforth grammatical priming). Early work looked at the effects of inflectional congruity across word classes. For example, in Serbian, inflected nouns are recognized faster when primed by case-appropriate adjectives (e.g., Gurjanov, Lukatela, Moskovljević, Savić, \& Turvey, 1985). More recent work has looked at contextualized reading effects. Nouns and verbs that are biased to occur in congruent syntactic constructions (e.g., direct-object vs. subordinate clause continuations; I need some coffeelto go to the market) facilitate processing of later content (Novick, Kim, \& Trueswell, 2003). Thus, accessing a noun primes expectations about its syntactic context. Congruity effects have been interpreted as evidence for robust, probabilistic syntactic specifications for lexical items.

The empirical evidence outlined so far is complemented by work in theoretical linguistics. Usage-based linguistic theories argue that all facets of grammar, including words
and syntactic structures, are potentially interconnected on the basis of one's experience with language (e.g., Diessel, 2015). Let us refer to this position as the probabilistic network hypothesis. Results such as those reported by Novick et al. (2003) are easily accounted for under this framework. To use the connectionist metaphor, connections between lexical and syntactic nodes are tuned as a function of their frequency of distinctive co-activation (e.g., Gries \& Stefanowitsch, 2004). Stronger connections are processed more efficiently. Further support for this hypothesis comes from work on word production: the probability distributions of words in particular syntactic structures influence picture naming latencies (Lester \& Moscoso del Prado Martín, 2016).

Direct, probabilistic relationships between words and syntactic structures are not universally accepted across linguistic models. Many models argue that syntax only enters the lexicon through general categorical specifications (i.e., most generative approaches to syntax). Accordingly, words may have a feature indicating the part-of-speech category to which they belong (noun, verb, adjective, and so on). More recent work in this vein has expanded the syntactic content of the lexicon to include more fine-grained syntactic categories. For example, in current mainstream generativist syntax (the Minimalist Program; Chomksy, 1995), words contain information about the syntactic frames with which they can combine as functional head (sometimes called subcategorization or c-selection; for a similar approach, see Bresnan, 2001). Crucially, these syntactic specifications represent categorical constraints on the possible distributions of words. We will call this the categorical constraint hypothesis. Under this account, probabilistic relationships are simply not available to the grammar. Any effects of probability are designated "extra-grammatical" (Stabler, 2013) and are instead usually attributed to relationships in other mental systems, such as the Conceptual-Intentional system.

This theoretical distinction leads to different predictions about the nature of grammatical priming. The probabilistic network hypothesis predicts that probabilistic information about the semantic and syntactic similarity of words should produce independent priming effects. The categorical constraint hypothesis predicts that probabilistic effects
should only arise for semantic similarity (as the syntactic system does not encode such relationships). We test this contrast using a simple lexical priming paradigm.

Research on grammatical priming has largely relied on syntactic or pseudo-syntactic contexts (e.g., using an adjective as a prime for a noun). However, the predictions of usage-based theory, along with recent evidence from production (e.g., Lester \& Moscoso del Prado Martín, 2016), suggest that syntactic information -all of it- should be automatically activated every time a word is accessed. This should be true even when the word is presented in isolation for purposes of the task, as in visual lexical decision (see also Durán and Pillon, 2011). We therefore use a simple overt lexical priming paradigm with visual lexical decision. We restrict our analysis to nouns to guard against intercategorical effects. We predict RTs based on the similarity of semantic and syntactic distributions across a range of words words. The probabilistic network hypothesis would be supported by evidence of priming for similar syntax and semantics, independently. The categorical constraint hypothesis would be supported by priming only in the domain of semantics.

## Methods

## Data

We used the response latencies contained in the Semantic Priming Project (SPP; Hutchison, et al., 2013). The SPP contains response times and accuracies, along with a host of norming data, that were collected using a visual lexical decision task with overt orthographic priming. On each trial, participants were shown a centered fixation cross for 500 ms , followed by a prime word (all caps) for 150 ms . The prime was followed by a blank screen lasting either 50 or 1050 ms . The target word was displayed (all lowercase) until a either decision was made or $3,000 \mathrm{~ms}$ elapsed, at which point the experiment would advance to the next trial.

We used only those trials containing primes and targets that also appear both in the British Lexicon Project (BLP; Keuleers, Lacey, Rastle, \& Brysbaert, 2012) and the age of acquisition norming database of Kuperman, Stadthagen-Gonzalez, \& Brysbaert (2012). We limit the data in this way to take advantage of the additional lexical controls afforded by these databases. To ensure that all stimuli were understood primarily as nouns, we further limited the trials to include only those in which both prime and target received majority noun tags in the British National Corpus (BNC). In this way, we obtained a dataset consisting 1,305 unique primes and 821 unique targets (a total of 1,670 unique nouns).

## Syntactic space

To measure the relationship between the noun-pairs in the syntactic system, we first need to operationalize the syntactic system itself. Decades of research have failed to produce an exhaustive list of the syntactic constructions of English (let alone any other language), and we do not presume to offer such a list here. Instead, we rely on the set of low-level
relations as defined within Dependency Grammar formalisms (e.g., Mel'čuk, 1988; Nivre, 2005). Dependency Grammars model only relations (dependencies) between pairs of words. These relations are asymmetric: each extends from a head (the syntactic and conceptual core word) to a modifier (whose syntactic role is contingent on the head). Each dependency is labeled to reflect its syntactic function. For example, the and waffle in the noun phrase the waffle would be bound by the det relation, which attaches a determiner (the, the modifier) to a noun (waffle, the head). Other examples include the nsubj relation, which binds a noun (modifier) to a verb (head) as its subject, and the pobj relation, which binds a noun (modifier) to a preposition (head) as its object. A further detailed description and discussion of Dependency Grammar formalism is beyond the scope of this study. We adopt the dependency formalism implemented in the spaCy parser (Honnibal \& Johnson, 2015), one of the fastest and most accurate dependency parsers available.

We define the syntactic space for nouns as the set of dependencies for which at least one noun from our sample of SPP primes and targets has been attested either as head or as modifier. For each noun in our dataset, we extracted all sentences containing that noun from the BNC. We conditioned the search to include only sentences in which the word form was indeed tagged as a noun. Those sentences were parsed using spaCy. We then compute the frequency distribution of each noun across the dependencies for which it serves as head or modifier. To increase the reliability of our frequency estimates, we discard vectors for all nouns that occurred in fewer than 100 sentences in the BNC ( $\sim 1$ per million words). The total syntactic space is defined as a vector in which each column reflects one among the set of unique dependencies occurring across all nouns. Finally, we merge the individual frequency distribution of each noun into the total syntactic space, creating a matrix of $n$ rows by $m$ columns, where $n=$ the number of total unique dependency types (46) and $m=$ the number of unique SPP/BLP nouns $(1,241)$. The result is therefore a uniform syntactic space for all nouns, where individual nouns may or may not be attested in each possible dependency. In theoretical terms, we treat these vectors as reflecting the statistical connectivity between each noun and the syntactic structures in which it takes part, as is proposed in the usage-based literature. Psycholinguistic support for this treatment comes from an earlier study showing that these and similar dependency vectors affect processing latencies in noun production over and above the effects of other known factors (Lester \& Moscoso del Prado Martín, 2016).

## Measuring syntactic similarity

We are interested in the possibility that pre-activation of shared syntactic representations will affect the speed of word recognition. Therefore, we need some measure of the similarity between the syntactic distributions of primes and targets in our behavioral data. Note that similarity in syntactic space outlined above does not reduce solely to shared types of dependencies. For example, consider two
words, $w 1$ and $w 2$, that occupy the same set of 20 dependency types. Suppose that $w 1$ and $w 2$ have roughly equivalent overall frequencies and that those frequencies are distributed equally across the dependency types for both words. In this case, we would call them syntactically similar, and consider the number of overlapping types as an appropriate measure of the strength of their similarity. Now suppose that the two words have similar overall frequencies, but that these frequencies are distributed over complementary sets of the dependencies that they share, such that $w 1$ has a frequency of 1 wherever $w 2$ has a frequency >100 and vice versa. In this case, we would call them dissimilar. For this, we need to simultaneously account for shared types, as well their probability distributions. One measure well suited to this task is the Jensen-Shannon Divergence (JSD; Lin, 1991). JSD is a symmetric variant of the Kullback-Leibler Divergence (KLD). The KLD between two probability distributions $P$ and $Q$ is defined in Eq. 1.

$$
\begin{equation*}
K L D(P \| Q)=\sum_{\mathrm{i}} P(\mathrm{i}) \log \frac{P(\mathrm{i})}{Q(\mathrm{i})} \tag{1}
\end{equation*}
$$

This measure captures the average amount of additional information that one would need in order to recode an event from distribution $P$ as if it belonged to distribution $Q$. Importantly, $\operatorname{KLD}(P \| Q) \neq \operatorname{KLD}(Q \| P)$, meaning that one must decide a priori in which direction to take the distance. JSD provides a solution to the asymmetry problem by taking the midpoint between the two distributions, then taking the mean distance of the distributions to the midpoint. Formally, JSD is expressed as follows (Eqs. 2 and 3).

$$
\begin{equation*}
J S D(P \| Q)=\frac{1}{2} K L D(P \| M)+\frac{1}{2} K L D(Q \| M) \tag{2}
\end{equation*}
$$

where

$$
\begin{equation*}
M=\frac{1}{2}(P+Q) \tag{3}
\end{equation*}
$$

This measure has the advantage of being both symmetrical $[\mathrm{JSD}(P \| Q)=\mathrm{JSD}(Q \| P)]$ and bounded $(0 \leq \mathrm{JSD} \leq 1)$.

JSD measurements depend on estimates of the probability distributions of events within a distribution, rather than on their actual probability distributions. Maximum-likelihood estimates of information-theoretical measures are known to be biased. To guard against this bias we apply a bias-reducing frequency correction to our syntactic vectors, using the plug-in James-Stein shrinkage estimator (Hausser \& Strimmer, 2009).

The methods above provide an operationalization of syntactic similarity between primes and targets. For each prime-target pair in the sample, we compute the JSD between their syntactic vectors. A value of 0 indicates identity; a value of 1 indicates complete independence. According to usage-based theories, (at least the bulk of) syntactic structure is meaningful- that is, directly linked to semantic representations in the same way as words (e.g., Diessel, 2015). This means that any effect we uncover for our
measure may actually reflect semantic similarity, which is well known to affect priming magnitudes (e.g., Neely, 1991). Moreover, the contrast between the probabilistic network and categorical constraint hypotheses depends on a direct comparison of syntactic and semantic sources of similarity. Fortunately, the SPP contains annotation of the degree of semantic similarity between prime and target, indicated by cosine similarities in Latent Semantic Analysis space (LSA). LSA measures the extent to which words occur in similar texts, with higher cosine values indicating greater similarity (Landauer \& Dumais, 1997). We transformed the cosine similarities into distances (i.e., 1-cos).

Figure 1 plots the relationship between the syntactic distances (JSD) between pairs of words as a function of their semantic distances (LSA) values. As one would expect, there is a significant positive (linear) ${ }^{1}$ correlation between both measures, meaning that words that are similar in meaning tend to occur in similar syntactic contexts. However, an important feature of Figure 1 is the triangular shape of the variance: words that are very close in meaning vary only slightly in syntactic similarity, while words that are distant in meaning vary more widely. This relationship supports the account of Jackendoff (2013), who argues for the existence of syntactic generalizations (i.e., constructions) that allow structural inheritance among sets of semantically heterogeneous sub-constructions. In other words, nouns that are extremely similar in meaning (e.g., synonyms) will always appear in extremely similar syntactic contexts. However, there is large variability in the syntactic similarities of words with different meaning (or there is large variability in the semantic similarity between pairs of words that appear in very different syntactic contexts). This suggests that syntax and semantics are not as tightly coupled as some would argue (e.g., Goldberg, 1995), and their contributions can indeed be considered separately.

Figure 1: Relationship between syntactic and semantic distance measures

[^384]To disentangle the purely syntactic aspects of lexical similarity from what can be attributed to similarity in meaning, we residualized the semantic measure out of the syntactic measure. This was achieved by fitting a linear regression predicting the JSDs as a function of the LSA distances, and using the residuals of this regression as our measure of syntactic difference. This measure captures the information in JSD that is not attributable to semantics (cf., Hendrix, Bolger, \& Baayen, 2017; responding to the concerns expressed by Wurm \& Fisicaro, 2014).

## Further controls

A number of other factors are known to impact recognition latencies in the primed lexical decision paradigm. These fall into three categories: effects related to recognizing individual words, (other) effects based on the relationship between prime and target, and effects related to the nature of the task itself. From the first set, the most important predictor is the surface frequency of the target: i.e., more frequent words are recognized faster. We use the SUBTLEX-UK frequencies, which are based on movie subtitles and known to outperform estimates drawn from other corpora, including the BNC (van Heuven, Mandera, Keuleers, \& Brysbaert, 2014). We also include a measure of the density of the orthographic neighborhood of the target known as OLD20 (Yarkoni, Balota, \& Yap, 2008). The more similar the spelling of the word to its closest neighbors, the faster it is recognized. Another predictor that has been proposed is age of acquisition: the earlier a word is acquired in the lifespan, the faster it is recognized (e.g., Kuperman et al., 2012). Less important, but nevertheless known to exert an effect, is the orthographic length of the word: longer words take longer to recognize (New, Ferrand, Pallier, \& Brysbaert, 2006).

Besides our residualized syntactic measure, we included two additional predictors relating the prime and target: We included semantic distance (i.e., the LSA distances), as semantic similarity is known to facilitate access to targets (i.e., semantic priming). In addition, we considered the Levenshtein distance (LD; Levenshtein, 1966; van der Loo, 2014) between prime and target to account for possible effects of orthographic relatedness. We expect orthographically similar prime-target pairs to result in slower recognition latencies (cf., Adelman, et al., 2014). In addition to these main effects, we tested two-way interactions between the inter-stimulus interval (ISI) on the one hand, and LSA distance, LD, and residualized JSD on the other. This was done to account for the possibility that priming effects might change with the different offsets between prime and target.

Finally, we included the (log) sequential position of each trial in the overall experimental order of presentation. As participants move through the trials, we expected some degree of fatigue to set in (each participant performed over 800 trials).

## Results

We fitted a linear mixed-effect regression model predicting response latencies from the SPP primed lexical decision database as a function of the variables outlined above. In addition to the fixed effects, we included random effects for participants and prime-target pairs (i.e., random slopes). We discarded $6.7 \%$ of all trials as outliers (all latencies falling below 400 ms or 2 standard deviations above the mean). In addition, we corrected for a strong positive skew in the response times by taking the logarithm of RTS (as suggested by a Box-Cox power analysis; Box \& Cox, 1964). Visual inspection of the model residuals with and without the corrections confirmed the adequacy of these steps.

All main effects for the control predictors besides OLD20 surfaced as significant at the $\alpha=.05$ level, and in the expected direction. The model also revealed a significant ( $p<.001$ ) effect of the two-way interaction between LD and ISI: at 50 ms ISI, LD had a negative impact on response times $(-2.5 \mathrm{~ms}$ per unit increase in LD), with no effect at 1050 ms . Importantly, the model revealed a significant interaction ( $p<.01$ ) between ISI and LSA distance, consistent with what one would expect. Response latencies increased by about 5 ms per .1 increase in cosine distance at a short ISI. At a long ISI, this effect was reduced to $\sim 3 \mathrm{~ms}$ per .1 increase. As semantic distance between prime and target increased, so did target recognition latencies, with stronger effects at the shorter ISI.

Over and above the effects of the controls, and crucially over that of semantic similarity, the model revealed a statistically independent significant main effect ( $p<.001$ ) of the residualized syntactic distance. For every . 1 increase in residualized syntactic distance, response latencies were increased by $\sim 4 \pm \sim 3 \mathrm{~ms}$. As predicted by the probabilistic network hypothesis, the less related the prime and target in syntactic space, the longer it takes to recognize the target. There was also a marginal interaction of JSD with ISI ( $p=.07$ ). The trend resembled that observed for LSA: longer ISIs lead to an attenuated contribution of syntactic similarity. However, given the marginal status of the effect, we do not interpret it further.

## Discussion

The present study finds a relatively strong effect of syntactic similarity on lexical priming magnitudes. In fact, the effect was similar in strength -if anything stronger- to that of semantic similarity. To our knowledge, this study is the first to demonstrate that pre-activating a word's syntactic space affects access to that word in a prima facie non-syntactic task. This effect provides support for the probabilistic network hypothesis, which predicts that words and syntactic structures are interdependent, and that these connections are forged and tuned by experience. Crucially, these probabilistic relationships are at the core of the grammatical apparatus they are not simply attributable to the extra-grammatical conceptual system. If that were the case, we should have found no effect of syntactic similarity once semantics was accounted for.

The data we rely on here do not provide us with a non-primed baseline, meaning that we cannot distinguish a facilitation effect of syntactic similarity from an inhibitory effect of syntactic dissimilarity. We therefore leave this question for further research. However, the similarity in shape between the syntactic and semantic effects suggest that syntax -as is argued for semantics (e.g., Lam et al, 2015)constrains the set of lexical candidates prior to the lexicality judgment. Furthermore, it suggests that syntax, like semantics, is obligatorily accessed as soon as lexical forms become active. Crucially, the relationships between words and syntax become active even when (overt) syntactic structure is not built into the stimuli and not really necessary for performing the task. Recent psycholinguistic work on single-word production has echoed this point. For example, Lester and Moscoso del Prado Martín (2016) report chronometric findings suggestive of large-scale interactivation between syntax to lexicon in a bare-noun picture-naming task. Other studies have found that syntactic category information is likewise obligatorily activated in non-syntactic production tasks (e.g., Durán and Pillon, 2011). The present study extends these findings from production to comprehension, from spoken language to written language, and from a simple to a primed paradigm. Hence, the converging evidence suggests that obligatory syntactic access, along with bi-directional activation between syntax and lexicon, is a general, modality-independent property of language processing.

These data also speak to linguistic representation. Branigan and Pickering (in press) argue that, in order for priming to take place, some common connection must exist between the prime and target on the one hand, and the representations underlying the measurement of their similarity. This notion is applied to the relationship between words and conceptual content in the semantic priming literature (e.g., Lam, Dijkstra, \& Rueschemeyer, 2015). Likewise, our results can be interpreted as reflecting that each noun's representation is explicitly connected to the set of syntactic structures in which it participates and that these representations are shared across words. Moreover, the probabilistic nature of our measure suggests that connection weights -not just the set of shared syntactic types- are represented in the lexico-syntactic network, exactly as predicted by usage-based models of linguistic representation (Diessel, 2015) and as evidenced in sentence-reading paradigms (Novick et al., 2003). Importantly, these findings are not consistent with modular-syntactic models (e.g., Chomsky, 1995), which posit only categorical relationships between words and syntax. Adapting the old adage, "you can take the noun out of syntax, but you can't take the syntax out of the noun."

A possible limitation is that we used Latent Semantic Analysis as a proxy for semantic related when 'cleaning' our syntactic measure of its semantic component. It remains possible -albeit, in our opinion, unlikely- that part, or even all, of the effects of syntactic similarity could be accounted
for by a more fine-grained measure of semantic relatedness or similarity than that provided by LSA.

Another possible limitation concerns the morphological structure of the words in our study. While we only included monosyllabic and disyllabic nouns, some of the tokens contained derivational morphology (e.g., actor). Morphology is known to interact with priming from other domains (e.g., semantics; Feldman et al., 2015). Therefore, it remains unclear to what extent morphology was contributing to both the shapes of the distributions we computed from the corpus and/or aspects of the priming relationship. In future research, it will be necessary to account for possible derivational relationships between target and prime, and to explore how morphological structure impacts syntactic diversity.
The interaction between our measure and the temporal offset between the prime and the target was only marginally significant. The SPP contains only two such offsets: extremely fast and extremely slow. We suspect that a more robust interaction might arise if one considers offsets intermediate between these extremes. Furthermore, by incrementally increasing the offset between 50 and 1050 ms , we would allow considering the ISI as the numerical magnitude it is (cf., Feldman et al., 2015), rather than as a bi-valued factor.

In sum, our results suggest that, in line with the predictions of usage-based theories of grammar, the representation of words is inextricably tied to the grammatical contexts in which these words are encountered. The results indicate that even the extremely fine-grained differences in syntactic use that can be found between words of a single class (nouns) have detectable effects on their processing and representation. This is true even in tasks -such as visual lexical decision- that do not to involve any explicit involvement of the syntactic system. In other words, in comprehension, the activation of the syntactic properties of a word is automatic. The word comes with its whole syntactic baggage. Furthermore, this syntactic baggage goes well beyond mere grammatical category information, and includes a rich, fine-grained account of the syntactic contexts in which each particular noun is used.

# How the Mind Exploits Risk-Reward Structures in Decisions under Risk 

Christina Leuker (leuker@mpib-berlin-mpg.de)<br>Timothy J. Pleskac (pleskac@mpib-berlin.mpg.de)<br>Thorsten Pachur (pachur@mpib-berlin.mpg.de)<br>Ralph Hertwig (hertwig@mpib-berlin.mpg.de)<br>Max Planck Institute for Human Development<br>Lentzeallee 94, 14195, Berlin, Germany

#### Abstract

In many natural domains, risks and rewards are inversely related (Pleskac \& Hertwig, 2014). We sought to understand how people might use this relationship in choosing among risky gambles. To do so we, manipulated risk-reward structures of monetary gambles to be either negatively or positively correlated, or uncorrelated. After substantial exposure to these environments, participants completed a speeded choice task among non-dominated gambles. Eye-tracking data from this task suggests that participants often shifted their attention to mainly one attribute in the correlated conditions, in which the risk-reward relationship was present. This was an adaptive strategy that resulted in a similar proportion of expected-value maximizing choices, compared to a more compensatory processing strategy.

Keywords: risk-reward relationship; decisions under risk; attention; noncompensatory processing; adaptive cognition

## Introduction

How likely is it to win the jackpot in the state lottery? Although many people play this game for a small pay-to-play fee, most of them also know that they are unlikely to win it. In fact, the larger rewards that we desire are usually unlikely to occur. While such a negative relationship between risks and rewards or probabilities and payoffs exists across gambles in many monetary and nonmonetary domains in the environment, this relationship is hardly every present in empirical studies of risky choice (Pleskac \& Hertwig, 2014). In this study, we investigated how people's experience with different risk-reward relationships impact how they process explicitly stated payoffs and probabilities in decisions under risk. In particular, we studied how an environment in which risks and rewards are correlated would be conducive for the use of noncompensatory processing strategies, that ignore part of the attributes, in a situation where time was limited.

## Adaptive Decision Making

According to an adaptive view of cognition, people exploit statistical regularities in the environment (Simon, 1956). As Payne, Bettman and Johnson (1993) found, the extent to which people exploit structures in the environment can largely depend on "the structure of the available alternatives, and [...] the presence of time pressure" (p. 534). For instance, people can decide to rely on a subset of cues in the environment because cues are often interrelated (Brunswik, 1952). Despite using a reduced amount of information, this can lead to good choices (Gigerenzer, Todd, \& the ABC Research Group, 1999). Here, we propose that the risk-reward relationship is a key structure that people capitalize on to make fast, adaptive (or value-maximizing) decisions.

## Choice in Risk-Reward Environments

When should and do people rely on risk-reward structures to inform their decisions? One case is when information is missing, such as in decisions under uncertainty, where the probabilities of obtaining a reward are unknown. In this case, Pleskac and Hertwig (2014) showed that people use a riskreward heuristic, inferring the probability of a payoff from the magnitude of the payoff itself. In a new set of studies, we have also found that in using the risk-reward heuristic people appear to adapt to different risk-reward structures (Leuker, Pleskac, Pachur, \& Hertwig, in prep.). In particular, we exposed participants to different risk-reward environments by asking them to price gambles from different risk-reward environments. Then we asked participants to choose between an uncertain prospect (where the probabilities were unstated) and a certain payoff. Participants' preferences were again consistent with them using a risk-reward heuristic, inferring probabilities from payoff magnitudes. Moreover, their preferences depended on the environment they had been exposed to previously. For example, participants in the negative condition chose the lower payoff, uncertain options more often compared to the positive condition. Based on these results, we sought to examine if and how people adapt their decisionmaking processes to risk-reward structures in decisions under risk, when payoffs and probabilities of the option are known.

## The Current Study

Processing strategies. One way to distinguish between processing strategies is to consider the amount of attributes they rely on. Compensatory strategies process and trade off of all available and relevant information. Noncompensatory strategies "typically reduce processing demands by ignoring potentially relevant information" (Payne, Bettman, \& Johnson, 1988). Thus, one important reason to consider noncompensatory processing strategies (despite information being, in principle, available, as in risky choice) is when time or cognitive resources are limited.

Strategy-environment dependence. Early research on these two classes of strategies demonstrated that their success largely depends on the environment in which they are recruited. Specifically, in environments with nondominated options (e.g., gamble $A$ offers a higher payoff $x$, but gamble $B$ offers a higher probability $p: x_{A}>x_{B}$ and $p_{A}<p_{B}$ ), people should rely on compensatory strategies (see Table 2, Payne et al., 1988). A decision maker who processes the dimensions

Figure 1: Choice stimuli based on their relationship between probabilities and payoffs. Each point depicts one gamble from the choice phase. Across conditions, probabilities and payoffs were (A) negatively correlated, (B) positively correlated or (C) uncorrelated. Black circles are environment gambles (60 pairs). Triangles are common gambles interspersed in all three conditions (15 pairs). Dominated options not depicted (5 pairs).
in a noncompensatory fashion in these environments-for instance by relying on a simplifying heuristic that attends to outcomes only-will suffer "a substantial loss in accuracy" (Payne et al., 1993, p. 539). In contrast, such noncompensatory processing strategies have been shown to perform well when dominance is possible (that is, one gamble is better on all dimensions: if $x_{A}>x_{B}$ and $p_{A}>p_{B}$ ).

Local vs. global environment. By definition, nondominated options create an inverse risk-reward relationship in a given set of alternatives, because the gamble offering a higher payoff will always be associated with a lower probability relative to the other gamble $\left(x_{A}>x_{B}\right.$ and $\left.p_{A}<p_{B}\right)$. However, this "local" risk-reward relationship (within a pair of gambles) can differ from a "global" risk-reward structure (across a larger reference class of gambles). That is, nondominated alternatives can be drawn from globally structured or unstructured environments. We propose that both the use and performance of either type of strategy is also highly dependent on these global risk-reward structures. Global correlations between risks and rewards make one of the cues redundant (payoffs predict probabilities and vice versa). Therefore, we hypothesized that, when options are drawn from correlated riskreward environments, noncompensatory strategies can lead to accurate, expected-value maximizing choices even if neither option is dominated. For choices between nondominated options from globally uncorrelated environments, results may resemble those of Payne, Bettman and Johnson (1988).
To test these ideas, we employed a between-subjects design manipulating the global risk-reward relationship between the possible options participants experienced (Figure 1). In a first pricing phase, we showed participants individual gambles and asked them to state their willingness to sell each gamble. We used this phase to expose people to different risk-reward environments. Detailed data from this phase will be reported else-
where. Our focus in this paper is the second phase, where participants chose between pairs of risky options under moderate time pressure (Figure 2). The gambles in the choice phase were drawn from the same, condition-dependent risk-reward environments, and paired such that neither option was dominated. We tracked participants' eye movements to dissociate between processing strategies across the different risk-reward environments, as choice patterns alone may not be sufficient to do so. As an independent test of whether participants had picked up the different risk-reward relationships, we asked them to estimate probabilities from payoffs at the end of the experiment.

## Method

## Participants

Ninety-three ( 55 female) participants (mean age $=25.6 \mathrm{yrs}$, $S D=3.7 ; N=31$ per condition) from the participant pool at the Max Planck Institute for Human Development, Berlin, completed the experiment (duration $\sim 75 \mathrm{~min}$ ). All participants were paid a fixed rate of $€ 12$ plus a bonus based on their performance in a random subset of trials from the pricing phase and choice task (€3.53-11.67).

## Design

The experiment consisted of three phases. In the pricing phase, participants were presented with single gambles and asked to indicate their willingness to sell for each of them. Between subjects, we manipulated the types of gambles people were presented with such that payoffs and probabilities were positively or negatively correlated, or uncorrelated. In the subsequent choice task, these different risk-reward structures were maintained. People were asked to choose between gamble pairs within 3s. All gambles were in the gain domain (" $p_{1}$ chance of winning $x_{1}$, otherwise nothing"). We used an experimental currency, the $\mathrm{E} \$$ (conversion rate $2500 \mathrm{E} \$=€ 1$,
disclosed in the instructions). We collected eye-tracking data during the exposure phase and the choice task. As people are merely exposed to different risk-reward structures, participants picking up risk-reward structures despite not being told about the presence of any relationship in the data would constitute a form of unsupervised learning. Finally, in the third phase we asked participants to estimate the probabilities they thought were associated with various payoff levels. We did this to test whether participants had picked up the different risk-reward structures from the gambles they were exposed to throughout the study. Participants were not informed about the estimation task beforehand.

Gamble environments. The gambles from the pricing and choice phases were constructed such that across gambles, there was a negative, a positive, or no relationship between risks and rewards. For the negative condition, we drew random payoffs from a uniform distribution (range 1.01 $2500 E \$$ ). The probabilities for each payoff were inversely related to the payoff $x$ such that, $p=1-\frac{x}{2500}$. We added normally distributed noise to logit-transformed payoffs and probabilities. For the positive condition, we reversed the order of probabilities such that the highest probabilities were now associated with the highest rewards (and vice versa). For the uncorrelated condition, we re-linked payoffs and probabilities randomly.

Pricing task. The pricing task served to expose participants to different risk-reward environments. Briefly, participants were shown each of the 90 gambles from one of the environments and asked to state a price they would be willing to sell the gamble for. In addition to 90 condition-dependent gambles based on the aforementioned construction rule, participants were also asked to price 30 gambles that were common to each of the three conditions (triangles in Figure 1), yielding 120 gamble stimuli per condition. To motivate participants to report their true valuations of the gambles, we implemented a Becker-DeGroot-Marschak auction (Becker, Degroot, \& Marschak, 1964). In particular, ten gambles were selected at the end of the experiment and participants either played out the gamble or received their stated selling price.

Choice task. Gambles were created using the same construction rule as above. An initial set of 100 gambles yields 4950 possible gamble pairs. We randomly drew 60 nondominated gamble pairs per condition (see circles in Figure 1). By design of the study, expected value differences were largest in the uncorrelated and smallest in the positive condition (uncorrelated: $M d=173 E \$$, $.53-1374 \mathrm{E} \$$; negative condition: $M d=134 E \$$, $49-511 \mathrm{E} \$$; positive condition: $M d=23 E \$$, $43-146 \mathrm{E} \$$ ). In addition, we interspersed 15 gamble pairs that were common to each of the conditions in the second half of the choice task (triangles in Figure 1), and 5 choices with dominated options as catch trials, yielding 80 choices in total. Common gambles allowed us to examine condition-dependent processing differences on precisely the same stimuli. Participants were instructed to choose their

Figure 2: Typical choice trial. For trials that exceeded the time limit, we presented an additional screen informing participants that they had lost payoffs in that particular trial (not shown). Eye-tracking data was recorded throughout, analyses are based on the second screen.
preferred gamble within 3s (see Figure 2). Crucially, participants were informed in this task that the gambles were drawn from the same population of gambles they had experienced in the previous pricing task. Five randomly selected choices were played out at the end of the experiment.
Estimation task. We drew 20 payoffs (range 1.01 $2500 E \$$ ) and asked participants to estimate the probabilities that had been associated with these payoffs in the main experiment.

## Eye-tracking

During the pricing and choice tasks, we collected binocular eye position data with an EyeTribe tracker, sampled at 60 Hz . The experiment was implemented in PsychoPy 1.83.01 and the eye-tracking interface PyTribe (Dalmaijer, Mathôt, \& Van der Stigchel, 2013). Each participant's eye movements were calibrated using the Eyetribe UI with a 9-point grid before each task ( $<0.7$ ). Participants were seated approximately 60 cm from the screen using a chinrest affixated to the table, in a room with negligible ambient light. We preprocessed raw samples by parsing eye-tracking data into fixations and saccades using the saccades package in R (Saccades Version 0.1-1, 2015), based on a velocity-based algorithm (Engbert \& Kliegl, 2003). Eye-tracking analyses in this paper are based on fixation data.

## Analysis

The data were analyzed using Bayesian General Linear Models using Stan in R for regression analyses (RStanArm Version 2.9.0-4, 2016). We ran 3 chains ( 2500 samples each, burn-in of 500), and investigated (convergence of) our posteriors visually and with the Gelman-Rubin statistic (Gelman \& Rubin, 1992). We report the mean of the posterior distribution of the parameter of interest and two-sided $95 \%$ equal tail credible intervals (CI) around each value.

## Results

## Behavioral

We excluded one participant in the negative condition who chose the dominated option in 4 out of 5 catch trials.
Pricing task. For all participants, prices were strongly related to the expected values of the gambles (credible payoff $\times$ probability interaction, $b=.70, \mathrm{CI}=[.66, .74])$.

Choice task. Participants across all three conditions chose the expected-value-maximizing options above chance level ( $M=.71$, $\mathrm{CI}=[.56, .85]$ ). As expected, in the positive condition (in which the EV differences between the options were rather small) participants made fewer EV-maximizing choices $(M=.59, \mathrm{CI}=[.51, .67])$ than in the uncorrelated condition (in which the EV differences were larger; $M=$ $.70, b=.11, \mathrm{CI}=[.00, .22]$ ), and the negative condition ( $M=.74, b=.25, \mathrm{CI}=[.14, .37]$ ). Controlling for EV differences and individual variation, participants in the negative condition achieved a higher proportion of expectedvalue maximizing choices $(M=.70, \mathrm{CI}=[.52, .88])$ compared to the uncorrelated condition $(M=.31, b=-.39, \mathrm{CI}=$ $[-.63,-.16])$, and the positive condition ( $M=.39, b=-.32$, $\mathrm{CI}=[-.54,-.09])$. In both models, the highest accuracy was achieved in the negative condition. In the subset of gambles that were common across all conditions, there were no differences in accuracy between the conditions $(M=.53, \mathrm{CI}=$ [.35, .72]).

Response times were comparable across all conditions and gamble types. In addition, small proportions of timed-out trials (negative: .006, positive: .016, uncorrelated: .013) indicate that participants were well-adjusted to the speed instruction of $3 \mathrm{~s}(M d=1.63 \mathrm{~s}$ even suggest that people could have taken more time on many trials).

Estimation task. Participants' probability estimates reflected the risk-reward structure they had been exposed to previously. That is, participants in the negative condition provided lower probability estimates for gambles with higher payoffs ( $b=-.64, \mathrm{CI}=[-.68,-.60]$, \% per $100 \mathrm{E} \$$ ), and in the positive condition participants provided higher probability estimates for gambles with higher payoffs ( $b=.16$, $\mathrm{CI}=[.10, .14])$. In the uncorrelated condition, participants provided lower probability estimates for gambles with higher payoffs (weaker slope compared to the negative condition: $b=-.32, \mathrm{CI}=[-.37,-.26])$.

## Eye-tracking

We defined four areas-of-interest (AOIs), one for each payoff and probability. We visually inspected the quality of every participant's eye-tracking data by plotting their fixations over time. Seven participants whose fixations did not map onto the screen correctly were excluded, a possible result of the eyetracker being moved during the experiment. We excluded one further participant who was blind in one eye, leaving $N=84$ for the eye-tracking analyses ( 27,29 , and 28 in the negative,

Figure 3: Number of AOIs inspected per condition. Each dot represents one participant's average number of AOIs visited per trial. Dashed line $=$ mean number of AOIs visited across participants. Differences between conditions are driven by the composition of compensatory/noncompensatory strategies (percent compensatory in negative: $44 \%$; positive: $34 \%$, uncorrelated: 61\%).
positive, and uncorrelated conditions, respectively).
Number of AOIs viewed. To test whether the presence of a risk-reward relationship led to more noncompensatory processing, we averaged the number of AOIs each participant viewed (max. 4). Participants in the uncorrelated condition inspected the largest number of AOIs ( $M=3.46, \mathrm{CI}=$ [3.45, 3.48]). Participants in the positive condition inspected a credibly lower number of AOIs ( $M=3.20, b=-.20$, CI $=[-.23,-.18])$. The negative condition also inspected credibly fewer AOIs, but the difference was smaller ( $M=3.40$, $b=-.06, \mathrm{CI}=[-.08,-.03]$, model on the trial level). Using the average number of fixations as an alternative indicator resulted in the same pattern of results, and only a marginally higher count (uncorrelated condition $M=3.71$, negative condition $M=3.51$, positive condition $M=3.39$ ), likely because the time limit imposed in the experiment did not allow for many re-acquisitions (i.e., fixations back to a previously acquired AOI). Note that the mean number of fixations is rather low (i.e. <4). We ran the same AOI model using only common gamble data (see triangles in Figure 1). Again, the uncorrelated condition inspected most AOIs ( $M=3.21$, $\mathrm{CI}=[3.09,3.34]) . \quad$ This number was lower in the positive condition $(M=2.83, b=-.38, \mathrm{CI}=[-.57,-.20]$, difference credible), and in the negative condition ( $M=3.07$,
$b=-.14, \mathrm{CI}=[-.34, .04]$, difference however not credible). Because these gambles were identical across conditions, this suggests condition-dependent processing strategies are not merely a by-product of specific risk-reward environments that vary on crucial dimensions such as EV differences between gambles. Figure 3 suggests substantial individual differences among participants in the conditions (indeed, differences in numbers of AOIs inspected can be accounted for by including participant as a grouping factor). More importantly, however, visual inspection of the data suggests two subgroups that can roughly be split by the mean number of AOIs inspected across participants ( $M=3.11$, dashed line in Figure 3): Participants who tend to inspect all four AOIs ("compensatory") and participants who ignore some of the AOIs ("non-compensatory"). Thus, differences between conditions may be driven by the composition of compensatory/noncompensatory strategies (proportion compensatory in uncorrelated: .61, positive: .34, negative: .44). That is, participants in the uncorrelated condition were 2.85 times more likely to rely on a compensatory strategy than participants in the positive condition ( $b=1.05, \mathrm{CI}=[.07,2.04]$ ). The difference between the negative and positive risk-reward environments was not credible ( $b=.68, \mathrm{CI}=[-.29,1.73]$, OR $=1.97)$. A majority of participants in the correlated environments thus seemed to rely on a noncompensatory strategy (note that here such a strategy could also mean attending to three out of four AOIs per trial, see Figure 3).

Attention to attributes. Which attributes did participants attend to, especially when choosing to ignore some of the information? All participants fixated most on payoff information (. 57 of fixations, $\mathrm{CI}=[.53, .61]$ ). This proportion decreased for participants who inspected more AOIs ( $b=-.98$, $\mathrm{CI}=[-1.56,-.38]$; no credible effect of condition). At the extreme end, participants who, on average, inspected roughly two AOIs fixated on the payoff $80 \%$ of the time. An alternative viable noncompensatory strategy would have been to focus more on the information presented at the top or the bottom of the screen. We counterbalanced the location of attributes (between-participants). However, top/bottom fixation proportions were unrelated to the number of AOIs inspected ( $b=.03, \mathrm{CI}=[-.60, .66]$ ), suggesting that participants considered payoff information as more relevant when using noncompensatory strategies.

EV choices by strategy. Do compensatory or noncompensatory strategies differ in performance within the three environments? Figure 4 shows that users of a noncompensatory strategy (triangles) achieved similar levels of EV-maximizing choices compared to users of a compensatory strategy (circles), overall ( $M=-.10, \mathrm{CI}=[-.39, .18]$ ). Unexpectedly, this held irrespective of condition (no credible strategy $\times$ condition interaction). This result also held when controlling for differences between the condition in EV difference between the options. We expected that in the uncorrelated condition, decision performance would be compromised for users of a

Figure 4: Proportion of higher EV choices by a participant's average number of AOIs inspected per trial, condition, and decision strategy. Circles = noncompensatory strategy users, triangles $=$ compensatory strategy users. The gain in EVmaximizing choices associated with inspecting more AOIs is more pronounced for participants in the uncorrelated condition.
noncompensatory strategy-who should lack critical information to determine the EV maximizing option.

At the same time, across conditions, the proportion of EV-maximizing choices was higher for participants who inspected more AOIs (main effect of AOIs inspected on EV choice irrespective of processing strategy, $b=.044, \mathrm{CI}=$ [.001, .089]). Within each subgroup, the increase in EV choices with increasing numbers of AOIs inspected is more pronounced for participants in the uncorrelated condition (see black regression line, Figure 4). Yet, this interaction effect is not credible, potentially due to the small number of participants in each subgroup (AOI $\times$ condition interaction with the positive condition as a reference; compensatory: $b=.02$, CI $=[-.04, .09])$, noncompensatory: $b=.05, \mathrm{CI}=[-.01, .11])$. In general, one would indeed expect that the increase in the proportion of EV choices with higher number of AOIs inspected is more pronounced for the uncorrelated condition because this condition allows for least simplification.

## Discussion

Risk-reward relationships allow people to make fast, valuemaximizing decisions. A majority of people exposed to correlated risk-reward structures used noncompensatory processing strategies, likely as a result of time pressure. With fewer AOIs inspected, participants focused more on payoff
information. In turn, most people who experienced an uncorrelated risk-reward environment attempted to take into account all attributes, speaking in favor of a more compensatory processing strategy. This strategy use is adaptive given the affordances of the different environments. While correlated risk-reward environments made one of the attributes redundant, such a relationship did not exist for gamble problems in uncorrelated risk-reward environment. Condition-dependent processing differences (i.e., numbers of AOIs visited) persisted when restricting the analysis to a common set of gambles interspersed in each of the conditions. Surprisingly, these differences only had a minor impact on EV choice.
Earlier research suggested that noncompensatory strategies fare well when dominance is possible, but not when neither option is clearly dominated (Payne et al., 1988). We identify one qualification of this prediction, showing that noncompensatory processing strategies can also perform well for nondominated option pairs; namely when a risk-reward relationship is present in the global set that gamble pairs are drawn from. Researchers have studied the influence such contextual factors before. Birnbaum (1992) found that participants' certainty equivalents for gambles were larger when a set of certainty equivalents to choose from was positively skewed (vs. negatively skewed). In addition, the marginal distributions of payoffs, probabilities and delays can account for psycho-economic functions that are often described in the literature (Stewart, Chater, \& Brown, 2006). Here, we extend such considerations by manipulating the joint distribution of payoffs and probabilities.

Several limitations of the current study should be mentioned. First, it is currently unclear what underlies the strong individual differences in noncompensatory/compensatory strategy use in each condition. Potentially, some participants did not perceive a time limit of 3 s as pressing enough to opt for noncompensatory strategies, or turned to different simplification strategies. Overall, the dichotomous distinction between compensatory and noncompensatory processors may be too simplistic: For instance, some individuals attended to three attributes on average (i.e., more than one class of attributes such as two payoffs, one probability). Another possibility is that users of a noncompensatory strategy fixated on some but glanced the other attributes (covert attention), or changed strategies across trials. Lastly, more research is needed to study the process by which people learn about different risk-reward structures (Klayman, 1988).

## Conclusion

People's choices and processing strategies are impacted by the risk-reward structure in a given environment. Specifically, correlated risk-reward environments allow decision makers to use noncompensatory strategies when they need to reduce processing demands. This strategy use is adaptive, given that it does not need to compromise accuracy if it matches the environment. Many natural environments exhibit an inverse relationship between payoffs and probabilities that can thus be
exploited in a similar way, when time or cognitive resources are limited. These findings challenge theories of decision making under risk, that often treat payoffs and probabilities as independent attributes determining the value of an option. In comparison, an adaptive decision maker may often have good ecological reasons to process payoffs and probabilities dependently.

#### Abstract

Vectors derived from patterns of co-occurrence of words in large bodies of text have often been used as representations of some aspects of the meanings of different words. Generally, the distance between such vectors is used as a measure of the semantic similarity between the word meanings they represent. One important way of evaluating the performance of these vectors has been to use them to answer vocabulary multiple choice questions (MCQs) where the participant is asked to judge which of several choice words is closest in meaning to a stem word. The existing vocabulary MCQ tests used in this way have been very useful but there are some practical problems in their use as general evaluation measures. Here, we discuss why such tests remain useful evaluation measures, introduce a new vocabulary test, evaluate several current sets of semantic vectors using the new test and compare their performance to human data.

Keywords: Distributional semantics; vocabulary MCQ.

## Introduction

There are many potential applications for a method that can reliably form the basis for measuring the semantic distance between words or concepts. Many methods achieve this by placing each word/concept in a multidimensional space where the dimensions are defined by the way in which words co-occur in corpora of real language use (Schütze, 1993; Bullinaria \& Levy, 2007; Turney \& Pantel, 2010). The simplest such methods place a target word in a space defined by the count of how many times this word co-occurs with other words in the corpus with each of these context words defining a dimension. The resulting semantic vectors may also be smoothed by some kind of dimensionality reduction technique. Most current techniques retain only a small proportion of the number of initial dimensions (often 300) and refer to these dense vector sets as "word embeddings" (e.g., Mikolov et al., 2013). Two words are then judged to be semantically similar if the vector distance between them is small.

Various validation approaches have been used, but a particularly convenient way of evaluating such techniques is
to measure how well they perform in a vocabulary multiple choice question (MCQ) test where a participant is asked to choose which of a number of choice words is closest in meaning to a stem word (not to be confused with a morphological stem). Often this amounts to choosing a ("key") synonym, or the word that is closest to being a synonym, from the other choice words that act as distractors. For human participants, these tests are used to measure vocabulary knowledge. Such tests are ideal methods to use to evaluate co-occurrence techniques which construct semantic vectors for each word such that their distances are related to how substitutable the words are for each other. A linguistic intuition would be that if two words are substitutable for each other in everyday language then they are synonyms or at least very closely semantically related.

Landauer and Dumais (1997) used the performance of their LSA (Latent Semantic Analysis) method on the retired items of a once commercially available test of English vocabulary the TOEFL (Teaching of English as a Foreign Language). They reported a performance of $64.4 \%$, well above chance and equivalent to acceptable performance for entry to a US University. This MCQ test has been the most widely used vocabulary test to date for evaluating distributional semantic vectors ${ }^{1}$. Turney (2001) also describes a commercially available test, the ESL, and this has been used to evaluate such methods. Another candidate MCQ test would be the one used by Adelman et al. (2014) from Shipley (1940). This is a 40 item vocabulary MCQ using some now somewhat archaic US English usages. It has the advantage of being freely available in the appendix of a historic journal article. Such tests are valuable evaluation measures for semantic representations in that they are independently designed to measure the performance of human participants. However, they have a number of disadvantages if they are used as the only evaluation:

[^385]- They are at least relatively commercially sensitive as making a real-word test freely available would render it useless as a fair measure of human vocabulary knowledge. We have always found that researchers who report the use of such tests have been helpful and generous in making the test items available to other researchers but, inevitably, the commercial/practical sensitivity of the items is an obstacle for widespread open publication of them. This can prevent the clear reporting of slight changes made to the items due to low frequency word forms (or USA/UK spelling variants) not appearing, or not appearing frequently enough, in the corpora used, which can lead to papers reporting results of slightly different tests.
- They are relatively small as they are designed to be completed in a reasonably short period of time by the human testees.
- The individual questions may not be uniform in terms of difficulty or kind of semantic relationship being tested. A question may test knowledge of near-synonymy or one of a degree of some other kind of semantic similarity such as category membership.

In this paper, we describe a new 200 item MCQ vocabulary which we will make freely available. The test has been constructed using the lexicographical judgements implicit in the construction of the noun entries in WordNet (Fellbaum, 1998). Half of the stem words in the test are relatively high frequency (in the psycholinguistically relevant sense) and half are low frequency. Word frequency is a dominant lexical variable for human language processing and especially so in instruments, such as this one, that are designed to measure vocabulary knowledge. The 200 MCQ set is large enough to be performed comfortably by human participants and to be split into subsets for training and testing when using machine learning techniques.

As noted above, vocabulary MCQ tests have frequently been used as evaluation measures for distributional semantic vectors. However, some of the most recent methods for generating such semantic vectors (e.g., Mikolov et al., 2013; Pennington et al., 2014) have emphasised evaluation using sets of analogy problems. We would argue that both vocabulary and analogy tests are important in evaluating the semantic competence of distributional semantic vectors, as well as being useful in models of human semantic performance. Here, we therefore evaluate three promising recent semantic vector techniques using our new vocabulary test.

In constructing our new test, we use WordNet (Fellbaum, 1998), a freely available lexicographic database organised around lists of synonyms (synsets) for the different senses of each word in the database. This allows us to use the independent linguistic judgements of the WordNet team as a standard for competence in tests of synonymy judgements on the vocabulary MCQ items that we construct.

We consider that MCQ vocabulary tests are interesting psychological tasks in their own right. It is likely that word frequency measures will dominate any quantitative model of
relative question difficulty and that word familiarity (and proxies for this such as level of education or experience with English in the case of the data described here) is likely to dominate models of individual differences in performance on these tasks. If a participant has never or very rarely come across a stem or synonym then, apart from the possibility of sensitivity to form-meaning symbolism (e.g., Levy \& Thompson, 2008; Monaghan et al., 2014), they are unlikely to perform well on test items containing these words. However, there remains the strong possibility that semantic distances between stem and synonym, stem and distractors and synonym and distractors will affect question difficulty and the choice of distractor when an MCQ item is answered incorrectly. Semantic vector techniques are a good resource for calculating these distances. Thus, vocabulary MCQs are useful measures for evaluating the competence of semantic vector techniques, and semantic vectors are likely to be components of any complete model of human vocabulary MCQ performance.

In the rest of this paper, we outline how we constructed a new 200 item vocabulary MCQ test, show how well three recent methods for generating distributional semantics vectors perform on the test, and compare the performance of the semantic vectors with human performance on the same test items. We intend to make the MCQ items and human data freely available as a research resource.

## Construction of New Vocabulary Test

We constructed a set of 200 vocabulary MCQ items. This is larger than most of the evaluation benchmarks that have been suggested (allowing the set to be potentially split into independent training and testing components for reliable model selection purposes) but still a manageable number of items for individual human participants.

The words in the MCQs were chosen by using the entries for nouns in WordNet. All words considered for selection appeared in both the SUBTLEX-UK (Van Heuven et al., 2014) and WordNet databases, and were dominantly tagged in their noun form in both databases. SUBTLEX-UK is a database constructed from BBC TV subtitling records and so this ensured that the words chosen were in common usage in the UK.

We chose to generate stem-synonym pairs by using the synsets in WordNet because this gives us an independent benchmark for lexical semantic relations. By dividing the MCQ items into two subsets where one has relatively high stem frequencies and the other has relatively low ones, the vocabulary test controls one of the most important influences on human linguistic performance.

The potential candidate list of stem words was divided into lower-frequency (LF) and higher-frequency (HF) subsets using the "Zipf" scale (van Heuven et al., 2014), which is based on the $\log _{10}$ transform of word frequency. Those authors argue that this scale is a better way to control frequency in a psycholinguistically relevant way than frequency per million word (fpmw) counts. For example, using these counts to select stimuli results in an
underrepresentation of relatively low frequency words that are familiar to human participants.

These candidate lists were randomly sorted. Stems and synonyms (taken from the synsets associated with each stem noun) were selected from this list such that the final HF and LF subsets consisted of pairs that were matched for stem word length, synonym frequency and synonym length. Hyphenated stem words or synonyms were excluded from selection. Three distractor words were selected at random from the remaining nouns in WordNet and SUBTLEX-UK with a Zipf frequency greater than two. The mean distractor length and frequency (over the three distractors) was pairwise matched to the synonym. Mean stem, synonym and distractor characteristics are shown in Table 1.

Table 1: Mean Zipf Frequency (F) and word length (L) for Stem, Synonym (Syn) and Distractor (Distr) words

| MCQs | Stem | Stem | Syn | Syn | Distr | Distr |
| :--- | :--- | :--- | :--- | :--- | :--- | :--- |
|  | F | L | F | L | F | L |
| LF | 3.0 | 6.3 | 3.6 | 6.4 | 3.6 | 6.3 |
| HF | 4.8 | 6.4 | 3.7 | 6.5 | 3.7 | 6.6 |

## Human Performance on the Vocabulary Test

The vocabulary MCQ test was given to 85 monolingual English speaking undergraduate student participants and 77 non-monolingual students. Their performance is summarised in Table 2.

Table 2: Performance (\% correct) of monolingual and non-monolingual participants

| MCQs | mean | SD | range |
| :--- | :---: | :---: | :---: |
| Monolingual |  |  |  |
| All 200 | $79 \%$ | $10 \%$ | $56 \%-97 \%$ |
| 100 LF | $72 \%$ | $13 \%$ | $46 \%-96 \%$ |
| 100 HF | $86 \%$ | $8 \%$ | $63 \%-98 \%$ |
| Non-monolingual |  |  |  |
| All 200 | $71 \%$ | $10 \%$ | $49 \%-92 \%$ |
| 100 LF | $61 \%$ | $12 \%$ | $32 \%-88 \%$ |
| 100 HF | $81 \%$ | $10 \%$ | $52 \%-96 \%$ |

Mean performance is high but does not appear to be close to ceiling. The very best performance is close to maximal demonstrating that it is possible for humans to achieve a close to perfect score.

The mean scores for monolingual participants are higher than that for non-monolingual participants for the complete MCQ set and the two subsets.

As would be expected for human performance, performance for the high frequency stems exceeds that for the low frequency ones with the non-monolingual participants demonstrating a larger deficit for low frequency stems. Clearly, human performance has been affected by our manipulation of stem frequency whilst matching the
synonym and distractor frequencies between the low- and high-frequency subsets. The correlation between MCQ question item difficulty (as measured by overall percentage correct) and stem SUBTLEX-UK frequency is 0.41 , suggesting that factors other than word frequency may be affecting human vocabulary test performance.

Three participants achieved overall scores of 97\% - six errors from the 200 MCQ items. These few errors were sometimes made on the same question by more than one participant and were also sometimes also made by the semantic vector methods.

## Semantic Vectors for Evaluation

In addition to testing our new MCQ vocabulary test on human participants, we also used it to evaluate three available sets of semantic vectors, all derived from large text corpora but using contrasting methods to capture the patterns of word usage regularities. Our aim here is to illustrate how well a few recent methods that have been most successful on other semantic tasks are able to perform on this task, and not to make any claims about optimal methods or parameters.

We compared the levels of success on the new vocabulary test using three different kinds of semantic vectors that span the range of approaches available: vectors derived from the methods described by Bullinaria \& Levy (2012), the publicly available semantic vectors that were generated using one of the word2vec (Mikolov et al., 2013) methods (available at: https://code.google.com/archive/p/word2vec/) and the GloVe (Pennington, Socher \& Manning, 2014) vectors derived from the co-occurrence matrix from 6, 42 and 840 billion word corpora available at: http://nlp.stanford.edu/projects/glove/.

The Bullinaria \& Levy ( $\mathrm{B} \& \mathrm{~L}$ ) vectors are derived from the ukWaC (Baroni et al., 2009) (2 billion words) corpus by counting word co-occurrences in a context window of size one and using those counts to generate a starting matrix of positive pointwise mutual information (PPMI) values for about 50,000 target words and 50,000 context words. This choice of window size and co-occurrence statistic was previously shown to be optimal for a range of semantic tasks (Bullinaria \& Levy, 2007) and is now widely used. Singular Value Decomposition (SVD) dimensionality reduction is then used to generate orthogonal matrices $U$ and V and diagonal singular value matrix S such that $\mathrm{M}=$ $\mathrm{USV}^{\mathrm{T}}$, and dimensionality reduction is performed by taking the principal components of $\mathrm{US}^{\mathrm{P}}=\mathrm{MVS}^{\mathrm{P}-1}$ to produce semantic vectors with a dimensionality of 5,000 with the components weighted using a Caron (2001) P value of 0.25 . These parameter values were optimised so as to perform well on four different semantic evaluation measures including a version of the Landauer \& Dumais (1997) TOEFL MCQ vocabulary test, and achieved the current state-of-the art performance on the TOEFL MCQ ${ }^{1}$ test.

The word $2 \mathrm{vec}(\mathrm{W} 2 \mathrm{~V})$ vectors were generated using a 100 billion word sample of the Google News dataset. Word2vec uses supervised learning algorithms to train a simple but
very large neural network model to predict either which words will appear in a window around the current word (the context given the current word) or which word will appear given the current context words. There are a number of different methods and parameters that can be varied in what amounts to a family of techniques. We made use of the publicly available vectors which have 300 dimensions.

The GloVe (G6, G42, G840) vectors were extracted from the files linked to on the GloVe website. The G6 vectors were generated from a 6-billion-word corpus derived from Wikipedia. The 42B and 840B vectors were generated from 42 billion and 840 billion word corpora derived from Common Crawl archives (obtained by an automated process of systematically browsing the web). All the GloVe vectors used here have 300 dimensions. The GloVe method uses regression modelling to learn semantic vectors from the non-zero entries of a word co-occurrence matrix such that the dot product between the vectors for a pair of words equals the logarithm of their probability of co-occurrence. Pennington et al. (2013) show that their vectors perform well on the analogy problem set that was also used to evaluate the word2vec methods.

Levy, Goldberg and Dagan (2015) have argued that the three broad semantic vector techniques used here have similar levels of overall performance when appropriately tuned.

17 of the 1,000 words within the 200 MCQs did not appear in the word2vec vector sets due to differences in UK and USA English. For these words, we used the vectors derived from the USA spelling variants. 7 words did not appear in the GloVe vectors derived from their 6 billion word corpus. For these words, we substituted related words that did appear in the vector set. The other semantic vector sets contained all the 1,000 words used in this MCQ vocabulary set.

Clearly, there are a number of differences in the corpora and parameters used for the three methods and so this exercise cannot reliably compare the success of the different methods in general, but serves as a comparison of a number of different off-the-shelf semantic vector sets.

## Semantic Vector Performance on the Vocabulary Test

We compared the performance of the five different vector sets on all 200 items and on the LF and HF subsets. Mean performance is summarised in Table 3.

Table 3: Performance (\% correct) of the five different vector sets.

| MCQs | B\&L | W2V | G6 | G42 | G840 |
| :--- | :--- | :--- | :--- | :--- | :--- |
| All 200 | 91.0 | 87.0 | 86.5 | 89.5 | 92.0 |
| 100 LF | 93.0 | 87.0 | 86.0 | 92.0 | 95.0 |
| 100 HF | 89.0 | 87.0 | 87.0 | 87.0 | 89.0 |

All three types of semantic vector perform well but not perfectly. None of them match the competence standard of
the WordNet-based MCQ test. The GloVe vectors trained on an 840 billion word corpus comes closest to matching the very best performance of human participants. However, all the vector sets exceed the mean performance of the human participants by large margins.

The LF and HF subsets are distinguished by the SUBTLEX-UK frequencies of their stem words. The frequencies (and word lengths) of synonyms and distractors were matched between subsets. Unsurprisingly, the human participants performed better on the HF subset than on the LF subset, presumably reflecting the association between word frequency and the familiarity that participants had with the stem words. However, in three of the five sets, the semantic vectors performed better on the LF subset than the HF one. Since even the smallest corpus used for generating the semantic vectors was 2 billion words in size, it is likely that all the words used in the vocabulary MCQ test were sampled a great many times and that this overcame any difference in the reliability of the semantic representations due to frequency differences. For the 2 billion word ukWaC corpus that we used (by far the smallest of the corpora used to train the methods compared here), Table 4 gives the frequency statistics for the vocabulary MCQ test synonyms. There is a very large variance in frequency values within each subset. The mean frequency for the LF subset is 3993 with the lowest stem frequency being sampled 98 times in the corpus. The correlation between the $\log _{10} \mathrm{ukWaC}$ corpus synonym frequencies and their SUBTLEX-UK Zipf frequencies is 0.93 .

Table 4: ukWaC frequencies for the stem words in the vocabulary MCQ test

| MCQs | mean | SD | range |
| :--- | :--- | :--- | :--- |
| All 200 | 119,809 | 198,796 | $98-1,057,891$ |
| 100 LF | 3993 | 5099 | $98-36,571$ |
| 100 HF | 235,625 | 228,725 | $12,291-1,057,891$ |

We suppose that any differences in performance for the semantic vectors on the LF and HF subsets is due to an inadvertent bias in the distribution of semantic distances between the MCQ words that is revealed when the statistical reliability related to word frequency differences is made irrelevant due to very high degrees of corpus sampling. It is likely that there is a higher degree of semantic ambiguity for the high frequency stems and this may have affected the MCQ results. We will explore these issues in further detail in modelling work in a future paper.

The corpora used to train the vector generation methods ranged from 2 to 840 billion words. Although performance of the different methods differed by only a few percent, it is notable that the $\mathrm{B} \& \mathrm{~L}$ vectors achieved one of the higher scores using a corpus of 2 billion words and that the GloVe vectors achieved higher scores as the corpus size used increased from 6 to 42 and then 840 billion words. The B\&L method was tuned for previous work on a different
vocabulary MCQ test whilst W2V and GloVe have been reported as having notable success on the rather different domain of analogy problems. It is likely that further parameter tuning would increase the scores of all three methods on this specific task if not in general for other tasks.

Landauer \& Dumais (1997) reported that their LSA semantic vectors performed at a level of $64.4 \%$ on a TOEFL vocabulary MCQ test. This matched the performance of a large sample of applicants to colleges in the USA from nonEnglish speaking countries who averaged a score of $64.5 \%$. This is close to the performance of our non-monolingual group on the 100 low frequency MCQs ( $61.4 \%$ ). These LSA vectors were trained on a much smaller corpus than the other semantic vectors describe here ( 6.4 million words) and so, arguably, are a better psychological model of attaining a degree of semantic competence from a realistic scale of linguistic input. However, they did not approach the high scores required to claim to be a model of idealised semantic competence.

As noted above, there were several MCQs where the same errors were made by some of the highest performing human participants and some of the vector methods. In some of these cases, it appears that the questions were made more difficult than expected by the random choice of distractor items leading to one of the distractors potentially being more closely semantically related to the stem than the intended synonym. An example is the intended stem, synonym, distractor1, distractor2, distractor3 MCQ: benefit, welfare, flask, advantage, lipstick. Here, two of the three highest performing participants and four of the five semantic vector methods made an error. Mean human accuracy was at below chance level. Because the vector methods have captured synonymy well, they show the potential for automatically measuring vocabulary MCQ difficulty in terms of semantic similarity over and above the effect of word frequency.

## Discussion

In cognitive science, we are often interested in building idealised or technologically useful models of intelligent behaviour as well as psychologically valid ones. Ideally, these are complementary aims. The development of methods to generate distributional semantic vectors over the past 20 years is an interesting example of the possible tensions between these two types of model. Landauer \& Dumais (1997) proposed LSA as a model of human semantic performance. LSA was partly validated by its success in matching human non-native performance in the TOEFL MCQ test. However, LSA was not capable of approaching perfect performance on the task. Current techniques have achieved very high levels of success on that task and similar ones such as the test proposed here. However, the amount of data used to train these models is very far in excess of the amount of text that a human could read in a lifetime. The use of distributional semantic vectors in the modelling of human performance (e.g., Pereira et al.,

2015; Mandera et al., 2017) and human brain activity (e.g., Mitchell et al., 2008; Bullinaria \& Levy, 2013) is becoming more widespread due to better and more easily available semantic vectors. However, it remains unclear how the balance between idealised competence and realistic human performance can be modelled by such techniques and which corpora and parameter settings should be used. Some of these issues can be addressed in the straightforward arena of vocabulary MCQ tests.
In this paper, we introduce a vocabulary test, based on WordNet synsets, that is both challenging enough for human participants not to be performed at ceiling and large and uniform enough to be useful as an evaluation measure for corpus-derived semantic vectors.
We argue that we are within reach of developing distributional semantic vectors that can demonstrate competence in the important, if narrow, domain of synonymy judgement. However, there is much to be done in using such representations as components of models that can successfully account for actual human performance on these same tasks.
Although the semantic vectors we tested were close to an idealised level of competence, they do not reflect the clear effect of synonym frequency in the human data. However, the ability of the semantic vectors to provide reliable measures of semantic similarity does show promise for modelling aspects of vocabulary MCQ question difficulty that are left after the influence of word frequency is accounted for.
A single set of semantic vectors cannot both account for idealised semantic competence as defined by a resource such as WordNet and provide a model of average imperfect human performance. For tasks such as vocabulary MCQ tests, it may be necessary to use semantic vectors as models of competence and account for varying performance using simple psychologically valid variables such as word frequency or familiarity. Certainly, current methods for the generation of semantic vectors only obtain very high performance scores after training on enormous corpora, orders of magnitude larger than any human would experience. This may make them poor or partial models of human semantic learning but useful technological tools and cognitive modelling components. It remains to be seen whether semantic vectors with somewhat lesser levels of competence, perhaps trained on much smaller corpora, are better tools for modelling ordinary levels of human performance.

Vocabulary MCQ tests have been useful measures of human word knowledge. In the past they have proved their worth as evaluation measures for semantic vector generation. They are psychological tasks in themselves and we have suggested here that semantic vector methods may allow us to model aspects of question difficulty that are related to relative semantic distances and this may also prove useful for the design of such instruments.
Vocabulary MCQ tests are an important component in the evaluation of representations of lexical semantics. We have
argued that it is important that such representations can account for idealised performance and so reach perfect performance in these tests. Current techniques have not yet reached this level of competence. It would also be highly desirable if these techniques contributed to our ability to model the imperfect performance of human participants on semantic tasks. We argue that vocabulary MCQ tests serve as useful psychological tasks to model. By making our new test freely available along with human data, we hope to stimulate further research.

## Acknowledgments

We acknowledge the funding given by our Universities and thank the student participants in our vocabulary MCQ experiment and our colleagues who facilitated this data collection. We also thank the authors of the $u \mathrm{kWaC}$ corpus, word2vec methodology and GloVe methodology for making their data and code available to us.

## Availability of the MCQ word list

We have made the new vocabulary MCQ test words, and various earlier test sets, available to be downloaded from: http://www.cs.bham.ac.uk/~jxb/corpus.html

# "I'm Better than You at Labeling!": Preschoolers Use Past Reliability when Accepting Unexpected Labels 

Xiaoqian Li (xiaoqian_li@mymail.sutd.edu.sg) \& W. Quin Yow (quin@sutd.edu.sg)<br>Singapore University of Technology and Design, 8 Somapah Road, Singapore

#### Abstract

How do young children decide to trust testimony that contradicts their initial beliefs? The current study examined whether children rely on cues to informant credibility (i.e., history of accuracy) to determine if they would endorse an unexpected label from an informant. Three- and 4-year-olds $(N=60)$ saw a picture of a hybrid artifact that consisted of features of two typical familiar artifacts. Children made initial judgments about the name of the hybrid object and subsequently received a different name offered by an informant who had earlier either accurately or inaccurately named familiar objects. Children were more willing to revise their own judgment and accept the unexpected label if it was from a previously accurate informant than if it was from someone who had made obvious naming errors. This suggests that preschool-aged children selectively revise their own knowledge; they are more trusting toward sources proven accurate than inaccurate.

Keywords: selective trust; accuracy; reliability; unexpected testimony; preschoolers

## Introduction

Children not only learn from their own perceptions and observations of the world around them but also learn from information provided by others. Research on young children has underlined the importance of others' testimony in knowledge acquisition in the early stages of development (see Gelman, 2009; Harris, 2007; Mills, 2013, for reviews). In particular, extensive studies have demonstrated that children show selective trust in testimony depending on an informant's previously established credibility (e.g., Koenig, Clément, \& Harris, 2004; Sabbagh \& Baldwin, 2001; for a review, see Koenig \& Sabbagh, 2013).

Children show sensitivity to the prior accuracy of informants and make persistent use of such information to learn new words and new object functions (Birch, Vauthier, \& Bloom, 2008), learn novel rules (Rakoczy, Warneken, \& Tomasello, 2009), and solve problems (Palmquist \& Jaswal, 2015). This effect of accuracy has been established in studies that present children with two unfamiliar informants who consistently provide accurate or inaccurate information in the context of familiar objects and examine whether these children subsequently prefer the accurate over the inaccurate informant when the two informants offer conflicting novel information (e.g., two different names for the same novel object). By applying such a two-informant paradigm, research has shown that children aged 4 years, and 3 years under certain conditions, selectively endorse new information from the accurate informant over the inaccurate one (e.g., Koenig et al., 2004; Nguyen, Gordon, Chevalier, \& Girgis, 2016).

Although the two-informant paradigm has proven informative, children's selective trust toward one of two informants leaves open questions of how children evaluate and learn from a single informant-a situation in which children are typically involved in everyday interactions (e.g., Lane \& Harris, 2015). Furthermore, the mechanisms underlying children's assessment of the testimony from a single source versus two contrasting sources may be different. For example, 3- and 4-year-olds would endorse new information from a previously inaccurate informant as long as there was no other informant who proposed an alternative (Vanderbilt, Heyman, \& Liu, 2014). This suggests that in general children prefer to endorse testimony from an accurate versus an inaccurate informant, but yet they are willing to trust the testimony of a single inaccurate informant if that is the only testimony available.

The studies presented above are related to children learning something that they do not have any prior knowledge of. However, acquiring new knowledge is plausibly a simpler process than accepting something that conflicts with one's own knowledge or violates one's expectations (hereafter as unexpected testimony). It remains unknown to what extent children's acceptance of unexpected testimony would be influenced by the informant's past accuracy. Specifically, in the absence of another person's testimony, would children still trust a previously inaccurate (or accurate) informant's testimony when it is contrary to one that they have previously formed on their own? A related line of research has shown that 3- to 4 -year-olds are indeed credulous and tend to give up their own beliefs to accept other's statements that are counterintuitive or overtly misleading, particularly when the speaker's communicative intent is salient (e.g., Heyman, Sritanyaratana, \& Vanderbilt, 2013; Lane \& Harris, 2015). Research examining preschoolers’ advice-taking (Rakoczy, Enrling, Harris, \& Schultze, 2015) also demonstrated that 3to 6 -year-olds were more likely to adjust their own social judgments when receiving advice from an expert rather than an ignorant advisor, suggesting that children do keep track of informants' credibility and use such cues in adjusting their own inferences. However, no studies have examined whether an informant's history of accuracy would affect children's willingness to revise their own testimony in face of testimony different from their own beliefs, and in the context where there was no other informant offering alternative testimony.

The current study seeks to use the single-informant paradigm to explore the extent to which 3- and 4-year-olds use informants' past accuracy as a cue to evaluate testimony that contradicts their own beliefs about object labels. The
task was modeled after Vanderbilt et al. (2014) and Jaswal, Lima, and Small (2009). Children were presented with pictures of ambiguous hybrid artifacts each involving features of two typical and familiar objects (e.g., car-shoe), and were asked to provide a name for each hybrid artifact. We examined how children would react to a previously accurate or inaccurate informant who provided an unexpected label, which was not misinformation, but one that always contradicted the children's own beliefs. This would test whether children are willing to give up their own (prior) beliefs to accept the informant's testimony. Based on previous findings that preschoolers show robust sensitivity to informants' past accuracy, we predicted that children would be trusting toward the previously accurate informant and accept this informant's unexpected labels, and that they would be skeptical about the previously inaccurate informant and, therefore, rather not change their initial judgments about the object labels. Additionally, it has been found that children with larger vocabulary (Jaswal, 2007) and those with disadvantaged executive function (Jaswal et al., 2014) were more credulous toward others' testimony than those with smaller vocabulary and advanced executive function skills, respectively. Hence, children's vocabulary and executive function ability were also assessed to control for potential confounds in this study.

## Method

## Participants

A total of 603 - and 4-year-olds ( $M_{\text {age }}=49.64$ months, $S D=$ 6.69 , range $=35-61$ months; 26 girls) participated in this study. Half of them were randomly assigned to the accurate condition and the other half to the inaccurate condition. Children were recruited from private childcare centers in a middle-class neighborhood in Singapore. Only children whose parents had given their consent were included in the study. The majority of participants ( $96 \%$ ) were Asian and the rest were Eurasian. All children spoke English and the experiment was conducted in English. One additional child did not want to provide answers in the test phase and, therefore, was excluded from the final sample. Another eight children participated but were excluded due to experimenter error $(n=2)$ or failure to name familiar objects (see Design and Procedure, $n=6$ ).

## Materials

Video clips of a single informant naming photographs of objects were prepared and shown to children on a 13 -inch laptop computer. The informant was a college-age female actor and with neutral facial expressions. In each video clip, the informant was seated behind a table with a picture placed on it. Pictures of three familiar objects (i.e., apple, ball, and book) were used in the familiarization trials to establish the informant's accuracy. Eight typical exemplars of familiar categories were selected and paired to form four stimulus sets to be used in the test trials (i.e., key-spoon, car-shoe, toothbrush-pen, and hat-cup). For each stimulus
set, features from the pair of typical exemplars were integrated to form a "hybrid" exemplar. These hybrid exemplars were designed such that each hybrid object looked mostly like one of the two typical exemplars of that set (i.e., dominant exemplar) but also shared some features of the other exemplar (i.e., non-dominant exemplar) such as a spoon-like key (see Figure 1).

A total of 14 video clips was made, corresponding to three familiarization clips with the informant naming each of the familiar objects correctly (accurate condition), three familiarization clips with the informant naming each of the familiar objects incorrectly (inaccurate condition), four testimony clips featuring the informant naming the hybrid objects with the labels for the dominant exemplars, and four testimony clips featuring the informant naming the same hybrid objects with the labels for the non-dominant exemplars (see Figure 2).

## Design and Procedure

This study employed a between-participants design. The procedure for both the accurate and inaccurate conditions was the same, except that the history of the informant was established differently during the familiarization phase.

Children were tested individually in a quiet room at their childcare centers. Children were randomly assigned to one of the two conditions. All children were seated in front of a laptop computer and a female experimenter (a different

Figure 1. Hybrid objects used in the experiment.

Figure 2. Screenshots from familiarization video clips in the familiarization phase (top) and testimony video clips in the test phase (bottom).
person from the informant in the video clips) was seated beside the child. The whole procedure was videotaped and children's responses were coded from the videos. Each child received three familiarization trials (Familiarization Phase), followed by four test trials (Test Phase), and two explicit judgment trials. The experiment was designed and written using PsychoPy (Peirce, 2007).

Familiarization Phase In the familiarization phase, the experimenter introduced the children to a single informant, a still image of whom was shown on the screen. In the accurate condition, children were then presented with three familiarization video clips, each showing the informant accurately naming a familiar object (i.e., labeling an apple, a ball, and a book correctly). In the inaccurate condition, children were familiarized with the same informant providing inaccurate information (i.e., saying that the above three objects were a dog, a tree, and a chair, respectively). After each familiarization video clip, children saw a picture of the same familiar object presented in the previous video (without the informant) and were asked by the experimenter, "Can you tell me what this is called?" This question was to make sure that each child knew the correct labels of the familiar objects, implying that the child was able to tell whether the informant had made errors or not. Children did not receive any feedback about whether they or the informant was correct. The order of the presentation of the three familiar objects was the same for all participants.

Test Phase The experimenter proceeded to the test phase where children had to respond to a testimony that conflicted with their initial judgments (i.e., an unexpected but possible label for a hybrid object). Each test trial began with a picture of a typical object (e.g., a key) appeared on the computer screen and the experimenter asked the children for the name of the object. The purpose of the question was to ensure that the children knew the names of the typical objects. Six children were excluded because they failed to name one or more typical objects (two in accurate and four in inaccurate condition). The experimenter then showed a picture of the other typical object from the same stimulus set (e.g., a spoon) on the screen, and children were again asked what that object was called. Children were then presented with a picture of the hybrid object that included features of the two previously shown typical objects (e.g., a keyspoon), and were asked if they knew what that object was called (pre-testimony test). Children's answers to this pretestimony test were recorded as their initial judgments about the name of the hybrid object. The experimenter then told the children, "Okay. Now, let's hear what the girl will say about this." and played a testimony video clip, where the informant and the picture of the same hybrid object appeared in the clip, and the informant always provided a label that was different from what the children had indicated earlier. Subsequently, children were shown the picture of the hybrid object on the computer screen for a second time (without the informant) and were asked by the experimenter
what the hybrid object was called (post-testimony test). During the test phase, children received neutral feedback following a response, regardless of what their answers were (e.g., "Thank you!"). All children completed four test trials. The order of the two typical exemplars of each stimulus set was fixed, such that, for two sets of stimuli (key-spoon and hat-cup), the dominant exemplars were shown first, and for the other two sets (car-shoe and toothbrush-pen), the nondominant exemplars were shown first. The order of the four test sets was randomized for each participant.

Explicit Judgment Trials After children completed all four test trials, the experimenter asked two questions assessing children's evaluation about the informant. With the picture of the informant presented on the screen, children were asked, "Was this girl good or not good at telling the names of the pictures?" Finally, the experimenter showed a picture of a novel object and asked children whether they would seek the informant's help for the name of the object, "If you wanted to know what this new thing was called, would this girl be a good person to ask?" This question was included to replicate Vanderbilt et al.'s (2014) results on children's overwhelming judgment of the accurate/inaccurate speaker as being a good person to ask for the label of a novel object.

In addition to performing the above experiment investigating selective trust in unexpected testimony, all children completed the Peabody Picture Vocabulary Test (PPVT-4; Dunn \& Dunn, 2007), which measures receptive English vocabulary, and the Dimensional Change Card Sort task (DCCS-standard version; Zelazo, 2006), which assesses executive function. Both PPVT and DCCS tasks were administered and scored following standard procedures. For the PPVT, each child obtained a standardized score with a mean of 100 . For the DCCS, children were classified as passing or failing the task based on performance on the post-switch phase of the DCCS.

## Results

The number of times (out of 4 trials) when children adopted the different labels provided by the informant rather than persisting with their initial answers about the names of the hybrid objects on post-testimony test was calculated for each participant as the dependent variable. Thus, the scores indicate how children are willing to trust the informant and accept the informant's testimony that is contrary to their own. Preliminary analyses confirmed no effects or interactions involving children's age, gender, stimulus set, or test order; therefore, further analyses collapsed across these factors. We report $95 \%$ confidence intervals and effect sizes for our statistical tests. In the case of comparisons of group means these confidence intervals refer to the observed mean difference.

We first evaluated whether children in the two conditions had comparable language and executive function abilities. Vocabulary scores on PPVT-4 were not significantly different between the conditions (accurate: $M=95.07$; inaccurate: $M=96.17$ ), $t(58)=-0.35, p=.73$, Cohen's $d=-$
$0.092,95 \%$ CI of the difference $[-7.45,5.25]$. Regarding performance on the DCCS task, children in the two conditions were comparable in terms of the proportion of children who passed the task (accurate: $20 / 30$ passing, $67 \%$; inaccurate: $20 / 30,67 \%), \chi^{2}(1, N=60)=0.00, p=1.00$, Cramer's $V=.00$. Correlational analyses revealed that neither the PPVT scores nor the DCCS scores were related to children's likelihood of endorsing the informant's testimony across the two conditions, $r \mathrm{~s}<.042, p \mathrm{~s}>.74$.

In addition, all children, regardless of the experimental condition, correctly named the familiar objects and the typical exemplars during the familiarization and test phase respectively. Analyses of children's responses in the pretestimony test trials, where children were to name the hybrid objects for the first time, indicated that children provided labels matching the dominant exemplars on $92 \%$ of the trials and labels matching the non-dominant exemplars $8 \%$ of the trials. There were equivalent number of pre-testimony trials where children chose the non-dominant label in accurate and inaccurate conditions (7 vs. 13 trials, respectively). Nevertheless, the informant always provided the label that was different from the children's label for the hybrid object in the testimony video clips (thus unexpected).

Crucially, we were interested in whether 3- and 4-yearolds would respond less credulously to the unexpected testimony from an informant who demonstrated inaccuracy at naming familiar objects compared to an informant with a history of accuracy, that is, whether children would discard their own labels and accept the unexpected labels from the informant in the post-testimony test.

As seen in Figure 3A, children were more willing to revise their answers and accept the unexpected testimony in the accurate condition ( $M=3.60,95 \% \mathrm{CI}[3.15,4.06]$ ) than in the inaccurate condition $(M=1.33,95 \% \mathrm{CI}[0.88,1.79])$, $U=123.50, z=-5.12, p<.001, r=-.66$. Examining patterns of individual behavior revealed similar differences between accurate and inaccurate conditions. We calculated the number of children in each condition who endorsed the unexpected testimony on $0,1,2,3$, or 4 out of four trials. Chi-square tests showed that the distribution of children across various patterns of responses was different between the accurate and inaccurate conditions, $\chi^{2}(4, N=60)=$ 30.64, $p<.001$, Cramer's $V=.72$. There were more children who accepted the informant's testimony on 3 or 4 trials in the accurate condition $(n=28)$ than the inaccurate condition $(n=7)$. None of the significance levels were affected by removing data from test trials where the child chose the non-dominant label in the pre-testimony test before the informant providing different testimony.

Lastly, children's responses to the two explicit judgment questions were analyzed ${ }^{1}$. In line with the patterns of information endorsement, significantly more children in the accurate condition agreed that the informant was good at

[^386]naming the pictures compared with those in the inaccurate condition $(90.0 \%$ vs. $51.9 \%), \chi^{2}(1, N=57)=10.24, p=$ .003 , Cramer's $V=.42$ (see Figure 3B). However, there was no significant effect of condition on the question assessing children's willingness to seek help from the informant for the label of a novel object, $\chi^{2}(1, N=59)=2.59, p=.18$, Cramer's $V=.21$ (see Figure 3C). Children overwhelmingly judged that the informant, regardless of whether she showed a history of accuracy or inaccuracy, would be a good person to ask about the label of a novel object- $89.7 \%$ of children did so in the accurate condition, and it was the case for $73.3 \%$ of children in the inaccurate condition. These rates were in a similar range as those reported by Vanderbilt et al. (2014) where children were asked to judge whether an accurate or inaccurate source, either alone or paired with each other, would be a good person to ask for labels of novel objects ( $76 \%-90 \%$ ).

## Discussion

The current study examined the extent to which an informant's history of accuracy influenced children's endorsement of claims that conflicted with their independent beliefs about ambiguous hybrid artifacts. Using a single-informant paradigm, we found that 3- and 4-yearolds' trust toward unexpected testimony differed depending on the informant's past accuracy. Specifically, while children consistently revised their own initial judgments and endorsed unexpected testimony from an informant who appeared to be accurate and knowledgeable about common objects, they were less likely to do so in response to someone who made naming errors with these common objects. This study provided novel findings that children consider an informant's previous epistemic history when determining whether or not to revise their own prior beliefs in light of unexpected testimony.

The present results challenge the notion that in the absence of conflicting testimony from another informant, young children generally trust a single informant who has a record of inaccuracy. This notion of trust toward a single inaccurate informant may be true only if children themselves do not hold any conflicting information at all. Vanderbilt et al. (2014) found that 3- and 4-year-olds were willing to trust the testimony of an inaccurate informant when there was no other informant offering an alternative. In contrast, children in the current study were less willing to accept the testimony provided by a single inaccurate informant in the absence of competing testimony from another informant. An important difference between this study and Vanderbilt et al.'s (2014) work, however, is that children in this study held a different interpretation of an object than the informant, whereas children in the previous study did not. Thus, the present results suggest that children's own prior knowledge play an important role in selective trust, and that children would evaluate all available sources of information, including themselves, when determining whom to trust. In situations where children are mostly ignorant, such as labeling unfamiliar

Figure 3. Evaluation of the informant by condition: (A) number of trials (out of 4) children adopting unexpected testimony from the informant, (B) percentage of children agreeing the informant being good at naming pictures, and (C) percentage of children being willing to seek novel information from the informant. Error bars represent $95 \%$ confidence intervals.
objects, children are likely to perceive an informant who confidently provides testimony as more knowledgeable than them, even if the informant has made errors previously. Whereas in situations where children possess some prior knowledge, albeit loosely formed ones, such as labeling ambiguous hybrid objects in this study, children would evaluate the relative trustworthiness of the source of information against themselves.

How do children determine the trustworthiness of an informant in relation to themselves? Past accuracy is one important factor. In the current study, children were more willing to discard their own beliefs in favor of an adult informant's testimony when this adult had been proven accurate compared to an inaccurate informant. However, it remains an open question that whether the current results were due to a negative bias toward the inaccurate source of information, or due to both a preference for the accurate source and an avoidence of the inaccurate one. Future studies could further investigate this question by examining children's responses in a control condition where no history of accuracy/inaccuracy would be provided. Age is another factor. Children in the accurate condition might perceive the accurate adult as a more credible source of information about what artifacts are called than them. In fact, 3- and 4-year-olds were more willing to learn novel labels from an adult than from a child when both were equally reliable (Jaswal \& Neely, 2006). However, children appeared to weigh accuracy over age in selective trust; they were found to trust a previously accurate child more than a previously inaccurate adult when learning new words. This is also true in the inaccurate condition reported here, such that children's distrust toward inaccuracy was so robust that they assumed that an inaccurate adult was less reliable than them (a child). These results suggest that children consider multiple factors when evaluating the trustworthiness of another source of information compared with them, but weigh certain factors more than others (i.e., accuracy over age).

Even though the present results showed that children demonstrated a reduced tendency to accept the testimony against their own judgments in the inaccurate condition, it remains debatable whether it was because the children believed that the inaccurate informant was not trustworthy, or that they simply had alternative information available (i.e., their own), or both. Our results showed that children gave up their own beliefs and accepted the testimony from an accurate informant on an average of $90 \%$ of trials (nearceiling), yet they were still willing to give up their own beliefs and accept the inaccurate informant's testimony on an average of $33 \%$ of trials (a $0 \%$ would indicate absolute rejection). This implies that children may be more ready to accept an adult informant's testimony than to reject it, even when the adult informant had been inaccurate previously, and even when the testimony conflicted with their own, at least possibly until they are provided with stronger evidence of the negative credibility of the adult informant (Ronfard \& Lane, in press).

Children's degree of selective trust may thus be affected by various factors that reflect the extent of an informant's credibility. For instance, children were found to be more forgiving with errors in the episodic domain (e.g., locations of objects) than in the semantic domain (e.g., names of objects); they used semantic errors but not episodic errors when evaluating informants' trustworthiness in labeling objects (Palmquist \& Jaswal, 2015). It is unknown whether children would remain skeptical toward unexpected testimony from an inaccurate informant who made episodic errors. Furthermore, hybrid artifacts were used in this study and the unexpected labels provided by the informant were always possibly "correct" and not entirely wrong, as the labels did contain some features of the hybrid, although they were contrary to children's inferences. It is unknown whether children would still be willing to accept the accurate informant's unexpected labels if the labels were not possibly correct (e.g., calling a spoon-like key a cat). Further research is needed to investigate how children's
selective trust may change depending on the types of errors made by the informants and when the unexpected labels are not actually possible.

Last but not least, children's openness to alternative information may be dependent on the strength of their initial beliefs. Indeed, Chan and Tardif (2013) found that 6-yearolds were more accepting an alternative when they felt less certain about their own prior knowledge. In the current study, children who chose the non-dominant label in the pre-testimony trials might be less certain about their answer and more prone to revise. Therefore it was important to control for children's initial choice (there were only limited number of trials with the non-dominant label thus they were excluded).

To conclude, the current study showed that when confronted with different testimony from others, young preschoolers selectively revised their own inferences depending on the informant's past accuracy. Young children are savvy in that they can use such credibility cues to evaluate another individual who holds different opinions from them and decide whether to adjust their own beliefs or not accordingly. The ability to appropriately evaluate the reliability of various sources of information and update their own knowledge correspondingly is important, since reliable sources allow children to learn efficiently while unreliable sources increase the risk of being misinformed. Our findings suggest that this ability is emerging in 3- and 4 -year-old children.

## Acknowledgments

We are grateful to the children and parents who participated and to the teachers and staff of the Creative O Preschoolers' Bay, Red SchoolHouse, MacPherson Sheng Hong Childcare Centre, and Safari House Preschool. We thank Eilise Francesca for serving as the actor in our videos. This research was supported by Singapore University of Technology and Design President's Graduate Fellowship awarded to the first author.

# How does Music Reading Expertise Modulate Visual Processing of English Words? An ERP study 

Tze Kwan, Li (saralis@hku.hk)<br>Hei Yan Veronica, Chan (veron919@connect.hku.hk)<br>Luhe Li (rhys@connect.hku.hk)<br>Janet H. Hsiao (jhsiao@,hku.hk)<br>Department of Psychology, University of Hong Kong<br>627 Jockey Club Tower, Pokfulam Road, Hong Kong SAR

#### Abstract

Music notation and English word reading have similar visual processing requirements. It remains unclear how the two skills influence each other. Here we investigated the modulation of music reading expertise on visual processing of English words through an ERP study. Participants matched English real, pseudo, and non-words preceded by musical segments or novel symbol strings in a sequential matching task. Musicians showed smaller N170 amplitude in response to English non-words preceded by musical segments than by novel symbol strings in the right hemisphere. This effect was not observed in real or pseudo-words, or in any of nonmusicians' responses. Similar to English non-words, musical segments do not have morphological rules or semantic information, giving rise to this modulation effect. This finding suggested a shared visual processing mechanism in the right hemisphere between music notation and English non-word reading, which may be related to serial symbol processing as suggested by previous studies.

Keywords: Music reading expertise; EEG; event-related potential (ERP); English word reading

## Introduction

Recent research has shown that different perceptual expertise domains can influence each other. For example, car perception was interfered by concurrent face perception in car experts (presumably also face experts) but not in car novices, suggesting shared neural processing mechanisms between car and face recognition expertise (Gauthier, Curran, Curby \& Collins, 2003). In an ERP study, Rossion, Kung, and Tarr (2004) showed that expertise with Greebles led to a decrease in N170 in response to faces with concurrent Greeble presentation, suggesting competition between expertise domains in early perceptual processing.

Similarly, music notation and English word reading expertise may influence each other due to their similarities in visual processing. For example, both music notation and English word reading involve decomposing visual input into components (i.e., letters or notes) for mapping to components in sounds (i.e., phonemes or pitches; Brown, Martinez \& Parsons, 2006; Hsiao \& Lam, 2013). The requirement of grapheme-phoneme conversion in English word reading has been suggested to lead to a strong left hemisphere (LH) lateralization. For example, a right visual field (RVF)/LH advantage has been found in word naming (e.g. Brysbaert \& d'Ydewalle, 1990). Consistent with these findings, fMRI studies have shown a region inside the left fusiform area
responding selectively to words (e.g. McCandliss, Cohen, \& Dehaene, 2003). ERP studies showed that English words elicited larger N170 amplitude in the LH than the RH in a repetition detection task (Maurer, Brandeis \& McCandliss, 2005). This LH lateralization may be attributed to the leftlateralized phonological processing (Rumsey et al., 1997).

Similarly, in music notation processing, Segalowitz, Bebout, and Lederman (1979) reported a RVF/LH advantage in chord playing, which may be related to the requirement of mapping individual notes to different pitches/fingerings. Indeed, music notation and English word reading are shown to have shared neural mechanisms in the LH. For example, musicians with brain lesions in the LH showed difficulties in both music and English word reading (Hébert \& Cuddy, 2006). Also, both English and music notations are read from left to right, and thus letters and music notes are recognized in the RVF more often than the left visual field (LVF) during reading, resulting in a similar RVF processing advantage due to perceptual learning (Wong \& Hsiao, 2012).

While the LH is shown to play an important role in English word and music notation reading, the RH is also involved, particularly in visual form processing of words and notes. For example, in a lexical decision priming task, English word processing in the LVF/RH was shown to benefit from orthographically similar primes, whereas that in the RVF/LH benefitted from phonologically similar primes. This result suggested that the RH and the LH had differential advantages in orthographic and phonological processing of English words (Lavidor \& Ellis, 2003). Consistent with this finding, English word processing in the RH has been reported to be more sensitive to variations in visual word forms. For example, the word length effect in English lexical decisions (i.e., faster and more accurate responses to shorter words) was only observed when words were presented in the LVF/RH but not the RVF/LH, suggesting that RH word processing involves more letter-by-letter recognition/serial processing than that in the LH (Lavidor \& Ellis, 2001). Similarly, in music note processing, a right lateralized or bilateral visual processing mechanism has been observed. For example, fMRI studies have shown that the right occipitotemporal region was associated with music sightreading (Schön, Anton, Roth \& Besson, 2002). Bilateral activations in the fusiform and inferior occipital gyri in musicians were also reported in a note selection task. (Proverbio, Manfredi, Zani \& Adorni, 2013). In a divided
visual field study, no lateralization effect was observed in sequential matching of notes and chords (Li \& Hsiao, 2015).

Although previous research has suggested similarities between English word and music notation reading processes, it remains unclear how they influence each other. We have previously found that, whereas non-musicians showed a typical RVF/LH advantage in naming English words, musicians showed an LVF/RH advantage and responded significantly faster than non-musicians when words were presented in either the LVF or the center position (Li \& Hsiao, 2015). This effect suggested a facilitation of RH English word processing due to music reading experiences. This phenomenon may be due to shared neural mechanisms between the two expertise domains in the LH that lead to resource competition, consequently making musicians rely more on RH processing for English word recognition. It may also be the similarities between music notation and English word reading processes in the RH accommodate each other, making the relevant processes more efficient and consequently facilitating RH English word processing.

While English word and music notation reading share similar visual processing requirements, they differ significantly in their involvement in lexical processing. More specifically, English words follow morphological and orthographic rules with clearly defined segment boundaries and lexical representations, whereas musical segments do not follow as strict sequencing rules as words and are not associated with specific semantic representations (Chan \& Hsiao, 2016). Since previous research has suggested that LH English word processing is more relevant to phonological processing of English words whereas RH English word processing is more sensitive to variations in visual word forms, the modulation of music reading experience on visual processing of English words is likely to be mainly due to a shared processing mechanism in the RH. In addition, this modulation may be stronger in English non-word processing than the processing of real or pseudo-words, since nonwords do not follow morphological rules or have meanings, similar to musical segments. To test these hypotheses, here we conduct an EEG study to examine how music reading expertise influences visual processing of English stimuli. A sequential matching task is used to focus on visual processing of English words. Following Rossion et al. (2004), here we examine how N170 responses to English words are influenced by the processing of music notes in musicians and non-musicians. We expect that musicians will have a stronger reduction in N170 response to English stimuli under the processing of music notes than non-musicians in the RH, particularly for English non-words.

## Methods

## Participants

Participants were 60 Cantonese (L1)-English (L2) bilinguals from Hong Kong, whose ages ranged from 18 to 29 ( $M=$ $21, S D=2.8$ ). They had similar language and college education backgrounds, with normal or corrected to normal vi-
sion. They were categorized as 30 musicians ( 14 males, 16 females) and 30 non-musicians ( 12 males, 18 females).

Musicians were well-trained pianists, who started music training at age 3-8 $(M=5.33, S D=1.47)$. All of them were either piano teachers, music major students, or frequent piano players. They had attained grade 8 or above in the graded piano examinations of the Associated Board of The Royal Schools of Music (ABRSM), with 8-25 year experience in piano playing ( $M=15.03, S D=3.89$ ) and regular music reading hours per week ( $M=7.16, S D=12.33$ ). Musicians outperformed non-musicians in musicality, as assessed by the Goldsmiths Musical Sophistication Index (Müllensiefen, Gingras, Musil, \& Stewart, 2014; $t(58)=9.97, p<.001)$. In contrast, non-musicians did not receive any music training.

Aside from their music background, musicians and nonmusicians were closely matched in handedness and language exposure. Most participants were right-handed, which was assessed using the Edinburgh Handedness Inventory (Oldfield, 1971; M: 54.33, $3^{\text {th }}$ right decile; NM: 64.33, $3^{\text {rd }}$ right decile, n.s.). All participants started learning English as a second language at age 3 , and have similar self-reported English reading hours (M: 27.48; NM: 18.77; n.s.). No participants had experience with the Tibetan language.

## Materials

Materials consisted of 3 types of English words (real, pseudo, and non-words with 4-6 letters) as target stimuli and two types of comparable pre-/post-stimulus masks: musical segments with 4 random notes without clefs ( $n=1323$ ) ranging from D4 to G5 and Tibetan letter strings with 4 random letters ( $n=1323$ ). Tibetan letter strings, a novel stimulus type that no participants had any experience with, were included as a control condition.

English real words ( $n=126$ ) were selected from the SUBTLEX-US corpus (Brysbaert, New \& Keuleers, 2012) and Wuggy (a word generator, Keuleers \& Brysbaert, 2010). To control information distribution within a word, the same number of high-frequency words and low-frequency words were selected within the informative beginning and informative end subsets in Bryden, Mondor, Loken, Ingleton \& Bergstrom (1990). Word frequency was closely matched between 'same' and 'different' trials in the matching task and between music and Tibetan conditions. For 'same' trials, two target stimuli were identical. For 'different' trials, half trials had shared beginnings (e.g. banker, banner), while the other half had shared ends (e.g. salary, notary).

English pseudo-words (i.e. non-existing words with legal letter strings at the word beginning and word end, $n=126$ ) were created by extracting and recombining word beginnings and ends from our English real word list. This is to control information distribution at the word beginnings and ends between real and pseudo-word stimuli. For 'same' trials, two target stimuli were identical. For 'different' trials, half trials had shared beginnings (e.g. banher, banord), while the other half had shared ends (e.g. saliew, supiew).

English non-words (i.e., illegal letter strings, $n=126$ ) were created by re-ordering the letters in the word begin-
nings and word ends from our English pseudo-word list such that the letter combinations do not follow morphological rules in English. This is to closely match the letters used in all conditions. For 'same' trials, two target stimuli were identical. For 'different' trials, half trials had shared beginnings (e.g. nbaerh, nbaodr), while the other half had shared ends (e.g. alsiwe, spuiwe). The non-words were checked against the morphologically ambiguous syllables in the ARC Nonword database (Rastle, Harrington, \& Coltheart, 2002) to ensure their suitability for our task.

## Design

To focus on visual processing of English words, a sequential matching task similar to Gauthier et al. (2003) was used. The design consisted of 2 within-subject variables: English word type (real/pseudo/non-words), stimulus mask (musical segments vs. Tibetan letter strings), and 1 between-subject variable: group (musicians vs. non-musicians). In the ERP data analysis, an additional variable hemisphere (LH vs. RH) was included. Participants completed the task with English real, pseudo, and non-word stimuli with either musical segment or Tibetan letter string masks (Fig. 1). For each mask type, 36 'same' and 36 'different' trials were included for each word type condition. Half of the stimulus pairs in 'same' and 'different' trials were different in the two mask conditions to avoid practice effects.

English words were displayed in Courier (a serif font with fixed width) to ensure constant center-to-center spacing between letters. Under the viewing distance 50 cm , each English word subtended a horizontal and vertical visual angle of $4.06^{\circ} \times 0.95^{\circ}$ (4 letters), $5^{\circ} \times 0.95^{\circ}$ ( 5 letters) and $6.35^{\circ} \times 0.95^{\circ}$ ( 6 letters). Musical segments with 4 random notes in crotches ( 1 beat) with the five-line staff subtended a horizontal and vertical visual angle of $6.90^{\circ} \times 1.62^{\circ}$. Tibetan letter strings with 4 random letters were presented in Himalaya font and subtended a horizontal and vertical visual angle of $6.90^{\circ} \times 1.62^{\circ}$. All stimuli were presented in black with a white background on a CRT monitor. Experiments were conducted using E-Prime v2.0 with 64-channel ANT EEG recording. A chinrest was used to reduce head movement. The block and trial orders were randomized.

## Procedure

Each trial started with a central fixation with a randomly determined presentation duration between $400-600 \mathrm{~ms}$. A pre-stimulus mask (a musical segment or a Tibetan letter string) was presented for 600 ms , followed by an 800 ms presentation of the first target stimulus (a real/pseudo/non word). Then, a post-stimulus mask (a musical segment or a Tibetan letter string) was presented for 600 ms , followed by an 800 ms presentation of the second target stimulus (a same or different real/pseudo/non-word; Fig. 1). All stimuli were presented at the center of the screen. Participants judged whether the two target stimuli were the same or not by pressing buttons with both hands. The trial did not proceed to the 800 ms 'blink' period until receiving partici-
pants' response. Accuracy (ACC) and response time (RT) were recorded by Eprime with EEG recording.

Prior to the English word sequential matching task, a demographic and music background questionnaire, the Goldsmiths Musical Sophistication Index (Müllensiefen et al., 2014) and Edinburgh Handedness Inventory (Oldfield, 1971) were conducted to assess participants' language, music background, and handedness.

Fig. 1. Procedure of the English word sequential matching

## Results

In the English word sequential matching task, no significant difference was observed between musicians and nonmusicians in ACC and RT of matching real (M: 97.27\%, 606.02 ms ; NM: $94.31 \%, 774.41 \mathrm{~ms}$ ), pseudo (M: 97.04\%, 619.90 ms ; NM: $93.29 \%, 698.58 \mathrm{~ms}$ ) and non-words (M: $95.88 \%$, 598.58 ms ; NM: $91.20 \%$, 727.38 ms ), suggesting that they had a similar performance level in the task.

The 64-channel EEG data were analyzed using EEGLAB (Delorme \& Makeig, 2004) and ERPLAB (LopezCalderon \& Luck, 2014) in MATLAB. Bin-based epochs were extracted from -100 ms to 600 ms of the stimulus onset and corrected from baseline deviations using a prestimulus window of 99 ms . The analyses of the N170 component were based on the electrode pairs with the largest N170 amplitude from the grand average data. Accordingly, electrodes PO7 (LH) and PO8 (RH) were selected for the analysis of N170 response to the pre-stimulus masks (musical segments vs. Tibetan letter strings), while electrodes P7 (LH) and P8 (RH) were selected for N170 responses to the first presentation of the English real, pseudo, and non-words preceded by musical segments or Tibetan letter strings, using repeated measures ANOVA. Note that we only analyzed the N170 responses to the first presentation of the English word stimuli since the EEG responses to the second stimulus may be contaminated by button responses..

Figure 2. Average N170 amplitude at PO7 and PO8 in response to musical segments and Tibetan letter strings (error bars $=+/-1 S E ; * * * p<.001, * p<.05)$.

In the ERP response to the pre-stimulus mask, a significant interaction between mask type (music vs. Tibetan) $\times$ group (musicians vs. non-musicians) was observed, $F(1,52)$ $=31.80, p<0.001$ : musicians had a larger N170 amplitude than non-musicians in response to musical segments, $t(52)=$ $-2.07, p=.044$ (Fig. 2), whereas no difference was observed between the two groups in response to Tibetan letter strings. When we split the data by group, musicians had a larger N170 amplitude in response to musical segments than to Tibetan letter strings, $F(1,27)=68.98, p<0.001$ (Fig. 2), whereas non-musicians did not show any significant differences in response to musical segments and Tibetan letter strings. These findings were consistent with the perceptual expertise literature showing that visual expertise increases the N170 amplitude in response to the stimuli in experts as an expertise marker (Rossion et al., 2004). No main effects or interactions with hemisphere were observed (Fig. 3).

Figure 3. N170 amplitude in response to musical segments and Tibetan letter strings between musicians and nonmusicians in $\mathrm{PO} 7(\mathrm{LH})$ and $\mathrm{PO} 8(\mathrm{RH})$.

[^387]Figure 4. N170 amplitude in response to English (a) real, (b) pseudo and (c) non-words preceded by musical segments and Tibetan letter strings between musicians and nonmusicians in P7 (LH) and P8 (RH) in sequential matching.

For N170 responses to English words (the first target stimulus), a significant four-way interaction, mask type (music vs. Tibetan) $x$ word type (real vs. pseudo vs. nonwords) x hemisphere (LH vs. RH) x group (musicians vs. non-musicians), was observed, $F(2,53)=3.32, p=.044$. To better understand this interaction, we examined the N170 amplitude in response to real, pseudo, and non-words separately (Fig. 4). A significant interaction among mask type, hemisphere, and group was found in English non-words, $F$ $(1,54)=6.27, p=.015$, but not in real or pseudo-words. This three-way interaction suggested that musicians and non-musicians had different N170 amplitudes in response to non-words preceded by musical segments and Tibetan letter strings in the LH and the RH. This effect was not found in real or pseudo-words.

When we examined the data of non-words in two participant groups separately, musicians showed a significant interaction between mask type (music vs. Tibetan) and hemisphere (LH vs. RH), $F(1,26)=10.60, p=.003$, whereas non-musicians did not. When we examined musicians' data in the two hemispheres separately, a significant main effect of mask type (music vs. Tibetan) was observed, $F(1,26)=$ 9.004, $p=.006$ : musicians had a smaller N170 amplitude in response to English non-words preceded by musical segments $(-2.17 \mu \mathrm{~V}, S D=3.88$, Fig. 5) than those preceded by Tibetan letter strings in the RH $(-4.11 \mu \mathrm{~V}, S D=2.11)$. This mask type effect was not observed in the LH. Note that this mask type effect was also not observed in either participants' N170 responses to real and pseudo-words, or nonmusicians' N170 responses to non-words. This phenomenon demonstrates a modulation of musicians' musical segment processing on English non-word processing in the RH.

Figure 5. Musicians had a greater reduction in N170 amplitude in response to non-words preceded by musical segments than that preceded by Tibetan letter strings in the RH. No reduction effect was observed in the LH or in nonmusicians. (error bars $=+/-1 S E ; * * p<.01$ ).

## Discussion

Here we examined how music reading expertise influences visual processing of English stimuli. Since music notation reading does not involve semantic processing as English word reading does, we hypothesized that the modulation of music reading experience on English word processing would be mainly in the RH, which is shown to be important for visual form processing of English words. In addition, the modulation would likely be stronger in English non-word processing than the processing of real or pseudo-words, since similar to musical segments, non-words do not follow morphological/orthographic rules. Consistent with our hy-
potheses, we showed that musicians had a reduced N170 amplitude in response to English non-words preceded by musical segments as compared with that preceded by novel symbol strings in the RH, whereas non-musicians showed no difference in N170 response to non-words preceded by either musical segments or Tibetan letter strings. In addition, this reduction in N170 in musicians was only observed in non-words, but not in real or pseudo-words. This result suggests a shared neural mechanism between English nonword and musical segment processing in the RH.

The RH N170 modulation effect of musical segments in musicians was only observed in English non-words but not in real or pseudo-words. This effect suggests that the interaction between visual English word and music notation processing depends on the similarities of the cognitive processes involved. More specifically, in contrast to English real and pseudo-words, non-words and musical segments do not follow any morphological or orthographic rules (Chan \& Hsiao, 2016). Given that they share similar global forms, containing components of similar sizes arranged horizontally, their recognition may both rely on component by component serial processing, giving rise to the modulation effect. Consistent with this speculation, a RH advantage in the perception of global forms has been consistently reported (Sergent, 1982). English word processing in the RH is also shown to be more sensitive to variations in visual word forms than the LH, such as words in case alternation (Lavidor \& Ellis, 2001). In particular, Lavidor and Ellis (2001) found that the word length effect in English lexical decisions (i.e., faster responses to shorter words) was observed only when words were presented in the LVF/RH but not in the RVF/LH. However, when words in MiXeD CaSe were used, encouraging letter-by-letter processing, the word length effect was observed in both visual fields. These results suggest a letter-by-letter, serial processing engaged in the RH word recognition, in contrast to a left-lateralized automated, whole-word lexical processing unaffected by word lengths (see also Lavidor, Ellis, \& Pansky, 2002). Similarly, patients with LH lesions retained letter-by-letter reading ability, suggesting that the nature of RH word processing involves letter-by-letter recognition (Cohen et al., 2004). Our results here were consistent with these findings, suggesting that RH English word processing was modulated by music notation reading experience due to their similarity in letter-by-letter or note-by-note visual processing. Consistent with our finding, in an fMRI study, Proverbio et al., (2013) reported that musicians recruited the right fusiform gyrus and the right inferior occipital gyrus in an orthographic letter recognition task, whereas non-musicians showed activations at the corresponding regions in the LH. This finding again suggests that music reading expertise modulates English word reading in the RH.

This RH modulation effect of music reading expertise was also consistent with our recent study showing that musicians named English words faster than non-musicians when words were presented in the LVF/RH (Li \& Hsiao, 2015). More specifically, this LVF/RH advantage in word naming
in musicians may be due to the facilitation of shared neural information processing mechanisms in the RH between music notation and English word reading, resulting in a transfer effect from music note to English word processing in the RH. Note that in the current study, the lack of the N170 modulation effect in real and pseudo-words does not necessarily mean that this modulation from music notation reading experience does not affect real word and pseudo-word processing. English word recognition involves the processing of visual word forms, phonology, and semantics. While the LH is shown to involve critically in lexical processing, the RH is reported to be important for the processing of visual word forms. Our current results suggest that the modulation of music experience is mainly in the RH. Since the processing of real and pseudo-words involves both visual word form and lexical/sublexical processing, these lexical effects may also influence N170 amplitudes measured in both hemispheres. Indeed, Ziegler et al. (1997) showed that real and pseudo-words elicited more negative early visual ERPs than non-words in bilateral posterior regions in a lexical decision task, with this difference appearing earlier in the LH than the RH. Thus, the RH N170 modulation effect of music reading expertise may have been contaminated by lexical/sublexical effects in real and pseu-do-word processing. It is also possible that the lack of the modulation effect in real and pseudo-word processing is because random musical segments were used. Future work will examine whether musical segments from real musical pieces (motifs) will have different modulation effects.

Note also that the current results do not rule out possible modulation effects of music reading experience on phonological processing of English words, since our task, sequential matching, involved mainly visual word processing. Previous studies have reported benefits of music training on the phonological processing of English words, as shown in phonological skill training (Degé \& Schwarzer, 2011). Thus, musicians' LVF/RH advantage in English word naming over non-musicians observed in our previous study (Li \& Hsiao, 2015) could also be related to modulation effects of music reading experience on English phonological processing in the LH. Future work will examine this possibility.

In short, here we show that music notation and English non-word processing share similar neural mechanisms in the RH, as demonstrated in the reduced N170 responses to English words under the processing of musical segments. This effect was not observed in real or pseudo-words. Similar to English non-words, musical segments do not follow orthographic rules. Their processing may rely on serial processing of horizontally arranged components of similar sizes, giving rise to the modulation effect. This effect demonstrates that the interaction between different perceptual expertise domains depends on the similarities of the cognitive processes involved. Future work may use Korean Hangul stimuli, in which letters are arranged into a square shape instead of horizontally, to examine whether the modulation effect of music reading expertise in the RH was restricted to words with a global form similar to music notations (i.e.,
components of a similar size arranged horizontally) or could be applied to words in alphabetic languages in general.

# Metaphor Congruent Image Schemas Shape Evaluative Judgment: A Cross-Linguistic Study of Metaphors for Economic Change 

Patricia Lichtenstein (plichtenstein@ucmerced.edu)<br>Cognitive \& Information Sciences, University of California, Merced<br>5200 N. Lake Road; Merced, CA 95343 USA<br>Ekaterina Shutova (es407@cam.ac.uk)<br>Computer Laboratory, University of Cambridge<br>15 JJ Thomson Avenue; Cambridge CB3 0FD UK

#### Abstract

Metaphor pervades discussions of important socio-political topics. Recent research indicates that metaphorical language can influence how people reason about such topics, potentially affecting real-world decision-making. In this study, we report on research into the effects of metaphor on evaluative judgment, another aspect of decision-making that has been less well studied than reasoning. We use a cross-linguistic difference in the metaphors used by English and Spanish speakers to discuss economic change to investigate how metaphorical language affects evaluative judgment. We show that the image schematic information inherent in the semantics of the different metaphors performs a central role in shaping this process.

Keywords: metaphor; evaluative judgment; cross-linguistic variation; image schemas; socio-political discourse

## Introduction

I say, block those metaphors. America's economy isn't a stalled car, nor is it an invalid who will soon return to health if he gets a bit more rest. Our problems are longer-term than either metaphor implies. And bad metaphors make for bad policy. - Paul Krugman

We often use metaphorical language to express a stance toward an object or event. The metaphors invoked by Mr. Krugman operate by applying a basic image schema from the domain of spatial motion to the complex socio-political domain of the economy. The image schema is that of BLOCKAGE. Image schemas are dynamic representations of spatial relationships, force relationships, and motion in space (Langacker, 2001; Talmy, 1990). They develop through experience as encoded in our daily sensory-motor activities, and are thought to be the basis of the human conceptual system (Lakoff \& Johnson, 1999). The Blockage image schema entails an entity whose tendency towards motion is being impeded. It can be used in metaphorical expressions to signal evaluative judgment.

Evaluative judgment is the process of assessing a stimulus through the filter of an internal network of beliefs, values, and aesthetics. This process interacts with sensory-motor nervous system circuitry to influence how we interpret other people's behavior and whether we participate in select activities or events (Norman et al., 2011). It contributes to basic human impulses, such as avoidance and approach. It further serves to guide complex behavior. For example, evaluative judgment informs activities such as participating in a social movement,
contributing to a charity, and voting for a presidential candidate where the choice of candidate can be based more heavily on evaluative processes than on reasoning.

Evaluative processes pervade human language on many levels. People use linguistic information as an input into evaluative judgments at the social and interpersonal level: we assess our partners in communication positively or negatively based on accent, intonation, prosody, word choice, and grammatical complexity (Berger \& Calabrese, 1975; Fuertes et al., 2012). Evaluative information is, in turn, directly encoded in the lexical semantics of language. For instance, cross-linguistic research shows evaluative information to be the semantic component that factors most frequently and consistently into lexical expressions from a wide variety of language families (Triandis \& Osgood, 1958). The words in an utterance, then, potentially lead to entailments and evaluative inferences that are congruent with the stance of the speaker. Similarly, framing a topic to highlight and promote one's own evaluative judgment can influence how that topic is evaluated by others.

Framing can be achieved through metaphorical language, the semantics of which convey an evaluative component that can be as basic as avoidance versus approach: while the specter of urban violence must be strictly avoided, an epidemic of urban violence can be cautiously approached (Thibodeau \& Boroditsky, 2011). Metaphor theorists from ancient times to the present have considered evaluative judgment to be one of the primary functions of metaphorical language (Lakoff \& Johnson, 1980). This evaluative information is conveyed largely through the image schemas that are encoded in language and accessible to human cognition through our experiences of perceiving, interacting with, and emotionally responding to our environment (see for example Barsalou, 2010; Zwaan, 2008).

Interestingly, recent experimental research on metaphorical language provides evidence for the influence of image schematic information on evaluative judgment. In one study, participants were more likely to judge immigrants negatively after being primed to view their own country as a human body (e.g., a nation undergoing a growth spurt) rather than as an abstract entity (e.g., a nation undergoing a period of innovation), an effect that is congruent with a conventional metaphor that describes immigrants and immigration in terms of dis-
ease (Landau et al., 2009). Keefer et al., (2014) have characterized this effect as metaphoric fit. Metaphoric fit refers to maintaining consistent image schematic information across metaphors during discourse. In a test of the metaphoric fit hypothesis, they asked participants to read an article on depression and its symptoms, and then evaluate the effectiveness of a proposed antidepressant medication. Three versions of the article framed depression in terms of a spatial metaphor (DEpression is Down), or in terms of a visual metaphor (DEPRESSION IS DARK), or using non-metaphorical language. Participants in the spatial metaphor condition judged a drug called Liftix as more likely to be effective, whereas participants in the visual metaphor condition judged a drug called Illuminix more likely to be so. Recent results from another study (Thibodeau, 2016) support the metaphoric fit hypothesis, finding that people evaluated solutions to social problems more favorably when the solution and the problem were framed with congruent metaphoric schemas. For example, given a description of economic hardship in terms of a BALANCE schema, participants preferred a solution that involved "returning to equilibrium". When the description was given in terms of a Splitting schema, they preferred one that "narrowed the gap". Taken together, these findings present compelling evidence that the image schematic information specified by metaphorical language can impact how people evaluate situations. A question that naturally follows from such findings is whether cross-linguistic differences in metaphor usage produce similar effects. For example, if spatial metaphors for depression were predominant in one language, while visual metaphors for depression were in another, would speakers of the first language favor Liftix and speakers of the second Illuminix?

Although several studies have demonstrated that spatial metaphors for time vary across languages (e.g., Chan \& Bergen, 2005; Fuhrman \& Boroditsky, 2010; Nuñez \& Sweetser, 2006), and that these distinctions are reflected in differences in how speakers conceptualize and reason about time (e.g., Casasanto \& Boroditsky, 2008), less attention has been directed towards cross-linguistic contrasts in other conceptual domains. Nor has evaluative judgment, as opposed to reasoning, been the focus of previous cross-linguistic research on metaphor. Here, we discuss an investigation into cross-linguistic differences in metaphors for economic change and whether these differences are reflected in speakers' evaluative judgments about economic change. In this study, we focus on the domain of the economy for a few reasons. Behavior related to the economy and financial decisionmaking is largely motivated by evaluative judgment, and evaluative judgment is consequently a topic of great interest in behavioral economics. In addition, patterns of cross-linguistic differences in the metaphors used to discuss economic change and issues related to the economy have been identified in previous research (e.g., Boers \& Demecheleer, 1997). CharterisBlack \& Ennis (2001), for instance, compared metaphor use in news coverage of business and financial matters across

English and Spanish publications. They found many crosslinguistic similarities in metaphor use, including the tendency to characterize the state of the economy in terms of the physical or psychological health of an organism, to characterize change in the economy in terms of physical motion, and to characterize unusual economic events in terms of natural disasters. At a higher resolution of analysis, however, divergent patterns emerged. The salience of certain metaphors varied across the two languages, as did the types of subordinate concepts favored in metaphor use. Nautical metaphors, for example, were found to be common in English reports on the economy but rare in Spanish reports.

Recent developments in natural language processing approaches to metaphor research have allowed the analyses of much larger corpora to corroborate such hand-annotated corpus studies. Gutiérrez et al., (2017) present a method for detecting fine-grained, cross-linguistic textual differences through the automated analyses of large multilingual corpora. Employing data-driven techniques from natural language processing and machine learning, this method can identify crosslinguistic variation in the use of metaphor among multiple topics. Regarding the topic of the economy, the study found that English discussions of economic change most frequently employ metaphors based on locative motion verbs (e.g., "the economy was going backwards" to describe negative growth). In comparison, Spanish discussions typically rely on metaphors based on expanding/contracting motion verbs (e.g., "la economia se contrajo" to describe negative growth). The image schematic structure of locative motion verb metaphors as in the English example can be categorized as Source-Path-Goal with a focus on Path. Figure 1a illustrates how the English phrase instantiates this schema. The image schematic structure of volumetric motion verbs as in the Spanish example can be categorized as EQUILIBRIUM. Figure 1b illustrates how the Spanish phrase instantiates it. Notably, locative motion verbs feature movement out-of-place whereas expanding/contracting motion verbs feature movement in-place. The experiment in the present study was designed in accordance with these results. In the experi-

Figure 1: The Source-Path-Goal and Equilibrium image schemas prominent in English and Spanish metaphors for economic change.
ment, conducted across a sample of native English and native Spanish speakers, we tested whether people were more sensitive to information presented in a form congruent with the more salient metaphors for economic change in their language. For the experimental task, participants made an evaluative judgment ("Improved" or "Worsened") regarding economic change in a fictional country based on a representative graphic. Change was depicted in the graphic along the two dimensions characteristic of the Source-Path-Goal image schema (henceforth referred to as Motion) and the EQUILibrium image schema (henceforth referred to as Volume). That is, the figure in the graphic progressed from a starting point along a linear path to an end point at the same time that it expanded or contracted. If metaphor-congruent image schemas are active during the process of forming evaluative judgments, we expect English speakers' evaluations of the economy to align more closely with the direction of change in the linear dimension of the graph, and Spanish speakers' evaluations to align more closely with change in the volumetric dimension.

## Experiment

## Methods

Participants We recruited 60 participants from one English-speaking country (the US) and 60 participants from three Spanish-speaking countries (Chile, Mexico, and Spain) using the CrowdFlower crowdsourcing platform. ${ }^{1}$ All participants answered a demographic questionnaire, reporting gender, age, location, native language, level of education, color vision deficiencies, and use of touchscreen device during task. Results from nine US and three non-US participants were discarded for failure to meet the language requirement.

Materials \& Design Participants first read a brief description of the experimental task, which introduced them to a fictional country in which economists are devising a simple but effective graphic for representing change in the economy (see Figure 2 for the English version). Spanish speakers read a translation of the English text provided by a native speaker of Spanish who is also fluent in English. They then navigated to a new page to begin the task. Stimuli were presented in a 1200 -pixel by 700 -pixel frame. The center of the frame contained a sphere with a 64-pixel diameter. For each trial, participants clicked on a button to activate an animation of the sphere which involved (1) a positive displacement (in rightward pixels) of $10 \%$ or $20 \%$, or a negative displacement (in leftward pixels) of $10 \%$ or $20 \%$; and, (2) an expansion (in increased pixel diameter) of $10 \%$ or $20 \%$, or a contraction (in decreased pixel diameter) of $10 \%$ or $20 \%$. Participants saw each of the resulting conditions three times. The displacement and size conditions were drawn from a random permutation of conditions using a Fisher-Yates shuffle (Fisher \& Yates, 1963). Crucially, stimuli in half of the trials contained conflicting image schematic information with respect

[^388]
#### Abstract

Oxar is a country on the planet Xor. Oxarian economists are experimenting with new ways of modelling economic trends in their country. A group of economists are attempting to design a simple yet intuitive way of representing changes in the economy of the country. You are here to help them in their mission! During the experiment, you'll see a series of graphics representing change in Oxar's economy. Your task will be to decide, according to the dynamic graphic you have just seen, whether the economy has improved or worsened. Then, you will be asked to estimate how much the economy changed according to the graphic. Please try and give your judgments about the economy as accurately as possible.

Figure 2: Description of the experimental task in English.
to the displacement and volumetric metaphors for economic change (e.g., the sphere could both expand and move backwards).

Once the sphere had completed its movement across the screen, participants recorded a judgment of whether the economy improved or worsened by clicking on the appropriate radio button. They then indicated on a seven point scale how confident they were in their judgment and by how much they judged the economy to have changed.

## Results \& Discussion

Congruence \& Direction To analyze participant judgment of the direction of economic change, we first coded the responses as being Motion-congruent or Volumecongruent. For instance, if on a given trial the sphere was expanding while moving backwards and the response was "Economy Improved", the result was coded as Volumecongruent. If the response had been "Economy Worsened", the result would have been coded as Motion-congruent. Figure 3 presents the mean proportion of responses that fall into these categories for both languages, ${ }^{2}$ showing that Spanish speakers' judgments were more likely to align with the Volume dimension of the stimuli (i.e., the dimension encoded in the image schemas used most frequently in Spanish to discuss economic change metaphorically), and English speakers' judgments were more likely to align with the Motion dimension (i.e., the dimension encoded in image schemas used most frequently in English to discuss economic change metaphorically). To test whether people's judgments followed a language-specific, metaphor-congruent response more often than predicted by chance, we used a mixed effects logistic regression model to analyze the data using the lme4 package in the R statistical language. ${ }^{3}$ We compared two models: one that modeled the influence of language on

[^389]

Figure 3: Mean proportion of dimension-congruent responses by language for Both-congruent, Motion-congruent and Volume-congruent judgments.
judgment for the conflicting trials ( $n=2520$ ), and one that modeled the influence of language on judgment for the nonconflicting trials $(n=2520)$. We reasoned that, if the image schematic information in the experimental stimuli is influencing judgment in a manner that is both language-specific and metaphor-congruent, language would be a significant predictor of judgment in the conflicting trials but not in the nonconflicting trials.

Both models included random effects for participant and item to control for their associated intraclass correlation, and both used the Laplace approximation for parameter estimation. The results of the analyses show an effect of language in the conflicting trials $(\beta=3.96, p<0.001)$, but not in the nonconflicting trials ( $\beta=0.23, p=0.57$ ). To evaluate model fit, we randomized the subset of our data containing the results of the conflicting trials and split it into testing and training sets. We then modeled the data in the training set using the same mixed effects logistic regression equation from our original analysis, and used this model to predict participant judgment in the testing set. The prediction accuracy of our model was 0.84. The AUROC (area under ROC curve) for predicting judgment with the model was 0.93 (see Figure 4), indicative of the expected proportion of true positives ranked before a uniformly drawn random negative. The above analyses indicate that participants' judgments of whether the economy improved or worsened varied in a predictable manner based on their native language. The estimated odds that the judgment of a Spanish speaker aligned with changes in Volume image schematic information in the stimuli rather than MoTION image schematic information were 52.46 greater than the corresponding odds for an English speaker.

Congruence \& Magnitude We also examined whether image schematic information influenced participants' judgments of the magnitude of economic change. Here, we focused on the nonconflicting trials. Recall that for these trials when-

Figure 4: The ROC curve showing the ability of our model to correctly classify the judgments of participants.
ever the sphere was moving forward, it was expanding; and, whenever it was moving backwards, it was contracting. However, in half of the trials ( $n=1260$ ), the sphere was either expanding or contracting to a greater degree than it was moving forward or backwards, or vice versa. If metaphor-congruent image schemas are affecting speakers' judgments, then we would expect Spanish speakers to increase their estimates of the magnitude of change when expanding or contracting of the sphere is the dominant schema. Similarly, we would expect English speakers' judgments to be greater when forward or backward motion is the dominant schema.

On average, English and Spanish speakers estimated the amount of economic change to be greater when the sphere was expanding/contracting than when it was moving forward/backwards, as shown in Figure 5. To assess whether the differences across language and dominant schema were significant, we analyzed the data using cumulative link (probit) models via the ordinal package in R. ${ }^{4}$ We first modeled amount of change with additive predictors of language and dominant schema, with participant and item as random effects. To test for an interaction between these factors, we fit a second model with the interaction as a predictor and used the likelihood ratio test to compare the two models. Our analysis indicated no main effects for language or for the interaction between language and dominant schema. There were marginal effects for Volume as the dominant schema both when contracting $(\beta=0.3122, p=0.009)$ and when expanding ( $\beta=0.3150, p=0.009$ ). These results tell us that a $10 \%$ change in contraction of the sphere increases the probability of higher estimates of the amount of change by $31.22 \%$ for Spanish and English speakers. A $10 \%$ change in expansion of the sphere increases the probability of higher estimates of the amount of change by $31.50 \%$, again for both groups of speakers.

[^390]

Figure 5: Mean estimated amount of change per language and stimuli dimension.

Congruence \& Confidence With the last metric we collected from participants, that of confidence, we investigated whether one group of speakers found a particular set of stimuli (or the experimental task itself) to be more difficult or confusing than was the case for the other group of speakers. English speakers, for example, may have had more difficulty in assessing the stimuli with contradictory information since English employs Motion and Volume based metaphors in discussions of economic change.

We again analyzed the data using cumulative link (probit) models, here with additive predictors of language and stimuli class, with participant and item as random effects. To test for an interaction between the factors, we fit a second model with the interaction as a predictor and used the likelihood ratio test to compare the two models. We found no significant differences across languages and no significant interaction between language and stimulus condition. English speaking participants and Spanish speaking participants both showed a highly significant increase in confidence for judgments in three of the stimulus conditions: when the sphere was contracting by $20 \%$ and moving backward by $20 \%(\beta=0.4907, p<0.001)$, when the sphere was expanding by $20 \%$ and moving forward by $20 \% ~(\beta=0.6553, p<0.001)$, and when the sphere was expanding by $20 \%$ and moving forward by $10 \% ~(~ \beta=0.4815, p<0.001)$.

Both groups of participants, then, showed greater confidence in their judgments, with a $49.07 \%$ increased probability, given a stimulus congruent with a large decline in the economy across both image schemas. Given a stimulus suggesting a large improvement in the economy across image schemas, participant confidence increased with a probability of $65.53 \%$. Given a stimulus congruent with a large improvement in the economy per the Volume dimension of the stimuli and a moderate improvement per the MOTION dimension, confidence improved with an increased probability of $48.15 \%$. These results suggest that, for all participants,
confidence in judgment relied on magnitude. In the first two conditions where confidence increased, the sphere was increasing or decreasing to a maximum degree along both dimensions. Hence, it is unclear whether participants were more sensitive to language-specific, metaphor-congruent image schematic information. That participant confidence increased in the third condition noted above suggests that participants overall were more confident when the sphere was moving forward rather than backwards. Since the results were consistent across languages, we found no evidence that any particular combination of schemas were more difficult to parse for one, but not the other, group of speakers.

## General Discussion

Metaphors based on movement are regularly used in English and Spanish (amongst other languages) to discuss the economy and economic change. Past research suggests that in discussions of important socio-political topics, such as the economy, metaphorical language can influence people's reasoning. Here, we presented evidence that metaphorical language also affects people's evaluative judgment. Evaluative judgment, which differs from reasoning in that it is not logicbased, is a crucial component of decision-making. The results of our study thus serve to tease apart how these two mechanistically different processes influence decision-making, with our results indicating that metaphorical language affects the evaluative judgment component of decision-making through the image schematic information present in the semantics of the metaphor. These findings corroborate accounts of language and cognition that emphasize the role of language in the development of associative and representational routines. In line with such accounts, the current findings reflect Spanish speakers learning to associate economic change with shifts in Volume and habituating focus to volumetric image schematic information. English speakers, who learn to associate economic change with shifts in Motion, habituate focus to image schematic information involving displacement.

Our findings with respect to congruence and amount of change, and with respect to congruence and confidence, provide further nuance to this view. While judgments of economic improvement or decline aligned more consistently with language-specific, metaphor-congruent dimensions in the stimuli, judgments regarding the amount of change were more consistent with changes in Volume for both groups of speakers. A possible explanation for this effect is that visual experience of a change in amount is more strongly correlated with a change in density than with a change in location. Another possible explanation is that English speakers associate direction of change with motion through space but associate amount of change with manner of motion, and changes in the size of the sphere were more suggestive of manner of motion. As noted above, judgments of confidence were consistent with changes across both schemas for both groups of speakers, as long as the changes were consistent across schemas. This indicates that, while participant focus
may have been driven by metaphor-congruent schemas, they were still sensitive to both aspects of the stimuli. This latter finding supports the view that language probabilistically influences other cognitive functions as opposed to those that consider language to have a more discrete effect on other aspects of cognition.

Evaluative judgment is a core component of decisionmaking, especially in the socio-political domain, and it is highly reliant on the image schematic information shared across percepts and concepts. Such image schematic information is also key to the cognitive function of metaphor. The present work represents a preliminary step in linking evaluative judgment and its reliance on image schematic information to cross-linguistic variation in metaphor use. Future studies along these lines should shed further light on how the image schematic information intrinsic to metaphorical language shapes evaluative judgment in discussions of the economy, as well as discussions of other important socio-political domains.

#### Abstract

Language entails many nested time scales, ranging from the relatively slow scale of cultural evolution to the rapid scale of individual cognition. The nested, multiscale nature of language implies that even simple acts of text production, such as typing a sentence, entail complex interactions involving multiple concurrent processes. As such, text production may have much in common with other cognitive phenomena thought to emerge from multiplicative interactions across temporal scales, namely those that exhibit fractal properties. We investigated the relationship between fractal scaling and the quality of produced text. Participants ( $N=131$ ) wrote essays while their keystrokes were recorded. Fractal analyses were then performed on time series of interkeystroke intervals (IKIs). Results showed that fractal properties characterizing IKIs positively predicted expert ratings of essay quality, even after accounting for essay length. The results support our hypotheses concerning multiscale coordination and text production.

Keywords: text production; writing; keystroke; multifractal; essay quality

## Introduction

Recent theoretical and empirical work characterizes language as a complex, dynamic system that involves the coordination of multiple nested time scales (Dale, Kello, \& Schoenemann, 2016; Rączaszek-Leonardi, 2010; Rączaszek-Leonardi \& Kelso, 2008). Consider three time scales that have been highlighted extensively in the literature. Language can evolve on a relatively slow scale along with changes in cultures and significant historical events. On a faster scale, language can be altered throughout an individual's life, based on their experiences and knowledge. Lastly, language can change at more rapid scales in response to cognitive events that can span days, hours, or mere fractions of a second.

These time scales span several orders of magnitude and paint a complex picture of language. The picture is further complicated because each of the time scales implicates different systems (e.g., cultural, interpersonal, physiological) and suggests that language processes should be studied as complex, dynamical systems. The current work explores this idea in the context of text-based language production. We examine whether dynamic analyses of typing behaviors during essay writing provide empirical support for the notion of writing as a complex, dynamical system.

The nested, multiscale character of text production is apparent in the simple example of typing an essay. The
relatively fast time scale of word selection is nested within and constrained by the slower time scale of idea generation. Singular ideas are further nested within the subtopics and global topic of the essay that change at even slower rates. Beyond these examples, nesting can continue at both faster and slower time scales. Rapidly changing physiological processes influence and support the act of writing that would not be possible without a lifetime of learning or the evolution of a language within a culture. Thus, even the seemingly simple act of typing one sentence of an essay may entail complex interactions of any number of processes, each with its own characteristic rate of evolution. The implication is that language production involves the coordination of numerous systems over many different time scales. Our assumption is that the act of text production (i.e., typing an essay) provides a window into ongoing cognitive processes (Pinet, Ziegler, \& Alario, 2016). As such, we expect that keystroke dynamics will reveal the multiplynested character of text production.

## Multiscale Interactions in Human Behavior

A wide range of cognitive phenomena have been described as emerging from the interaction of multiply-nested time scales (Ihlen \& Vereijken, 2010). The principle evidence for that claim is the observation of fractal scaling. Fractal scaling typically refers to two qualities: long-range autocorrelation and scale dependence. Long-range autocorrelation implies that time series observations exhibit significant correlations over large timespans (Beran, 1994). That is, an observation made at one point in time is related to subsequent observations that extend into the future. Scale dependence suggests that measurements of time series (e.g., variance) depend on the temporal scale at which they are measured (Mandelbrot \& Van Ness, 1968).

There are numerous examples of behavioral time series known to exhibit fractal scaling: reaction times (Gilden, Thornton, \& Mallon, 1995; Van Orden et al., 2003), time estimation (Wagenmakers et al., 2004), eye movements (Stephen \& Anastas, 2011), hand movements (Anastas, Stephen, \& Dixon, 2011; Stephen, Arzamarksi, \& Michaels, 2010), arm movements (Chen, Ding, \& Kelso, 1997), postural corrections (Collins \& DeLuca, 1993), and various forms of tool-use (Likens, Fine, Amazeen, \& Amazeen, 2015; Nonaka \& Bril, 2014).

Much of the work on fractal scaling in cognition has emphasized interaction across scales as its primary theoretical contribution (Ihlen \& Vereijken, 2010; Kelty-

Stephen \& Wallot, in press). The basic idea is that the rich structure observed in behavioral time series is the product of many simultaneously occurring processes (e.g., physical, cognitive). Each process exists on its own time scale, with effects of slower time scales multiplicatively cascading to faster and faster time scales. As such, fractal scaling reflects on-the-fly cognitive organization during tasks (Van Orden et al., 2003; Wallot, Hollis, \& van Rooij, 2013). Further, variability in fractal properties reflects the flexibility and adaptability in typical cognitive tasks necessary for coordination across those levels (Anastas et al., 2011).

If fractal scaling reflects the flexibility and adaptability that stems from multiscale coordination, then reliable relationships should exist between fractal scaling and other meaningful aspects of behavior. The literature contains several such examples. Visual search is faster when eye movements exhibit fractal properties (Stephen \& Anastas, 2011). Fractal variability in hand movements predicts better perceptual estimates (Stephen et al., 2010). Moreover, fractal patterns distinguish between various forms of skilled and non-skilled behavior (e.g., Nonaka \& Bril, 2014). These examples are not exhaustive but hint at the large number of skillful behaviors that exhibit fractal characteristics.

The current work explores the idea that fractal scaling might also reflect the multiscale coordination involved in the skilled production of text. Across domains, the evidence implies being skilled means adapting to task demands, and fractal scaling characterizes flexibility (Gorman et al., 2010; Nonaka \& Bril, 2014). The observation of flexibility in skilled text production (Allen, Snow, \& McNamara, 2016) leads to the hypothesis that fractal scaling will reveal the flexibility required from the nested, multiscale act of composition. That is, we expect more skilled text production will be characterized by fractal variability.

We are not aware of any studies that have examined the time course of text production for evidence of fractal scaling; however, work related to reading and skilled typing provides some bases for exploration (e.g., Wallot \& Grabowski, 2013; Wallot et al., 2013; Wijnants et al., 2012). For example, Wijnants and colleagues (2012) showed that the presence of fractal scaling in word naming times distinguished dyslexic and non-dyslexic readers. They also found a positive relationship between fractal scaling and reading fluency. Another study involving skilled typing suggests that fractal properties may depend on task complexity/difficulty (Wallot \& Grabowski, 2013). The relevant finding in that study was that there was greater fractal variability over time when participants typed a set of directions than when they typed simple lyrics from memory or simply copied text.

## Current Study

This study investigates how fractal properties in keystroke logs are related to the quality of written text. Participants wrote timed, prompt-based argumentative essays while their keystrokes were recorded. Time series were constructed from the latencies between keystrokes and analyzed by
fractal analysis. Essays were scored by experts on holistic quality and analytical subscales. This study is exploratory and the first of its kind; nonetheless, our general expectation is that, like performance on other tasks, fractal properties will serve as reliable predictors of essay quality.

## Method

Participants Undergraduate students $(N=131$, Female $=$ 58 , mean age $=19.8$ years) were recruited from a large university in the United States. Students participated in the study in exchange for course credit.
Procedure Participants wrote a timed (25-minutes), promptbased, argumentative essay. Essay prompts were similar in structure to Scholastic Aptitude Test (SAT) prompts in that participants were asked to take either a supporting or contrary position on a given topic. Keystrokes and their respective time stamps were recorded while students composed their essays. Unsurprisingly, participants varied considerably in the number of keystrokes they produced ( $M$ $=3,385.40, S D=1,107.03$ ). To prevent bias, only the first 999 keystrokes were retained for further analysis, corresponding to lowest number of keystrokes in our sample. No other keystrokes (e.g., backspaces) were omitted. Keystroke timestamp series were then differenced to obtain time series of interkeystroke intervals (IKIs). Mouse movements were not recorded.

Text Analyses Pairs of raters evaluated the essays based on holistic quality and analytic subscales. Raters received extensive training before scoring and received compensation for their time. Holistic scores ranged from one (minimum) to six (maximum) and were based on a standardized rubric used in the assessment of SAT essays. Interrater reliability was good $(r=0.75)$. Raters were instructed to treat the distance between points (e.g., 1-2, 3-4, 4-5) as equal. The nine subscales, also based on a 6-point scales, were:

Introduction. $(M=3.97, S D=0.96)$ Demonstrates mastery in meeting the goals of an introduction (e.g., presenting a topic, providing a purpose, clearly stating a thesis, previewing arguments).

Body. ( $M=4.08, S D=0.90$ ) Demonstrates mastery in meeting the goals of body arguments (e.g., transition between arguments, using topic sentences, supporting arguments with evidence, and maintaining a flow throughout the arguments).

Conclusion. $(M=3.19, S D=1.32)$ Demonstrates mastery in meeting the goals of a conclusion (e.g., summarizing the essay, re-establishing the significance of discussion, capturing the reader's attention, and effectively closing the essay).

Organization. $(M=3.86, S D=0.98)$ Follows a logical structure, beginning with the introduction, through the arguments and evidence presented in the body arguments, and to the conclusion.

On-Topic/Global Cohesion. $(M=4.13, S D=0.85)$ Details presented throughout the essay support the thesis
and do not stray from the prompt and the main ideas and organizing principles presented in the introduction.

Grammar, Syntax, \& Mechanics. $(M=3.70, S D=0.79)$ Employs correct Standard American English, avoiding errors in grammar, syntax, and mechanics; the essay conveys strong control of the standard conventions of writing.

Voice. $(M=4.09, S D=0.76)$ The writer is expressive, engaging, and sincere, with a strong sense of audience.

Word Choice. $(M=4.07, S D=0.71)$ Word choice is precise and effective.

Sentence Structure. $(M=4.06, S D=0.75)$ Sentence patterns are varied effectively, enhancing the quality of the essay.
Fractal Analysis Fractal analysis comes in two forms, monofractal analysis and multifractal analysis, both of which were performed on the IKI time series. The goal of monofractal analysis is to understand how variability depends on scale (e.g., Eke, Herman, Kocsis, \& Kozak, 2002). In general, evaluating monofractality means estimation of scaling exponents from the relationship, $F^{2}(s)$ $\sim s^{H}$ where $H$ is the Hurst exponent, and $F^{2}(s)$ is a measure of fluctuation. Being a singular measure, the Hurst exponent provides a measure of typical scaling behavior in a time series. Moreover, $H$ ranges from zero to one and has useful interpretive ranges (Collins \& DeLuca, 1993; Gorman et al., 2010). When $H=0.5$, the time series exhibits random variation. When $\mathrm{H}>0.5$, the series contains long-range autocorrelation, and when $\mathrm{H}<0.5$, the series exhibits longrange anticorrelation such that small values generally follow large values and vice versa. Many series have been shown to require not one but a spectrum of exponents to characterize their variability (Ihlen \& Vereijken, 2010; Kantelhardt et al., 2002). Hence, the goal of multifractal analysis is to determine whether fractal scaling is fixed across time; that is, whether a time series exhibits multifractality (Kantelhardt et al., 2002).

We used Multifractal Detrended Fluctuation Analysis (MFDFA; Kantelhardt et al., 2002) to evaluate both monofractal and multifractal properties in IKIs. The outcome of MFDFA is the multifractal spectrum. MFDFA is the generalization of Detrended Fluctuation analysis (DFA) and has been used in diverse literature to characterize time-varying structure (Kantelhardt et al., 2002; Peng et al., 1994). The MFDFA procedure consists of five steps. The first step is to create the profile by integrating over a meancentered time series. In a second step, the time series of length, $N$, is divided into $N_{s}=\operatorname{int}(N / s)$ non-overlapping bins, such that each bin contains $s$ observations. To compensate for $N_{s}$ often being a non-integer multiple of $s$, the binning procedure is performed twice by starting from each end of the time series. The result partitions the time series into $2 N_{s}$ bins. In a third step, data in each bin is fit with a least squares regression line that is subtracted from the binned data to obtain local residuals. The bin-wise residuals are squared and averaged to obtain a measure of variance within
each segment, $v$. The fourth step averages over all the bins to obtain the $q$ th order fluctuation function as captured in

$$
\begin{equation*}
F_{q}(s)=\left\{\frac{1}{2 N_{s}} \sum_{v=1}^{2 N_{s}}\left[F^{2}(v, s)\right]^{q / 2}\right\}^{1 / q} \tag{1}
\end{equation*}
$$

where $F^{2}(v, s)$ is the variance calculated in Step 3 and $q$ takes on both positive and negative values. Steps 2 through 4 are repeated for several $s$, increasing $s$ by a power. The current work used a fractional power $(11 / 10)$ for varying $s$ which allowed for a larger range of scales over which scaling estimates were made. The maximum $s$ was $\leq N / 4$. Step 5 evaluates scaling behavior by performing a log-log regression of $F_{q}(s)$ on $s$ for each value of $q$. We used 101 values of $q$, ranging from -3 to 3 . When scaling properties are present, the result from Step 5 is a linear slope equal to the $q$-order Hurst exponent, $H(q)$. When $q=2$, the procedure is equivalent to standard DFA. $H(q)$ can then be used to estimate the width of the multifractal spectrum $d h(q)$. In contrast $H, d h(q)$ provides a measure of the variability in scaling over time.

## Results

Hierarchical multiple regression was used to explore the relations between the fractal properties in IKIs (i.e., $H$, $d h(q))$ and holistic essay scores $(M=3.85, S D=0.89)^{1}$. Table 1 presents the descriptive statistics for the predictor variables used in constructing regression models.

Table 1. Descriptive statistics

| Variable | $M$ | $S D$ |
| :--- | ---: | ---: |
| Number of Words (NW) | 412.67 | 162.22 |
| $d h(q)$ | 1.32 | 0.26 |
| $H$ | 0.51 | 0.06 |

In addition to fractal properties, we included the total number of words (NW) in each essay as a predictor in the regression model because of the known positive relationship between essay length and essay quality (e.g., McNamara, Crossley, \& Roscoe, 2013; McNamara, Crossley, Roscoe, Allen, \& Dai, 2015). Predictors were checked for multicollinearity and all variance inflation factors were less than $2\left(\mathrm{VIF}_{\mathrm{NW}}=1.09 ; \mathrm{VIF}_{H}=1.21 ; \mathrm{VIF}_{d h(q)}=1.26\right)$, indicating that multicollinearity was not a concern. Note that, NW, $H$, and $d h(q)$ were converted to $z$-scores to aid in interpretation. This was especially crucial in the case of $H$ as its theoretical domain is $(0,1)$. NW was entered in the first model step; $H$ and $d h(q)$ were both entered in the second model step. As expected, the initial model was significant, $\beta$ $=0.47, R^{2}=0.28, p<0.001$; however our interest was in characterizing whether fractal properties predicted essay quality over and above NW. The results showed that fractal properties improved model fit, $F(2,127)=6.68, p<0.01, R^{2}$ $=0.35$. As expected NW was a significant predictor such that a one standard deviation increase in essay length predicted a 0.54 increase in holistic score, $t(127)=8.09, p<$

[^391]0.001. After controlling for NW, the model also revealed that a one standard deviation increase in $H$ predicted a 0.21 increase in holistic score, $t(127)=2.92, p<0.01$. Furthermore, a one standard deviation increase in $d h(q)$ predicted a 0.29 increase in holistic score, $t(127)=3.19, p<$ 0.01 .

Following the analysis of holistic essay scores, nine additional sets of regression models were fit predicting each subscale from NW, $H$, and $d h(q)$. The modeling strategy for these additional models was the same as for overall essay quality. A summary of those models appears in Table 2. The table shows that fractal properties explain significant variance for seven out of nine subscales, with Conclusion and Organization being the exceptions. Of note is the fact that, for several outcomes, the fractal properties explain more than twice the variance explained by NW.

Table 2. Regression models for expert rated subscales Predictors

|  | Predictors |  |  |  |  |  | $F$ |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  | Model 1 |  | Model 2 |  |  |  |  |
| DV | NW | $R^{2}$ | NW | H | $d h(q)$ | $R^{2}$ |  |
| Intro | 0.30*** | 0.10 | 0.39*** | 0.27** | 0.29*** | 0.20 | 7.85*** |

## Discussion

In this study, we investigated how the multiscale characteristics of text production relate to essay quality. In general, we found that the Hurst exponent was a positive predictor of holistic essay quality and analytical scores. Similarly, we found that broader multifractal spectra predicted better quality essays, overall, and on several analytical subscales. The remainder of the discussion is structured as follows: First, we give an overview and basic interpretation of the scaling behavior observed for IKIs during essay production. Second, we speculate on how those interpretations inform patterns of prediction observed with respect to essay quality. Lastly, we offer ideas for potential applications and future research.

## Scaling Properties in IKIs

We found that IKIs in this study were characterized by global $H$ close to the value typical of random variation (i.e., $H=0.50$ ). The observed mean of $H$ was surprising given the prevalence with which $H$ s indicative of long-range correlation (i.e., $H>0.5$ ) have been observed in other tasks (Kello et al., 2010). The result was further surprising
because keystrokes observed during typing tasks have been previously characterized as being anti-correlated, where $H<$ 0.5 (Wallot \& Grabowski, 2013). One possible reason for the difference in results is those authors' use of power spectral density to estimate $H$ (labeled $\alpha$ in that study). Simulation work has shown power spectral density underestimates $H$ (Delignières et al., 2006). The reason for those differences may be the method used to estimate $H$.

A more likely and substantive reason relates to nature of the tasks used in each study. In Wallot and Grabowski (2013), participants performed one of three relatively simple tasks: type a nursery rhyme from memory; copy text from a page; and generate a novel set of directions from school to home. The latter condition was the closest to essay writing but still differs substantially in complexity and difficulty, factors known affect the scaling properties in basic motor control tasks and complex tasks like steering (e.g., Chen et al., 2001; Likens et al., 2015). Writing a timed essay is arguably more difficult and more complex than giving familiar directions. Perhaps, then, the Hurst exponents we observed in this study reflect those differences in task difficulty. The results concerning $d h(q)$ lends further, albeit tentative, support for that conclusion.

The trend across tasks observed in Wallot and Grabowski (2013) permits cautious speculation about the meaning of spectral widths within the current context. Note that a direct comparison between the widths we observed and those in Wallot and Grabowski is not possible because they used a wavelet form of multifractal analysis, and different methods are known to produce different widths (Ihlen \& Vereijken, 2013). In Wallot and Grabowski, the multifractal spectrum width increased as a function of task complexity, with the generative task producing the broadest spectrum. Similar results have also been reported in the motor control and social coordination literatures where an increase in task difficulty has been associated with widening $d h(q)$ (e.g., Davis, Brooks, \& Dixon, 2016; Romero, Coey, Beach, \& Richardson, 2013). A reasonable conclusion is that the relatively broad spectra we observed reflect the difficulty inherent in writing a timed essay.

Unlike $H$, the multifractal spectrum does not have the same useful interpretive indices concerning long range correlation and randomness. However, a few words are possible concerning why task complexity or task difficulty would affect the width of the multifractal spectrum. The multifractal spectrum provides a summary of scaling behaviors that evolve over time (Ihlen \& Vereijken, 2013; Kantelhardt et al., 2002). If the Hurst exponent were sufficient to describe the scaling behavior present in the IKI time series, then one would expect a narrow spectrum - a time-invariant monofractal process. Instead, we observed broad multifractal spectra that are more consistent with interpretation of a time-varying multifractal process. Timevarying scaling behavior is thought to reflect the ongoing dynamics in complex, dynamical systems that range from individual physiological processes to entire human teams (Likens et al., 2014). Time-varying scaling behavior in the

IKIs might reflect changes in cognitive state or changes in strategy that accompany the multiscale coordination involved in writing an essay (e.g., Stephen et al., 2009). That idea is elaborated in the following section in the context of essay quality.

## Scaling Properties as Predictors of Essay Quality

We have suggested that changes in scaling behavior may reflect changes in cognitive state or strategy. If so, then a broader multifractal spectrum could reflect flexibility in writing. Multifractal scaling is synonymous with flexibility and adaptability in other contexts (e.g., Collins \& De Luca, 1993), and flexibility in the use of cohesive devices (i.e., flexibility in writing) predicts higher quality essays (e.g., Allen et al., 2016; Snow et al., 2015). The implication is: if multifractal scaling reflects flexibility in writing, then wider multifractal spectra may also indicate higher quality essays. The current findings seem to support such reasoning. Results from regression analyses suggest fractal properties positively predict overall essay quality as well as quality on analytical subscales.

Another notable feature of the regression analyses was that $d h(q)$ did not predict the quality of either the Body or Conclusion. As a potential explanation of those results, we refer to our data preparation steps. The time series in our sample were truncated to accommodate participants with short essays. Given the average length of intact series was over three times the length of the truncated series we analyzed, there is a strong possibility the fractal analyses did not equally represent Body and Conclusion aspects of text. If true, then perhaps $d h(q)$ did not adequately capture variability with respect to Body and Conclusion sections. In addition, neither $H$ nor $d h(q)$ predicted the organization subscale. A similar interpretation could be made concerning the length of the time series analyzed with respect to the length of a typical essay in our sample.

## Applications and Future Directions

In this study, we have shown for the first time that fractal properties measured while writing an essay predict essay quality. Being the first of its kind, we have interpreted the results cautiously. However, the results are promising and suggest opportunities for future research and applications.

One promising area of research pertains to flexibility and adaptability in writing. As already discussed, multifractal scaling may suggest flexibility and adaptability in writing. If so, then it should be possible to link multifractal characteristics with other aspects of writing flexibility (Allen et al., 2016; Snow et al., 2015). In those studies, flexibility was characterized over several essays; however, if flexibility is important on the timescales of days and weeks, then flexibility should also be important within the context of a single essay. If so, then the fractal properties of keystrokes may also relate to the flexibility at those slower time scales.

Another related area of investigation involves the use of fractal properties in applied settings. The results of the
current study, if replicable, could inform applied educational settings such as those involving learning analytics and automated writing evaluation systems. The analyses we have presented here are algorithmically efficient enough to be implemented in real time. Real-time assessment of fractal properties is promising on several fronts. Real-time fractal properties could be monitored by instructors for early signs of writing difficulty and provide faster, targeted feedback. The same notion could apply within automated writing evaluation systems to augment automated feedback systems.

Lastly, the methods we have presented are not limited to the analysis of keystrokes. The use of physiological measurements and various movement registration devices is becoming more common in applied literature on intelligent tutoring systems (D’Mello, Picard, \& Graesser, 2007). Fractal analyses have proven beneficial in other settings involving physiological data, primarily because of relationship between fractality and flexibility (e.g., Chen et al., 2001; Ivanov et al., 2001). An open, empirical question is whether fractal analysis of physiological data may reveal flexibility in intentional forms of behavior. In conclusion, we have demonstrated that text production exhibits scaling properties like those observed in other cognitive phenomena. In doing so, we have also supported the idea that language is a complex, dynamical system involving coordination across many nested time scales. Going forward, our goal will be to further articulate time scales relevant to text production.

#### Abstract

Visuomotor adaptation plays an important role in motor planning and execution. However, it remains unclear how sensorimotor transformations are recalibrated when visual and proprioceptive feedback are decoupled. To address this question, the present study asked participants to reach toward targets in a virtual reality (VR) environment. They were given visual feedback of their arm movements in VR that was either consistent (normal motion) with the virtual world or reflected (reversed motion) with respect to the left-right and vertical axes. Participants completed two normal motion experimental sessions, with a reversed motion session in between. While reaction time in the reversed motion session was longer than in the normal motion session, participants showed the learning improvement by completing trials in the second normal motion session faster than in the first. The reduction in reaction time was found to correlate with greater use of linear reaching trajectory strategies (measured using dynamic time warping) in the reversed and second normal motion sessions. This result appears consistent with linear motor movement planning guided by increased attention to visual feedback. Such strategical bias persisted into the second normal motion session. Participants in the reversed session were grouped into two clusters depending on their preference for proximal/distal and awkward/smooth motor movements. We found that participants who preferred distal-smooth movements produced more linear trajectories than those who preferred proximal-awkward movements.

Keywords: Virtual reality; motor planning; scene representation; visual misalignment

## Introduction

## Virtual Reality

Virtual reality (VR) technology provides an analog experience in a three-dimensional environment similar to that of the real world. In the real world, certain environmental factors and physical constraints are fixed and cannot be modified. However, VR allows researchers to design controlled virtual environments with ease and precision. In addition, modern advancements in VR tracking allow for accurate measurements of human body movements. Thus, task success, motor error and correspondence with candidate trajectories can be accessed directly.

Although previous studies in VR have focused primarily on hardware problems in order to improve user experience (Shotton et al., 2013; Weichert, Bachmann, Rudak, \& Fisseler, 2013), simulation performance (e.g., Unreal Engine 4, Unity3d, and NVidia Flex), system integration (Lin et al., 2016; Shah, Dey, Lovett, \& Kapoor, 2017), and locomotion in immerse experience (Bruder \& Steinicke, 2014), recently efforts have been increasingly devoted to examining human perception and reasoning in virtual scenes (e.g., Azmandian, Hancock, Benko, Ofek, \& Wilson, 2016; Mehra et al., 2016;

Patney et al., 2016; Ye et al., 2017; Li, Liang, Quigley, Zhao, \& Yu, 2017).

## Motor Planning

The process of reaching toward an object in the environment involves minimizing the distance between the hand and target locations in the physical world (i.e., the hand and target states) over time. This is achieved by (1) planning a motor movement to achieve a desired task goal, (2) sending the associated motor command to the arm, and (3) comparing observed sensory feedback to predicted sensory feedback to infer the current hand state and form subsequent motor commands (i.e., sensorimotor transformation; BattagliaMayer et al., 2014; Wolpert, 1997). The present study examined how reaching movements change in response to misaligned sensory feedback in a VR environment. Specifically, how do reaching trajectories change as visual and proprioceptive feedback are decoupled?

When visual and proprioceptive feedback are inconsistent, new mappings between visual and proprioceptive inputs are reestimated (Cressman \& Henriques, 2009). Results from Cressman and Henriques's (2009) study suggest that in addition to sensorimotor recalibration, visuomotor adaptation involves partial proprioceptive recalibration: i.e., humans "realign proprioceptive estimates of hand position to match visual estimates." However, it has been demonstrated that visuomotor adaptation can occur in the absence of proprioceptive input, for example, in the case of deafferented individuals (Ingram et al., 2000; Miall \& Cole, 2007). It is therefore possible that proprioceptive recalibration does not underlie visuomotor adaptation and that the two processes are independent from one another. This hypothesis is consistent with empirical results showing that humans curtail the contribution of proprioceptive input in the case of misaligned visual feedback (Bernier, Burle, Vidal, Hasbroucq, \& Blouin, 2009; Wont \& Henriques, 2009) when performing motor movements. Thus, when visual and proprioceptive feedback are inconsistent, people could reduce the contribution of proprioceptive information to the motor planning process and form new visuomotor transformations to achieve extrinsic goals.

In this study, participants reached toward targets in a virtual environment where their hand movements were shown to be either consistent or reversed (in the vertical and leftright axes) with respect to virtual movement. If proprioceptive inputs are ignored (perhaps due to their unreliability in the reversed movement environment), participants should rely more heavily on visual inputs when planning and executing movements. Moreover, we expect participants will adapt to the reversed environment by constructing and implementing new visuomotor mappings. Although we pre-

Figure 1: Participants reached toward targets in a virtual environment where their hand movements were shown to be either (a) consistent, or (b) reversed (in the vertical and left-right axes) with respect to virtual movement. (Top) Real world actions. (Bottom) Virtual simulation.
dict proprioceptive inputs to be ignored or even suppressed, we expect proprioceptive feedback to be considered in cases where visually-guided movement is kinesthetically awkward. Using rich trajectory measurements from a VR system, we compared performance between participants who appeared to adopt different strategies guided either by visual or proprioceptive feedback. In summary, the purpose of the present study was to quantitatively compare reaching strategies in a novel VR task across normal- and reversed-motion environments and to determine whether changes in reaching strategies persist when visual and proprioceptive information are re-coupled.

## Experiments

In the present study, we examined whether humans can adapt to environments where visual estimates of objects' positions are inconsistent with proporioceptive input. Participants interacted with virtual targets using two motion controllers in a VR application, where the movement of the virtual controller either matched the motion of the physical controller or was flipped on certain axes (both vertical and left-right). Participants were instructed to touch a series of virtual targets with the virtual controllers and then return to a neutral pose in between targets. Response time and arm movement trajectories were recorded and analyzed.

## Participants and Apparatus

A total of 20 participants ( 10 female and 10 male) participated in the study. Participants were graduate students at the University of California, Los Angeles. The average age of participants was 22.8 years old with a standard deviation of 2.67. All participants had normal or corrected-to-normal vision. Of the 20 participants, 16 had never interacted with VR technology prior to participating in the experiment.

The VR system integrated Unreal Engine 4 with an HTC Vive headset and two motion controllers, one held in each hand. 3D meshes which matched the Vive motion controllers in size and shape were used to represent controller position in the virtual environment. To generate the visual display of reversed movement, the virtual controller in VR was moved in opposite directions (i.e., in both the vertical and left-right
axes) to the physical displacement of the controller moved by human participants in the real world (Fig. 1). Participants began the experiment by moving their hands into a neutral pose where the physical and virtual controllers were aligned to the same position. Movement along the depth axis (i.e., forward vs. backward) was not reversed.

The targets were cyan capsules of 20 cm height and diameter. We chose cyan as the color of the targets in order to ensure the targets would be visible against the background of the environment. The targets began glowing when touched by a controller, providing visual feedback to the subject indicating whether they had successfully touched the target. The color of the targets did not change between experimental sessions. To ensure that for any given target location each participant reached approximately the same distance, we required that the participants assume a neutral pose before the next target was spawned. We define the neutral pose as follows:

At the beginning of each testing block, participants were told to hold both controllers in front of them at waist level with their elbows held loosely at their sides. Participants were allowed to adjust their pose until they were comfortable, but were informed that they needed to be able to comfortably reach forward, up-down and side-to-side from this pose. Participants then started an experimental block by pressing the trigger button on the bottom of either motion controllers. A transparent rectangular prism was spawned such that its center was located at the midpoint of the two controllers. This rectangular prism defined each participant's neutral zone, and we considered the participant to be in a neutral pose when both controllers overlapped with the neutral zone for an uninterrupted 0.5 seconds. In order to provide feedback to the user about whether they were in a neutral pose, the neutral zone changed color to reflect how many controllers overlapped with it: black for zero controllers, grey for one, and green for two. The neutral zone only changed color when the participant needed to enter a neutral pose, and otherwise remained green.

Response time was defined as the duration between the initial spawning of the target to when it was deactivated. Trajectory was defined as the three-dimensional movement of the controllers over this time period. For a video demonstrating the experimental setup, please see https://vimeo.com/216580864.

## Procedure

The experiment was conducted in a quiet office, and all physical obstacles were removed from the testing area. Participants remained standing and stationary for the duration of the experiment. They received a warning signal if they moved near the boundaries of the virtual environment.
Practice Session First, participants familiarized themselves with the VR headset and motion controllers. Participants were given a demonstration of the neutral position and told to move both of their controllers to the indicated locations. After participants confirmed that they were capable of comfortably performing the required range of movements from their neutral pose, they were informed that both response time and movement trajectories would be recorded. Prior to the testing session, participants completed a practice session with five

(a)

Figure 2: Response time analysis for the normal- (N1 and $N 2$ ) and reversed-motion ( $R 1$ ) trial sessions. Red horizontal lines indicate median response times. The bottom and top edges of the blue boxes indicate the 25 th and 75 th percentiles, respectively. The whiskers extend to the most extreme data points that were not considered outliers, and red ' + ' symbols indicate outliers. (a) Session median times to reach targets: $1.29,5.71$ and 1.03 seconds. (b) Block median times to reach targets: $1.30,1.22,1.34,6.10,5.68,5.36,1.13,1.06$ and 0.94 seconds.
targets in the normal condition. This session served to familiarize participants with the experimental procedure and provide the experience of interacting with objects in the virtual environment.

Testing Session Participants completed nine blocks consisting of ten trials each. The first three blocks ( $N 1$ session) were completed with normal movements. The subsequent three blocks ( $R 1$ session) were completed with reversed movements. Participants were informed along which axes arm movement would be reversed (i.e., the left-right and updown directions). The last three blocks ( $N 2$ session) were completed with normal movements once again. Participants were given breaks between blocks to rest their arms. After indicating that they were ready to continue, participants proceeded to the subsequent block.

At the start of each block, the virtual meshes were aligned with the locations of the physical controllers. Each participant completed the same nine blocks. Target locations were evenly distributed throughout an $80 \times 20 \times 80 \mathrm{~cm}$ region located 35 cm in front of the neutral zone. The order of the target positions within each block was randomized between participants.

## Results

## Response Time Analysis

As expected, participants showed much longer response times (RT) in the reversed-motion condition than in the normalmotion condition. There was a four-fold increase between median RT for the $N 1$ relative to the $R 1$ session. Interestingly, upon returning to normal movement in the $N 2$ session, participants showed a $20.1 \%$ improvement in response time compared to the $N 1$ session $(t(600)=7.07$, $p<.001$; see Fig. 2a). Moreover, response times in the three blocks of the $N 2$ session displayed a decreas-

Figure 3: Trajectory analysis using DTW to quantify the discrepancy between human reaching behavior and a linear motion trajectory - the straight line between the hand's starting position and target location. Median distance scores for each session: $505.62,613.24$, and 483.55 cm . Block medians: 501.03, 525.70, 496.62, 671.75, 648.25, 582.34, 513.57, 490.28 , and 435.84 cm .
ing trend $(b=-0.0067[-0.0101,-0.0033])$, indicating a learning effect that was not present in the $N 1$ session ( $b=$ $-0.0009[-0.0053,0.0035])$; Fig. 2b).

## Trajectory Analysis

Next, trajectory analysis was performed to further quantify human performance relative to candidate trajectories. We define the baseline trajectory as the shortest linear path between the hand start position and the target location. All trajectories were interpolated to 500 3D points to account for variation in trajectory length. Dynamic Time Warping (DTW) was then utilized to determine the minimum distance mapping between the ideal and behavioral trajectories. DTW is a distance measure algorithm that has been used extensively in the speech recognition community (e.g. Berndt \& Clifford, 1994). By estimating a non-linear mapping between two time-dependent sequences, DTW provides a numerical representation of the similarity between any pair of spatiotemporal sequences. Other communities including robotics and biology have also adopted and modified this algorithm for various signal-comparison applications.

The DTW trajectory distance measure revealed closer correspondence to baseline trajectories in the $N 2$ session compared to the $N 1$ session (Fig. 3a), suggesting a learning effect through practice. There was also a clear decrease in DTW distance across the three blocks within the $N 2$ session that was not evident in the $N 1$ session (Fig. 3b), suggesting humans moved their arms more linearly (i.e., closer to the baseline linear trajectory) upon return to the normal motion environment. To rule out the possibility that the increasing linear movements in the $N 2$ session was due to familiarization with the VR system, we performed a linear regression on the median trajectory difference among participants (Fig. 4). Although there is no noticeable trend in the $N 1$ session, performance in the $N 2$ session shows a strong improvement that falls well outside the $95 \%$ confidence region for $N 1$. Moreover, the slope in $N 2$ was approximately equal to that in the $R 1$ session, although the regression coefficient in the $R 1$ ses-

Figure 4: Linear regression results using median DTW distance among 20 subjects across 90 trials divided into 3 sessions and 9 blocks. Red dashed lines represent 95\% confidence intervals for the regression coefficient estimates. Slopes in the three sessions are $0.216,-3.810$, and -4.436 .
sion is more uncertain: i.e., the confidence interval of the $R 1$ slope is greater than that of $N 2$. This suggests a large degree of within-group variability, which is further explored in the following sections.

After forming new visuomotor mappings in the the $R 1$ session, participants' movement trajectories became increasingly linear: i.e., closer to the baseline trajectory. If participants began relying on visual feedback when constructing and revising their motor plans (i.e., proprioceptive inputs were suppressed), we would expect them to execute linear movement paths. The increasingly linear motor movements over the course of the $R 1$ session are consistent with this prediction. Interestingly, reliance on visual inputs appeared to persist in the following $N 2$ session when proprioceptive and visual information were recoupled. We predict that with further exposure to the normal-motion environment, the linearity of participants' reaching patterns would return to the level measured in the $N 1$ session.

## Possible Planning Models in Reversed Motion Blocks

While the shortest linear path between two points is the most direct trajectory, it is not necessarily the most optimal reaching strategy: e.g., due to mechanical limb constraints. To examine this, we used DTW to compare against other candidate trajectories to assess their potential as possible movement strategies. One possible alternative strategy is to consider each axis independently in order to plan motor movements in the reversed motion condition. To examine this alternative strategy, human trajectories were compared to all six possible axis decompositions (Fig. 5a) using DTW. While some participants did demonstrate paths that were more similar to various axis decompositions, participants' trajectories were generally more similar to the shortest linear path (Fig. 3b), indicating that most participants were not considering each axis independently.

Another observation of participants' trajectories is that they were noisy, especially during the reversed motion session. Since participants were instructed to reach a set of given targets, their movements were goal-directed and partially guided. We compared participants' trajectories with predictions from a guided random walk model Pearson (1905).

Figure 5: (a) Six possible axis decompositions were generated by computing the shortest path along each axis. (b) Human trajectories were compared against all six axis decompositions using DTW, and the minimum value was reported. Session medians: $736.72,734.38$, and 661.90 cm . (c) 10 of the guided random walks generated between the given start and end point. (d) Human trajectories were compared against 100 guided random walks using DTW, and the most similar value was reported. Block medians: 315.03, 307.15, 300.95, $522.34,515.89,452.21,310.25,278.97$, and 247.46 cm .
Given a starting point, a set of 100 proposed moves were generated within a 5 cm radius. Next, the model computed the distance between each of the proposed movements and the end point. A movement was then chosen from two options: 1) the shortest distance with probability .2 , or 2 ) randomly chosen movement among the 100 (random) proposed movements with probability .8. Finally, after approximately a few hundred iterations, the guided random walk model converged and reached the end point, as shown in Fig. 5c. Measured by DTW, human movement trajectories were found to be more similar to the guided random walks not only during the reversed-motion session but also during both normal-motion sessions (Fig. 5d). The fit of the model predicted trajectories to human performance across all the three sessions suggests that participants' motor movements were goal-directed but executed with inherent motor noise.

## Movement Strategies in Reversed Motion Blocks

In the normal-motion sessions, participants consistently used both arms to perform the reaching task, while favoring the controller closest to the target. In the reversed-movement session, however, a variety of strategies emerged. Some participants predominantly used one hand regardless of the location of the target relative to their neutral zone. Others favored the hand that was furthest from the target. Thus, we further examined the distribution of participants' reaching strategies.

In certain experimental trials, touching the target with the nearest hand required the participant to reach across their body while looking in the opposite direction, due to the reversed axes. This pose is physically difficult to accomplish. In contrast, the participant could reach for the target with their opposite hand, resulting in a pose that was physically comfortable. However, this would require the participant to use the hand that was physically furthest away, which is highly nonintuitive (Fig. 6). The cost to execute a path is thus dependent on not just proximity but also kinesthetic ease of execution.

We examined the interplay between the two constraints (i.e., proximity and ease of motor execution) in planning motor movements. Criteria were defined as follows: a trajectory

Figure 6: Illustration of different movement strategies in the reversed-motion session. (a) Solid lines indicate the trajectories visualized in VR. Dashed lines indicate the corresponding real-world trajectories of participants' hands. Red trajectory indicates the path executed by the participant, and the blue trajectory indicates the shortest computed path from the opposite hand. In this case, the target is located to the left of the participant in the virtual environment. (b) The experimenter demonstrates the awkward pose with the shorter trajectory (top) and the equivalent comfortable pose with the longer trajectory (bottom).
is considered proximal if a participant uses the hand initially closest to the target, and considered distal if he uses the hand initially furthest from the target. The trajectory is considered awkward if it requires reaching across the body's center and smooth if it does not. These criteria result in four different trajectory categories: proximal-smooth, proximalawkward, distal-smooth, and distal-awkward (See Fig. 7). In the normal-motion sessions, participants strongly favored the proximal-smooth strategy, with the distal-awkward strategy occurring only in a few selected trials where the target was close to the mid-line. In the reversed motion session, participants demonstrated all three strategies except the distalawkward.

We performed k-mean clustering on participants' trajectories in the reversed-motion session and found that two stable clusters emerged. Cluster size was split evenly at ten participants each, indicating that half of the participants were more likely to use the proximal-awkward strategy and the other half

Figure 7: Four different trajectory categories. (a) Proximalsmooth.
(b) Proximal-awkward.
(c) Distal-smooth. Distal-awkward.

Figure 8: K-mean clustering ( $k=2$ ) results on reversed strategy. (Left) 10 participants favored distal-smooth reaching strategies, indicating that they were utilizing predictions about proprioceptive feedback and actively reasoning about whether the motions would lead to awkward movements, whereas (Right) the other 10 participants preferred proximalawkward reaching strategies, indicating that they primarily utilizing visual information.
were more likely to use the distal-smooth strategy. The former group favored visual proximity: i.e., they attempted to reach the target using the hand that was closest to the target. The latter group favored smooth motion: i.e., they used learned associations between proprioceptive feedback and visual movement to predict which hand choice would result in the least awkward pose. In this case, participants were required to imagine the potential trajectories and associated proprioceptive feedback to plan their movement. These findings suggest that humans adopt different strategies to cope with the novel task in the reversed motion session by focusing on either spatial proximity for efficiency or smooth motion to avoid impossible or awkward poses.

A linear regression analysis was performed on DTW measurements after separating participants into the two groups as shown in Fig. 9. It is clear that the pose-focused participants demonstrated greater improvement compared to proximityfocused participants, although this learning effect did not persist in the subsequent normal-motion session.

## Discussion

When planning motor movement according to misaligned visual feedback, proprioceptive feedback has been shown to be suppressed while attention to visual information is enhanced. We hypothesized that in the case of reversed virtual feedback, target-directed reaching movements would rely primarily on visual feedback and thus accord with candidate linear trajectories. This prediction is confirmed by participants in the reversed-motion session using only a single hand, which arguably arises due to the relative ease of forming new visuomotor mappings with a single arm compared to both arms simultaneously. We found that participants in the reversedmotion session ( $R 1$ ) exhibited a preference for linear trajectories, which agrees with increasing suppression of using proprioceptive information to guide motor movements. Interestingly, this increasing linear preference-and corresponding reliance on newly formed visuomotor mappings-persisted into the second normal motion session ( $N 2$ ) although it was not observed in the first normal session ( $N 1$ ). We predict that this bias toward linear movement strategies would diminish with

Figure 9: DTW distance to linear reaching trajectories for (a) reasoning-focused and (b) perception-focused participants. Those participants that utilized predictions about proprioceptive feedback to guide their reaching movements showed increasingly linear trajectories compared to those participants who primarily utilized visual information. Slopes in (a): -$0.11,-5.22,-4.58$. Slopes in (b): $-0.23,-2.10,-4.38$
further exposure to the normal-motion environment, as traditional sensorimotor mappings utilizing proprioceptive information are employed.

However, the main finding of the present study could have resulted from increased familiarity with the VR system and environment. Thus, a follow-up study to this experiment is to establish a second control condition where each of the three experimental sessions involve normal motion. If performance does not vary across the three normal sessions, the finding that reversed motion increases preference toward visuallyguided, linear motor movements would be strengthened. Additionally, movement in the virtual world was reversed on two axes (vertical and left-right) in the present study. Future work should examine how performance changes when a single axis-or different pairs of axes-are flipped. Moreover, would exposure to one reversed axis improve performance under a second (different) reversed axis?

Tactile signals are an important cue for planning and executing object interactions (Johansson \& Flanagan, 2009). One of the major disadvantages with current commercial VR products is that tactile feedback is missing in the virtual world. In the present study, we compensated for the lack of tactile feedback by using additional visual cues to indicate successful reach events; however this does not change the fact that a significant source of feedback is missing. For future studies it would be worth providing a haptic signal through the controller's actuators or using a tactile data glove to administrate more fine-grained feedback. We predict that implementing haptic feedback to the current experimental method would inhibit suppression of proprioceptive information and consequently interfere with the formation of new visuomotor mappings.

Future work should also examine sensorimotor recalibration in more complicated tasks than the present reaching movements: e.g., stacking blocks or completing towers of Hannoi problems. In these tasks, cognitive resources are devoted to planning a sequence of motor movements, which may yield strong interference to the visuomotor adaptation process and provide a unique window to study the interplay between motor planning and reasoning.

# The development of turn-taking: Pre-schoolers may predict what you will say, but they don't use those predictions to plan a reply. 

Laura Lindsay<br>University of Edinburgh, Edinburgh, United Kingdom<br>Chiara Gambi<br>University of Edinburgh<br>Hugh Rabagliati<br>University of Edinburgh, Edinburgh, UK

#### Abstract

Whereas adults exchange conversational turns very rapidly, children often respond after long gaps. However, it has been proposed that the infrastructure necessary to take turns develops in infancy. Why are children slow to respond to turns? Adults' turn-taking skills, it has been argued, rely on an ability to both predict when the current turn will end and prepare a response as soon as possible. In two experiments, we ask how these two abilities (prediction and early preparation) develop. Adults and 3-to-5-year-olds answered yes/no questions while playing an iPad-based maze game. Distributional analysis of answer latencies suggest that (i) neither children nor adults rely on fine-grained predictions of turn duration and (ii) both children and adults use predictions about turn content to prepare their answer early. In sum, by the age of three, children already have the cognitive architecture necessary to take turns successfully.,

# Mouse Tracking Shows Attraction to Alternative Targets While Grounding Spatial Relations 

Jonas Lins (jonas.lins@ini.rub.de) Gregor Schöner (gregor.schoener@ini.rub.de)

Institut für Neuroinformatik, Ruhr-Universität Bochum, 44780 Bochum, Germany

#### Abstract

Evidence that higher cognitive processes are coupled in a graded and time-continuous way to sensory-motor processes comes, in part, from mouse-tracking studies. In these, curved mouse trajectories toward one of two fixed response locations reveal the evolution of certainty about a cognitive task that participants solve. We present a paradigm in which selection of the response location is itself the cognitive task. From among items in a visual scene, participants select a target that is described by a spatial relation (e.g.,"the red to the left of the green"), where one target item (here, "red") matches the description better than alternative same-colored targets. In the mouse trajectories, we find clear evidence for attraction to the alternative targets, attraction to the reference item (here "green"), and an early biasing influence of the spatial term.

## Introduction

Over the last two decades, a major theme in cognitive science has been that cognitive processing is graded in nature, unfolds continuously in time, and is coupled to perceptual and motor processes (Schöner, Spencer, \& the DFT Research Group, 2015; Spivey, 2007). Movement preparation, for instance, was shown to occur in a graded and continuous form when the time interval between imperative stimulus and response was varied experimentally in the timed movement initiation paradigm (Ghez et al., 1997). The theoretical account (Erlhagen \& Schöner, 2002) linked this phenomenon to graded distributions of population activation in the motor and premotor cortex (Bastian, Schöner, \& Riehle, 2003; Cisek \& Kalaska, 2005). That higher-level cognitive processes, such as understanding spatial concepts, interact with perceptual and motor processes has been seen through interaction effects in reaction time tasks that probed potentially overlapping perceptual and motor representations (e.g., Richardson, Spivey, Barsalou, \& McRae, 2003). Mouse tracking and similar techniques have been a major tool to study and establish this link between cognitive and sensory-motor processes (for review see Freeman, Dale, \& Farmer, 2011; Song \& Nakayama, 2009).

In mouse tracking paradigms, participants are asked to solve a cognitive task that may engage high-level concepts. The response is usually ensured to begin early in relation to the decision process, analogously to the timed movement initiation paradigm. Typically, a computer mouse must be moved toward one of two (sometimes a few) response locations. What varies over time is the certainty over the response, which is reflected by the movement deviating somewhat into intermediate directions. A limitation of previous mouse tracking research with respect to the interaction of cognitive and sensorimotor processes is that the motor responses are usually fixed and assigned symbolically to the
solutions of the cognitive task (e.g., left button for "yes" and right button for "no"). When a small number of possible movement targets is known in advance, it is not the decision itself that specifies the metrics of the required movement.

We developed an experimental paradigm in which the spatial target of a mouse movement was directly specified by the cognitive task and unknown in advance. Participants read a target description invoking colors and spatial relations (e.g., "the yellow to the left of the green") and then saw a complex layout of colored objects (e.g., Fig. 1c). A selection decision had to be made among multiple same-colored target items ("yellow"), clicking the one best matching the spatial term. Although some aspects of the visual arrays are tightly coupled and impossible to vary independently, we were able to unravel their effects by counter-balancing those aspects that posed potential confounds, separately for each comparison.

We looked for three signatures of interaction among the task's cognitive and sensory-motor dimensions. First, the alternate targets (i.e., distractors) were predicted to metrically attract the trajectories, in analogy to the effect of alternate but incorrect choice alternatives in classic mouse tracking research. Second, while the reference item is never an alternate target, it likely engages attentional focus during processing (Franconeri, Scimeca, Roth, Helseth, \& Kahn, 2012), which we predicted to also cause attraction. Third, based on previous evidence (Tower-Richardi, Brunye, Gagnon, Mahoney, \& Taylor, 2012), we expected a bias into the direction described by the spatial term. In our recent neural process model of spatial language grounding (Richter, Lins, \& Schöner, 2017), discrete amodal representations of target, reference, and spatial term guide activation in continuous perceptual representations. In the model, target and reference must become active sequentially, because overlapping substrates are engaged to spatially index the corresponding visual items. We thus expected some temporal displacement in the biases toward these items. The spatial term, in contrast, impacts another substrate and is active early and in parallel to target and reference. We thus expected the spatial term effect to bias movement metrics globally and early on.

## Methods

Participants Twelve participants ( 5 female, 7 male, mean age 27.4 years $\pm 3.8$ s.d., one left-handed) were recruited by notices at the local department, receiving EUR 10 for participation. All were naïve to the experimental hypotheses, native German speakers, and had normal vision.

Material The experiment was run using Matlab and the Psychophysics Toolbox (Brainard, 1997) and presented on a 22 " LCD screen (Samsung, 226BW; visible image $475 \mathrm{~mm} \times$ 197 mm ) at a viewing distance of approximately 70 cm (subtending approx. $40.4^{\circ} \times 16.2^{\circ}$ of visual angle, v.a.). Trajectories were collected using a standard computer mouse (Logitech, M-UAE96, mean sampling rate 92.17 Hz ). Mouse speed was set such that movement on the tabletop translated to cursor movement over the same distance, to make motions more similar to natural arm movements and simplify cognitive transformation from hand coordinates to screen space.

Procedure A trial began with a black start marker in the bottom center of an otherwise gray screen. To proceed, the participant moved the mouse cursor (a white dot) onto the start marker. After resting there for 300 ms , a German spatial phrase appeared at a position somewhat random around the center of the stimulus region (up to $\pm 48 \mathrm{~mm} / 20 \mathrm{~mm}$ horiz./vert.), for instance, "Das Gelbe links vom Grünen." ("The yellow left of the green."), denoting a target item by its color and its position in relation to a reference item, which was also specified by color. Display duration ranged randomly from one to two seconds. The phrase then disappeared and a beep signaled the participant to start moving the cursor upwards within one second (if movement started too late, the trial was aborted and appended at the end). Movement onset was registered when a velocity of $20 \mathrm{~mm} / \mathrm{s}$ was exceeded. At that point, twelve colored items appeared above the start marker (e.g., Fig. 1c). Thus, movement was already in progress when the selection process started. One of the twelve items was the uniquely colored reference mentioned in the phrase, one was the target, and one was the main distracter, which had the same color as the target but provided a worse match for the spatial term, according to a spatial template described below. The participant had to select the item which in his or her opinion best matched the preceding phrase (participants could select any item). If time since movement onset exceeded two seconds, the trial was aborted and appended at the end. Participants were instructed that there were no incorrect responses, that items were not obstacles, and that response time was limited such that they had to respond promptly. After 13 practice trials, each participant completed 446 trials in random order (one completed eight more, to use the entire set of 5360 trials, described below).

Spatial phrases Spatial phrases were in German and of the form "Das art Grüne $_{\text {tgt }}$ rechts vom ${ }_{\text {spt }}$ Roten $_{\text {ref }}$ " ("The ${ }_{\text {art }}$ green $_{\text {tgt }}$ to the right of spt $^{\text {the }}$ red $_{\text {ref }}$ "), where art denotes the article, which was always "Das", tgt denotes a target component from the set \{Rote, Grüne, Blaue, Gelbe, Weiße, Schwarze\}, ref denotes a reference component from the set $\{$ Roten, Grünen, Blauen, Gelben, Weißen, Schwarzen\} ("the \{red, green, blue, yellow, white, black\} one"), and spt denotes a spatial term from the set \{links vom, rechts vom, über dem, unter dem \} (\{left of, right of, above, below \}). In all trials, the spatial phrase posed a valid
description of an item in the stimulus display.
Stimulus displays Visual items were irregular polygons with an outer diameter of 16.4 mm ( $1.34^{\circ}$ v.a.), each colored in one of the six colors that also occurred in the spatial phrases (red, green, blue, yellow, white, and black). Items were combined into stimulus displays as described in the following.

We generated multiple three-item configurations of a reference item, a target item, and a distracter, differing in how target and distracter were situated relative to the reference. Their positions were selected based on a spatial template, a fit function $f(\phi, r)$ with the reference at $[0,0]$ that indicates how well a given position, defined by angle $\phi$ and radius $r$, matches a spatial term. ${ }^{1}$ Fig. 1a (left panel) shows a plot over Cartesian coordinates for "right of". The shape of the spatial templates is inspired by behavioral data (e.g., Logan \& Sadler, 1996) which computational modeling work reproduced using similar functions (Lipinski, Schneegans, Sandamirskaya, Spencer, \& Schöner, 2012).

Targets were placed in a region where $f(\phi, r)>0.6$ and where the outer radices of reference and target were separated by at least $0.5 \mathrm{~mm}\left(0.04^{\circ}\right.$ v.a.; Fig. 1a, center panel). Within this region, targets were centered on the junctions of a square grid, resulting in sixteen evenly distributed target positions. For each of the 16 target positions a separate set of distracter positions was determined (out of which one distracter was used per trial, paired with the respective target). These were obtained with the same method as the targets, but the general region for distracters was constrained by $f(\phi, r)>0.4$ (green outline in Fig. 1a, center panel), and as an additional constraint distracters' fit had to be at least 0.03 lower than target fit (min. border-to-border distance again 0.5 mm ; see Fig. 1a, right panel). Hence, the shape of distracter regions differed between target positions so that distracter numbers differed as well, varying from 16 to 25 (mean 20.9) per target position. Colors for each three-item set were randomly picked, with target and distracter being colored alike.

A set of 335 different three-item configurations was obtained for each spatial term, differing between terms only in orientation. We thus arrived at 1340 configurations, each of which was presented at four different positions on the screen, such that the target item of each configuration appeared once in each of four different on-screen target locations (black X's in Fig. 1b). These were arranged in a square around the cen-

$$
\begin{aligned}
& { }^{1} \text { In polar coordinates the function is given by } \\
& f(\phi, r)=e^{\left[-\frac{\left(\phi-\phi_{0}\right)^{2}}{2 \sigma_{\phi}^{2}}\right]} \cdot e^{\left[-\frac{\left(r-r_{0}\right)^{2}}{2 \sigma_{r}^{2}}\right]} \cdot\left(1+e^{\beta\left(\left|\phi-\phi_{0}\right|-\phi_{\text {fex }}\right)}\right)^{-1}
\end{aligned}
$$

where $\phi$ denotes polar angle, $r$ is the radius, $\phi_{0}$ is the mean of a Gaussian function over angle, $\sigma_{\phi}$ is its standard deviation, $r_{0}$ and $\sigma_{r}$ are analogue parameters for a Gaussian over radius, $\beta$ is the steepness of a sigmoid function over angle, and $\phi_{\text {flex }}$ is the separation of its inflection point from the mean of the Gaussian over angle. We used $\sigma_{\phi}=1.05, r_{0}=0 \mathrm{~mm}, \sigma_{r}=47 \mathrm{~mm}, \beta=25$, and $\phi_{\text {flex }}=1.45$. Parameter $\phi_{0}$ depended on the spatial term, with "right of", "above", "left of", and "below" corresponding to $\phi_{0}=\left\{0, \frac{\pi}{2}, \pi, \frac{3}{2} \pi\right\} \mathrm{rad}$.

Fig. 1: (a) left panel: Spatial template for "right of". (a) center panel: General item regions defined by fit and distance constraints. White outline denotes outer radius of reference item. (a) right panel: One specific three-item configuration (target in red, distracter in green). The green dotted line here shows the region where distracters were placed for that specific target position. (b) Experimental screen area with regions and locations constraining stimulus placement; item arrangement for "left of". The red dot corresponds to the reference item, the closer green dot on the left corresponds to the target item, and the green dot below that to the (main) distracter. The green dot on the right is the opposite distracter. Gray dots are fillers. Black X's are potential target positions, the yellow diamond marks the center of mass of all items, the dotted square denotes the region generally eligible for item placement, and the dashed gray line illustrates the direct path to the target. The start marker is located at the bottom center (black dot). (c) The stimulus arrangement from (b) as viewed by the participants.
ter of the stimulus region, at a distance of $28.3 \mathrm{~mm}\left(2.32^{\circ}\right.$ v.a.) horizontally and vertically. Restricting target positions to a few fixed locations and having the stimulus array sample space around those locations alleviated the common problem of different movement metrics for different spatial locations.

Nine filler items were added to each trial, each colored randomly in one of the four remaining colors. Locations were restricted to a square region of 184 mm ( $15.1^{\circ}$ v.a.) side length, whose midpoint was 200.8 mm ( $16.6^{\circ}$ v.a.) straight above the start marker. The center of mass (CoM) across all 12 visual items had to be congruent with the center of that region ( $\pm 0.8 \mathrm{~mm}$ ) so that it was identical across conditions and positioned in the horizontal screen center, allowing to more easily partial out a putative bias to either one (a bias to the horizontal screen center was expected because the items appeared only as soon as upward movement was detected). Fillers retained a border-to-border distance of at least 0.5 mm . Locations were random otherwise. Finally, as an additional incentive to evaluate the spatial relation, in some trials ( $27 \%$ ) one filler was turned into an additional distracter by giving it the same color as target and (main) distracter. It had to be located on the side of the reference opposed to the spatial term, and separated from the reference along the term's axis (e.g., horizontal for "right of") by at least 28.3 mm ( $2.32^{\circ}$ v.a.).

The full stimulus set included 335 configurations $\times$ 4 spatial terms $\times 4$ target positions $=5360$ trials, which were randomly assigned to the twelve participants.

## Analysis

We analyzed only trials where participants selected the item best matching the spatial phrase according to the fit function (hereafter called target). We refer to the straight line from a trajectory's first point to the target item's center as direct path.

Sharply curved trajectories were discarded from analyses, in order to consider only trajectories exhibiting graded attrac-
tion while excluding re-decisions in mid-flight and mouseovershoots. Curvature was assessed by temporarily interpolating to a uniform segment length of 5 mm and then applying the osculating circle method (considering each vertex and its two neighbors). Trajectories exceeding a curvature of 0.1 were discarded. We chose this approach over other values such as area under curve (Hehman, Stolier, \& Freeman, 2015), as these are less informative in a setup with multiple potential effect sources on both sides of the direct path.

Trajectory preparation Trajectories were trimmed to start with movement onset and to end with the first data point after crossing the target border. They were then translated to start at $[0,0]$ and rotated around that point by the angle between the target's position vector and the $y$-axis. Positive $x$-values thus denote deviation from the direct path to the right, negative values indicate leftward deviation. Trajectories' spatial coordinates were linearly interpolated over 151 equidistant time steps to enable averaging (combining position data from identical values of elapsed proportion of total movement time).

Statistical analysis Mean trajectories were compared by testing for differences between x-coordinates at each of the 151 time steps using two-tailed paired-sample t-tests with $p<0.01$. Since data points in each mean trajectory are highly interdependent, and given the large number of tests, the informative value of each individual t -test is limited. To remedy this, we used the bootstrapping procedure introduced by Dale, Kehoe, and Spivey (2007), providing a criterion for how many t-tests in sequence must yield significance before a difference between trajectories can be considered overall significant. A separate criterion with $p<0.01$ was computed for each comparison based on 10,000 artificial experiments each.

Balancing to isolate main effects To obtain unbiased estimates of the individual effects of distracter, reference, and CoM position by comparing two conditions (e.g., all trials
where the distracter was left versus right of the direct path), the impact of the others (e.g., reference and CoM side) must be taken into account. For this, we distinguished trials into categories that indicated whether a potentially confounding item was on the same or opposite side of the direct path as the item of interest. There was a different set of four categories for each item of interest. For instance, balancing categories for the distracter effect were rs/cs, rs/co, ro/cs, and ro/co, " $r$ " denoting the reference, " $c$ " the CoM, and " $s$ " and " $o$ " denoting whether the respective item was on the same or opposite side of the direct path as the distracter. Corresponding categories for considering reference and CoM were named analogously ("d" denoting the distracter). When comparing two sets of trials for one effect, balancing out the other two then works by ensuring that each set is composed of an equal number of trials from each relevant balancing category. This requirement is not fully satisfied by our full set of trials and some comparisons. To allow judging how imbalances may have affected the respective data, Fig. 2 plots the distribution of trial numbers over the relevant balancing categories alongside each comparison. To further validate that observed effects were not due to imbalances, post hoc balancing was conducted: We did a second analysis for each comparison, identical to the one performed on the full trial set, but beforehand randomly discarded trials from over-represented categories such that a balanced distribution was obtained within each condition and participant. We report when this substantially changed effects. For the overall mean trajectory, categories were based on item sides relative to the direct path. Category labels used the same letters as above, in addition to "l" (left) and "r" (right; e.g., dr/rl/cl means that the distracter was on the right and the other items on the left side).

## Results

A total of 5245 trajectories was obtained ( 115 were lost due to technical problems) and participants selected the best-fitting item in 4710 (mean $89.82 \% \pm 3.3$ s.d.). Of these, 446 ( $9.47 \%$ ) exceeded curvature threshold, leaving 4264 (81.3\%) for analysis. Mean movement time was $1061 \mathrm{~ms}( \pm 116$ s.d.); noteworthy differences occurred only between upper and lower target positions ( $1140 \mathrm{~ms} \pm 119$ s.d. and 977 ms $\pm 114$ s.d.). Participants reported not to have noticed that target positions were limited to four locations.

Fig. 2 shows mean trajectories for all comparisons, along with trial distributions over balancing categories for each condition. The overall mean trajectory (Fig. 2a) slightly curved rightwards, likely reflecting kinematic bias. To provide an idea of this bias in relation to other effects, dotted gray lines in each panel of Fig. 2 show the mean over trials from the compared conditions. As expected based on the task instructions, a strong bias toward the CoM was evident (Fig. 2b).

We report statistical test results in this form: 46/8, 5-50\%, providing the number of successive significant time steps (46) along with the bootstrap criterion for overall significance (8), followed by the percentages of elapsed movement time at the
start and end of the sequence (5-50\%). Considering all trials, there was a significant bias away from the reference side in the first half of the movement (57/6, 1.3-38.4\%; Fig. 2c) and a significant bias in reference direction in the second half (52/6, 66.2-100\%). Assessing the effect of reference side separately for trials with horizontal-axis spatial terms ("left" and "right") and for vertical ones ("above" and "below") showed that the bias away from the reference was driven by the horizontal term trials (69/30, 1.3-46.4\%; Fig. 2d). Note that in these trials deviation away from the reference is congruent with spatial term direction. Correcting for the overrepresented distracter-opposite trials (cs/do, co/do) by post hoc balancing did not remove the effect (70/47, 1.3-47\%; Fig. 2f). The later bias toward the reference was driven by the vertical spatial term trials (94/31, 38.4-100\%; Fig. 2e). Post hoc balancing showed that it was not due to the overrepresented distracter-same trials and resulted in an earlier onset of the reference effect (102/31, 33.1-100\%; Fig. 2g).

As shown in Fig. 2h, there was a sustained, significant bias in distracter direction for the whole trial set (100/15, $33.4-100 \%$ ). Assessing the effect separately by spatial term axis showed that the effect's early component was driven exclusively by horizontal term trials (140/6, 8-100\%; vertical: 86/33, 43.7-100\%; Fig. 2i,j). These included a pronounced majority of reference-opposite trials (ro/cs, ro/co), suggesting that the distracter effect's early component may in fact be a bias in spatial term direction (i.e., away from the reference), as reported above. Post hoc balancing indeed reduced the distracter bias to the second half of the movement (81/8, $47-100 \%$; Fig. 2k). Post hoc balancing the vertical term trials left the effect largely unchanged (89/11, 41.7-100\%; Fig. 21).

Post hoc balanced vertical term trials (Fig. 2g) provide the most unbiased estimate of the reference effect. Comparing its onset in these trials to that of the distracter effect in the analogous comparison (Fig. 21) shows an earlier onset of the reference effect by $8.6 \%$ of movement time (equaling 91.1 ms , based on mean movement time in these trials).

## Discussion

We have described a mouse tracking paradigm in which unknown spatial targets were specified by the task through a relational description and demonstrated how influences from multiple effect sources in such a setup may be disentangled.

As predicted, distracters attracted mouse paths, similar to decision alternatives in classic mouse tracking studies (e.g., Dale et al., 2007). The predicted attraction toward reference items was observed as well, for the spatial terms "above" and "below". Moreover, as hypothesized, a bias in spatial term direction was present from early on for horizontal-axis spatial terms. We interpret this as a spatial term effect rather than repulsion from the reference based on the very early onset (note that the spatial term was not predictive of absolute target location in the paradigm) and in line with previous evidence (Tower-Richardi et al., 2012). Its apparent absence in vertical term trials is unsurprising, as it would act orthogonally to the

Fig. 2: Mean trajectories and comparisons between conditions. Trajectory plots show the distance from the direct path to the target $(x=0)$ against the proportion of elapsed movement time. Negative values indicate leftward deviation and vice versa. Conditions compared within a panel differ with respect to the position, relative to the direct path, of either the center of mass $(\mathrm{CoM})$, the reference item (Ref), or the distracter ( Dtr ). Blue and red circles in the top of each plot indicate the direction in which the item of interest was situated for the trajectory in the same color. Gray dotted lines represent the mean across all trajectories in the two compared conditions. Color-coded p-values and effect sizes (absolute Cohen's d) for each time step are shown on the left and right side of each plot. The black line on the left side of each plot indicates individual significant t-tests $(p<0.01)$ at the spanned time steps. Asterisks next to these lines indicate overall significance ( $p<0.01$ ) for a given sequence of individually significant time steps (based on bootstrap criterion; see Methods for details). A bar graph below each trajectory plot shows the distribution of trials over categories relevant for counter-balancing in the respective comparison; bars correspond to trajectory lines of the same hue. (a) Mean across all trials. (b) Means by CoM side, (c) by reference side, across all trials, (d) by reference side, only including trials with spatial terms "left" and "right", (e) by reference side, only including trials with spatial terms "above" and "below"; (f) and (g) show the same comparisons as (d) and (e), but with a post hoc balanced set of trials. (h) Means by distracter side, across all trials, (i) by distracter side, only including trials with spatial terms "left" and "right",(j) by distracter side, only including trials with spatial terms "above" and "below"; (k) and (l) show the same comparisons as (i) and (j), but with a post hoc balanced set of trials.
axis along which deviation was assessed. This may also explain why reference attraction is visible only in vertical term trials: If the spatial term effect impacts the entire length of trajectories as hypothesized, the two effects may cancel each other out in the late portion of horizontal term trials.

The attraction to the reference item confirms that it engages spatial attention during relational processing (e.g., Franconeri et al., 2012), even when it is unique in color. This may hint that spatial indexing (Logan \& Sadler, 1996) of its position is mandatory for grounding. It further suggests that computationally relevant non-targets can impact the motor level.

The observed distracter attraction is reminiscent of reaches to average locations under target uncertainty (e.g., Chapman et al., 2010). Aspects specific to relation grounding may as well play a role, though, for instance, through locations in a neural map being differentially activated by a relational template. A hint at this interpretation is the small extent of distracter attraction compared to a mean distracter distance to the direct path of 20.59 mm , calling into question mere averaging. The latter aspect, as well as the early spatial term effect, the mandatory reference selection, and the offset time courses of reference and distracter attraction, parallel our neural process model of grounding, in which item positions are sequentially stored in distinct neural substrates to apply a concurrently active, graded relational template (Richter et al., 2017).

There is ample room for new research in the direction suggested here. One step may be to clarify in how far distracter attraction is specific to relational processing. The temporal order of effects must be probed more formally. Finally, higher cognitive processes may further be unraveled through additional variations of spatial phrase structure or visual displays.

## Conclusion

As participants perceptually ground spatial phrases such as "the red to the left of the green", they attend to potential target objects (here, red ones) and typically select the one best matching the spatial relation. Mouse trajectories toward the ultimately selected target reveal transient biases in multiple directions. First, they show attraction to the alternative targets, consistent with previous evidence. Second, an attraction to the reference object ("green") begins somewhat earlier and may reflect allocation of spatial attention. Third, a bias in spatial term direction is present from early on. Overall, this study frames motor responses as direct reflections of the perceptual grounding of spatial phrases, bringing evidence for the coupling of cognitive to sensory-motor processes to a new level.

#### Abstract

Probabilistic prediction is a central process in language comprehension. Properties of probability distributions over predictions are often difficult to study in natural language. To obtain precise control over these distributions, we created artificial languages consisting of sequences of shapes. The languages were constructed to vary the uncertainty of the probability distribution over predictions as well as the probability of the predicted item. Participants were exposed to the languages in a self-paced presentation paradigm, which provides a measure of processing difficulty at each element of a sequence. There was a robust pattern of graded predictability: shapes were processed faster the more predictable they were, as in natural language. Processing times were also affected by the uncertainty (entropy) over predictions at the point at which those predictions were made; this effect was less consistent, however.

Keywords: Entropy, prediction, statistical learning, artificial language, psycholinguistics

## Introduction

Our environment is characterized by recurring temporal patterns; the sound of an ambulance siren, for example, tends to predict the appearance of an ambulance. Humans can quickly learn to exploit these contingencies between stimuli to anticipate future events and react to those events more effectively. The ability to track dependencies across the elements of a sequence is central to language processing: prediction of upcoming words is employed during language comprehension (DeLong, Urbach, \& Kutas, 2005) and may play a central role in acquisition (Gómez, 2002).

Prediction in natural language is rarely categorical: there is generally some uncertainty as to the upcoming word. Rather than predict a single word or avoid making predictions altogether, readers maintain a probability distribution over the upcoming words: words that are more likely to come up are activated to a greater extent (Smith \& Levy, 2013). Probability distributions over predictions are often difficult to study in natural language, due to the need to find sets of words that happen to have the desired probabilistic relations in a natural corpus. The present study builds on work that shows that the processing of temporal contingencies can be studied using artificial language learning experiments. These experiments typically consist of a familiarization phase, in which participants are exposed to the artificial language, and a test phase, in which they are requested to distinguish sequences that follow the patterns of the language from sequences that do not. We use this paradigm to study probabilistic prediction in sequence learning and processing.

Quantifying probabilistic prediction: A predictive dependency is made up of two parts: the point at which the
prediction is generated (the predictive item) and the point at which it is matched against the incoming input (the predicted item). We study both parts of the process. At the predictive item, multiple probabilistic predictions can typically be generated. Higher uncertainty over the correct prediction may lead to increased competition among those predictions and slower processing. We follow earlier work in quantifying uncertainty using the entropy of the distribution over possible predicted items (Linzen \& Jaeger, 2014; Hasson, 2017):

$$
\begin{equation*}
H=-\sum_{w \in W} P(w) \log _{2} P(w) \tag{1}
\end{equation*}
$$

where $W$ is the set of possible items and $P(w)$ is the probability of $w$ in the current context. At the point at which predictions are matched against the input, input items that were predicted with a higher probability may be processed more quickly. In natural language, processing difficulty at an item $w$ is proportional to its surprisal $\left(-\log _{2} P(w)\right)$ : more surprising words tend to be read more slowly (Smith \& Levy, 2013). A final expectation-based measure that has been argued to be a reliable predictor of reading times (RTs) in natural language is uncertainty reduction: words that reduce uncertainty about the sequence to a greater extent are predicted to be read more slowly (Hale, 2003; Frank, 2013).

The experiments: We report two experiments designed to examine these quantitative measures of probabilistic prediction in artificial languages. In what follows, we briefly discuss our general methodological strategy.

In many artificial language learning experiments, the familiarization phase consists of passive exposure; as such, the only behavioral measure collected in these studies is the proportion of correct grammaticality judgments given after the familiarization stage is over. Recently, a number of online paradigms have been proposed that track the learning process as it unfolds over the course of the familiarization phase (Siegelman, Bogaerts, Christiansen, \& Frost, 2017). Online paradigms also provide an index of processing time at each individual item of the sequence, making them particularly well-suited to studying the generation and validation of predictions. We adopt one of these paradigms, the selfpaced reading paradigm (Just, Carpenter, \& Woolley, 1982), adapted to artificial language learning by Karuza, Farmer, Fine, Smith, and Jaeger (2014). In this paradigm, the elements of each sequence are presented sequentially; the participant controls when the next sequence element is revealed.

Previous studies of prediction have focused on sequences with nonadjacent dependencies: the sequence is of the form
$A X B$, where $A$ predicts $B$ (Karuza et al., 2014; Misyak, Christiansen, \& Bruce Tomblin, 2010). Instead, we use dependencies of the form $A B$, without an intervening element; such dependencies are in general easier to learn (Newport \& Aslin, 2004). By increasing the likelihood that our participants will learn the language, we can ask more fine-grained questions than would be possible using nonadjacent dependencies.

Summary of goals: We address the following issues:

1. Does the probability of the second shape $B$ given the first shape $A$ affect the processing of $B$ ?
2. Are processing times at the point where the prediction can be made (shape $A$ ) affected by the uncertainty of the probability distribution over predictions?
3. Does the reduction of uncertainty about the sequence at shape $B$ entail greater processing difficulty?

## Experiment 1

## Stimuli

Following Karuza et al. (2014), we used sequences of letters from the Ge'ez script, which is used to write several Ethiopian and Eritrean languages. We refer to these letters as shapes since none of our participants were familiar with this script. As in Karuza et al. (2014), our sequences consisted of three shapes. As we have mentioned, we omitted the intermediate shape - the dependency was adjacent. To keep the structure of the stimuli similar to the stimuli used in the previous study and to avoid task effects related to the beginning of a new sequence, all of the sequences started with a fixed shape $r$ (distinct from the $A$ and $B$ shapes). This shape was the same in all trials for a given participant and was not analyzed.

The language used in this experiment is described in Table 1 . Each participant was exposed to two types of $A$ shapes. Low entropy $A$ shapes were followed by one of two $B$ shapes, with probability $1 / 4$ and $3 / 4$ respectively. High entropy $A$ shapes were followed by one of four $B$ shapes, each with probability $1 / 4$. There were two $A$ shapes of each type, for a total of four $A$ shapes. None of the $B$ shapes were repeated across $A$ shapes: there were 12 distinct $B$ shapes. We refer to the $B$ shapes with a probability of $1 / 4$ as high surprisal shapes, and to shapes with a probability of $3 / 4$ as low surprisal shapes.

To control for potential differences in the visual complexity of particular shapes, the shapes that served as $a_{1}, a_{2}$ and $b_{1}, \ldots, b_{6}$ were counterbalanced across participants.

## Participants

A total of 44 participants ( 24 women and 20 men; age range: 20-28, mean age: 23.4) from the Hebrew University of Jerusalem community completed the experiments.

## Procedure

The experiment consisted of three phases: familiarization, test and a post-test phase.

| Shape $R$ | Shape $A$ | Shape $B$ | TP | Surprisal |
| :--- | :---: | :---: | :---: | ---: |
| High entropy: $(H=2)$ |  |  |  |  |
| $r$ | $a_{1}$ | $b_{1}$ | $1 / 4$ | 2 |
| $r$ | $a_{1}$ | $b_{2}$ | $1 / 4$ | 2 |
| $r$ | $a_{1}$ | $b_{3}$ | $1 / 4$ | 2 |
| $r$ | $a_{1}$ | $b_{4}$ | $1 / 4$ | 2 |
| Low entropy: $(H=0.81)$ |  |  |  |  |
| $r$ | $a_{2}$ | $b_{5}$ | $1 / 4$ | 2 |
| $r$ | $a_{2}$ | $b_{6}$ | $3 / 4$ | 0.41 |

Table 1: Half of the language used in Experiment 1 (the other half is duplicated: a high entropy $a_{3}$ paired with high surprisal $b_{7}$ through $b_{10}$ and a low entropy $a_{4}$ paired with a high surprisal $b_{11}$ and a low surprisal $b_{12}$ ). TP indicates the transitional probability between the $A$ and the $B$ shape (e.g., $\left.P\left(b_{1} \mid a_{1}\right)=1 / 4\right) . H$ indicates the entropy of each distribution.

Familiarization phase: Each trial started with a sequence of dashes where the shapes would be; participants pressed the spacebar to reveal the next shapes one by one. When a shape was revealed, the previous shape was replaced by a dash again. Before this phase of the experiment began, participants were instructed to try to remember the sequences, since they would be tested on them later on.

There were 288 sequences in this phase. This contrasts with the familiarization phase in Karuza et al. (2014), which consisted of 432 sequences; we chose to have a shorter familiarization phase because prediction effects in Karuza et al. (2014) plateaued about half way through the experiment. We further simplified their design by eliminating the catch trials meant to ensure that participants were paying attention. These trials were not necessary because we analyzed data only from participants who successfully learned the language: our assumption was that participants who were not paying attention would fail to learn the language.

Test phase: This phase consisted of 24 trials, each of which elicited a judgment for one sequence. All three shapes of the sequence were presented at once (not in self-paced presentation). Half of the trials contained sequences that had been presented during familiarization; the other half contained the shapes from the familiarization phase arranged in unseen sequences. Participants were asked to press one button if the sequence appeared familiar given the sequences they had seen in the first phase, and another button if it did not.

Post-test phase: The test phase was followed by another self-paced presentation phase. This phase was somewhat shorter, consisting of 192 trials. Participants were again instructed to attempt to remember the shapes. The goal of this phase was to examine the behavior of participants who have already learned the language; for example, if predictability effects were found, are they restricted to the stages in which the participant has not yet mastered the language?

Figure 1: Reading times in Experiment 1 (above: $A$ shape; below: $B$ shape).

## Results

Accuracy: We briefly analyze the familiarity judgments from the test phase before moving on to the analysis of the processing time data from the familiarization phase, which is the focus of this study. On average, participants were more likely to judge a sequence as grammatical, leading to higher accuracy on grammatical than ungrammatical sequences ( $82 \%$ vs. $60 \%$ ). To test for differences across types of test sequences, we coded the test sequences based on the category of their $A$ and $B$ shapes (e.g., low entropy + high surprisal). Logistic mixed-effects models fitted separately to grammatical and ungrammatical sequences did not find significant differences across sequence types (grammatical: $\chi^{2}(2)=2.8, p=.24$; ungrammatical: $\left.\chi^{2}(2)=4.4, p=.11\right)$.

RT preprocessing and analysis: We refer to the sequential processing times measured by key press latencies as reading times (RTs) for consistency with the sentence processing literature. Following Karuza et al. (2014), we excluded shapes on which RTs were (1) longer than six seconds or (2) three standard deviations higher or lower than the participant's mean RT for shapes in the same position. This resulted in the exclusion of $1.1 \%$ and $2.5 \%$ of the shapes respectively.

We only analyzed RTs from participants who gave correct grammaticality judgments to at least 18 of the 24 sequences
(the lowest number for which $p<.05$ according to an exact binomial test). Of the 44 participants, 23 passed this threshold. Our statistical analysis largely followed Karuza et al. (2014). RTs were log-transformed and submitted to a linear mixed-effects regression with a random intercept for shape and a random intercept and slope for all fixed effects. Trial number and its interaction with the experimental factors were included in all models.

RT results: The time course of the results is plotted in Figure 1. Overall, RTs decreased markedly over the course of the familiarization phase, picked up in the beginning of the post-test phase, then decreased again.

The average difference in RTs between high and low entropy $A$ shapes in the familiarization phase was 119 ms ( 877 ms for high entropy and 758 ms for low entropy shapes). The linear mixed-effects model analysis indicated that this difference was statistically significant $\left(\chi^{2}(1)=4.2, p=.04\right)$. The effect of trial number was highly significant $\left(\chi^{2}(1)=31.5\right.$, $p<.001$ ). The interaction between trial number and entropy did not reach significance $\left(\chi^{2}(1)=.06, p=.81\right)$, suggesting that there was no clear evidence that the effect of entropy changed over the course of the experiment.

There were three types of $B$ shapes: high surprisal ones that followed a low entropy $A$ shape (e.g., $b_{5}$, see Table 1); high surprisal ones that followed a high entropy $A$ shape (e.g., $b_{1}$ ); and low surprisal ones that followed a low entropy $A$ shape (e.g., $b_{6}$ ). We first examined the effect of surprisal, collapsing across the two categories of high surprisal shapes. We found that high surprisal shapes were read more slowly than low surprisal shapes $\left(\chi^{2}(1)=17.8, p<.001\right)$; the average difference in RT was 200 ms ( 812 ms for high surprisal and 612 ms for low surprisal shapes). The effect of trial number was highly significant again $\left(\chi^{2}(1)=44.6, p<.001\right)$, and interacted with surprisal such that the effect of surprisal weakened over the course of the familiarization phase $\left(\chi^{2}(1)=9.9\right.$, $p=.002$ ).

Finally, we compared the two types of high-surprisal $B$ shapes, which were matched for surprisal but differed in the entropy of the $A$ shape that preceded them. The mean RTs were almost identical across these two types of shapes (812 ms after high entropy $A$ shapes and 813 ms after low entropy ones). This difference was not significant in the statistical analysis (main effect of entropy: $\chi^{2}(1)=1.2, p=.27$; interaction with trial number: $\left.\chi^{2}(1)=.9, p=.35\right)$.

## Discussion

In this experiment, participants were taught a language designed to assess the effect of measures of probabilistic prediction on sequence processing. Neither surprisal nor uncertainty reliably affected judgment accuracy in the test phase; they did, however, modulate processing times during the familiarization phase. First, predictability affected RTs in the expected way: high surprisal $B$ shapes were read more slowly than low surprisal ones. Second, uncertainty at the $A$ shape affected RTs in a way that is consistent with competition among
the predictions: higher entropy shapes were read more slowly than low entropy ones.

Finally, we did not find evidence for an effect of uncertainty reduction on the $B$ shape. To see why, note that the $B$ shapes are the last item in the sequence; as such, they reduce the uncertainty about the sequence to 0 . The amount by which uncertainty is reduced is therefore equal to the entropy of the distribution over predictions at the $A$ shape; yet there was no evidence for a difference in reading times between high surprisal $B$ shapes that followed a high entropy $A$ shape (and therefore reduced entropy by 2 bits) and high surprisal $B$ shapes that followed a low entropy $A$ shape (and reduced entropy by only 0.41 bits).

## Experiment 2

In Experiment 1, uncertainty was perfectly correlated with the number of possible predictions: high entropy $A$ shapes had four prediction options compared to two options in low entropy $A$ shapes. The goal of the current experiment is to examine whether we can find entropy effects when the number of options is kept constant. For a given number of options, entropy is highest when the distribution is uniform; we therefore compare a uniform distribution to a skewed one, that is, with one option that is more likely than the others.

## Participants

A total of 49 participants completed the experiment. Two participants were excluded for not completing the experiment and one for having prior exposure to Amharic, which uses the Ge'ez script; of the remaining participants, 35 were women and 11 men (age range: 19-31; mean age: 23.8).

## Materials

The language used in Experiment 2 is shown in Table 2. There were three types of $A$ shapes. Two of the $A$ shapes could be followed by three possible $B$ shapes (to avoid having to teaching participants a very low probability option, we used three options instead of four as in Experiment 1.) After $a_{1}$, the distribution of the $B$ shapes was uniform: each of the shapes had a probability of $1 / 3$. After $a_{2}$ the distribution was skewed: one of the shapes had a probability of $2 / 3$ and the other two $1 / 6$ each.

To control for the possibility that any difference between the two 3-option shapes could reflect skew rather than entropy as such, we additionally included a third type of $A$ shape that was followed by one of two $B$ shapes, each with probability $1 / 2$. As this distribution is uniform, we expect this shape to pattern with $a_{1}$ if the relevant factor is skew. Conversely, since its entropy is lower than either 3-option shapes, it should be processed faster than either of them if entropy is the relevant factor.

Due to the larger number of conditions and the need to provide sufficient exposure to lower probability $B$ shapes $(1 / 6$ compared to $1 / 4$ in Experiment 1), each type of $A$ shape was represented by a single shape only.

| Shape 1 | Shape 2 | Shape 3 | TP | Surprisal |
| :--- | :---: | :---: | :---: | :---: |
| Three options, uniform: $(H=1.58)$ |  |  |  |  |
| $r$ | $a_{1}$ | $b_{1}$ | $2 / 6$ | 1.58 |
| $r$ | $a_{1}$ | $b_{2}$ | $2 / 6$ | 1.58 |
| $r$ | $a_{1}$ | $b_{3}$ | $2 / 6$ | 1.58 |
| Skewed, three options: $(H=1.25)$ |  |  |  |  |
| $r$ | $a_{2}$ | $b_{4}$ | $4 / 6$ | 0.58 |
| $r$ | $a_{2}$ | $b_{5}$ | $1 / 6$ | 2.58 |
| $r$ | $a_{2}$ | $b_{6}$ | $1 / 6$ | 2.58 |
| Uniform, two options: $(H=1)$ |  |  |  |  |
| $r$ | $a_{3}$ | $b_{7}$ | $3 / 6$ |  |
| $r$ | $a_{3}$ | $b_{8}$ | $3 / 6$ | 1 |

Table 2: Language used in Experiment 2. $H$ indicates the entropy of each distribution.

## Procedure

The structure of the experiment was the same as in Experiment 1. The familiarization self-paced presentation phase consisted of 324 sequences. This phase was followed by 16 familiarity judgments, and an additional post-test self-paced presentation phase with 216 sequences.

## Results

Accuracy: Overall accuracy was higher than in Experiment 1, though the bias for marking sequences as grammatical remained: $93 \%$ of the grammatical sequences and of $77 \%$ of the ungrammatical sequences were identified correctly. We tested for an effect of the four types of sequences (see Table 2) on accuracy rates on grammatical sequences. A logistic mixed-effects model did not reveal an effect of sequence type $\left(\chi^{2}(3)=4.5, p=.21\right)$. Likewise, there was no effect of either $A$ or $B$ shape type on accuracy rates in ungrammatical sentences $\left(A: \chi^{2}(2)=2.65, p=.27 ; B: \chi^{2}(3)=3.2, p=.36\right)$.

RT preprocessing and analysis: As before, we restricted our analysis to participants who showed evidence of learning the language, defined as giving correct judgments more often than chance ( $p<.05$ according to the binomial test); this translates to performing at least 13 of the 16 trials correctly. Of the 46 participants, 33 passed this threshold. We excluded key presses with extreme RTs using the same criteria as before, resulting in the exclusion of $3.38 \%$ of the shapes. Analysis methods were in general identical to Experiment 1, with the exception that our mixed-effects models did not include a random intercept for shape in cases where there was only one shape in each condition (i.e., in the analysis of $A$ shapes).

RT results: The qualitative pattern of results was similar to Experiment 1: RTs globally decreased over the course of the familiarization phase, briefly increased in the post-test phase, then decreased again.

Figure 2: Condition means in the familiarization phase of Experiment 2 (above: $A$ shape; below: $B$ shape). Error bars represent $95 \%$ within-subject confidence intervals.

We first discuss the statistical analysis of familiarization phase RTs on $A$ shapes, starting with an analysis of entropy as a numerical predictor There was a main effect of entropy $\left(\chi^{2}(1)=5.1, p=.02\right)$, a main effect of trial num$\operatorname{ber}\left(\chi^{2}(1)=40.3, p<.001\right)$ and a nonsignificant interaction $\left(\chi^{2}(1)=3.3, p=.07\right)$. RTs in the individual conditions were longest on the uniform 3-option shape and shortest on the skewed 3-option shape; although the entropy of the 2-option shape was lowest of all three shapes, average reading times on this shape were somewhat higher than the skewed 3-option shape (see Figure 2). The difference in RTs between the two 3 -option shapes was significant $\left(\chi^{2}(1)=5.1, p=.02\right.$ ), but the interaction with trial number was not $\left(\chi^{2}(1)=2.3, p=.13\right)$. The difference between the two shapes with a uniform prediction distribution (3-option vs. 2-option) and the interaction between this difference and trial number did not reach significance (main effect: $\chi^{2}(1)=3.5, p=.06$; interaction: $\chi^{2}(1)=3.1, p=.08$ ), and neither did the difference between the skewed 3-option and uniform 2-option shapes (main effect: $\chi^{2}(1)=.5, p=.48$; interaction: $\chi^{2}(1)=.03, p=.87$ ).

We next discuss the $B$ shapes. Again, we first enter surprisal as a numerical predictor. The statistical analysis found a highly significant effect of this predictor $\left(\chi^{2}(1)=36.2\right.$, $p<.001$ ) and of trial number $\left(\chi^{2}(1)=75.3, p<.001\right)$, as well as an interaction between the two $\left(\chi^{2}(1)=20.3\right.$, $p<.001$ ). Inspection of the average RTs for each level of surprisal (see Figure 2) suggests that not all differences between
consecutive levels of surprisal are equally large; in fact, only the difference between the $p=2 / 6$ and $p=3 / 6$ shapes was statistically significant $\left(\chi^{2}(1)=21.3, p<.001\right)$.

## Discussion

RTs on the two 3-option $A$ shapes were consistent with the hypothesis that higher uncertainty leads to longer RTs. The difference was smaller than in Experiment 1 (around 60 ms ), though that is to be expected given the smaller difference in entropy between the two shapes in the current experiment. The same hypothesis, however, predicts that RTs on the 2option shape should be lower than either 3-option shape; there was no evidence for such an effect.

There was a strong effect of surprisal overall, but there was often no evidence for differences between consecutive levels of surprisal. The difference between the two $B$ shapes that followed the 3-option skewed $A$ shape was particularly large. Finally, since no two $B$ shapes were matched on predictability and at the same time differed in the entropy of the $A$ shape that predicted them, the design of Experiment 2 did not allow us to test for an effect of uncertainty reduction.

## General Discussion

Probabilistic prediction plays a central role in language processing: a predictive item sets up expectations for predicted items later in the sequence. We studied the reflexes of probabilistic prediction in two artificial languages, which allowed us to exert precise control over the distribution over predictions. We used self-paced presentation (Just et al., 1982; Karuza et al., 2014), which yields implicit measures of processing at every element of the sequence. Two experiments revealed graded predictability effects parallel to those found in natural language. They also suggested that higher uncertainty over predictions at the point where predictions are generated leads to longer processing times, although these effects were weaker. No clear support was found for an effect of uncertainty reduction, even when controlling for predictability.

To further investigate the results, we pooled the data from both experiments and plotted the mean RTs in the familiarization phase by numerical entropy and surprisal in Figure 3 (since Experiment 2 was slightly longer, we discarded the trials following the first 288 trials for the purpose of this analysis). The evidence for a linear effect across experiments of the numerical predictors appears stronger for surprisal than for entropy. In particular, there are no clear differences among low-entropy distributions (lower than 1.5), and the slight differences that do exist are in the opposite direction than predicted by a linear relationship between entropy and RTs. Statistical models including data from both experiments did not reveal overall entropy effects at the $A$ shape (entropy: $\chi^{2}(1)=0.4, p=.53$; trial number: $\chi^{2}(1)=63$, $p<.001$; interaction: $\chi^{2}(1)=2, p=.16$ ), but did reveal clear surprisal effects at the $B$ shape as well as an interaction with trial number (surprisal: $\chi^{2}(1)=25.5, p<.001$; trial number: $\chi^{2}(1)=104.1, p<.001$; interaction: $\chi^{2}(1)=21.7$, $p<.001$ ).

Figure 3: Comparison across the experiments: means of the first 288 trials of the familiarization phase (above: A shape; below: $B$ shape). Error bars represent within-subject confidence $95 \%$ confidence intervals based on two standard deviations from the mean.

While any conclusion from pooling together two experiments with a different design and a different set of subjects should be taken as tentative, the nonlinear relationship between entropy and processing times suggests that entropy may not be the best metric for difficulty in prediction generation; additional properties of the distribution over predictions, such as the number of options or the probability of the most likely option, may need to be taken into consideration.

Figure 1 suggests that RTs in Experiment 1 may have reached a plateau about 250 trials into the familiarization phase; differences among conditions appeared to grow increasingly small around this time (Karuza et al. (2014) report a similar pattern). RTs increased at the beginning of the posttest phase, and then plateaued again around 100 trials into the pre-test phase. We did not present an in-depth analysis of the post-test phase for reasons of space; however, the fact that the overall increase in RTs at the beginning of the post-test phase was accompanied by a re-emergence of predictability and entropy effects suggests that the convergence between the conditions at the end of the familiarization phase is due to a floor effect rather than due to participants abandoning predictive processes once the language has been learned.

We made relatively few modifications to the methodology developed by Karuza et al. (2014), with the goal of building on their established paradigm. This entailed in particular that
our sequences were made up of visual symbols rather than auditory or written words; none of the symbols had any semantic content. The encouraging results of the present study suggest that this method may be extended to richer artificial languages that are a closer approximation of natural languages.

# Explain, Explore, Exploit: Effects of Explanation on Information Search 

Emily G. Liquin (EmilyLiquin@Berkeley.Edu)<br>Tania Lombrozo (Lombrozo@Berkeley.Edu)<br>Department of Psychology, 3210 Tolman Hall<br>Berkeley, CA 94720 USA

#### Abstract

How does actively seeking explanations for one's observations affect information search over the course of learning? Generating explanations could plausibly lead learners to take advantage of the information they have already obtained, resulting in less exploration. Alternatively, explaining could lead learners to explore more, especially after encountering evidence that suggests their current beliefs are incorrect. In two experiments using a modified observe or bet task, we investigate these possibilities and find support for the latter: participants who are prompted to explain their observations in the course of learning tend to explore more, especially after encountering evidence that challenges a current belief.

Keywords: explanation; exploration; learning; decision making

In the decades leading up to his publication of On the Origin of Species, Charles Darwin recorded the titles of 687 books of English non-fiction that he read. According to analyses by Murdock, Allen, and DeDeo (2017), Darwin's reading fell into three epochs, each defined by a certain pattern of exploration, or broad search across new topic areas, and exploitation, or extended examination of texts within a similar topic area. Darwin's example raises questions about the relationship between explanation and information search. In searching for an explanation (in Darwin's case, a scientific explanation for the diversity of living things), do people pursue evidence broadly (i.e., exploring), or restrict their search to align with their current beliefs (i.e., exploiting)? Do these tendencies shift over time as new evidence is acquired? And if so, how?

Lombrozo and colleagues have proposed that when engaged in explanation, children and adults recruit explanatory considerations as evaluative constraints, rendering them more likely to generate and favor hypotheses that support "good" explanations - namely those that are simple, broad, and exhibit other explanatory virtues (Lombrozo, 2016; Williams \& Lombrozo, 2010, 2013). There is also evidence that the hypotheses one generates and considers influence information search (Bonawitz, van Schijndel, Friel, \& Schulz, 2012). Combining these proposals thus predicts that patterns of information search could be affected by engaging in the process of explanation.

To date, few studies have investigated the relationship between explanation and information search. In one study, Legare (2012) found that children's explanations for an unexpected piece of evidence predicted their subsequent exploratory behavior. In more recent work, Ruggeri, Lombrozo, and Xu (in prep) found that prompting children
to explain relationships in a target domain prepared them to ask more efficient questions on a subsequent 20 -questions task in that domain. Neither study, however, was designed to test the causal influence of generating explanations on decisions to explore in a dynamic learning task, nor were they designed to examine adults' exploratory behavior.

In two experiments, we investigate how explanation generation affects patterns of exploration by prompting adult learners to explain as they search for information over the course of a category learning task. To accomplish this, we draw on research from the reinforcement learning literature on the explore-exploit dilemma (Cohen, McClure, \& Yu, 2007; Kaelbling, Littman, \& Moore, 1996). As defined in this literature, exploration involves seeking new information, while exploitation involves seeking reward (by taking advantage of the information one has already acquired). For example, in the observe or bet task (Navarro, Newell, \& Schulze, 2016; Tversky \& Edwards, 1966), agents must choose between "observing" which of two bulbs lights up on a given trial (without receiving any reward) or "betting" which bulb they think will light up for the chance to earn a reward (without observing that trial's result). Each bulb lights up with some fixed probability that the learner must infer through a period of observation. In this task, observation is equated with exploration (i.e., information seeking with no potential for reward) and betting is equated with exploitation (i.e., reward seeking with no potential for information).

## The Present Research

In the present research, we propose a new method, the contextual observe or bet task (inspired by the contextual multi-armed bandit task; Langford \& Zhang, 2008). In this task, a set of "context variables" (i.e., features of the options that vary across trials) can be used to predict the option that will provide a reward on each trial. Successful performance depends on learning to identify and use these variables. This method integrates a more complex, real-world learning task into an active, dynamic learning environment. We can answer the question "when do explainers choose to explore?" by measuring when learners choose to observe rather than bet.

To develop a contextual observe or bet task well suited to exploring the effects of explanation on information search, we adapt the stimuli from Williams and Lombrozo (2010). In a set of three studies, Williams and Lombrozo presented learners with four exemplars from each of two novel categories. Category members could be classified by a

Figure 1: a. Typical trial (Expts. 1 and 2): Both robots can be classified by the $100 \%$ rule (foot shape) and the $75 \%$ rule (body/head shape); b. Non-obvious anomaly trial (Expts. 1 and 2): Both robots can be classified by the $100 \%$ rule but not the $75 \%$ rule; c. Obvious anomaly trial (Expt. 2): Both robots can be classified by the $100 \%$ rule, but only one robot can be classified by the $75 \%$ rule. Category labels were only displayed if a participant chose to observe and are included here for clarity.
salient rule that accounted for $75 \%$ of exemplars or a subtle rule that accounted for $100 \%$ of exemplars. Participants who were asked to explain the category membership of each exemplar were more likely to discover the $100 \%$ rule than participants who engaged in a control task.

For our contextual observe or bet task, we present learners with pairs of category exemplars over a number of trials. On each trial, learners can choose to "observe" the category labels of the exemplars or "bet" which exemplar they believe belongs to a given category. Learners are thus free to determine when to seek information (exploration/ observation) and when to seek reward (exploitation/betting) as they learn the features that predict category membership (context variables).

Prior work motivates two hypotheses regarding the effects of explanation generation on explore-exploit decision making. By Hypothesis 1, explaining could lead learners to greater exploitation. Previous research suggests that people use the first explanation they receive as a benchmark by which to judge subsequent explanations (Ihme \& Wittwer, 2015) and use their current explanation to decide between competing hypotheses for new data (Johnson \& Krems, 2001). Learners may thus prefer the first explanation they generate. This tendency towards accepting the first explanation in a series could lead people to switch to exploitation after arriving at an initial explanation, even if it is based on scant evidence. We suggest that learners may thus be more willing to quickly settle on a hypothesis that aligns with their initial beliefs based on the first pieces of information gathered, leading to increased exploitation.

By Hypothesis 2, explaining could lead learners to greater exploration. This hypothesis is consistent with one interpretation of the findings from Williams and Lombrozo (2010): when prompted to explain, participants continued to "search" the stimuli until they found a good explanation, rather than settling for the salient but imperfect $75 \%$ rule. Relatedly, Williams, Lombrozo, and Rehder (2013) found that explainers seemed to perseverate in looking for a perfect classification rule, even when none was available. If explainers explore until they find a good explanation, then evidence that a candidate explanation is inadequate could be a critical cue that leads explainers to engage in further exploration. Indeed, Williams and Lombrozo (2010) found that explaining anomalies (i.e., exceptions to the $75 \%$ rule) was particularly powerful in encouraging learners to reject
an imperfect rule and discover a better alternative (see also Williams, Walker, \& Lombrozo, 2012). However, this finding was not experimentally linked to an increase in exploration or information search, which makes it possible that anomalous evidence influenced discovery via other mechanisms. It is thus an open question whether explanation has a causal impact on exploration, and if so whether this impact is most pronounced when the evidence that is being explained contradicts one's current beliefs.

For our contextual observe-or-bet task, Hypothesis 1 thus predicts that relative to control participants, those who are prompted to explain will make more "bet" choices. In contrast, Hypothesis 2 predicts that relative to control participants, those prompted to explain will be more likely to observe, especially on trials following the observation of information that is anomalous with respect to initial beliefs, which we expect to correspond to the obvious rule that accounts for $75 \%$ of exemplars. In two experiments, we test these hypotheses.

## Experiment 1

## Method

Participants Participants for both experiments were recruited from Amazon Mechanical Turk and paid $\$ 0.85$ for participating in the 8.5 -minute study. Participation in both experiments was restricted to users in the United States with a $95 \%$ or higher approval rating based on at least 50 previous tasks. Participants in Experiment 1 were 302 adults ( 143 males and 159 females) ranging from 18 to 74 years of age $\left(M_{\text {age }}=34\right)$ and were randomly assigned to the explain condition $(N=151)$ or the control condition $(N=151)$. Ninety-four additional participants (44 in the explain condition and 50 in the control condition) were excluded for failing to pass two attention checks (see below).

Materials Thirty-two images of "alien robots" (see Figure 1) were designed based on the stimuli used by Williams and Lombrozo (2010). Robots varied along four dimensions: foot shape, body/head shape, left-half color, and right-half color. Twenty-two different foot shapes were used, each of which appeared on no more than two robots. All Glorps had feet that were pointy on the bottom surface, and all Drents had feet that were flat on the bottom surface. Overall, $75 \%$ of Glorps had round bodies/heads, $25 \%$ of Glorps had
square bodies/heads, $75 \%$ of Drents had square bodies/ heads, and $25 \%$ of Drents had round bodies/heads. The color dimensions were irrelevant to category membership.

Foot shape (pointy/flat) was a " $100 \%$ rule" that accounted for the category membership of all robots, and body/head shape (round/square) was a " $75 \%$ rule" that only accounted for the category membership of $75 \%$ of the robots.

Procedure Participants were introduced to Glorp robots and Drent robots. On each of 16 trials, participants were shown a Glorp-Drent pair. Robots were paired such that no color appeared more than once in a pair, and all atypical Glorps were paired with atypical Drents. The side on which Glorps and Drents appeared was counterbalanced across trials. Pairs were presented in a random order, aside from the first four trials. For these trials, typical exemplars were presented on trials one, two, and three ("typical trials"), and atypical exemplars were presented on trial four ("anomaly trial").

On each trial, participants were given the choice to "observe" - offering the opportunity to gain information but no reward - or "bet" - offering the opportunity to gain reward but no information. If a participant chose to observe, the participant was shown which robot from that pair was a Glorp and which was a Drent. Participants in the explain condition were asked to explain why the indicated robot was a Glorp robot, while participants in the control condition were asked to write down any thoughts they had about that trial. Participants were required to spend at least 10 seconds completing these tasks before advancing to the next trial. No points were awarded when a participant chose to observe.

If a participant chose to bet, the participant was asked to indicate which robot they thought was a Glorp. If their choice was correct, the participant would gain one point, and if their choice was incorrect, they would lose one point. However, no feedback was given on bet trials; participants were not shown their scores until the task was complete. ${ }^{1}$

Participants were instructed to attempt to maximize their score, but also to learn how to differentiate Glorps and Drents. All participants were explicitly told that they would be asked to report any patterns that could help differentiate Glorps and Drents at the end of the task. Participants were not incentivized on the basis of their score, a point to which we return in the General Discussion.

After the 16-trial observe or bet task, participants reported any patterns they had found that differentiated Glorps and Drents and indicated what percentage of robots they thought could be accurately characterized using that pattern. Participants could report up to eight patterns. Participants also completed an attention check in which they had to distinguish between a robot they had seen during the previous task and three robots that they had not seen before. All novel robots were obviously different in appearance from Glorps and Drents. A second attention check required

[^392]participants to read the instructions from the first attention check, which directed them to ignore the question that followed and instead type a specific word into the answer textbox.

## Results

Rule Discovery In the explain condition, $17 \%$ of participants reported the $100 \%$ rule after completing the observe or bet task, while only $6 \%$ of participants in the control condition reported this rule. A chi-square analysis revealed that this difference was significant, $\chi^{2}(1)=8.27, p$ $=.004$. While these discovery rates seem quite low, they are not inconsistent with previous research (Williams \& Lombrozo, 2010). Additionally, these results replicate Williams and Lombrozo's (2010) finding that generating explanations promotes the discovery of broad rules.

Figure 2: Experiment 1 choices by condition and trial. Vertical line indicates first anomaly trial. Error bars: 1 SE.

Explanation and Exploration We used a generalized linear mixed effects model to predict participants' observe/bet choices over time, with a random intercepts term to capture individual differences. The choice to observe rather than bet was significantly predicted by linear and quadratic effects of trial number, analysis of deviance: $\chi^{2}(1)=212.70, p<.001$ and $\chi^{2}(1)=78.04, p<.001$, respectively. Increasing trial number led to more betting at a decreasing rate over time. Condition was not a significant predictor of observe/bet choices (see Figure 2). This indicates no overall differences between the two conditions in explore/exploit decisions.

Next, we investigated the effect of explaining anomalies on subsequent exploration. For participants who observed on the first anomaly trial and thus received information contradicting the $75 \%$ rule, explain condition participants were more likely than control condition participants to continue to observe on the following trial, at a level approaching significance, $\chi^{2}(1)=3.49, p=.06$. There was no condition difference in observation on the trial following the first anomaly for participants who did not observe on the anomaly trial, and thus did not receive information contradicting the $75 \%$ rule, $\chi^{2}(1)=0.55, p=.46$. However, a logistic regression predicting observation following the anomaly trial by condition and observation on the anomaly
trial did not reveal a significant interaction ( $b=0.71$, $\mathrm{OR}=$ $2.03, z=1.24, p=0.21$ ), likely due to the small proportion of our sample that observed the anomaly ( $27 \%$ ).

To analyze whether the increased exploration following an observed anomaly led to increased discovery of the $100 \%$ rule, we performed a logistic regression predicting $100 \%$ rule discovery by condition and observation on the trial following the first anomaly. Both condition $(b=1.12, \mathrm{OR}=$ $3.05, z=2.73, p=.006)$ and post-anomaly observation $(b=$ $0.80, \mathrm{OR}=2.23, z=2.17, p=.03$ ) were significant predictors. Thus, while explanation had an effect on $100 \%$ rule discovery above and beyond the effects of postanomaly observation, this increase in exploration following the observation of an anomaly also predicted rule discovery.

## Discussion

In Experiment 1, we found that after observing information that contradicted the $75 \%$ rule, participants who were asked to explain tended to explore more often than control participants. This exploration increased the probability of discovering a broad rule that accounted for all observations. These findings support Hypothesis 2: explanation led learners towards greater exploration after receiving evidence that current beliefs were wrong or incomplete.
These results leave open two possibilities for how explanation interacts with anomalous information. We previously suggested that explaining anomalies encourages learners to reject their current (imperfect) hypothesis, prompting subsequent exploration in the service of finding a more satisfactory alternative. On this view, explanation affects the downstream processing that follows the detection of an anomaly. However, there is also evidence that generating explanations can help learners articulate and recognize their current beliefs, rendering a conflict between those beliefs and subsequent information more apparent (Chi, de Leeuw, Chiu, \& LaVancher, 1994). Extending these ideas, it could be that generating explanations on trials that preceded an observed anomaly helped learners recognize the anomalies as such, and that increased sensitivity to anomalies is what drove effects of explanation.

In Experiment 2, we evaluate these alternatives by introducing violations of the $75 \%$ rule that are detectable whether or not the participant chooses to observe on that trial ("obvious anomalies"). When an atypical exemplar from one category (e.g., a round Drent) is paired with a typical exemplar from the other category (e.g., a round Glorp), both robots have the same shape. Since each trial contains one Glorp and one Drent, the trial is a clear violation of the $75 \%$ rule. If explanation enhances anomaly detection by solidifying learners' initial beliefs, we would expect participants who are prompted to explain to observe at a higher rate on the first obvious anomaly trial relative to those who are not prompted to explain. On the other hand, if explaining an anomaly is instead what prompts learners to reject prior beliefs and seek out better alternatives, we would expect effects of explanation to emerge only after an anomaly has been observed, and to manifest as an increase
in observation on trials following obvious anomalies. In Experiment 2, we test these potential accounts.

We additionally varied the point at which the first obvious anomaly was introduced - on trial 4 versus trial 8 - to test whether the timing of anomalous information affects rule discovery and/or interacts with explanation. If the power of explaining anomalous information emerges from the conflict between the novel information and prior beliefs, then introducing anomalous evidence later in the task (after beliefs have been solidified) should lead to a larger effect of explanation on exploration. If, however, explanation biases learners towards their prior beliefs (Walker, Lombrozo, Williams, Rafferty, \& Gopnik, 2017; Williams \& Lombrozo, 2013), increasing the strength of learners' beliefs by increasing the amount of consistent evidence prior to introducing an anomaly could decrease the effect of anomalous evidence on subsequent exploration.

## Experiment 2

## Method

Participants Participants were 400 adults ( 192 males, 204 females, and 4 who did not specify gender) ranging from 18 to 73 years of age $\left(M_{\text {age }}=34\right)$ who were randomly assigned to the explain condition $(N=203)$ or the control condition ( $N=197$ ), as well as early anomaly timing ( $N=197$ ) or late anomaly timing ( $N=203$ ). One hundred fifty-three additional participants ( 73 in the explain condition and 80 in the control condition) were excluded for failing to pass two attention checks mirroring those used in Experiment 1.

Materials The 32 alien robot images used were identical to those used in Experiment 1.

Procedure The procedure was largely identical to Experiment 1. Three atypical Glorps were paired with atypical Drents ("non-obvious anomalies"). One atypical Glorp was paired with a typical Drent, and one atypical Drent was paired with a typical Glorp ("obvious anomalies").

For those assigned to early anomaly timing, the first obvious anomaly was presented on trial 4. For late anomaly timing, the first obvious anomaly was presented on trial 8. The second obvious anomaly was always on trial 15 . Nonobvious anomalies were randomly distributed throughout the remaining trials, excluding the first three trials.

## Results

Rule Discovery Within early anomaly timing participants, $33 \%$ of explain participants and $27 \%$ of control participants reported the $100 \%$ rule. Within late anomaly timing participants, $30 \%$ of explain participants and $14 \%$ of control participants reported the $100 \%$ rule. A logistic regression analysis revealed that participants in the explain condition were significantly more likely than participants in the control condition to discover the $100 \%$ rule ( $b=0.60$, $\mathrm{OR}=$ $1.81, z=2.55, p=.01$ ). Participants with late anomaly timing were somewhat less likely than participants with
early anomaly timing to discover the $100 \%$ rule ( $b=-0.43$, $\mathrm{OR}=0.65, z=-1.84, p=.07$ ).

Explanation and Exploration We used a generalized linear mixed effects model to predict participants' observe/bet choices over time, with a random intercepts term to capture individual differences. The choice to observe rather than bet was significantly predicted by condition (explain vs. control) and linear and quadratic effects of trial number, analysis of deviance: $\chi^{2}(1)=4.47, p=.03 ; \chi^{2}(1)=273.93, p$ $<.001$; and $\chi^{2}(1)=150.40, p<.001$, respectively. Anomaly timing (early vs. late) was not a significant predictor of observation. Explain participants were more likely to observe than control participants, and increasing trial number increased the likelihood of betting at a decreasing rate over time (see Figure 3).

Next, we analyzed exploration on the first obvious anomaly trial by performing a logistic regression with task (explain vs. control) and anomaly timing (early vs. late) as predictors. Participants with late anomaly timing were 56\% less likely to observe on the first anomaly trial relative to participants with early anomaly timing ( $b=-0.82$, $\mathrm{OR}=$ $0.44, z=-2.81, p=.005$ ), indicating that fewer participants observed the first obvious anomaly when it was presented later in the task. Condition was not a significant predictor of anomaly observation, nor was the interaction between condition and anomaly timing. These findings suggest that explanation did not exert effects on discovery by increasing the rate at which obvious anomalies were detected.

To analyze exploration following an anomalous observation, we performed a logistic regression predicting observation on the trial following the first obvious anomaly, with condition (explain vs. control) and anomaly timing (early vs. late) as predictors. This revealed a marginally significant interaction between task and anomaly condition ( $b=0.88, \mathrm{OR}=2.40, z=1.78, \mathrm{p}=.07$ ). For late anomaly timing, explain participants were more likely than control participants to observe on the trial following the first obvious anomaly, $\chi^{2}(1)=6.85, p=.009$. This difference was not significant for early anomaly timing, $\chi^{2}(1)=0.01, p$ $=.92$. These findings support the idea that explanation affects learning by increasing exploration in the face of anomalous evidence; they also challenge the idea that effects of explanation are restricted to anomaly detection. Explainers were no more likely to choose to observe an obvious anomaly, but were more likely (in the late anomaly condition) to follow up with additional observation.

To analyze whether this increased exploration following an observed anomaly led to increased discovery of the $100 \%$ rule, as well as whether condition had an effect on rule discovery above and beyond the effects of such exploration, we performed a logistic regression predicting $100 \%$ rule discovery by condition and observation on the trial following the obvious anomaly. Both condition ( $b=0.49$, $\mathrm{OR}=1.64, z=2.10, p=.04)$ and observation following the first obvious anomaly $(b=0.79$, $\mathrm{OR}=2.20, z=3.12, p=$ .002 ) were significant predictors of $100 \%$ rule discovery.

## Discussion

These results suggest that explanation generation leads to greater exploration after observing evidence that challenges a current hypothesis. This difference in exploratory behavior does not depend on simply noticing the presence of contradictory information, but instead depends specifically on one's attempts to explain this anomalous information.

We also found a suggestive difference between early and late anomaly timing. Further research is clearly warranted, but the effect of explaining an obvious anomaly may be more powerful as the degree of conflict between the anomaly and one's current beliefs is increased.

Figure 3: Experiment 2 choices by condition, anomaly timing, and trial. Vertical lines indicate obvious anomaly trials. Error bars: 1 SE.

## General Discussion

In two experiments, we investigated how explanation generation affects exploration over the course of a category learning task. Lombrozo and colleagues (Lombrozo, 2016; Williams \& Lombrozo, 2010, 2013) have proposed that generating explanations recruits a set of inductive constraints on hypothesis generation and selection, which can lead to the discovery of broad, simple, and generalizable rules and patterns. In the present research, we extend this account, suggesting that this learning outcome is partially dependent upon generating explanations for anomalous observations, which increases a learner's propensity to seek additional evidence.

Our results are consistent with Legare's (2012) finding that children's explanations for surprising events predicted their exploratory behavior. In the present research, however, we establish a causal link between explanation and exploration, and demonstrate that this link holds not only for children's causal learning (as proposed by Legare), but also for adults' category learning.

That said, many open questions remain. For example,
might explanation affect explore/exploit decisions by shifting participants' confidence on each trial (e.g., Auer, 2002)? Does explaining affect motivation, which could also be achieved by incentivizing reward? Equally important is identifying boundary conditions on our effects: are there situations in which explaining anomalies could lead learners to explain them away (Chinn \& Brewer, 1998), and thus engage in greater exploitation?

While some of the effects reported here failed to reach statistical significance, we did find similar results across two experiments. Unfortunately, the effect sizes are limited by the small proportion of participants who are able to discover the $100 \%$ rule. Future work might benefit from more sensitive paradigms. Additionally, the paradigm used here allowed participants to gain some information on each trial without engaging in exploration. Since exemplars from one category were always presented with exemplars from the other category, participants could identify the features that differed between the two categories without choosing to observe. Future work will limit potential learning to observation trials in order to better isolate the effects of explanation on information search.

In sum, our findings suggest that attempting to explain observations that are anomalous with respect to one's current beliefs encourages further exploration. This may be one mechanism by which generating explanations affects learning, and provides compelling evidence that top-down constraints on hypothesis generation and selection affect not only the conclusions that learners draw, but also the ways in which they seek information - whether that information comes from $19^{\text {th }}$ century texts or a robot classification task.

# Can Illness be Bright? Metaphor Comprehension Depends on Linguistic and Embodied Factors 

Pei Liu (p.liu1@lancaster.ac.uk)<br>Louise Connell (l.connell@lancaster.ac.uk)<br>Dermot Lynott (d.lynott@lancaster.ac.uk)<br>Department of Psychology, Fylde College,<br>Lancaster University, Bailrigg, Lancaster, LA1 4YF, UK

#### Abstract

Conceptual representations in language processing employ both linguistic distributional and embodied information. Here, we aim to demonstrate the roles of these two components in metaphor processing. The linguistic component is captured by linguistic distributional frequency (LDF), that is, how often the constituent words appear together in context. The embodied component, on the other hand, refers to how easy it is to generate an embodied simulation, operationalised by a previous norming study. In the current study, we looked at the interplay of these components in metaphor processing, and investigated their roles at different depths of processing in two experiments. Thus, we required participants to engage in shallow processing (Experiment 1: Sensibility Judgement), or deep processing (Experiment 2: Interpretation Generation). Results showed that the increase of both variables made it more likely to accept a metaphor. However, whereas ease of simulation (EoS) contributed to the speed of processing at both levels of depth, LDF only affected the speed in shallow processing. Specifically, LDF acted as a heuristic, both to speed up responses to accept metaphors as sensible when the frequency is high, and to flag up potentially unsuccessful processing when it is low. Overall, these results support views of language processing that emphasise the importance of both linguistic and embodied components according to task goals.

Keywords: metaphor processing; embodied cognition; linguistic distribution; simulation; depth of processing

## Traditional views of metaphor processing

In a metaphoric expression, a word or a phrase (the source) is applied to an object or an action (the target) to which it cannot be literally applied. In the expression "a bright student", a student is not an object to which the visual property of bright is usually applied. Nevertheless, we can comprehend it effortlessly meaning "clever or intelligent students". How is this comprehension achieved? Many factors have been implicated, namely the familiarity, conventionality and aptness of a metaphor. These factors can not only affect the speed of processing (Giora, 2007; Pierce \& Chiappe, 2008), but conventionality and aptness are also suggested to determine the mechanism of processing, whether by comparison or by categorisation (Bowdle \& Gentner, 2005; Jones \& Estes, 2006).

However, when it comes to understanding exactly how these three factors affect metaphor comprehension, they have problems with their theoretical specificity, and subsequently their operationalisation. Familiarity and conventionality are often used interchangeably, and they
face the same problem concerning their operational definitions. They are sometimes assumed to refer to how often people have encountered the metaphoric expression itself (e.g., how often is "bright" used to describe "students"? e.g., Cardillo, Watson, Schmidt, Kranjec, \& Chatterjee, 2012; Roncero \& de Almeida, 2014a) and sometimes to how accustomed people are to relating the expression to its metaphoric meaning (e.g., "bright" meaning intelligent and quick-witted: Campbell \& Raney, 2015; Mashal, Faust, Hendler, \& Jung-Beeman, 2009), but these are two very different and dissociable theoretical constructs. A particular linguistic expression might be encountered reasonably often but remain poorly understood (e.g., purple prose), or a metaphoric meaning might be encountered reasonably often via a different expression to the one supplied (e.g., "Solution can be bright").

Aptness also has received different definitions. It is sometimes assumed to reflect a very general, high-level quality or goodness of a metaphor and is often operationalised as such (Haught, 2014), whereas at other times represents a much more low-level specification of how well the metaphoric meaning (e.g., intelligent and quick-witted) fits or overlaps with the target (e.g., "student": Chiappe \& Kennedy, 1999). In addition, aptness appears to be theoretically confounded with familiarity and conventionality. Only apt metaphors are likely to become conventionalised or familiar, as a metaphor that does not work well is unlikely to become widely used by speakers of a language. Because familiarity and conventionality depend on usage patterns of metaphors across a language, and usage patterns depend to some extent on aptness, it means that there is a core dependency between the factors that is not trivial to disentangle. Indeed, ratings of aptness and familiarity are highly correlated ( $\mathrm{r}=.73-.82$ : Campbell \& Raney, 2015; Roncero \& de Almeida, 2014a), as are ratings of aptness and corpus frequency counts of the metaphoric expression ( $\mathrm{r}=.41-.57$ : Roncero \& de Almeida, 2014b; Thibodeau \& Durgin, 2011).

In summary, familiarity, conventionality and aptness have all been shown to affect metaphor processing. However, they have several theoretical and operational problems that mean they have limited utility in enhancing our understanding of what makes a metaphor easier to process. Rather than continuing to vary and refine how these factors are conceptualised, we propose a different approach to seek clearer predictors of metaphor processing that (a) are
theoretically and operationally distinct, and (b) are able to independently account for speed and accuracy performance in metaphor processing.

## Grounded views of language processing

Research in conceptual representation has tended to operate in parallel to that of traditional metaphor processing, and therefore takes quite a different perspective on how access to meaning takes place. Essentially, two components are employed in the mental representation of meaning when people process language (Barsalou, Santos, Simmons, \& Wilson, 2008; Connell \& Lynott, 2014). The first component relies on the statistical, distributional pattern of how words co-occur across contexts (Landauer \& Dumais, 1997). The second type of representation is the embodied (also known as the grounded, sensorimotor or situated) component, which relies on the process of simulation; that is the partial reactivation of past perceptual, motor, affective, introspective and other experiences (Barsalou, 1999).

Together, the linguistic and embodied components can explain language processing better than either alone (e.g., Andrews, Vigliocco, \& Vinson, 2009). In particular, research in the grounded linguistic-embodied approach has demonstrated that the linguistic distributional information provides a powerful tool for superficial language processing because activity of the linguistic component peaks earlier than that of the embodied simulation component (Louwerse \& Jeuniaux, 2008). People are more likely to rely on the embodied component when deeper processing is specifically cued in the task; but people will be reliant upon the linguistic component to generate a good-enough approximation (Ferreira, Bailey, \& Ferraro, 2002) when shallow processing can suffice.

In line with these arguments, Connell and Lynott (2013) proposed that information from the linguistic component could act as a cognitive triage mechanism during language processing by providing a guide to whether it is worth expending effort on costly embodied simulation. If the linguistic component indicates that future processing is likely to fail (e.g., the words rarely co-occur in the same context and so their combined meaning might not be simulated successfully), then the processing cold be abandoned before any more cognitive effort is expended by the embodied component. On the other hand, if the linguistic component indicates that future processing is likely to succeed (e.g., the words often co-occur in the same context and so their combined meaning can probably be simulated successfully), then it could either inform a response immediately (i.e., based on the linguistic shortcut alone) or allow the embodied component to continue developing a detailed simulation of meaning.

Connell and Lynott's proposal can be applied directly to the study of metaphor processing, because the interplay of the linguistic and embodied components, and the role of the linguistic shortcut as a cognitive triage mechanism, operate in theory across all types of language comprehension. In this study, we asked participants to process metaphors that
systematically varied on these two dimensions. The linguistic component is quantified by linguistic distributional frequency (LDF), that is how often constituent words ("bright" and "student") of a metaphor co-occur in a large corpus.

The embodied component, on the other hand, is operationalised by ease of simulation (EoS), a new normed metric that quantifies how easy it is to come to a mental representation of a metaphor (Liu, Connell, \& Lynott, 2016). This metric was extracted using a principle components analysis from the ratings on the sensibility (how much sense the sentence make if read or heard), usability (how easy it is to use it in conversation or writing), and imaginability (how easy it is to describe the concept) in the norming study. When combined into a single measure, these ratings offer a proxy for how easy it is to simulate a concept. That is, if people find it easy to make sense of and use the metaphor, as well as imagine the concept, they would find it easy to generate embodied simulations.

Although LDF and EoS may correlate to a certain degree, we expected them to play distinctive roles in metaphor processing after the common variance between them is removed. Both variables would independently affect the acceptance rate and speed of metaphor processing. Specifically, increase in both variables would make it more likely and faster for people to accept a metaphor, and meanwhile slower to reject the very metaphor. More crucially, participants performed one of two tasks: a sensibility judgement task (Experiment 1), which required relatively shallower processing because participants made only yes/no response; or an interpretation-generation task (Experiment 2), which was deeper because they specified the meaning verbally. We predicted that EoS would play a greater role in deep processing or when people accepted metaphors because it indicated successful simulation, while LDF should play a larger role in shallow processing especially when people rejected a metaphor as not being sensible.

## Experiment 1: Sensibility Judgement Task

## Method

Participants Twenty-eight participants took part (five male and 23 female), all of whom were students at Lancaster University and native speakers of English with mean age of 19.1 years ( $\mathrm{SD}=1.1$ ). The sample size was determined beforehand to achieve the same level of variability as the conceptual combination study in Connell and Lynott (2013).
Materials We used a total of 452 metaphoric sentences taken from Liu et al., (2016). All sentences took the form "Noun can be adjective" (e.g., Student can be bright), and were composed of 113 perceptual adjectives (e.g., bright: Lynott \& Connell, 2009), each paired with four nouns that were capable of eliciting metaphoric meanings that vary independently on the following two dimensions (see examples in Table 1):

Table 1: Sample metaphors, and their scores for ease of simulation and LDF.

| Metaphor | EoS | LDF |
| :--- | :---: | :---: |
| Illness can be bright. | -1.32 | 2.95 |
| Supply can be bright. | -1.02 | 3.72 |
| Solution can be bright. | 1.41 | 3.11 |
| Student can be bright. | 1.84 | 4.08 |

EoS for each sentence ranged from easy to difficult ( $M=$ $0.00, S D=1.00$ ), and was calculated in a novel norming study by Liu et al. (2016). The scores were a single principle component extracted from ratings of sensibility, imaginability and usability of the metaphors. LDF for each sentence ranged from low to high ( $M=2.95, S D=0.97$ ), and was calculated as the $\log$ of the summed bi- to fivegram frequencies of the sentence's noun and adjective in the Google Web1T Corpus (Brants \& Franz, 2006). To take the metaphor "Students can be bright" as an example, the LDF was the $\log$ of the sum of the frequencies of "student ... bright" and "bright ... student" with zero, one, two, and three intervening words.

The sentences were split into four lists, where each adjective appeared only once per list, and the distribution of easy/difficult to simulate and high/low distributional frequency was equal across lists (EoS: $F(3,440)=1.70, p$ $=.166$; LDF: $F(3,440)=0.43, p=.734)$. Each participant saw only one list.

Procedure Participants read one sentence in each trial and decided whether or not the sentence made sense. All trials had the same structure. Participants first saw a fixation cross for 1000 ms , followed by the noun for 500 ms , followed by the phrase "can be" for 500 ms , and then followed by the adjective. The adjective remained onscreen until participants made a response. Participants pressed either the comma key (",") if they judged that the sentence made sense; or the full stop key (".") if they judged that it did not make sense. The response could be made without a time limit; and participants were told explicitly that there were no right or wrong answers to the question. Both the response decisions ("yes" to accept the metaphor as sensible; or "no" to reject
the metaphor as nonsensical), and the response time in milliseconds (RT) from onset of the adjective were recorded as dependent variables.

Design and Analysis Response decisions were analysed in a mixed effects logistic regression (binomial distribution with logit link), with response as the dependent variable (coded as 1 for "yes", accepting the metaphor as sensible; and 0 for "no", rejecting the metaphor as nonsensical), participants and items as crossed random factors, and LDF, EoS, and their interaction as fixed factors. We only modelled random intercept because models with random slope failed to converge.

Response times (RTs) were analysed using mixed effects linear regressions, firstly in an omnibus analysis with crossed random factors of participants and items, and fixed factors of response, LDF, EoS, and their interactions. Then, we ran separate analyses on acceptance ("yes") and rejection ("no") responses because we expect the effects of the fixed factors to be opposite for "yes' and "no" responses. While the increase in LDF and EoS should make it faster to accept a metaphor, it should make it slower to reject a metaphor.

## Results and Discussion

All participants had mean response times within 3SD of the overall mean and so all were included in analysis. Two trials were removed because of motor error (RT < 200ms). Furthermore, individual trials with RT more than 3SD from each participant's mean per response decision were removed as outliers: $1.33 \%$ of "yes" responses and $2.20 \%$ of "no" responses.
Among 3105 valid trials, 1413 ( $45.51 \%$ ) were accepted as sensible ("yes" responses) and 1692 ( $54.59 \%$ ) were rejected as nonsensical ("no" responses). Logistic regression showed evidence for net suppression. This means that while metaphors with the "yes" response had a higher mean LDF than those with the "no" response (i.e. the higher LDF was, the more likely it should be to respond "yes"), the effect of LDF in the mixed effects logistic regression turned out negative (i.e., the higher LDF was, the less likely to respond "yes"). This suggested that LDF enhanced the effect of

EoS by explaining the residuals of EoS rather than the variance of response decision. In order to establish the true relationships between response decision and our independent variables, we therefore removed the shared variance between LDF and EoS (currently correlating at $r$ $=.27$ ) by orthogonalising the variables using a principal components analysis with varimax rotation and Kaisar normalization on a covariance matrix (Glantz \& Slinker, 2000). What this did was to create two new orthogonal variables ( $r=0$ ), each correlating highly with one original variable $(r=.99)$. These two new variables were thus named orthogonal EoS and orthogonal LDF. We re-ran the logistic regression with them and obtained results as follows (further analyses all used orthogonal variables).

The logistic regression with orthogonal variables showed that both variables had a positive effect on response decision. As the EoS increased by one unit, the odds to accept a metaphor as sensible increased 3.42 times $(z(3101)=25.03, p<.001, \beta=1.23)$. As the LDF increased, the odds to accept a metaphor increased with a marginally significant effect (1.084 times, $z(3101)=1.88$, $p=.06, \beta=0.08$ ).

RT was also analysed using orthogonal variables. Table 2 shows full results of the omnibus analysis. Overall, EoS had a positive effect on RT ( $M=1139 \mathrm{~ms}, S D=587 \mathrm{~ms}$ ), and it critically interacted negatively with response decision, suggesting that the direction of the EoS effect differed by the response type, and was greater for "yes" than "no" responses. LDF had no overall main effect, but interacted with response decision to indicate that the direction of LDF differed for "yes" and "no" RTs.

Since we had separate hypotheses for "yes" and "no" RTs, we divided the dataset by response decision and analysed their RTs separately. Results are given in Table 3. For "yes" responses (i.e. metaphors that were accepted as sensible; RT: $M=1150 \mathrm{~ms}, S D=589 \mathrm{~ms}$ ), the easier a metaphor was to simulate, the less time people took to accept it as sensible. Also, the more often the words in a metaphor co-occurred in language, the faster people were to accept it as sensible.

For "no" responses ( RT : $\mathrm{M}=1114 \mathrm{~ms}, \mathrm{SD}=603 \mathrm{~ms}$ ),
the effects ran in the opposite direction (Table 3). As predicted, people were faster to reject metaphors that were normally regarded as difficult to simulate. Furthermore, it interacted with LDF positively, such that the effect of EoS was reduced when LDF was low (the $\beta$ for the interaction term was positive).

## Experiment 2: Interpretation Generation Task

## Method

In this study, we asked 40 participants (native speakers of English, 11 males, age: $M=19.65, S D=2.08$ ) to judge whether they could think of a meaning for the metaphoric sentences instead of judging their sensibility. The procedure was the same as Experiment 1, except that participants needed to provide their interpretation of the sentences after they responded "yes". To reduce the possibility of fatigue, each participant saw half (56-57) of the items of Experiment 1.

## Results and Discussion

Data cleaning was performed as in Experiment 1. Furthermore, we also identified accept ("yes") trials with invalid interpretations (e.g., blank, "I don't know"). Two participants were excluded from analysis for providing more than $50 \%$ invalid interpretations. Amongst the remaining participants, $2.33 \%$ of interpretations were identified as invalid. For individual trials, $2.10 \%$ of "yes" responses and $2.00 \%$ of "no" responses were identified as outliers.

Among 2103 valid trials, 1302 (61.91\%) were accepted as interpretable whereas 801 ( $38.09 \%$ ) were rejected as uninterpretable. The logistic regression showed that both EoS and LDF had positive effects on response decision. For every unit of increase in EoS, the odds of accepting a metaphor as interpretable increased 2.826 times ( $z(2099)$ $=17.49, p<.001, \beta=1.04$ ); and for every unit of increase in LDF, the odds of accepting a metaphor increased 1.286

Table 4: Results of the mixed effects linear regression of RT in Experiment 2.

| Accept ("yes") | Intercept | 2961.19 | $[2507.85,3414.54]$ | 37.87 | 12.80 | $<.001$ |
|  | EoS | -538.01 | $[-665.18,-410.83]$ | 344.85 | -8.29 | $<.001$ |
|  | LDF | 17.48 | $[-103.06,138.02]$ | 275.02 | 0.28 | .776 |
|  | EoS * LDF | -34.12 | $[-149.71,81.46]$ | 319.23 | -0.58 | .563 |
| Reject ("no") | Intercept | 3245.15 | $[2507.68,3982.63]$ | 31.53 | 8.63 | $<.001$ |
|  | EoS | 213.38 | $[100.81,325.94]$ | 355.53 | 3.72 | $<.001$ |
|  | LDF | 44.11 | $[-62.70,150.92]$ | 321.04 | 0.81 | 0.419 |
|  | EoS * LDF | -56.58 | $[-158.14,44.98]$ | 413.74 | -1.09 | 0.276 |
|  |  |  |  |  |  |  |

times $(z(2099)=4.67, p<.001, \beta=0.25)$.
Linear regression of RT across both responses found no overall effects of either EoS or LDF (see Table 4). However, EoS interacted negatively with response decision, indicating the effect of EoS were in opposite directions for "yes" and "no" responses. Results separated by response decision are given in Table 5. As predicted, for "yes" responses (RT: M $=3083 \mathrm{~ms}, S D=2638 \mathrm{~ms}$ ), EoS had a negative effect, meaning that people were faster to accept a metaphor as interpretable when it was typically considered easy to simulate compared to difficult to simulate. LDF did not affect the speed of interpretation, nor was there an interaction. Also as predicted, for "no" responses (RT: $M=$ $2436 \mathrm{~ms}, S D=2105 \mathrm{~ms}$ ), people were faster to reject a metaphor as uninterpretable when it was normally considered difficult to simulate. LDF did not affect rejection speed, nor did it interact with EoS.

Since we had specific hypothesis with regards to the depth of processing, we examine such task differences further in cross-experiment analyses ( 0 coded for sensibility judgement task, and 1 for interpretation generation). As expected, the likelihood of accepting versus rejecting a metaphor varied by task: the odds to accept a metaphor increased 3.24 times in deep interpretation generation compared to shallow sensibility judgement; $(z(5200)=3.39$,
$p=.001, \beta=1.18$ ). As for response time, EoS interacted with task, showing that the effect is larger for deep interpretation generation than for shallow sensibility judgement, as predicted ("Yes": $t(2461.2)=-6.39, p<.001$, $\beta=-402.9$, "No" : $t(1936.6)=3.37, p=.001, \beta=145.00)$. The interaction between EoS and LDF also varied across tasks $(t(1933.3)=-2.10, p=.036, \beta=-81.67)$, which was larger for shallow than deep processing.

## General Discussion

Our goal in taking this grounded approach was to move the investigation of metaphor processing beyond the traditional factors of familiarity, conventionality, and aptness, which while having a long history of use - have been increasingly criticised for theoretical and operational problems that limit their utility in explaining what makes one metaphor easier to understand than another. Indeed, our study generated complex results that could not be accounted for by traditional theories with single factors.

The current study shows for the first time that both linguistic component (based on linguistic distributional frequency) and embodied component (based on ease of simulation norms) affect metaphor comprehension independently. Their roles are statistically distinct from each
other after we managed to remove their common variance with a principle components analysis. Whereas ease of simulation often had a large effect overall and was more prominent for the "yes" response because that was when simulation was eventually successful; linguistic distributional frequency represents a relatively coarsegrained, but nonetheless highly useful, approximation of whether a particular source and target have previously formed a metaphor. It informs people's responses, not only making acceptance more likely and faster when the words are likely to constitute a meaningful representation, but also flags up potentially unsuccessful simulation to be rejected right away without further processing when distributional frequency is low. Our findings are consistent with the grounded views which suggest that conceptual representation relies on both embodied simulation and linguistic distributional pattern ((Barsalou et al., 2008; Connell \& Lynott, 2014; Louwerse \& Jeuniaux, 2008).

However, against predictions, the main effect of linguistic distributional frequency did not differ between shallow and deep processing tasks according to the cross-experiment analysis (i.e., linguistic distributional frequency itself did not interact with task). This null effect could be because the tasks disincentivised using the linguistic shortcut by allowing people as much time as needed to make a response. That is, they had unlimited time resource to form a mental representation using the embodied component. In future research, we will impose time constraints on the task in order to further examine the utility of linguistic distributional information during metaphor processing, and provide an additional test of the linguistic shortcut hypothesis.

# Want to prime exercise? Calorie labels work better than activity ones! 

Dawn Liu (dliuxi@essex.ac.uk)<br>Marie Juanchich (m.juanchich@essex.ac.uk)<br>Department of Psychology, University of Essex<br>Wivenhoe Park, Colchester, CO4 3SQ, UK

#### Abstract

'Activity-equivalent' food labels are believed to encourage consumers to partake in exercise. This may occur by semantic priming, where featuring images of physical activity increases the mental accessibility of the concept of exercise, making it more 'fluent' and therefore more influential on people's behaviour. We tested how the format of labels (image vs. text) and representation of energy ('activity' vs. 'calorie) affected mental accessibility of exercise in a word-fragment completion task and participants' behavioural intentions for exercise $(N=142)$. Participants exposed to calorie labels produced more exercise-related words and viewed an imagined exercise scenario as shorter and more enjoyable. Images led to higher intentions to exercise than text when they described activities but they led to lower intentions to exercise than text when they described calories. Findings suggest that activity labels do not trigger more activity related thoughts, but could increase exercise intentions only if presented in pictorial format.

Keywords: priming; exercise; obesity; health; food labels; behavioural intentions

## Introduction

Obesity is a serious global issue, with nearly $40 \%$ of the world's population as overweight or obese in 2014 (World Health Organisation, 2016), a condition that is a major risk factor for noncommunicable diseases such as cardiovascular conditions and stroke (Grover et al., 2015). Physical inactivity has been identified as a main contributor to the obesity epidemic, due to the structure of work and transport become more sedentary in nature (WHO, 2004). People mostly agree explicitly that physical activity is good for health, but in the UK, about $40 \%$ of adults still do not achieve minimum recommended levels of physical activity in their daily life (Craig \& Mindell, 2012). While there may be various reasons for this discrepancy between attitudes and behaviour, closing the gap by increasing physical activity remains an important applied challenge.

The Royal Society for Public Health (RSPH, 2016) recently proposed to target obesity in the UK by the introduction of food labels that reflect the amount of physical activity required to burn off calories in the food. This label is intended to be easier to understand and to nudge people into exercising more. In this project, we assess which aspect of the new label would increase physical activities. We propose some hypotheses about the effect of using the concept of exercise instead of calories to represent food energy, and presenting an image instead of a text. We posit that mentioning exercise instead of calories could act as a semantic prime that increases the accessibility of
activity-related thoughts (Meyer \& Schvaneveldt, 1971) and therefore the intention to engage in physical activities. Compared to text, using an image may also influence the meta-cognitive processes involved in processing the label. Research suggests that the distinctive nature of pictures enhance their recollection over words (Curran \& Doyle, 2011), may generate more interactive information processing (Domke, Perlmutter, \& Spratt, 2002), and are superior to words in activating conceptual understanding (McBride \& Dosher, 2002). Images of a concept are thus more likely to increase its mental accessibility, priming it to be processed more quickly, or more 'fluently' when next encountered.
Concepts that have been activated are subsequently perceived more easily (i.e. more fluent) and are better liked (Winkielman, Schwarz, Reber, \& Fazendeiro, 2000). Factors that increase perceptual fluency, such as improved clarity of presentation, also increase liking of stimuli (Oppenheimer, 2008). Notably, exercise that was presented in a passage with easy-to-read font (high fluency) was estimated to take less effort to perform than when the font was illegible (low fluency) and this influenced people's willingness to engage in it (Song \& Schwarz, 2008).

Manipulating the accessibility of different options has also shown positive effects on healthy related behaviours. Environmental cues can increase the salience of healthy choices and subtly prime people to view these options more favourably (Marteau, 2011; Wilson, Buckley, Buckley, \& Bogomolova, 2016). For example, placing fruit instead of chocolate snacks at supermarket checkouts increased purchase of the healthier food options (Foster et al., 2014). Featuring healthier sandwiches in a more prominent and unhealthier ones in a less prominent spot on a menu made people more likely to order the healthy sandwiches (Wisdom, Downs, \& Loewenstein, 2010).

In sum, variables that increase perceptual fluency (such as familiarity and clarity) as well as variables that increase conceptual fluency (such as exposure to associatively related concepts) can influence the subjective ease with which a stimulus can be processed. We therefore hypothesised that image and activity labels would result in greater mental availability of exercise than text and calorie labels. Additionally, image and activity labels would result in exercise being rated as less effortful and more enjoyable, leading to greater willingness to engage in exercise behaviours than with text and calorie labels.

## Methods

## Participants

One hundred and forty-two English-speaking participants were recruited online through snowball sampling in the UK and Singapore, and sharing through social networking sites and online forums. Age ranged from 18 to 74 years ( $M=$ 40.30, $S D=15.47$ ). Ethnicity was $58 \%$ Asian and $23 \%$ percent white/Caucasian (19\% other races). Body Mass Index (BMI) estimates based on weight and height categories of participants ranged from 15.82 to 43.51 ( $M=$ $22.501, S D=4.66$ ).

## Materials ${ }^{1}$

Food labels We manipulated label format (image vs. text) and energy representation (activity vs. calorie) to create four labels as shown in Figure 1. The image labels were derived from existing activity-label depictions that have been proposed and tested in previous research (e.g. Swartz, Dowray, Braxton, Mihas, \& Viera, 2013; Van Kleef, Van Trijp, Paeps, \& Fernandez-Celemin, 2008). In order to keep image quality consistent, we standardised the walking image across both activity-image and calorie-image labels. Equivalent activity values were calculated from the chosen calorie value based on the mean weight of a UK individual (70kg).

Figure 1: Labels used as stimuli.
Word fragment completion task Participants read 17 word fragments, of which 12 could be completed with either exercise-related or neutral words. For example, the fragment 'S _ ORT' could be completed as SPORT (exercise-related) or $\overline{\text { SHORT }}$ (unrelated). This type of task has previously been used as a measure of mental availability (Tulving, Schacter, \& Stark, 1982). The fragments were chosen to keep the overall word frequency for potential completions as balanced as possible. Each word fragment was presented on a separate page. Participants were told that both speed and accuracy were important in the task.

Perception of exercise We measured participants' perception of exercise as an indicator of exercise favourability. Participants were asked to imagine they had agreed to go for a 5 km walk with their neighbour, and indicate how long (on a slider scale from 0 to 120 minutes)

[^393]and how enjoyable they thought it would be on a 5-point Likert scale (1: not at all, 5: extremely).

Exercise intentions In addition to direct questions about their intentions to exercise (defined as a sustained period of activity of at least 10 minutes) in the next week (likelihood and duration), participants were also given a role-play scenario where they could decide between a sedentary or active option to carry out the scenario task. For example, 'You leave your [2 ${ }^{\text {nd }}$ storey] flat and must go downstairs. You can either take the lift or the stairs. Both are equally accessible from your door. Which would you choose?' Participants' answers in this role-play scenario were scored on a 6-point scale between sedentary and active options (1: sedentary, 6 : active). This was averaged to create an overall score for active choices.

## Procedure

The experiment was delivered online via Qualtrics survey platform. Participants were randomly assigned to view one of the four labels and they answered filler questions about the labels to ensure that they processed it. Then the participants took the word fragment completion task presented as part of a separate study on language ability. After this, they completed the measures for perceptions of exercise, followed by the role-play and direct questions about their exercise intentions. Finally, they provided demographic information, which included scales assessing attitudes towards health (Steptoe, Pollard, \& Wardle, 1995) and exercise (Courneya, Conner, \& Rhodes, 2006).

## Results

The dependent variables in the experiment were analysed in a MANOVA with energy representation and label format as independent variables.

Mental availability of exercise As shown in Figure 2, more exercise-related word completions were observed for activity than calorie labels, $F(1,124)=3.94, p=.049, \eta_{\mathrm{p}}^{2}=$ .03. Label format had no significant effect on number of exercise-related words produced, $F(1,124)=.17, p=.682$, $\eta_{\mathrm{p}}^{2}<.01$. The interaction was not significant, $F(1,124)=$ $.12, p=.730, \eta_{\mathrm{p}}^{2}<.01$.

Figure 2: Number of exercise-related words produced by energy and format of label. Individual points reflect means and $95 \%$ confidence intervals.

Perception of exercise As shown in Figure 3, in the calorie condition, images led to higher walk estimates (suggesting greater perceived effort) than text, but the reverse was true in the activity condition, $F(1,124)=3.94, p=.049, \eta_{\mathrm{p}}^{2}=$ .03. Both main effects were not significant (energy, $F(1$, 124) $=.01, p .941, \eta_{\mathrm{p}}^{2}<.01$; format, $F(1,124)=.37, p=$ $\left..546, \eta_{\mathrm{p}}^{2}<.01\right)$. The MANOVA found no significant effect on enjoyability ratings, $F(3,124)=1.24, p=.300, \eta_{\mathrm{p}}^{2}=.03$.

Figure 3: Perception of exercise effort (in minutes to walk) by energy and format of label. Individual points reflect means and $95 \%$ confidence intervals.

Exercise intentions Participants' estimates of exercise time per day were multiplied by their judgements of exercise likelihood to form a combined measure for intention to exercise. We excluded 15 extreme scores with estimated intention to exercise of 10 hours or more (more than 1.5
standard deviations above the mean.) The resulting distribution is shown in Figure 4.
The analyses showed no significant effect of label conditions on scores for active choice, $F(3,124)=.37, p=$ $.776, \eta_{p}^{2}=.01$. However, we found that energy and format interacted to determine intention to exercise. In the activity condition, choices and intentions to exercise were greater when viewing images, but in the calorie condition, they were higher when viewing text, $F(1,124)=8.14, p=.005$, $\eta_{\mathrm{p}}^{2}=.06$. The individual main effects were not significant (energy, $F(1,124)=.29, p=.591, \eta_{\mathrm{p}}^{2}<.01$; format, $F(1$, 124) $\left.=.77, p=.382, \eta_{\mathrm{p}}^{2}<.01\right)$.

Figure 4: Exercise intentions (likelihood $x$ intended duration) by energy and format of label. Individual points reflect means and $95 \%$ confidence intervals.

We replicated the MANOVA with age, BMI, and attitudes towards health and exercise. The analysis showed that the interaction effect for label format and energy on exercise intentions remained significant, $F(1,117)=6.43, p=.013$, $\eta_{p}^{2}=.05$. The effect of energy on number of exerciserelated word completions and interaction effects for perception of exercise was no longer significant, $F(1,117)=$ $2.75, p=.100, \eta_{\mathrm{p}}^{2}=.03 ; F(1,117)=3.75, p=.055, \eta_{\mathrm{p}}^{2}=$ $.03)$. The effects of the covariates on the dependent variables were also non-significant (age, $F(5,113)=.66, p$ $=.652, \eta_{\mathrm{p}}^{2}=.03$; BMI, $F(5,113)=.28, p=.922, \eta_{\mathrm{p}}^{2}=.01$; health attitude, $F(5,113)=.06, p=.255, \eta_{\mathrm{p}}^{2}=.06$; exercise attitude, $\left.F(5,113)=.04, p=.422, \eta_{\mathrm{p}}^{2}=.04\right)$. We also analysed the effect of ethnicity. While Asian participants were less likely in general to pick active options in the scenario-based tasks, $F(3,112)=3.58, p=.016, \eta_{\mathrm{p}}^{2}=.09$, using Pillai's trace, we found no other main effects or interactions of ethnicity with label format, $F(10,218)=$ $1.16, p=.317, \eta_{\mathrm{p}}^{2}=.05$ or energy representation, $F(10,218)$ $=.97, p=.47, \eta_{\mathrm{p}}^{2}=.04$.

## Discussion

Two aspects of food labels were examined for their ability to increase intentions for exercise: representing food energy value in terms of activity time instead of calories, and using images instead of text. Building on empirical findings that greater perceptual and conceptual fluency from prior exposure increases liking, it was predicted that image and activity labels would prime greater mental availability of exercise and thus increase intentions to exercise. No significant main effects of label format were found, however calorie labels generated more exercise-related word completions. Exercise was perceived as more effortful for calorie labels in image format, but more effortful for activity labels in text format. For activity labels, intentions to exercise were greater for image than text formats, but the opposite was true for calorie labels.
It has been demonstrated that priming effects in word fragment completions occur when semantic information about the prime is retrieved (Smith, 1991), which we hypothesised to be facilitated by the perceptual and conceptual fluency of image and activity labels. However, we found instead a higher number of exercise-related words generated in calorie condition. It therefore seems propitious to consider what concepts are primed by the idea of calories. This term has been used as the current standard to represent energy values on packaged food for several decades (Wartella, Lichtenstein, \& Boon, 2010), and is also frequently associated with dieting and weight loss in popular media and health communications (e.g. Department of Health, 2015). While we assumed that people would have a more intuitive understanding of activity than calories, experience dealing with less intuitive but common conceptual representations may also affect semantic associations. For example, more people associate sugar amounts with grams instead of teaspoons, despite the latter being a more intuitive measurement (Vanderlee, White, Bordes, Hobin, \& Hammond, 2015). We cannot rule out that repeated exposure to calories in the context of exercise allowed participants to automatically generate the concept of exercise from viewing calorie labels.
The finding that format did not affect mental availability or intended behaviours directly, but had different effects depending on whether an activity or calorie label was presented, was unexpected. We speculate that activity and calorie labels have a processing advantage in image and text form respectively. Activity image labels are suggested to be visually and conceptually easier to understand (Campos, Doxey, \& Hammond, 2011), but the relative familiarity of calorie text labels (as opposed to calorie image ones) enhances its ease of processing (Zajonc, 1968). Since both calorie and activity labels showed an ability to prime exercise-related words, it is possible that the relative processing ease of activity image and calorie text labels further increased their fluency over activity text and calorie image labels and therefore the fluency of exercise associated with the label. This would subsequently drive more favourable emotions towards exercise (Song \& Schwarz,
2008) and explain the increased intentions to exercise in these conditions.

Practically, our results replicated previous survey findings of increased intentions to perform exercise after viewing activity labels (RSPH, 2016) for image labels but not for text labels, where calories outperformed activity. Overall, our data indicate that activity labels did not meeting the expectations of the RSPH, albeit with small effect sizes. Nonetheless, we question whether swapping existing calorie-based food labels for activity equivalent ones would be a wise investment. The use of images with the activity labels may generate a greater influence on people's association of energy with exercise over time, since pictures have been shown to improve memory performance over repeated trials more than words (Erdelyi \& Becker, 1974). However it is uncertain how long this effect would need to take hold in the population, or whether it would even surpass the current greater ability of calories than activity to generate exercise associations in text format.
However, before condemning activity labels, it would be prudent to compare activity and calorie labels to a control condition to determine if the mere presence of either label is indeed sufficient to prime exercise concepts and related behaviours. Previous work has indicated that the presence of either label on a menu can reduce energy ordered compared to a no-label condition (James, Adams-Huet, \& Shah, 2015), with activity labels being slightly (but not significantly) more effective than calorie labels. This also suggests that the effects of labels could extend beyond participants' intentions to influence their behaviour, which is not a foregone conclusion from our results. Indeed, a gap between intentions and behaviour often exists, especially for exercise-related behaviours (Sniehotta, Scholz, \& Schwarzer, 2005). The reporting of exercise intentions needs to be interpreted with caution, especially given the possibility that the social desirability of physical activity may prompt participants to overestimate their exercise intentions-although such an effect is likely to be consistent across experimental manipulations. Nevertheless, future research would do well to include measures that provide a more reliable indication of participants' actual exercise and food choice behaviours post exposure to different labels.
Further research should also look to replicate results with a variety of image samples for more robust consideration of the different types of activity images, as well as on a sample with more varied income and literacy levels. In our sample, nearly all respondents had completed tertiary education, which is often an indicator of higher literacy and income (McCoy, 2013). Groups with low literacy or income understand nutrition labels less well and are less familiar with calories, all of which could affect label fluency (for familiarity with calories, see Bleich \& Pollack, 2010; for income, see Rothman et al., 2006, also Viswanathan, Hastak \& Gau, 2009; for literacy, see Signal et al., 2008). Nevertheless, our study demonstrates the importance of psychological research in informing policy decisions and population-level health interventions.

#### Abstract

Sentence understanding is affected by recent experience. An important open question is whether this reflects adaptation to the statistics of the input. Support for this hypothesis comes from the recent finding that listeners can simultaneously learn and maintain the syntactic statistics of multiple talkers (Kamide, 2012). We attempt-and fail-to replicate this finding. This calls into questions whether recency effects in sentence processing originate in the same adaptive mechanisms operating during speech perception (for which talker-specific adaptation is well-established).

Keywords: sentence processing; attachment ambiguity; priming; adaptation; talker specificity

## Introduction

Talkers differ in how they realize the same sound categories and words. This inter-talker variability is known to be one of the biggest challenges to speech perception, and has been investigated by a large body of research. This work has identified adaptation as a central mechanism by which listeners overcome inter-talker variability (e.g., Bradlow \& Bent, 2008; Kraljic \& Samuel, 2007). With exposure to a novel talker, listeners seem to be able to adapt their category boundaries to the statistics of the current input (Clayards, Tanenhaus, Aslin, \& Jacobs, 2008; Kleinschmidt \& Jaeger, 2015). This adaptation can persist over time (Eisner \& McQueen, 2006), and listeners can maintain separate adaptations for different talkers (Kraljic \& Samuel, 2007; Trude \& BrownSchmidt, 2012). Findings like these suggest that listeners continuously infer and store talker-specific information about the realization of phonological categories (for review, see Kleinschmidt \& Jaeger, 2015).

Here we focus on adaptation beyond speech perception, and the extent to which it exhibits properties similar to those demonstrated for speech perception. It has long been recognized that talkers also vary in, for example, their lexical and syntactic preferences, and that these differences can impede processing (for a recent review, see Fine, Jaeger, Farmer, \& Qian, 2013). For example, the efficiency of expectationbased processing (i.e., utilizing expectations based on previous input to facilitate integration of bottom-up input) depends on the degree to which comprehenders' expectations-based on previously experienced input-match the statistics of the present input. Thus, if talkers differ in their preferences, and thus the statistics of the input they provide, this should impede processing. On the flip side, expectations that match the statistics of the current input will facilitate processing.

This and related considerations have motivated work on adaptation beyond speech perception, including lexical (e.g., Creel, Aslin, \& Tanenhaus, 2008), prosodic (e.g., Kurumada, Brown, \& Tanenhaus, 2012), and-most relevant to the present purpose-syntactic adaptation (e.g., Fine et al., 2013). For syntactic processing, there is now some evidence that experience with a novel environment (e.g., an experiment) can lead to longer-lasting changes in processing, persisting for at least several days (Wells, Christiansen, Race, Acheson, \& MacDonald, 2009). Further, paralleling studies on adaptation in speech perception, a recent study found that listeners can adapt to multiple talkers simultaneously (Kamide, 2012). As one of the few studies to demonstrate talker-specificity in syntactic adaptation, Kamide's study constitutes an important contribution to our current understanding of whether syntactic adaptation is best understood in terms 'dumb' priming mechanisms (Tooley, 2009) or 'smarter' learning mechanisms (Fine et al., 2013). This result has received a fair amount of attention (with about 10 citations/year); however, as we will discuss later, there are some reasons to interpret the finding with caution.

Here we report efforts to replicate Kamide (2012). We begin by summarizing the original study. Then we introduce our own paradigm, which closely follows this study (we gratefully acknowledge Yuki Kamide's generous willingness to discuss details of her design; errors remain our own). We note here that we made a few changes to the procedure and stimuli of Kamide's paradigm, which we introduce and motivate as we go through our experiment.

## Overview of Kamide (2012)

Kamide (2012) employed a look-and-listen visual world eyetracking paradigm to investigate changes in listeners' syntactic expectations for specific talkers. Participants saw visual scenes like that depicted in Figure 1.

These scenes were paired with sentences containing a syntactic attachment ambiguity. For example, in the sentence "The master of the dog who will bury the treasure is quite old now.", the relative clause, "who will bury the treasure," can describe "the master" or "the dog". These two interpretations correspond to different syntactic parses. The former constitutes high attachment, the latter low attachment.

This attachment ambiguity is assumed to be resolved at "treasure" since MASTER is more likely to be the agent of the BURYING-TREASURE event. Kamide's analyses focuses on the temporarily ambiguous stretch between the introduction

Figure 1: Example experimental scene paired with example (high attachment) sentence, both from Kamide (2012). Underlining marks the syntactically ambiguous sentence region, during which saccades to the target (treasure) and competitor (bone) objects are taken to indicate high vs. low attachment, respectively. (Target and competitor objects are not labeled in actual stimuli shown to participants).
of the relative clause verb and the resolution of the ambiguity ("will bury"). During this stretch, eye-movements to the master or dog can be seen as reflecting expectations that the relative clause will attach high (or low). Specifically, listeners should show more anticipatory eye-movements to referents that are plausible objects for the expected agent. In Figure 1, if high (low) attachment is expected, listeners should show anticipatory eye-movements to the treasure (bone).

This property theoretically makes it possible to investigate changes in syntactic expectations based on recent exposure, including changes in expectations for specific talkers. Specifically, Kamide exposed participants to sentences from three different talkers. One talker always used high attachment sentences, one talker always used low attachment, and the final talker used high and low attachment equally often. The question then is whether participants' eye-movements during the temporarily ambiguous stretch begin to reflect talkerspecific syntactic preferences. If so, participants should be more likely to exhibit anticipatory saccades toward the target object for the two talkers that consistently attached either low or high (cued talkers), compared to the talker who used high and low attachment equally often (uncued talker). This advantage should emerge with increasing exposure throughout the experiment.

Kamide tested this prediction by analyzing the number of trials in which at least one saccade was launched to each object (target vs. competitor) for the cued vs. uncued talkers during each phase of the experiment (beginning [first two blocks] vs. end [last two blocks]). Supporting the hypothesis of talker-specific syntactic adaptation, Kamide identified a statistically significant three-way interaction between object $x$ cue $x$ phase: at the end of the experiment (compared to the start), participants made more saccades to the target for the
cued talkers, compared to the uncued talkers.
However, there are reasons to interpret this result with caution. First, there were relatively few trials with fixations to either the target ( $12.1 \%$, averaged across the beginning and end of the experiment) or the competitor (11.8\%). Second, the looks to the target and the competitor actually decreased over the course of the experiment (from $15.0 \%$ to $9.2 \%$ for the target and $15.6 \%$ to $8.0 \%$ for the competitor). Both of these effects result in a small signal to detect potential effects, which we try to address by using a task-based paradigm.

## Experiment

## Methods

Participants We recruited 24 participants at the University of Rochester (c.f. 48 participants in the original study). Although we had originally intended to run 48 participants, a power simulation (reported below) following 24 participants suggested we would be unlikely to detect an effect, even with the additional participants. All participants were native speakers of English with normal vision. The experiment took about 1 hour and participants were paid $\$ 10$.

Visual Stimuli We used the visual scenes (20 experimental and 40 filler) from Kamide (2012). Each experimental scene consisted of six images arranged against a colored background (e.g., Fig. 1). Two images corresponded to the target and competitor agents of the sentence, and four images corresponded to the potential objects for the sentence.

Sentences We used the original sentences from Kamide (2012), with minor vocabulary adjustments to accommodate American listeners (e.g., motorcycle instead of motorbike). Each scene was paired with four training sentences (A) and four test sentences (B), which involved novel objects referenced in the training sentences. Sentences 1 and 3 are sentences with high attachment interpretations (i.e., in 1 A , the master is the agent of the main verb bury). Sentences 2 and 4 are sentences with low attachment interpretations (i.e., in 2 A , the dog is the agent of the main verb bury).

1. The master of the dog who will (A) bury the treasure /(B) drink the brandy is quite old now.
2. The master of the dog who will (A) bury the bone / (B) drink the water is quite old now.
3. The dog of the pirate who will (A) bury the bone $/(B)$ drink the water is quite old now.
4. The dog of the pirate who will (A) bury the treasure /(B) drink the brandy is quite old now.

Additionally, we used the 40 original filler sentences which did not contain a syntactic ambiguity, and instead contained a relative clause containing an unambiguous single noun phrase antecedent (e.g. "The woman who will lift the pet carrier has never had a dog.").

Auditory Stimuli American listeners might have difficulty distinguishing between the varieties of UK English used in
the original study (conducted in Scotland). We thus recorded new materials from talkers selected to be clearly distinguishable by American listeners. We recorded one Britishaccented male (BM; average sentence duration $=3,668 \mathrm{~ms}$, $\mathrm{SD}=485 \mathrm{~ms}$ ), one British-accented female (BF; $3,944 \mathrm{~ms}$, SD $=430 \mathrm{~ms}$ ), and one Indian-accented Male (IM; $4,358 \mathrm{~ms}$, SD $=516 \mathrm{~ms}$ ). The BM and BF talkers served as the cued talkers, consistently producing either only high attachment sentences or only low attachment sentences. Between participants, we counterbalanced the assignment of high vs. low attachment to talkers, so that each talker served as the high attachment talker for half of participants. Following Kamide, one talker (Talker IM) always served as uncued talker, producing equal amounts of high and low attachment sentences.

All audio recordings were scaled to an average intensity of 70 dB . Following Kamide (2012), the shared portion of each low attachment sentence (up to the relative clause; i.e. "the master of the dog") was then spliced into the corresponding high attachment sentence to ensure that any effects found would not be due to early prosodic cues; i.e. both high and low attachment sentences shared the same low attachment prosody.

Presentation Lists Following Kamide (2012), we created four presentation lists, crossing whether Talker BM and Talker BF served as the high and low attachment talkers, and which items were used in the cued vs. uncued talkers. Each participant was tested on one of these lists.

Each list was divided into six blocks, each consisting of 30 trials (20 experimental, 10 filler). Each experimental scene was presented once per block, with a different sentence each time (i.e. in the first four blocks, sentences 1-4A were heard, and in the final two blocks, either sentences 1-2B or 3-4B were heard). During each block, the uncued talker (IM) produced both five low and five high attachment sentences, and the cued talkers (BM and BF) each produced either five low or five high attachment sentences, along with five filler sentences. Sentence order within the lists was pseudorandomized following the criteria described in Kamide (2012).

Procedure Our procedure closely followed that of Kamide (2012) with the exception that we used a task-based clicking paradigm (described below) as compared to a look-and-listen paradigm. This decision was made because the results of the original study suggest that there was very little signal to detect potential effects. First, in the original study, the percentage of trials in which a subject makes a saccade toward the target or the competitor in the critical window was small (fewer than $24 \%$ ). Second, participants show a (highly significant) decrease in saccades to both target and competitor over the course of the experiment: $15.0 \%$ to $9.2 \%$ for the target object and $15.6 \%$ to $8.0 \%$ for the competitor object.

In a comparison between a look-and-listen paradigm and an explicit task-based paradigm, Altmann and Kamide (1999) find that although results between the two paradigms were qualitatively similar, the task-based paradigm had less-
delayed anticipatory eye movements, and subjects were almost twice as likely to fixate relevant referents (see Salverda \& Tanenhaus, in press).

Expecting more looks to the target and competitor (as taskrelevant objects), we incorporate the task of clicking on the target into Kamide (2012). This carries the additional benefit of allowing us to test whether participants are paying attention during the experiment (see Results).

Participants were seated in front of a 19 inch computer screen. Eye movements were monitored using an Eyelink 1000 , sampling at 500 Hz from the left eye. Recalibration was performed at the beginning of each new block (every 30 trials), and drift correction was performed every five trials.

At the start of each trial, participants saw a task prompt against a white background on the screen, e.g. "Click on what will be buried." Crucially, the object that should be clicked on varied between high and low attachment sentences (i.e. treasure or bone). After the participant clicked to verify that they had read the prompt, a fixation cross appeared in the center of the screen. After the participant clicked on the fixation cross, the visual scene appeared on the screen. The sentence played over loudspeakers after the scene preview period of 1000 ms elapsed. The trial ended after participants clicked in the scene after the audio file ended.

## Results

We begin by assessing how participants engaged in the experimental task. First, we test whether participants performed the task as intended. Second, we assess whether the taskbased paradigm caused participants to have more saccades to the task-relevant referents during the critical time window, thereby increasing our power to detect an effect. Third, we test whether the number of trials containing saccades to target, compared to competitor, objects decreases over the course of the experiment (as reported in the original study).

All analyses presented below include the maximal random effects justified by the design (i.e. by-participant and by-item intercepts and slopes for cue, phase, and their interaction). We treat sentences sharing the same prefix up to the relative clause as one item (e.g., 1A-B and 2A-B form an item), such that cue, phase, and their interaction varied within items. We continue to use the term target object to refer to the object that is consistent with the intended attachment interpretation (e.g., the treasure in 1A), and the term competitor object to refer to the object consistent with the unintended attachment (e.g., the bone in 1A).

Task performance: Click responses We find that participants overwhelmingly ( $98.3 \%$ of all trials) clicked on the correct target object (e.g., treasure in Fig. 1). This suggests that participants understood and successfully performed the experimental task. One scene showed a high incorrect response rate, with over $40 \%$ of subjects ( 10 of 24 ) clicking on the wrong object. This was likely due to the use of target label (hat) that is also a valid label for the competitor (cap). Trials involving this scene, and all trials with incorrect clicks, are
excluded from subsequent analyses.
Task performance: Saccades to task-relevant referents Next, we analyze the number of trials containing looks to task-relevant objects (i.e., either of targets and competitors) and the changes in this number over the course of the experiment. We analyze the same time-window as in the original study: from the start of the onset of the verb of the relative clause to the onset of the object of the relative clause (e.g. "bury the" in Fig. 1). The mean duration for this timewindow is 371 ms (cued; $\mathrm{SD}=66 \mathrm{~ms}$ ) and 430 ms (uncued; $\mathrm{SD}=82 \mathrm{~ms}$ ). These durations are somewhat different from, but similar to, the corresponding time-windows in the original study (cued: 528 ms , uncued: 365 ms ).

Compared to Kamide, we find nearly twice as many trials containing saccades to the target $(24.1 \%$ here vs. $12.1 \%$ in the original) or competitor objects ( $22.6 \%$ here vs. $11.8 \%$ in the original), averaged over the first and last two blocks. Like in the original study, we find that the overall probability of saccades to task-relevant objects decreases over the course of the experiment. However, this decrease was less dramatic than in the original study. In the first two blocks, $46.8 \%$ of all trials contained saccades to task-relevant referents and only decreased to $44.6 \%$ of all trials in the last two blocks. In fact, the number of trials in which there were saccades to the target object actually increased slightly, going from $22.2 \%$ in the first two blocks to $25.9 \%$ in the last two. This constitutes an increase of 0.2 in log-odds for the target object (compared to a decrease of 0.56 in the original study) and a decrease of 0.28 in log-odds for the competitor object (compared to a decrease of 0.75 in the original).

In summary, the task-based paradigm increases saccades to the task-relevant referents, as intended. This means that our estimates of the relative proportions of eye-movements to target vs. competitor objects-the dependent variable for the main analyses presented below-are based on more data. This should result in more reliable statistical signal for the main analysis (but see our discussion for caveats).

Main analysis: Anticipatory saccades during original time window We first analyze saccades during the time window employed in the original study. Failing to find evidence for talker-specific learning, we then present additional post-hoc analyses. Specifically, we extend our analyses to other time windows, and to individual cued talkers. All our analyses analyze the proportion (of eye-tracking samples with) fixations to the target vs. competitor objects during the time window. This differs from Kamide's, who analyzed the number of trials containing at least one saccade to the target vs. competitor during the time window. The two measures yield the same conclusions for the present data (see below). We chose our analysis approach, because Kamide's measure resulted in a model that converged only under a drastically reduced maximal random effects structure (byparticipant random intercepts and slopes, and by-item random intercepts). We also note that our approach is known

Figure 2: Proportion of fixations over the course of a trial. Colors show the different referents in the scene. Panels show the cued and uncued talkers. Regions A, B, and C correspond to the time windows in which participants heard the equivalents to "The master of the dog", "who will", "bury the", respectively. Kamide (2012)'s analysis was restricted to region C , as was our original analysis. We also present post-hoc analyses of regions A and B+C. For this plot, we normalized times within each region (essentially aligning all trials) before averaging across trials and subject.
to be anti-conservative (because of auto-correlations between eye-tracking samples), but not known to be underpowered.

The full time course for fixations over trials is shown in Fig. 2. Following Kamide (2012), we compare the data collected during the first two blocks (beginning) to the data collected during the final two blocks (end) during the time window between the start of the verb of the relative clause to the noun (e.g. "bury the").

We perform mixed logistic regression predicting fixations to target versus competitor from cue (sum-coded: cued $=1$ vs. uncued $=-1$ ) and phase (sum-coded: end $=1$ vs. beginning $=-1$ ). If participants are able to learn the syntactic preferences of specific talkers, then we expect more looks to the target object during the end of the experiment compared to the beginning. We would only expect this for the cued talkers, in which the talkers produced high or low attachment sentences consistently, and not for the uncued talker, in which the talker produced a mixture of both high and low attachment sentences. The critical result to replicate is the interaction between cue and phase of the experiment.

None of the factors reached significance ( $p s>0.14$ ). The analysis is summarized in Table 1 (penultimate column).

Critically, we did not find a significant interaction between cue and phase ( $p=0.8$ ). Using the reduced model based on Kamide's measure, where the critical measure is a 3-way interaction between object $x$ cue $x$ phase, confirmed this pattern. Specifically, Kamide's measure returned a significant two-way interaction between object and cue in the unexpected direction ( $\hat{\beta}=-0.08, p<0.05$ ). The critical 3-way interaction trended in the same direction as in the original study, but did not reach significance ( $p=0.11$ ).

For the remaining analyses we only present analyses over proportions of fixations. Using Kamide's measure led to models with reduced random effect structures, but did not change the results.

Post-hoc analyses over additional time windows We entertain two possibilities for the observed null effect. First, it is possible that the introduction of a task-based paradigm affected the time course of eye-movements (see e.g., Altmann \& Kamide, 1999). Specifically, in our paradigm listeners saw the verb prior to hearing the sentence, which may have allowed them trigger anticipatory eye-movements even earlier, before the onset of the RC verb. We therefore conduct posthoc analyses over two additional time windows (see Figure 2):

1. Start of the sentence to start of the relative clause (SentenceStart to RCStart; e.g. "The dog of the pirate")
2. Start of the relative clause to start of the relative clause noun (RCStart to RCNounStart; e.g. "who will bury the")
3. Start of the relative clause verb to start of the relative clause noun (RCVerbStart to RCNounStart; e.g. "bury the")

A second possibility is that participants look towards the agent, rather than object, of the verb. We thus also analyze looks to the target versus competitor agents. For example, in the low attachment sentence ( 1 A ), the target agent is the dog, and the competitor agent is the master. We do so also for the original time window analyzed in the previous section.

This results in 6 analyses ( 3 time windows by 2 ways to operationalize target vs. competitor), of which one is the original analysis. The results from all analyses are presented in Table 1 . None of the critical effects reach significance in any of the analyses. However, for the agents, we identified marginal interactions of cue and phase in two of the time windows (Table 1); however, both were numerically in the opposite of the expected direction. Following Kamide, we also performed each of these analyses for trials containing saccades to target or competitor (with a reducted random effects structure). None of the additional analyses reached significance in the predicted direction (predicted direction: $p>0.7$ ), though the agents analysis for region C was significant in the unpredicted direction ( $p<0.05$ ).

We did not find a reliable effect of talker-specific syntactic adaptation between the cued and uncued talkers, even when considering post-hoc analyses over additional time-windows. All remaining analyses therefore use the same time windows as the original study.

So far, following Kamide (2012), all our analyses compared eye-movements for cued vs. uncued talkers. Such analyses group the two cued talkers together, ignoring potential differences in listeners' expectations for a male and a female (British English) talker. We conducted several followup analyses, comparing eye-movements in response to these two cued talkers. We found no evidence that participants were biased toward expecting more high (or low) attachment for either talker. Nor did we find any evidence that participants adapted more for one talker over the other.

## General Discussion

In contrast to the growing literature on talker-specific adaptation in speech perception, one of the few studies that has directly addressed talker-specific syntactic adaptation is (Kamide, 2012). Here we were unable to replicate the original study's findings. We are aware of one other ongoing effort within the same paradigm as the original study, albeit with different stimuli (ongoing work by Ryskin, Fine, \& BrownSchmidt). Ryskin and colleagues do not find evidence for talker-specific syntactic adaptation over the original time window, while finding weak evidence over a larger time window.

One possibility why the present experiment failed to find talker-specific syntactic adaptation is that it had less power than Kamide's original study: we used fewer participants (24 here vs. 48 in the original study). On the other hand, presumably because of the use of a task-based paradigm in the present experiment, the proportion of trials containing a look to either the target or competitor was almost twice as high in the present study than in the original study ( $42 \%$ in the present study vs. $<24 \%$ in the original study), which should increase the power. Power analyses suggested that power in our experiment was slightly lower than, but comparable to, Kamide's. For example, even when assuming an increase of 0.6 in log-odds in looks to the target in the cued vs. uncued condition from beginning to end of the experiment (constituting a 9 -fold increase in effect size), the present approach (24 participants, $40 \%$ looks to task-relevant objects) yields power of $69.4 \%$, compared to $82.5 \%$ for Kamide's study ( 48 participants, $20 \%$ looks to task-relevant objects).

Another possibility is that limited familiarity with the British- and Indian-accented English could have affected participants' ability to understand our talkers. If participants were unable to parse our talkers' sentences, this would make it impossible to learn talker-specific syntactic statistics. We note, however, that participants almost always clicked on the correct object ( $98.3 \%$ of all trials), indicating that they were able to successfully understand talkers. Additionally, the three talkers were easily distinguishable, which would be expected to support the learning of talker-specific statistics.

Additionally, it might be that our task encouraged participants to listen for the correct object without processing the syntactic structure. Participants were asked to click on the object of the verb; the verb was always provided at the very end of the sentence, and participants were not allowed to click un-

Table 1: Output of mixed effects logistic regression comparing fixations to target versus competitor objects and agents (positive coefficient estimates indicate more looks to the target object). Marginal effects in italics. No factors reached significance.

| Predictors | SentenceStart to RCStart |  |  |  | RCStart to RCNounStart |  |  |  | RCVerbStart to RCNounStart |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  | Object |  | Agents |  | Objects |  | Agents |  | Objects |  | Agents |  |
|  | $\hat{\beta}$ | $p$ | $\hat{\beta}$ | $p$ | $\hat{\beta}$ | $p$ | $\hat{\beta}$ | $p$ | $\hat{\beta}$ | $p$ | $\hat{\beta}$ | $p$ |
| Intercept | 0.49 | 0.11 | -0.07 | 0.37 | 0.09 | 0.57 | 0.17 | 0.06 | 0.23 | 0.30 | 0.27 | 0.07 |
| Cue (Cued=1 vs Uncued=-1) | 0.27 | 0.33 | -0.04 | 0.56 | -0.17 | 0.30 | -0.06 | 0.56 | -0.22 | 0.35 | -0.08 | 0.63 |
| Phase (End=1 vs Beginning=-1) | -0.12 | 0.71 | 0.00 | 0.97 | 0.20 | 0.25 | 0.14 | 0.15 | 0.42 | 0.14 | 0.14 | 0.30 |
| Cue:Phase | -0.27 | 0.45 | 0.04 | 0.57 | 0.01 | 0.93 | -0.16 | 0.10 | 0.07 | 0.80 | -0.25 | 0.08 |

til then. This meant that participants did not derive any time benefit from correctly tracking the talker's attachment preferences. However, we note that in the original experiment, as participants were asked only to look at the scene while listening to the sentence, there was also no explicit incentive to track the talker's attachment preferences.

An alternate possibility is that listeners do not exhibit talker-specific adaptation to attachment structure because they are not capable of it. Why might this be the case, particularly given the growing body of evidence for talker-specific phonetic adaptation? As talkers vary systematically in how they sound, both due to physiological factors (e.g. vocal tract size), and sociolinguistic factors (e.g. regional dialect), phonetic adaptation to talker-specific pronunciations can lead to a large benefit in later encounters with that same talker (Bradlow \& Bent, 2008).

By contrast, syntactic adaptation, particularly syntactic adaptation to high and low attachment structure, may not carry the same utility: subject relative clauses alone occur fewer on than $2 \%$ of all noun phrases (Roland, Dick, \& Elman, 2007). Non-local subject relative clauses with two animate (potential) heads-like those used in our experimentare even rarer. Thus, talker-specific syntactic adaptation to such a low-frequency structure may not lead to the same benefits of improved language understanding as phonetic adaptation to much more frequent phonemes. It may be beneficial to address questions of talker-specific adaptation by examining more frequent syntactic structures.

In sum, the current experiment failed to replicate the effect that listeners are able to track talker-specific syntactic preferences for attachment (Kamide, 2012). This raises questions about the extent to which syntactic adaptation may involve the same adaptive mechanisms used in phonetic adaptation.

## Acknowledgments

We thank Yuki Kamide for generously providing her visual stimuli and sentences, and for helpful discussion. We thank Anne Pier Salverda for technical and design advice, and members of HLP and KurTan lab at Rochester for feedback. This work was funded by NIH R01 HD075797 to TFJ. # Instrumental Representations of Sensorimotor Control: Representations at Intermediate Level 

Hsi-wen Daniel Liu (hwliu@pu.edu.tw)<br>Center for General Education, Providence University<br>Taichung, Taiwan

#### Abstract

In cognitive science, computation is largely accompanied with representational theory of mind. Yet, it remains unclear whether this companionship also appears in the realm of sensorimotor control. Grush's (2004) and Pezzulo's (2008, 2011) account of anticipatory representations provide a limited answer, as they are only suitable for forward models, but not the entire sensorimotor control. Rescorla's (2016) representational explanation for sensorimotor psychology addresses several intentional states considered in Bayesian inference and optimal modeling. However, the above accounts does not explain how motor commands are produced and chosen in the course of sensorimotor control for maintaining accuracy of goal-achievement. The present paper aims to explain it with a representational account by considering instrumental representations of sensorimotor control, which appear at the intermediate level and are exemplified by motor commands and costs. Such representations do not presume decouplability, as they need to run on-line in the maintenance of accuracy.

Keywords: Sensorimotor control; representation; optimal feedback control; Bayesian decision theory.

## Introduction

Within cognitive science there is a long-standing dispute between different paradigms concerning the role of representation in computation. Classical cognitive science understands cognition in terms of computation over mental representations, and considers the role of cognition to be deriving world-models that provide a database for thinking, planning and problem-solving. Decouplability between representations and their immediate environment is taken as intrinsic to representation. By contrast, a 'pragmatic turn' raises the 'action-oriented paradigm' that considers cognition to be providing skillful know-how in situated and embodied actions (Engel et. el., 2013). Clark (1997) raises the notion of action-oriented representations, which do not presume decouplability, in his 'minimal representationalism'. Action-oriented representations, yet, are mostly applied to reactive motor activities, regardless of various models of motor control.

The computational theory of mind is largely accompanied with a representational theory for explaining a variety of faculties, including perception, language, thinking, and problem-solving. However, the role of representation is highly debated for the faculty of motor action. Within models of motor control, the forward model is firmly associated with a role of representation, in the notions of emulating representation or anticipatory representations (Grush, 2004; Pezzulo, 2008, 2011). For those
representations, decouplability is claimed to be an intrinsic property. In addition, Bayesian models of motor control are seen as highly associated with a robust notion of mental representation (Rescorla, 2016). Decouplability is also seen as intrinsic to that notion of representation (Haselager et al., 2003). As to other models of motor control, however, the role of representation is unclear. The computational theory of sensorimotor control has been established (Wolpert and Ghahramani, 2000; Franklin and Wolpert, 2011; Orbán and Wolpert, 2011). It is suggested that motor control is conformed to the notion of pragmatic representation, as different from that of semantic representation (Jeannerod, 2006). Yet, questions remain as to what the pragmatic representation is and how it is related to computational models of motor control.

Given that computation of cognition is an explanatory account of cognition (Marr, 1982), an explanation can be found in the computational theory of sensorimotor control, as shown above. The sensorimotor control, as seen in the determination of an appropriate motor command, is considered to be fundamentally a decision process (Körding and Wolpert, 2006). The decision is to choose an appropriate motor command in order to achieve a given goal. The present paper contends that the explanation of the sensorimotor control is to explain why and how the decision could determine an appropriate motor command that turns out to achieve the goal. The explanandum is the way in which the goal is achieved by choosing an appropriate of motor command. The present paper characterizes this way of goal-achievement in terms of the end-means relation. The goal of a motor task is the end, and a chosen motor command is its means. Humans can rationally consider the appropriate means for an end; similarly, the sensorimotor system can choose an appropriate motor command for a given goal. This similarity, yet, is subject to two caveats. Firstly, while in economic decision-making or daily affairs in general, the rationality proceeds at the personal-level, the sensorimotor processes largely operate at subpersonal-level. Secondly, while characterization of human rationality need not be put in terms of probability, the actual performance of sensorimotor control is found to be very close to descriptions made with Bayesian decision theory (Körding and Wolpert, 2006), a theory with probabilistic measures.

Explanation of sensorimotor control can be pursued in anti-representationalist accounts, which hold certain explanatory perspectives (Turvey and Fonseca, 2009). Motor control, as contended in such accounts, is determined by interactions between the neural system, body, and the environment. Different from such accounts, the present
paper preserves an explanatory role for representation in terms of a novel notion of representation-instrumental representation-and regards the above interactions as complementary to computation and representation. Arrangement of that complementarity is for two reasons. One is the overall success of the computational approach to sensorimotor control (Franklin and Wolpert, 2011; Orbán and Wolpert, 2011; Todorov, 2004; Wolpert and Ghahramani, 2000). The other reason is that problems of sensorimotor control, to put it in Clark's (1997) terms, are not 'representational-hungry'. The neural system of sensorimotor control has tight interactions with body, and the environment. The notion of instrumental representation differs from the mainstream conceptions of representation in that it does not presume decouplability from the environment. Putting above two reasons together has an implication in the level of instrumental representations. Like that the present account of representation stands between the classic account of representation and those antirepresentationalist accounts, instrumental representations can be conceived of as standing at the intermediate level of the mind.

The present paper aims to raise a representational account of the sensorimotor control. This aim is to be achieved by explaining computation of sensorimotor control in terms of representation, on grounds that computation is a way to explain the mind, in the first place. Section two discusses computational explanations of sensorimotor control in terms of end-means relations. Section three specifies the notion of instrumental representations for explaining the sensorimotor control, on grounds of computational explanations of sensorimotor control.

## Computation in the Sensorimotor Control

The Bayesian decision theory in sensorimotor control holds a computational perspective with two components-estimation of environmental and bodily conditions, on the one hand, and decision made upon motor commands for the most desirable performance, on the other. To put it in an epistemological dichotomy, the former component is to measure environmental and bodily facts, while the latter one is to evaluate motor actions. To put it otherwise, the former is close to perception, while the latter to decision-making.

## Uncertainty

Measurement of states in the sensorimotor system is affected with various factors of uncertainty, and consequently it cannot be accurate like that we manage to measure the length of an object left on the table with a ruler. Sensory signals of the environment have inherent delays, which affect signals at all stages of sensorimotor system from the afferent (coming-in-from-the-outside) sensory information, to conduction along the neural fibers, together with the complexity of processing (face recognition being longer than motion perception) and 'slower' modality (vision being longer than proprioception). It can be said that we 'live in the past' by accessing the 'out-of-date
information' about the common world and our own bodies (Franklin and Wolpert, 2011, pp. 425-6). In addition, the nervous system is corrupted by noise, which also affects sensorimotor control at all stages, from the reception of sensory information, to planning, resulting in variability in movement endpoints. Noise, hence, contaminates our observation of the sensorimotor system internally and externally, by affecting estimation of body states and world conditions (ibid., p. 425). Noise in motor commands, in particular, increases propositionally to the size of their signal (the so-called 'signal-dependent noise'). Different motor commands would incur different degree of variability in the resulting endpoints. To put it more specifically, the motor performance is subject to speed-accuracy trade-off described by Fitt's law (Harris and Wolpert, 1998). Noise in the sensorimotor system corrupts not only estimation of internal and external states, on the one hand, but also performance of motor actions, on the other.

Apart from delay and noise, there are more factors of uncertainty residing in the sensorimotor system. Environmental conditions are constantly subject to change, for example, forces imposed upon the arm in the reaching movement (Shadmehr and Mussa-Ivaldi, 1994). It is also uncertain as to which actions or tasks would be beneficial in the real world outside the laboratory (Franklin and Wolpert, 2011). Furthermore, our motor system is non-stationary, for example, the length and weight of our limbs are changing when we grow up, and our muscles are getting stronger with larger forces (ibid.). Those uncertain factors would constantly contaminate information of the sensorimotor system, information which consequently needs to be optimized in order to achieve the given goal.

Given the aforementioned factors of uncertainty, the computation of sensorimotor system needs to optimize its information, in order to find the best resolution in view of goal-achievement. The sensorimotor system should maintain optimal estimation of world and body states, and should conduct optimal choice of motor commands. This need of optimality, in both state estimation and action choice, introduces a version of instrumental rationality that is immanent in the sensorimotor system at the subpersonallevel.

## Decision on Grounds of Utility

By contrast, another version of instrumental rationality turns up in the sensorimotor system's course of decision-making for optimal choice of a particular motor command, given a particular goal. Various particular goals can be given to a sensorimotor system, which are ends for the system to seek appropriate means for their fulfillment. Whenever a means is determined, a decision is made for attaining the end. The degree of fulfillment can be evaluated in positive terms, such as benefit, reward, utility or prospect; or alternatively in negative terms, such as loss or cost (Körding and Wolpert, 2006). The degree of fulfillment is a foundational notion, the present paper proposes, for explaining the sensorimotor control. In the realm of sensorimotor control, the utility of a
motor movement is the decision theory's way of evaluating the fulfillment of the goal. The fulfillment to a higher degree would receive the evaluation of a higher utility.

According to the decision theory, the expected utility of an action is defined quantitatively in terms of probability, as follows:

$$
E[\text { Utility }]=\sum_{\substack{\text { possible } \\ \text { outcomes }}} p(\text { outcome } \mid \text { action }) U(\text { outcome })
$$

where $p$ (outcome | action) is the probability of an outcome given an action, and $U$ (outcome) is the utility assigned to that outcome. An action is chosen for maximizing the expected value, which is put in terms of utility. A decision made in this way is defined to be a rational choice (Körding and Wolpert, 2006). This is a normative theory that defines the way in which people should behave; that way is put in terms of rationality. In other words, the rationality of action urges that people in their actions should pursue a higher degree of utility. When it is put in the context of sensorimotor control, a utility function evaluates how well a movement is performed. This way of evaluation quantifies, in terms of utility, the total desirability of a chosen movement. In addition, the decision theory is also considered to be a descriptive theory by assuming that people act rationally. The rationality assumed in this theory explains why people behave in the way they do. In fact, empirical findings indicate that the Bayesian decision theory shows successfully how people actually perform their sensorimotor control (ibid.).

The decision theory measures a motor movement, in terms of utility (measuring positively) or cost (measuring negatively), by evaluating its degree of fulfillment, that is, how well it achieves the goal. The end-means relation is assumed in the notion of fulfillment. The utility, in a descriptive term, defines how well a means attains the end.

The measurement of a cost depends on the immediate conditions of all relevant factors in the sensorimotor processing. Specifically, it depends on current states of the sensory system and properties of the to-be-chosen motor commands. The considered states include body states and the environmental conditions, for example, joint angles and velocities, and positions of relevant objects. Properties of motor commands can be measured with different emphases, for example, the jerk, torque change, energy, time, variance, of the to-be-chosen motor commands. The measurement, whatever the emphasis, takes the form of 'minimize X ' (Todorov, 2004). It is to minimize the size of relating factors, for example, the energy-to-be-consumed of the motor commands. In other words, the measurement of cost is sensitive to the size of the system's immediate response to its (bodily and environmental) conditions, which are embodied properties (i.e. jerk, torque change, energy, time, variance, etc.) of the sensorimotor system. To be noted, measuring the cost is not purely an internal matter, but is to be put in real situations, which consist of bodily and environmental conditions.

## The Basics of Motor Commands

Choice of motor commands, as above considered, is to be managed after a series of motor commands is organized. The computation of sensorimotor control is required to explain how to transform a higher-level goal into a series of motor commands, which are strictly constrained in the embodied sensorimotor system. This explanation consists of two parts: coordinate transformation and modular structure, both of which assume the end-means relationship. The former, coordinate transformation, is to convert sensory signals of the goal into motor commands. Sensory signals consist of visual information of the object in the goal-state together with the signals relating to the posture of bodily parts (hands, arms, shoulders, head, and eyes). Those signals need to be transformed into a set of motor commands that would bring about the goal-state when they are performed. This task is named to be sensorimotor transformations, which are accomplished with the mapping of a three-layered neural network: from the input layer of posture signals, to the intermediate layer that consists of population codes, to the output layer of the motor command that consists of the change in joint angles needed for the task (Pouget and Snyder, 2000). This is a way of reverse engineering, which is called the inverse model, as its direction of transformation is opposite to the forward model of motor control (Wolpert and Ghahramani, 2000). The sensorimotor transformations and their products can be regarded as means for the end of achieving the given goal.

As for the construction of movements, it remains controversial as to how much of movement might be controlled by modular processes (Zelik et. el., 2014). Insofar as modular organization is applicable, various complex motor movements are constructed through flexible combinations of a limited number of modules, in order to simplify computation by reducing degrees of freedom (Jing et. el., 2004). In other words, a complex motor command is organized with a combination of motor primitives. A motor command consists of a series of muscle activations for the needed changes of joint angles. With a study in the vertebrate spinal cord, it is shown that a complex motor command is produced by combining a few motor primitives, which are 'unit burst generators' organized in the spinal cord. Each burst generator is to control the activation of a small group of synergistic muscles, or motor synergies (Tresch et. el., 1999). Such a combination is a modular representation (Mussa-Ivaldi, 1999). A motor task is to produce a motor command with an appropriate modular structure. The motor commands produced in the above way are basic elements for the choice of cost function (Wolpert and Ghahramani, 2000). Given that a single motor command has the above modular representation, it would naturally be questioned as to how the series of motor commands leading to the achievement of a goal are organized.

The notion of modular structure appearing in sensorimotor control does not strictly follow Fodor's (1983) sense of modularity. Firstly, Fodor (1975) argues that
mental modules are combined with a language of thought (LOT, Mentalese). The modular structure of movement generation, however, does not seem to follow the structure of LOT, in the following two aspects. The weighted and graded combination of modules (Jing and Weiss, 2005) does not show the structure of LOT. Furthermore, generation of movements out of modular organization has practical limitations, as is found in generation of movements for diverse locomotor behaviors; sufficient flexibility needs a further basis of coordination (Zelik, 2014). There may be no clear distinction between planning and execution, because coordinated motor movements may emerge out of real-time optimal feedback control (Todorov and Jordan, 2002), as discussed below. Emergence of coordinated movements out of interaction with the environment makes generation of a movement deviant from the modular organization. To summarize, the modular organization is only loosely applicable in sensorimotor control.

## Coordination During Execution

The sensorimotor control on the basis of decision, cost and optimality, as aforementioned, can be managed, to a certain degree, in abstraction from the real situations. A version of optimality can be so pursued, by way of open-loop optimization, with detailed planning in advance of execution. The accuracy can be maintained to a certain degree, yet with serious limitations. The application of optimal principles seeks average optimality over previous performance. As it is detached from the real situations, the sensorimotor control is like playing "a prerecorded movement tap" and consequently the given goal is treated like a laboratory task. It would be unable to encounter the trial-to-trial variability in the real situations (Todorov, 2004, p. 2).

Such an abstract way of sensorimotor control is rather like the maintenance of thought, as it can run in abstraction from the real environment. It has the merit of a Popperian creature, that is, planning internally for a best solution of the considered problem before its execution. Decision can be made for a relatively optimal performance. Yet, an important way of sensorimotor control would be completely missing-coordination during execution. Understanding how this is done is a central problem in motor control for nearly 70 years (Todorov and Jordan, 2002).

The coordination during execution presumes optimal feedback control-the optimal control with on-line sensory feedbacks. It does not plan a desired trajectory before execution, but maintain the coordination on-line in response to all the task-specific contingencies in the real situations. Coordination in the sensory system is highly important as such a system is highly redundant, with a high number of ways over the combination of motor activations, and full of a variety of uncertain factors such as noise and delay, as aforementioned. The optimal feedback control produce "continuous trajectory of movement in response to contiguous stream of sensory input (Körding and Wolpert, 2006)". Costs are continuously generated with on-line control of sensory feedbacks. The evaluation of cost is put in terms of 'cost-
to-go'- the continuous and integral summation of costs (Todorov, 2004). The optimal feedback control responds to real situations of the body and the environment, and fully manifests the continuous way of motor decision in fastchanging conditions. This cannot be done in a detached model.

When the optimal feedback control operates as a way of coordination, motor synergies and the achievement of the given goal emerges. It only asserts what to achieve, without dealing with the how question in detailed. After the goal is given, the optimal feedback control can keep on seeking an appropriate resolution because of its coupling with the plant, in a way like the operation in the dynamic systems view. The stages of planning and execution are not separate (Todorov and Jordan, 2002).

The success of the coordination, in the optimal feedback control, relies on a normative property of the end-means relation, which is immanent in the sensorimotor system. That is, the sensorimotor system as a system with the endmeans relation would seek appropriate means for its given end. This property of the optimal feedback control can be seen as endowed in evolution. It is a process that makes possible the emergence of coordination in the sensorimotor system. After it encounters its contingencies, including the fast-changing environment (with body) with various uncertain factors, the sensorimotor system operates like the way present in the dynamic systems view. In that dynamic relations, motor synergies will eventually emerge.

## Instrumental Representations

Representations in the sensorimotor system are generally divided into three types: end, means, and cost. The goals in the sensorimotor system are regarded as ends, and motor commands are means for attaining those ends. An end represents a world state that is to be attained. A common element in the latter two types is the end-means relation: a means can attain its end, but therein lies a certain cost; in this sense, the means and the cost are called 'instrumental representations'. The means are first-order representations, which represent ways to attain their relating ends. Costs, by contrast, are second-order representations that represent prospects of the relating means in the processes of attaining their ends. Furthermore, those three types of representations hold different foundations of representation qua representation. An end represents a to-be-attained future state, in which the end refers to the to-be-attained future state on grounds of similarity. By contrast, the means represents the to-be-attained end in the way that the end is to be attained through the means. The cost, in addition, evaluates the prospect of a means in the way to attain its end. Finally, whether a means represents an end successfully, is measured in terms of accuracy (as opposed to truth), that is, accuracy with which the means attains the end. As accuracy can be measured with various degree, misrepresentation is subject to different degree.

## Representations as Stand-Ins

Representation, generally speaking, is something $R$ that stands in a system $S$ for something else $E$. That is, $R$ is a surrogate in the system $S$ for $E$. Representation sometimes serves as a Poppian creature: something that can run internally in a system before it is actually carried out. Representation in this sense simulates what will actually happen. It $(R)$ is a surrogate of $E$ 's actual performance. Based on Cummins (1996), a surrogate in this sense refers to its target with the informatiom of its content. A city map refers to the city streets according to structures of the map. A map user can simulate a feasible route in the map without actually walking in the street. Further, in order to account for the wits in the sensorimotor control, the notion of representation can be extended from the predicative relation to the end-means relations, insofar as they bring about a certain target (the end) with recourse to a certain content (the means). That is, the predicative representation $R b$ in a descriptive relation describes $E . R b$ refers to the target of $E$, and the content of $R b$ describes $E$. By contrast, the instrumental representation $R m$ in an instrumental (that is, end-means) relation brings about $E$, and the content of $R m$ guides the system $S$ to reach the goal-state $E$. Furthermore, a different surrogate $R i$ in the system $S$ would be likely to bring about a different state, as opposed to $E . R m$ and $R i$, hence, are alternative means generated in the system S , alternatives which can be compared for a higher degree of prospect $P$ to bring about the end-state $E$. The prospect $P$ is a second-order instrumental representation, as it evaluates the degree in which certain means would bring about the end. $R m$ and $R i$ are exemplified in the instrumental system by motor commands, and the prospect $P$ is exemplified by costs. Thus, instrumental representations are genuine representations because they stand in a system ( $S$ ) for something else $(E)$ that they bring about. The instrumental representations stand in the sensorimotor system, rather than merely serving as physical components of a mechanism, because they always have alternatives to be chosen in their way to bring about an end. The above profile will be discussed more specifically below.

The decouplability between representations and their environments is but a particular case for a system capable of generating alternatives. The system produces something else apart from a fixed representation. In a dark night, as I encounter a distal horse (a target) I may consider it to be a cow; in a darker night, I may even feel that it is like a unicorn. For achieving a given goal, sensorimotor representations produce various motor commands that are all likely to achieve the goal. The inverse model of a sensorimotor system transforms a single goal-state $G$ into various motor commands, which would all be likely, to a certain degree, to achieve the same goal G. The sensorimotor system always has alternatives to be chosen, in a decision for an optimal motor command, as indicated by the redundancy present in the musculoskeletal system. This is unlike a physical causal relation, such as knocking a group of billiard balls with a single ball, where a move in a
particular circumstance will determine a single result. Alternatives, as aforementioned, are made by the system $S$ in a non-physical connection, when the system $S$ encounters a fixed condition (e.g. encountering a horse, or given a particular goal-state). In the sensorimotor system, the inverse model generates various motor commands in a nonphysical connection, which is non-physical insofar as it is computational. The mechanism on the basis of Bayesian decision theory, in addition, makes a choice among redundant motor commands for optimality with a lowest cost. The choice from alternatives justifies that the sensorimotor control is not a 'merely physical' device.

Decoding of sensorimotor representations in the sensorimotor control is grounded on the use of those representations in the way to achieving the goal. Therein, the pragmatic dimension of sensorimotor control is considered in terms of end-means relations. The use consists of estimation over environmental conditions for applying them and choice between them, as manifest in the application of Bayesian decision theory in sensorimotor control (Körding and Wolpert, 2006). The generated motor commands in the inverse model, in addition, are made with alternatives, which are available for choice in their use dedicated to the achievement of the goal.

The motor commands are genuine representations because their way of bringing about goal-achievement is internally rich. Based on Cummins' (1996) notion of representation, the goal-state is the target while the content in use is the information employed, serving as guidance of the instrumental control, for achieving the goal. Specifically, the estimation of environmental conditions in the Bayesian model of sensorimotor control presumes the need of achieving the goal, and so is the model of optimality. Thus, the sensorimotor representations are internally rich, even compared to the classic representations, which are dubbed as representation-hungry. For example, the Bayesian inference, in order to estimate external conditions out of noise, needs to take account of priors, that is, previous experiential outcomes. This makes the Bayesian model of the sensorimotor control even no less emphasized on internal wits than the computation related to the classic theory of representation. In addition, the decision made in relation to cost, as discussed previously, making a choice from various alternative motor commands. Furthermore, the on-line measurement of cost adds more wits on the top of the computation with open-loop optimization. The instrumental representation based on alternatives of action command, together with their accompanying estimation and choice, provides computation with internal alternatives, evaluation and inference. Such a way of representation is internally rich.

Representations can serve as stand-ins of a system without being predicative. Representations are stand-ins for the existence of certain states, or for those states' activities. The former relates to representational production and the latter representational consumption. As considered above, the stand-ins can be instrumental, and consequently need
not be built with the function of imagination, on grounds of which counterfactual representations are possible. Imagination is surely a characteristic of human cognition. Cognition, however, can have other characteristics, for example, instrumental allocation, that is, arrangement of end-means relations. The end-means relation, for a given end, need not consist of a single string of causal chain, as it can produce alternative means for the same end. Those alternatives can be evaluated with different degree of prospects for attainment of the end. The choice from alternatives justifies the cognitive bearing of the instrumental representations.

Before concluding, it should be noted that instrumental representations can have a combinatorial structure only in a loose sense. Instrumental representations of sensorimotor control do not follow the LOT, basically because its modular organization is only loosely applicable, as discussed in a previous section. As a consequence, the combinatorial structure-with which mental representations can be generated recursively and systematically from primitive states-would not be generally salient in the realm of sensorimotor control. In particular, the costs of motor commands are continuously generated in on-line feedback control, as manifest in 'cost-to-go'-the continuous and integral summation of costs, as aforementioned. With this way of computing costs, the consequently chosen motor commands can only have modular structures (if there are) in a loose sense.

## Conclusions

Computation of sensorimotor control employs instrumental representations-representations with end-means relations-as exemplified by motor commands and costs. Motor commands represent ways to achieve the goal, and costs represent prospects of goal-achievement. They are intermediate-level representations, because the computation of motor commands does not rely on reactive machinery, and because they appear at the sub-personal level. Although they have modular structures, sensorimotor representations are initiated continuously and connected integrally. In order to maintain accuracy of goal-achievement, the sensorimotor system needs on-line incorporation of sensory feedbacks, and consequently sensorimotor representations cannot be detached from the body and the environment.

#### Abstract

We offer a re-evaluation of the tone-monitoring technique in the study of parsing. Experiment 1 shows that reaction times (RTs) to tones are affected by two factors: a) processing load, resulting in a tendency for RTs to decrease across a sentence, and b) a perceptual effect which adds to this tendency and moreover plays a role in neutralising differences between sentence types. Experiment 2 successfully discriminates these two factors by registering event-related brain potentials during a monitoring task, establishing that the amplitudes of the N1 and P3 components -the first associated with temporal uncertainty, the second with processing load- correlate with RTs. Experiment 3 then behaviourally segregates the two factors by placing the last tone at the end of sentences, activating a wrap-up operation and thereby both disrupting the decreasing tendency and highlighting structural factors.

Keywords: Tone monitoring; Processing load; ERPs; Position effect.

## Introduction

Monitoring tasks have long been employed in psycholinguistics, and the end-of-clause effect is possibly the better-known result in the study of parsing. According to Abrams and Bever (1969), the end of a clause exerts a particular cognitive load in the parser: reaction times (RTs) to tones are higher when placed at the end of the first clause of biclausal sentences than in between clauses or at the beginning of the second clause. Other structural effects have been reported in complex sentences with this technique, such as differences in processing load between subject and object relative clauses (Cohen \& Mehler, 1996).

In this paper, we track the processing load of parsing monoclausal sentences carefully and show that the issues are rather nuanced. In particular, we show that the RTs of a tonemonitoring task are affected by the additive effects of perceptual and psycholinguistic factors, and this has gone unnoticed until now. Interestingly, perceptual and psycholinguistic factors can be both successfully discriminated by registering event-related brain potentials (ERPs) during a monitoring task and behaviourally segregated by placing the last tone at the end of sentences, where a wrap-up operation presumably takes place. Perceptual factors are rather strong in monitoring tasks and they appear to have been operative in past studies too, which now need to be reconsidered.

## Experiment 1

Monoclausal, subject-verb-object Spanish sentences were constructed. Starting from a matrix proposition, two different types of sentences were created: type $A$ sentences exhibited a complex subject but a simple object, and the reverse was
the case for type $B$ sentences. By a complex subject or object we mean a noun phrase which is modified by another noun phrase, whilst a simple subject or object is composed of a determiner and a noun only. Three tone positions were determined to probe the processing load of the parser, both within a sentence and between sentence types. The materials of Experiment 1 are shown below, where the $\mid$ symbol identifies the boundaries under study:

Type A: El candidato $\mid$ del partido $\mid$ se preparó $\mid$ el próximo discurso.
'The party's candidate prepared his next speech'.
Type B: El candidato | ha preparado | un discurso | sobre la sanidad.
'The candidate has prepared a speech about the health service’.

We chose to focus on two central operations of parsing phrase completion and clausal integration- and hypothesised that a) the tone position and sentence type factors would each be significant, and $b$ ) there would be an interaction between them. This general hypothesis yields a number of more specific predictions. In the first position, the parser has processed the same material in type A and type B sentences, identifying the noun phrase the candidate as the subject of the sentence, following the canonical subject-verb-object(s) order in Spanish, and thereby predicting the appearance of the verb. Thus, the cognitive load should be equal and the RTs similar. In the second position, the verb prediction is borne out in type B sentences and the parser successfully completes the subject noun phrase, whereas in type A sentences the parser is processing a longer subject noun phrase and the verb prediction is still active. Moreover, in type B sentences the parser has integrated the verb and the subject noun phrase and now expects an object noun phrase, whilst in type A sentences the parser is yet to conduct any integration. In this case, the processing load should be greater in type A sentences and RTs higher to those of type B sentences, given the central role of the verb in a sentence. Finally, in the third position the parser has integrated subject and verb in type A sentences and now predicts an object noun phrase, whereas in type B sentences the parser has successfully integrated part of the object noun phrase. In this case too type A sentences should involve more processing load and therefore higher RTs at this position.

## Method

Participants. 80 psychology students participated for course credit. The mean age was 20 years, and participants had no known hearing impairments.
Materials. Two variants of monoclausal, active, declarative, subject-verb-object Spanish sentences were constructed from 60 matrix propositions. Type A sentences exhibited an [NP-[PP-NP]-[VP-NP]] pattern whereas type B sentences manifested a [NP-[VP-NP-[PP-NP]]] form -these are the structural conditions of the experiment. All sentences were unambiguous and composed of high- or very high-frequency words. Three tone positions per sentence were established, the three positional conditions of the experiment (1-2-3). Tones were placed on the vowel of the second syllable following the relevant boundary, had a frequency of 1000 Hz , a duration of 25 ms ., and a peak amplitude equal to that of the most intense sound of the materials ( 80 dBs ). Every sentence had one tone only.
Procedure. The design of the experiment was a 2 (sentence type factor) by 3 (tone position factor) within-subjects, within-items factorial, and therefore six lists of the task were created. The sentences were presented over the headphones binaurally and participants were instructed to hold a keypad with their dominant hand in order to press a button as soon as they heard the tone. They were told to be as quick as possible, but to avoid guessing. Once a sentence had finished, the next sentence would be presented upon pressing the space bar, giving subjects control over the rate of presentation.

## Results

Reaction times were collected and trimmed with the DMDX programme. A response that occurred before the tone or 3 seconds after the tone was not recorded at all, while responses deviating 2.0 SDs above or below the mean of each participant were eliminated (this affected $4.3 \%$ of the data). Table 1 collates the RTs per condition.

Table 1: Experiment 1. RTs per tone position per sentence.

|  | Tone Position |  |  |
| :---: | :---: | :---: | :---: |
| Sentence Type | 1 | 2 | 3 |
| A | 257.22 | 222.51 | 206.78 |
| B | 252.40 | 217.33 | 205.26 |

As shown in Table 1, RTs are greater in Position 1 and decrease thereon for each sentence type. A repeated-measures analysis of variance showed that the tone position factor was significant for both the subjects and items analyses $\left(F_{1}(2,158)=144, p<.001, n_{p}^{2}=0.647 ; F_{2}(2,118)=295\right.$, $p<.001, n_{p}^{2}=0.834$ ), while the sentence type factor was only significant for the subjects analysis $\left(F_{1}(1,79)=4.66\right.$, $p<.05, n_{p}^{2}=0.056 ; F_{2}(1,59)=2.48$, n.s.). There was no interaction between the two experimental factors (all $F s<1$ ).

Pair comparisons between the three positions of the tone position factor show that the differences in RTs among the three positions were significant (all $p s<.01$ ).

## Discussion

The results show a clear decreasing tendency in RTs, and whilst the two experimental factors were significant in the subjects analysis, this was not the case in the items analysis, where only the tone position factor was significant. Moreover, there was no interaction between the two factors. Thus, not all of our predictions were confirmed. The decreasing progression is rather robust, and the high significance of the (tone) position factor is further confirmation. This would be in line with the general expectation that processing load decreases as a sentence is presented, which follows from the incremental nature of parsing; in this case, the least linguistic material to process, the easier it will be to respond to the tone. However, the fact that there was no interaction between the two factors is surprising, as tone monitoring was expected to be sensitive to structural features. Each tone was placed in a different segment in each sentence type, and thus the parser, except for the first tone position, cannot be computing the same predictions at each position -i.e., the processing load cannot be the same. This ought to be especially significant when it comes to integrating nouns and verbs during the course of a sentence, but as the data show the earlier or later appearance of the verb and whether noun phrases were simple or complex do not appear to have had an effect. It is worth restating that tones were placed a syllable after the main boundary, but this very short sound (/de/ or /a/, in one case) would not be enough to predict the precise nature of the new phrase in the absence of further material (prepositional, verb, etc.), as various continuations are possible; this extra syllable would only indicate that the previous phrase had finished and needs to be completed, which is precisely what we were aiming to track in the experiment.

The decreasing tendency can be observed in Abrams and Bever (1969) too (and in other past studies). These authors established three positions in sentences such as since she was free that $\mid$ day $\mid$ her $\mid$ friends asked her to come (i.e., before the main clause break, in the clause break, and right after the clause break, all marked with |), and the RTs they obtained certainly exhibit a decrease: 243 ms ., 230 and 216. Relatedly, Cutler and Norris (1979) report that monitoring tasks in general exhibit a tendency of RTs to decrease across a sentence, and this needs to be taken into consideration. Crucially, the results reported in Abrams and Bever (1969) cannot be wholly explained in terms of processing load as they used biclausal, complex sentences and the course of incremental parsing in that study ought to have been different to what we obtained here.

Thus, we postulate that there is a perceptual factor at play in monitoring tasks; roughly stated, the later the tone appears, the more prepared the participants are to respond to it. If this is the case, there would be two types of uncertainties to track in monitoring tasks: one linguistic, stemming from incremen-
tality (viz., what linguistic material is it left to process?), and the other perceptual (viz., when will the tone appear?), which we shall call the position effect. As such, the results of our experiment -a decrease in RTs and no interaction between factors- would be the product of the additive effects of perceptual and psycholinguistic factors. If this conjecture is correct, then the greater RTs in the first tone position in Abrams and Bever (1969) may not have been due to an end-of-clause effect, but the result of the combination of perceptual and psycholinguistic factors. Indeed, given that past studies did not consider this perceptual factor and thus did not control for tone position, we are unsure as to whether the end-of-clause effect is well supported. That being so, the results reported in Cohen and Mehler (1996) are at first sight structural rather than perceptual, and as such tone monitoring must be sensitive to both factors (our own results yielded clear structural factors too). In order to delve deeper into this issue, we can combine tone monitoring with the recording of ERPs, which will allow us to track two different ERP components, one related to processing load (and linguistic uncertainty), the other to the position effect (and temporal uncertainty). If there is a correlation between these ERP waves and RTs, our analysis would be confirmed.

## Experiment 2

Only type A sentences from the previous experiment were employed, as there was no need to use both sentence types; the tone positions, however, remained the same. We concentrated on two ERP components, yielding two broad predictions. It was hypothesised that the N1 wave, a component associated with temporal uncertainty (Näätänen \& Picton, 1987), would correlate with the RTs, and thus its amplitude would be highest at the first tone position, the perceptual uncertainty of the participants being greatest at that point, and decrease thereon. This part of the experiment aimed to evaluate the significance of the position effect, and the N 1 is a pertinent component for such a task, given that it tracks perceptual processes rather than (higher) cognitive ones.

The second component is the P 3 , a component whose amplitude to a secondary task has been shown to be affected by the difficulty of the primary task in dual-task settings such as ours. Past results with dual-task experiments (e.g., Wickens, Kramer, Vanasse, \& Donchin, 1983) indicate that the P3 associated with a secondary task (in this case, reacting to the tone) will have a low amplitude if the primary task (here, parsing the sentence) is of considerable difficulty. In other words, there ought to be a correlation between the fluctuations in difficulty in a primary task and the amplitude of the P3 to a secondary task. In our experiment, as the primary task decreases in difficulty (as manifested by the linear decrease in RTs from the first to the third position), the amplitude of the P3 was predicted to increase from position 1 onwards.

Crucially for our purposes, the biphasic pattern we are hypothesising is well established in the dual tasks literature. Wickens et al. (1983) report an N1-P3 pattern when an au-
ditory probe is employed, and this is precisely what we are after: an N1 wave tracking perceptual processes and a P3 component tracking cognitive processes. In particular, we expect to obtain an N1 wave with a frontal distribution and a P3 with a more posterior-paretial distribution, thus singling out two independent components and confirming the processes that interest us. If these two waves turn out to be present in the data, and their amplitudes go in the direction we are postulating, we would have clear evidence for the two factors we have postulated. To our knowledge, moreover, this is the first time that the P3 is employed in a study of parsing as a metric of processing load, and we hope our results constitute evidence for its general usefulness. Naturally, these two hypotheses hold if and only if the pattern in RTs obtained in the previous experiment does not vary, and we hypothesised that this would be the case indeed.

## Method

Participants. 18 psychology students participated in the experiment. The mean age was 22 years, and subjects had no known hearing impairments.
Materials. The same as type A sentences from the previous experiment, but these now numbered 120 items.
Procedure. Participants were exposed to a total of 120 items, presented in three blocks. Apart from the electroencephalography (EEG) measures that were undertaken and the greater number of items, the task remained the same as in the previous experiment. The EEG was recorded continuously by $19 \mathrm{Ag} / \mathrm{AgCl}$ electrodes which were fixed on the scalp by means of an elastic cap (Electrocap International, USA) positioned in accordance with the 10-20 International system. ERPs were algebraically re-referenced to linked earlobes offline. Electrode impedances were kept below $5 k \Omega$. All EEG and EOG channels were amplified using a NuAmps Amplifier (Neuroscan Inc., USA) and recorded continuously with a bandpass from 0.01 to 30 Hz and digitised with a 2 ms . resolution. The EEG was refiltered off-line with a $25-\mathrm{Hz}$, low-pass, zero-phase shift digital filter. Automatic and manual rejections were carried out to exclude periods containing movement or technical artefacts (the automatic EOG rejection criterion was $\pm 50 \mu \mathrm{~V}$ ).

## Results

## Behavioural Data

The reaction times of the 18 participants were collected and trimmed with the DMDX programme. As before, responses deviating 2.0 SDs above or below the mean of each participant were eliminated, which in this case affected $3.6 \%$ of the data. The data are presented in Table 2.

As expected, the RTs manifest the exact same pattern as in Experiment 1: reaction times decrease from the first position onwards. A repeated-measures analysis of variance showed that the tone position factor was significant for both the subjects and items analyses $\left(F_{1}(2,34)=39, p<.001\right.$, $\left.n_{p}^{2}=0.698 ; F_{2}(2,238)=93, p<.001, n_{p}^{2}=0.441\right)$. Regarding pair comparisons between the different tone positions (1

Table 2: RTs per tone position.

| Tone Position |  |  |
| :---: | :---: | :---: |
| 1 | 2 | 3 |
| 325.05 | 266.53 | 247.60 |

vs. 2, etc.), the analyses showed that all comparisons were significant (all $p s<.01$ ).

## Electrophysiological data

The data were processed using BrainVision Analyzer 2 (Brain Products, Gilching, Germany). Average ERPs were calculated per condition and per participant from - 100 to 500 ms . relative to the onset of the tone, and before grand-averages were computed over all participants. A 100 ms . pre-tone period was used as the baseline. Only trials without muscle artefact or eye movement/blink activity were included in the averaging process. The analyses were based on 15 channels divided into five separate parasagittal columns along the anteroposterior axis of the head. The columnar approach to analysing the ERP data provides both an anterior-to-posterior as well as a left/right comparison of ERP effects. The electrodes in each of two pairs of lateral columns (Inner Column: F3/F4, C3/C4, P3/P4; Outer column: F7/F8, T3/T4, T5/T6) and on the Midline Column ( $\mathrm{Fz}, \mathrm{Cz}, \mathrm{Pz}$ ) were analysed with three separate ANOVAs. The analysis of the midline column included the position factor (position 1 vs. position 2 vs . position 3) and the location factor with three levels (Fz vs. Cz vs. Pz ). The analyses of the two pairs of lateral columns involved repeated measures ANOVAs with within-participants factors Position (position 1 vs. position 2 vs. position 3) and Location (anterior, central, and posterior). Omnibus ANOVAS were followed up with pairwise comparisons intended to discern whether there were differences among the three tone positions. All post-hoc analyses were Bonferroni corrected. Based on prior reports, two time windows were selected for analysis of the mean amplitudes of the components of interest: the N1 component was analysed from 120 ms . to 200 ms ., and the P300 component was evaluated from 230 ms . to 400 ms . In order to not clutter the presentation of our results, we only report the main effect of the Tone Position factor and the significant interaction effects.

Fig. 1 depicts brain potential variations in the three midline electrodes included in the analyses. As can be observed, the three tone positions exhibit a clear biphasic pattern, with a first modulation in the N1 time window in frontal and central electrodes, followed by a second modulation in the P300 time window in the central and posterior electrodes.

N1 epoch ( $\mathbf{1 2 0 - 2 0 0} \mathbf{~ m s}$ ). During the N1 epoch, there was a main effect of Position in the Midline, Inner, and Outer columns. Bonferroni corrected pairwise comparisons showed that all three positions differ from each other significantly in the three columns (all $p s<.05$ ), reflecting a more negative-

Figure 1: ERP waveforms for the three tone positions shown from a 100 ms . before tone presentation to a 500 ms . posttone presentation. The waveforms depict brain potential variations in the three midline electrodes included in the analyses. Negative voltage is plotted up.

going amplitude for position 1 relative to position 2 , and a more negative-going amplitude for position 2 relative to position 3. There was also a significant interaction between Position and Location in the Midline, Inner, and Outer columns (all $p s<.05$ ). In the Midline and Inner columns, posthoc comparisons revealed that whereas in frontal and central electrodes position 1 was more negative relative to position 2, and position 2 more negative relative to position 3 (all $p s<.05$ ), there were no differences in the posterior electrodes (all $p s>.20$ ). In the Outer column, post-hoc comparisons revealed that whereas in frontal electrodes position 1 was more negative than position 2, and position 2 more negative than position 3 (all $p s<.05$ ), there were no differences in central and posterior electrodes (all $p s>.52$ ).

P300 epoch ( $230-400 \mathrm{~ms}$ ). During the P300 epoch, there was a main effect of Position in the Midline, Inner, and Outer Columns. Bonferroni corrected pairwise comparisons in the three columns showed all three positions to differ from each other significantly (all $p s<.05$ ), reflecting a more positivegoing amplitude for position 3 relative to position 2 , and a more positive-going amplitude for position 2 relative to position 1. There was also a significant interaction between Position and Location in the Midline, Inner, and Outer columns (all $p s<.05$ ). In all three columns, post-hoc comparisons revealed that whereas in central and posterior electrodes position 3 was more positive relative to position 2, and position 2 more positive relative to position 1 (all $p s<.05$ ), there were no differences in the frontal electrode (all $p s>.11$ ).

## Discussion

As the behavioural data show, the prediction regarding the RTs pattern was confirmed; that is, RTs to the first tone are slowest, and then become faster thereon. This allows us to discuss the ERP data in the terms we had devised. The ERP data confirm the hypothesised topographical distributions and amplitudes for the N1 and P3 waves we expected. The N1 pattern indicates that participants are indeed uncertain as to when the tone is going to appear, and their uncertainty decreases as the sentence unfolds. We stated in the previous section that the linear decrease in RTs must be due to a combination of two factors and the N1 data confirm that there is indeed a purely perceptual factor at play, what we called earlier the position effect. Regarding the P3, its pattern can be explained in terms of processing load. As the amplitude of the P3 increases from position 1 onwards, and there is furthermore a negative correlation between RTs and the amplitude of the P3, this confirms that as the sentence is being processed the parser's unfulfilled predictions decrease, and thereby more resources can be allocated to monitoring the tone.

The biphasic pattern we have recorded confirms our analysis. First, the correlation between the amplitude of the N1 wave and tone position confirms that there is a strong perceptual factor and that it has an effect on performance. Second, the correlation between the amplitude of the P3 and tone position confirms two interrelated points: a) that tone monitoring is a dual task in which sentence processing is the primary task and tone monitoring the secondary; and, consequently, b) that the fluctuations in processing load are in part due to the decreasing uncertainty the parser experiences, thus dismissing alternative explanations in terms of response strategies, guessing the position of the tone, etc. All in all, we have succeeded in discriminating - that is, recording - the two factors we had posited. In the next experiment we shall show how they can in addition be behaviourally segregated.

## Experiment 3

In the previous experiments we did not examine the end-ofclause effect directly, as we used monoclausal instead of biclausal sentences and moreover none of the tones were placed
at the end of the sentences. In this experiment, we change the tone positions of type $B$ sentences from Experiment 1 to probe if by placing a tone at the end of a sentence the strong tendency for RTs to decrease is disrupted. The end of sentences is the locus of a wrap-up operation, which need not be the same as an end-of-clause effect; the wrap-up would involve operations that would not apply at the end of clauses (e.g., closing off all syntactic phrases, completing the sentence's semantic representation, etc.). We only used type B sentences because a) no across-sentence-type comparisons were relevant, and b) type B sentences exhibit a complex noun phrase in the object position, and this is a better configuration for our purposes.

Three tone positions are maintained, but their locations were changed: one at the beginning of the sentence and two within the verb's complex object, shown in the next section. It was hypothesised that the wrap-up effect would be indeed applicable at the end of a sentence and therefore that the pattern in RTs should be different from the pattern observed in the previous experiments. In particular, we expected a V-shape pattern in which RTs to the first position were highest, descending significantly for the second position, but then raising for the third and last position, the postulated locus of the wrap-up.

## Method

Participants. 37 psychology students participated in the experiment for course credit. The mean age was 22 years, and none of the subjects had any known hearing impairments.
Materials. Type B sentences from Experiment 1 were employed. The tone positions were modified to evaluate the wrap-up effect, as shown in the sentence below (where marks tone position). 60 fillers were also employed. In all other respects, the task did not change.
(1) El candi|dato ha preparado un di| scurso sobre la sani|dad.

Procedure. The same as in Experiment 1.

## Results

The reaction times of the 37 participants were collected and trimmed with the DMDX programme. Responses deviating 2.0 SDs from the mean of each participant were eliminated, affecting $3.8 \%$ of the data. Table 3 presents the final data.

Table 3: RTs per tone position.

| Tone Position |  |  |
| :---: | :---: | :---: |
| 1 | 2 | 3 |
| 414.16 | 351.88 | 365.45 |

In this experiment, RTs were greatest in the first position, and there was a slight increase from the second to the third position. A repeated-measures analysis of variance showed that
the tone position factor was significant for both the subjects and items analyses $\left(F_{1}(2,72)=98, p<.001 ; F_{2}(2,118)=\right.$ $110, p<.001)$. All post-hoc pairwise comparisons proved to be significant (all $p s<.001$ ).

## Discussion

As predicted, the wrap-up effect was detectable with the tonemonitoring task, thereby disrupting the linear decrease in RTs, as can be seen in Fig. 2.

Figure 2: RTs progression in Experiment 3

Indeed, even though RTs to the first position were greatest and there was a noticeable decrease from the first to the second position, the processing load associated with the wrapup effect resulted in an increase in RTs from the second to the third position, in clear contrast with what was obtained in the previous experiments, and resulting in the V-shape pattern observed in Fig. 2. This would seem to indicate that tone monitoring is not entirely hostage to perceptual factors such as the position effect; a design can be found so that structural properties are brought out more clearly, resulting in the clear segregation of the two factors that have animated the whole discussion. This is behavioural confirmation of what was observed on the ERP record, vindicating the usefulness of tone monitoring as a psycholinguistic technique.

Whether the wrap-up operation can be related to the end-of-clause effect apparently unearthed in previous studies is not so clear. In those studies, and as already stated, the end of a clause was in fact the end of a subordinate clause within complex, biclausal sentences, and that introduces a specific level of complication. Moreover, the end-of-clause position was also the first tone position in those studies, pointing to the probable impact of the position effect.

## Conclusion

We have here reported three main results with the tonemonitoring technique: a) a pronounced decrease in RTs for each sentence type (Experiments 1 and 2), which suggests that the parser's processing load decreases as the sentence is presented, thus releasing more cognitive resources to monitor the tone in so doing, in accordance with well-known prop-
erties of parsing (viz., incrementality); b) no interaction between the tone position and sentence type factors (Experiment 1), the potential result, in part, of what we have called here the position effect; and c) perceptual and psycholinguistic factors can be separately observed in an ERP recording (Experiment 2) and behaviourally segregated in a carefully designed experiment (Experiment 3).

The position effect, in particular, seems to have gone entirely unnoticed in all previous tone-monitoring studies. Abrams and Bever (1969) explained their data solely in terms of what they called the end-of-clause effect, but the two factors we have analysed here seem to be operative in their study too, and that muddies their data significantly. That is, even though these scholars placed a tone at the end of a clause, this tone position constituted the first of a decreasing tendency in a series of three tones, and thus the higher RTs to this (first) position may not have been the sole result of structural factors. There is, therefore, a very possible confusion and conflation between perceptual and psycholinguistic factors in their data, and this merits a closer look.

The two main factors we have identified here - the position effect and processing load- conspire to yield the RTs that can be obtained with the tone monitoring technique, and as a result future experiments employing this technique, we advise, will need to take this contingency into consideration. In our study we have shown that the two factors can be certainly separated, especially when one sets out to do so, but the combination of these factors may hide or obscure structural effects in tone monitoring tasks, requiring a more focused design if structural effects constitute the focus point.

#### Abstract

According to most recent theories of multisensory integration, weighting of different modalities depends on the reliability of the involved sensory estimates. Top-down modulations have been studied to a lesser degree. Furthermore, it is still debated whether working memory maintains multisensory information in a distributed modal fashion, or in terms of an integrated representation. To investigate whether multisensory integration is modulated by task relevance and to probe the nature of the working memory encodings, we combined an object interaction task with a size estimation task in an immersive virtual reality. During the object interaction, we induced multisensory conflict between seen and felt grip aperture. Both, visual and proprioceptive size estimation showed a clear modulation by the experimental manipulation. Thus, the results suggest that multisensory integration is not only driven by reliability, but is also biased by task demands. Furthermore, multisensory information seems to be represented by means of interactive modal representations.

Keywords: Multisensory Integration; Multisensory Conflict; Object Interaction; Virtual Reality

## Introduction

Adaptive interaction with the environment requires the combination of various sensory signals. According to theories of predictive coding, this integration is driven by a desire for consistency between internal models and the external world (Friston, 2010), as well as by a desire for consistency across different internal models (Butz, Kutter, \& Lorenz, 2014; Ehrenfeld, Herbort, \& Butz, 2013). Research on the mechanism of multisensory integration has shown that this consistency is achieved in terms of a maximum likelihood integration which combines different sensory signals based on their respective reliability estimates, resulting in a Bayesian estimate about the state of the external world (Ernst \& Banks, 2002; Ernst \& Bülthoff, 2004). It is still debated, however, whether this estimate is represented by means of an integrated representation (Cowan, 2001) or by means of separate, modality specific representations which are integrated on demand (Baddeley \& Hitch, 1974). Experimental results show strong interactions between modalities in the internal representation, for instance between visual and auditory working memory (Morey \& Cowan, 2005). Furthermore, unimodal retrieval from a multisensory representation is affected by pre-
vious modal encodings (Thelen, Talsma, \& Murray, 2015). Quak, London, and Talsma (2015) suggest that task requirements typically determine whether a unimodal or a complex, multisensory representation is formed.

Our aim in the present study was two-fold. First, we wanted to investigate whether multisensory integration is modulated by task relevance. Second, we wanted to probe the nature of the stored representations. To investigate these questions, we combined an object interaction task involving multisensory conflict with a size estimation task. We let participants perform a grasp-and-carry task in an immersive virtual reality, by tracking the hands of the participants. Conflict was introduced in terms of a visual offset, either expanding or shrinking the visual grip aperture, thereby dissociating vision and proprioception. Moreover, we augmented the object interaction with vibrotactile feedback, which signaled when the relevant object was grasped. After the object interaction, we let participants judge the size of the object they interacted with either visually or based on the grip aperture. If vision and proprioception are integrated, visual estimates should be biased in the same way as proprioceptive estimates. On the other hand, if there was no bias in visual estimates, this would imply an independent storage of modal information.

## Method

## Participants

Twenty students from the University of Tübingen participated in the study (seven males). Their age ranged from 18 to 34 years $(\mathrm{M}=22.1, \mathrm{SD}=3.9)$. All participants were righthanded and had normal or corrected-to-normal vision. Participants provided informed consent and received either course credit or a monetary compensation for their participation. Three participants could not complete the experiment due to problems with the motion capture system, only the data of the remaining 17 participants was considered in the data analysis.

## Apparatus

Participants were equipped with an Oculus Rift(C) DK2 stereoscopic head-mounted display (Oculus VR LLC, Menlo

Park, California). Motion capture was realized by the combination of a Synertial IGS-150 upper-body suit and an IGS Glove for the right hand (Synertial UK Ltd., South Brighton, United Kingdom). Rotational data from the suit's and glove's inertial measurement units was streamed to the computer controlling the experiment via a Wifi connection. The data was then used to animate a simplistic hand model in a virtual reality. Since the IGS system only provides rotation data, we used a Leap Motion(C) near-infrared sensor (Leap Motion Inc, San Francisco, California, SDK version 2.3.1) to initially scale the virtual hand model according to the size of the participants' hands. To allow participants to confirm their size estimates without manual interactions, participants were equipped with a headset. Speech recognition was implemented by means of the Microsoft Speech API 5.4. The whole experiment was implemented with the Unity ${ }^{\circledR}$ ) engine 5.0.1 using the C\# interface provided by the API. During the experiment, the scene was rendered in parallel on the Oculus Rift and a computer screen, such that the experimenter could observe and assist the participants.

To provide the participants with vibrotactile feedback during object interactions, we used two small, shaftless vibration motors attached to the tip of the thumb and the index finger of the participants. The diameter of the motors was 10 mm , the height was 3.4 mm . The motors were controlled via an Arduino Uno microcontroller (Arduino S.R.L., Scarmagno, Italy) running custom C software. The microcontroller was connected to the computer via a USB port which could be accessed by the Unity® program. If a collision between the virtual hand model and an object was registered in the VR, the respective motor was enabled with an initial current of 2.0 V . The deeper the hand moved into the object, the higher the applied current (up to 3.0 V ) and the according vibration. At a current of 3.0 V , the motors produced a vibration with 200 rotations per second, the resulting vibration amplitude was 0.75 g . The wiring diagram as well as additional information regarding the components are available online. ${ }^{1}$

## Virtual Reality Setup

The VR scenario put participants in a small clearing covered with a grasslike texture, surrounded by a ring of hills and various trees. A stylized container was placed in the center of the scene and served as target for the transportation task (see Fig. 1, left panel). The to-be-grasped and carried object was a cube rendered with a marble texture. The size of the cube varied from trial to trial but the cube always appeared at the same position in the scene. Textual information, like trial instructions and error feedback were presented on different text-fields aligned at eyeheight in the background of the scene.

Centered at the participants' hip $^{2}$, the task space covered

[^394]60 cm from left to right and 55 cm in depth. Corresponding to the data generated by the IGS suit an upper body rig was placed in the scene. It was positioned about 45 cm in front of the spawning position of the cube, slightly behind the the container. Hence, participants could reach both the container as well as the cube comfortably with their right arm. The rig itself was not rendered, only the right hand of the participants appeared in the scene visually.

The multisensory conflict between visual and proprioceptive grip aperture was realized in terms of a visual angular offset on the root joints of the thumb and index finger. They could be rotated either $10^{\circ}$ towards each other, or away from each other. To maintain the same aperture, this visual offset had to be compensated by an adjustment of the actual aperture in the opposite direction. To compensate for a visual offset shrinking the grip aperture, the grip aperture had to be wider, while a visual offset extending the grip aperture required a closer grip aperture. In one third of the trials, no manipulation was applied (the different offset conditions are shown in Fig. 1, right panel).

## Procedure

Participants received a verbal instruction at the beginning of the experiment regarding the use and function of the applied VR equipment. Then, they were equipped with the inertial motion capture system, consisting of the suit and the glove. If necessary, the finger sensors of the glove were fixated with rubber bands. After aligning the sensors and enabling the data streaming, the vibration motors were fastened underneath the thumb and index finger tip with rubber bands. Participants were then seated comfortably on an arm chair.

After this, participants were asked to hold their right hand over the Leap sensor to scale the virtual hand size according to their actual hand size. The control was then switched to the IGS system and participants put on the HMD to start the training phase. Participants could practice the grasping and carrying of the cube until they felt comfortable with the task. They had to complete at least 15 successful repetitions of the task before they were allowed to proceed. The grasp and carry task is described in detail in the next section.

After completing the training, the experimenter switched manually to the main experiment. The experiment consisted of eight blocks, each composed of 15 trials. The multisensory conflict between seen and felt grip aperture was introduced during the intertrial interval while the screen was blacked out. ${ }^{3}$ In each trial participants had to grasp a cube and put it into the target container. After the object interaction, the scene faded out and one of two possible reproduction scenes

[^395]

Figure 1: The left panel shows the VR scene and the initial position and fixation checks before the presentation of the target cube. Participants had to maintain a stable fixation on the fixation cross, the green spheres represent the starting position. The right panel shows the different offset conditions. Inward offsets are indicated by the light gray joints, dark gray joints indicate the outward offset condition.
appeared. This was independent of the success in the object interaction, the reproduction scene was also shown in case of error trials. In these scenes participants had to reproduce the size of the cube they interacted with either visually or by indicating the size in terms of a grip aperture. After each block, there was a break of at least ten seconds, after the fourth block, a longer break of at least two minutes was administered. Participants were allowed to put off the HMD during the breaks. After the experiment, participants were asked to complete a presence questionnaire (IPQ, Schubert, Friedmann, \& Regenbrecht, 2001). The whole procedure took 90 to 120 minutes, including the preparation and the practice trials.

Grasp and Transportation Task At the beginning of each trial, participants had to move their right hand into a designated starting position, consisting of red, transparent spheres indicating the required positions of the fingers and the palm. The spheres turned green when the respective joints were in position. Furthermore, participants had to maintain a stable looking direction on a fixation cross (see Fig. 1, left panel). When both requirements were met, the fixation cross as well as the visible markers of the initial position disappeared and the target cube appeared. Participants were instructed to grasp the cube with a pinch grasp and to move it into the target container. A successful pinch required the tips of the thumb and the index finger to be placed on opposite sites of the cube and to maintain a stable grip aperture. Participants received vibrotactile feedback whenever touching the cube. The feedback scaled with the depth of penetration, becoming more intense the deeper the fingers were moved into the cube. The task was successfully completed by placing or dropping the cube into
the container. Success was indicated by the cube bursting into an explosion of smaller green cubes. Interactions were canceled if the cube was penetrated overly strongly, dropped outside the container, moved outside the reachable space (e.g. by throwing it), or in case the interaction took more than 20 seconds. If one of the conditions was met, participants received error feedback and the trial progressed with the reproduction task.

After completing or failing the interaction, the markers for the initial position reappeared and participants had to move their hands back into the initial position. Then a visual mask was applied, accompanied by random vibrations on the finger tips. The visual and tactile masking commenced for one second. After the masking the scene faded to black and after one second, one of the two reproduction scenes appeared. The offset manipulation was removed during the blank interval.
Size Estimation In both versions of the size estimation task, participants had to reproduce the cube size. For the visual reproduction, the scene was similar to the one in which the interaction took place. However, the ground textures were replaced and different tree models were used to avoid possible comparisons between the cube size and external landmarks. A cube was placed at the center of the scene, at the same position where the cube during the interaction phase appeared. Above the cube, a slider was displayed, which allowed the participants to scale the cube by dragging the slider button with their fingertips. The slider spanned approximately 20 cm from left to right. The initial position of the slider button and thus the initial size of the visual reference cube was determined by the cube size during the interaction phase. For the smaller three sizes the slider started out at $10 \%$ and for
the two larger sizes it started out at $90 \%$ of the sliding range.
For the proprioceptive reproduction, all visuals were deactivated (including the hand model), only the horizon as well as small white sparks in the center of the scene remained active to remind the participants that the experiment was still running. Participants were instructed to indicate the size of the cube they interacted with by means of the grip aperture between thumb and index finger. To confirm their estimate, participants were requested to say the German word for "continue" or "done" ("weiter" or "fertig"). The voice control identified these commands and ended the trial, recording either the slider position - indicating the visual edge length of the cube - or the grip aperture as the size estimate.

## Factors

We varied three factors across trials. First, the edge length of the cube, which had to be interacted with and which size had to be estimated, was either $7 \mathrm{~cm}, 7.35 \mathrm{~cm}, 7.7 \mathrm{~cm}, 8.05 \mathrm{~cm}$, or 8.4 cm . Second, the visual grip aperture was either shrunk, or extended by $10^{\circ}$, or corresponded with the felt grip aperture. In the following, we will refer to visual offsets shrinking the aperture as inward offsets, conversely, we will refer to offsets extending the aperture as outward offsets. Third, we varied the reproduction modality, which could either be visual or proprioceptive. Hence, the experiment followed a $5 \times 3 \times$ 2 within-subject design. Each of the 30 conditions was repeated four times, resulting in 120 trials. The trial order was randomized.

## Dependent Measures

Besides the size estimates in the two different reproduction conditions, we obtained several time measures. Movement onset was determined as the time between the end of the fixation until leaving the starting position. Contact time refers to the time between movement onset and successful grasp. Interaction time refers to the time interval between the grasp and reaching the container.

## Results

Data was aggregated according to the $5 \times 3 \times 2$ withinsubject design. Seeing that the size estimation had to be performed after error trials as well, there are no missing data with respect to the size estimates. For the duration measures, only correct trials were considered. The overall error rate was high (nearly $30 \%$ ), due to the task complexity. In case of missing time data, the respective cell mean was interpolated within participants by the mean over all conditions with the same offset type. For all dependent measures, values differing more than two times of the standard deviation from the mean were excluded, which was the case for $2 \%$ of all data points. ${ }^{4}$

Size estimates, time measures, and error rates were analyzed with repeated measures ANOVAs using R ( R Core

[^396]Table 1: ANOVA table for the analysis of the size estimates. The assumption of sphericity was violated for the cube size factor and the interaction between offset and reproduction condition, the according p -values were subjected to a Greenhouse-Geisser adjustment.

Team, 2016) and the $e z$ package (Lawrence, 2015). All post-hoc t-tests were adjusted for multiple comparisons by the method proposed by Holm (Holm, 1979). Results from the presence questionnaire were compared with the reference data from the online database. ${ }^{5}$ There were no significant differences.

## Size Estimates

Data were analyzed with a 5 (cube size) $\times 3$ (offset) $\times 2$ (reproduction type) factors repeated measures ANOVA. Results are shown in Tab. 1. The analysis yielded significant main effects for cube size and offset. The main effect for cube size matches the actual cube size: larger cubes were estimated larger and smaller cubes were estimated smaller. To check if the estimates were veridical, we tested whether the estimated cube sizes differed from the actual cube sizes. None of the respective comparisons yielded significant results.
With respect to the main effect of offset, participants overestimated the cube size in case of inward offsets, compared to conditions with no offset $(t(16)=3.45, p=.007)$. For outward offsets participants underestimated the cube size, compared to conditions with no offset $(t(16)=2.98, p=.009)$. Finally participants provided larger estimates in case of inward, compared to outward offsets $(t(16)=5.23, p<.001)$.

Both, cube size and offset interacted with the reproduction condition. The interaction between cube size and reproduction type is due to a systematic overestimation of the larger cubes in case of the visual reproduction. In both cases, the estimates are significantly larger than the actual sizes of 8.05 $\mathrm{cm}(t(16)=4.26, p=.003)$, and $8.4 \mathrm{~cm}(t(16)=3.21, p=$ .022 ), respectively. ${ }^{6}$
The interaction between reproduction condition and offset was further analyzed with post-hoc t-tests. Estimates in case of outward offsets were significantly smaller than in case of

[^397]

Figure 2: Three-way interaction between reproduction condition, cube size and offset. Significant differences with $p<.05$ between estimates in case of inward and outward offsets are indicated by an asterisk. The respective $t$-tests were one-sided (inward $>$ outward) and were adjusted for multiple comparisons. The dashed line indicates the actual cube size.
inward offsets, both, for visual $(t(16)=-2.21, p=.021)$, as well as for proprioceptive $(t(16)=-5.48, p=.002)$ reproduction. However, the differences between the offset conditions were much more pronounced in case of proprioceptive reproduction, resulting in the observed two-way interaction.

This pattern of results was modified by a three-way interaction between cube size, offset and reproduction condition. Separate ANOVAs for the different cube sizes showed that the interaction between reproduction condition and offset was only present for cubes of intermediate ( 7.7 cm ) and large size $(8.05 \mathrm{~cm})$. For these two conditions, there were no significant differences between the offset conditions in case of visual reproduction. The differences for proprioceptive reproduction remained significant. The main effect of offset, however, remained significant for all of these separate analyses.

With respect to our hypotheses, the difference between inward and outward offsets is most relevant. To check whether inward offsets always result in larger estimates than outward offsets, we checked whether the respective difference is significant for the five different cube sizes, separately for the two reproduction conditions. In case of proprioceptive reproduction, the difference is significant for all cube sizes, except the smallest one of 7 cm . For visual reproduction the differences reached significance for all cube sizes, except the intermediate $(7.7 \mathrm{~cm})$ and large size $(8.05 \mathrm{~cm})$. The results are shown in Fig. 2.

## Time Measures

Data were analyzed with a 5 (cube size) $\times 3$ (offset) factors repeated measures ANOVA. No significant effects were found for the movement onset times. The analysis of object contact times yielded a significant main effect for off-
set $\left(F(2,32)=76.57, p<.001, \eta_{p}^{2}=.83\right)$. Slowest contact times were observed for outward offsets, while inward offsets yielded the fastest response times. All of the respective pairwise comparisons yielded significant results. The analysis of the interaction times yielded a significant main effect for offset as well $\left(F(2,32)=4.90, p<.014, \eta_{p}^{2}=.23\right)$. Participants were slower in transporting the cube in case of outward offsets. Post-hoc t-tests showed that the interaction times were significantly elevated in case of outward offsets, both compared to inward offsets $(t(16)=2.39, p=.042)$, as well as to trials without offset $(t(16)=2.42, p=.042)$.

## Error Rates

The analysis of the error rates yielded significant main effects for cube size $\left(F(4,64)=4.27, p=.004, \eta_{p}^{2}=.21\right)$ and offset $\left(F(2,32)=12.22, p<.001, \eta_{p}^{2}=.43\right)$. In general, participants made fewer errors during interactions with larger cubes. Furthermore, error rates were higher in case of inward offsets. Post-hoc t-tests showed that error rates increased for inward offsets, when compared to both outward offsets $(t(16)$ $=-3.67, p=.004)$, and no offsets $(t(16)=-4.56, p<.001)$.

## General Discussion

Previous studies on multisensory integration have shown a dominance of visual information in the perception of object size (e.g. Ernst \& Banks, 2002). To investigate whether task demands, which require to focus on another modality, can reduce this dominance, we let participants perform a grasp-and-carry task under multisensory conflict between vision and proprioception. In order to do so, we manipulated the mapping between seen and felt grip aperture. After the ob-
ject interaction we let participants estimate the size of the object they interacted with - either visually or by providing a proprioceptive estimate via grip aperture. Our results show a systematic bias in the size estimates due to the introduced offset between seen and felt grip aperture. A wider grip aperture resulted in object size overestimations, while a smaller aperture yielded underestimations. This was true for both, visual and proprioceptive size estimates. Hence, the adaptation of the size estimation followed the proprioceptive adaptation, which was necessary to compensate for the visual offset.

While the offset manipulation led to different actual grip apertures for cubes of the same size, the visual impression of both the cube size and the grasp of the virtual hand remained the same. Thus, if the size estimate was dominated by the visual impression, there should have been no effect of the offset condition in the visual reproduction trials. In contrast, our results show a clear influence of proprioceptive information on the size estimates in both modalities. However, this influence was much more pronounced in the case of the proprioceptive reproduction. Apparently, proprioceptive information dominated the resulting percept, even if proprioception was much noisier than vision, indicated by the comparatively large variance in the proprioceptive size estimates.
The combination of VR with motion capturing enabled us to dissociate vision and proprioception in an interactive setup. Compared to previous studies, which investigated the effects of mismatching sensory information regarding an object, the applied setup allows to manipulate the own body perception without affecting the visual impression of the external, virtual world. Some issues with respect to the experimental setup remain. The high error rates imply that even with the vibrotactile augmentation, the object interaction remained difficult for the participants. Especially in case of outward offsets, participants took quite long to grasp and carry the cube. The error rates were elevated for inward offsets, which were associated with the fastest grasping and interaction times, implying a speed accuracy trade-off. Furthermore, our setup did not comprise a control condition without grasping. Including trials which only require touching the object will clarify whether the mere presence of a graspable object yields a bias towards proprioceptive information, or if performing the actual interaction is necessary to induce the bias.
Despite these issues, the results allow us to draw the following two conclusions. First, visual and proprioceptive information regarding the object size seem to be stored separately, but are able to affect each other. If there was only a single percept reflecting the cube size across modalities, then the reproduced size should be independent of the reproduction modality. This is clearly not the case, given the huge difference in the variance of the visual and proprioceptive estimates and the stronger bias in proprioceptive compared to visual reproduction. This conclusion dovetails with results reported by (Ernst \& Banks, 2002), who showed that sensory data are stored separately, when they originate from different modalities. Second, the integration process that produces a
visual or a proprioceptive estimate is influenced by the type of reproduction. The considerable difference between the effect sizes implies a different weighting of the modality-specific encodings in the two reproduction conditions.

# Goal-Directed Deployment of Attention in a Computational Model: A Study in Multiple-Object Tracking 

Andrew Lovett (andrew.lovett.ctr@nrl.navy.mil)<br>Will Bridewell (will.bridewell@nrl.navy.mil)<br>Paul Bello (paul.bello@nrl.navy.mil)<br>U.S. Naval Research Laboratory, 4555 Overlook Ave SW<br>Washington, DC 20375

#### Abstract

We present a computational model exploring goal-directed deployment of attention during object tracking. Once selected, objects are tracked in parallel, but serial attention can be directed to an object that is visually crowded and in danger of being lost. An attended object's future position can be extrapolated from its past motion trajectory, allowing the object to be tracked even when it is briefly occluded. Using the model, we demonstrate that the difficulty of tracking through occlusions increases with the number of objects because they compete for serial attention.

Keywords: attention; perception; cognitive model; multipleobject tracking; visual cognition

## Introduction

Our visual experience of the world is rich and exhilarating, full of a wide variety of objects that move either predictably or erratically. Making sense of what we see requires an ability to follow these objects over time, sometimes tracking two, three, or more at once. The criticality of this capability is reflected in the existence of low-level mechanisms in the vision system that can follow multiple objects in parallel, seemingly without explicit attention. However, when the paths of objects intersect or when one object occludes another, these mechanisms are insufficient, requiring that we attend to an object to disambiguate it from others.

What guides our attention toward any one particular object in the visual field? There is a considerable amount of literature that seeks to answer this question by appealing to visual salience (Borji \& Itti, 2013). That work emphasizes contrast effects in the early visual system that draw our eyes to regions of fast motion, bright lights, and flashes of color. The target phenomenon described by that literature is goalfree, visual perception-that is, where a person would look if told to freely examine an image. The corresponding results say little about top-down influences on visual attention, such as when a person adopts a goal to track an object over time.

Fortunately, there is a task that lets us study goal-directed, visual attention under exactly these conditions. Experiments on multiple-object tracking (MOT) have people distinguish one or more targets from a larger set of identical distractors as they move across an empty background (Pylyshyn \& Storm, 1988). In these studies, the only identifying
characteristic of each object is its motion history. As a result, the low-level mechanisms that maintain the identity of objects in parallel are taxed, which lets researchers study their limits and therefore determine the conditions that require visual attention.

We know, for instance, that when targets come close to other objects, they tend to draw attention (Iordanescu, Grabowekcy, \& Suzuki, 2009; Zelinsky \& Todor, 2010). This effect of crowding does not hold when distractors are clustered together, so the goal to track the targets must play a role in protecting them from possible confusion with the other objects. It also appears that the difficulty of MOT increases when multiple targets are crowded simultaneously (Srivastava \& Vul, 2016). These findings suggest that visual attention is deployed serially and can only disambiguate one threatened target at a time.

In this paper, we present a computational model that accounts for one of the roles that attention plays in object tracking. Our research builds on previous work by Bello, Bridewell, and Wasylyshyn (2016) that assumed attention is serially deployed to initially encode targets, after which a parallel process that does not require attention exclusively handles object tracking. In their model, the interaction between attention and the tracking goal was limited to keeping visual attention on the targets. The model's ability to track targets broke down when the targets' previous positions were insufficient for distinguishing them from other nearby objects (e.g., when the objects moved quickly or were close to each other). In the updated model presented here, the processes for serial shifts of attention are refined and contribute throughout the task.

Specifically, the updated model detects when objects flagged as targets are visually crowded and, in response, directs attention to them. Sustained attention on an object enables the construction of its motion trajectory, which can be used to predict its future position. This extra information gives the model the ability to follow a target through an occlusion event, where another object overlaps or covers the target. Because attention is deployed serially, only one target can be tracked in this way at a time. As a result, when two targets are crowded, they vie for attention and the one that is not selected remains in danger of being lost by the parallel, tracking process.

Figure 1. Flow of information between components, both bottom-up (black arrows) and top-down (gray arrows). Components in bold respond to the focus of attention. Components with dashed borders are task-specific.

We claim that tracking through occlusion is facilitated by goal-directed deployment of attention to the target involved. We support this claim by providing a computational model of visual attention described in the next section. Briefly, this model requires that crowded targets compete for attention and its associated computational benefits. To test the model, we apply it to stimuli drawn from the work by Luu and Howe (2015) showing that people are better at predicting target positions from past trajectories when there are fewer targets. We find that the model accounts for these results and is in accordance with a broader range of findings in the literature.

## Computational Model of Visual Attention

The computational model is implemented using ARCADIA (Bridewell \& Bello, 2016a), a cognitive system designed for exploring the role of attention. The system operates in cycles that correspond to 25 ms of activity in human perception. On each cycle components, which carry out all the computation in a model, place their results in a location called accessible content. ARCADIA uses an attentional strategy to select one of these results as a focus of attention, which directs processing in a subset of components. On the subsequent cycle, the components receive sense data (e.g., a video frame), accessible content, and the focus of attention as input and produce the next collection of accessible content as output.

Like other models built using ARCADIA, this model of visual attention consists of a set of components and an attentional strategy. Many of the components included in the current model were previously described by Bello, Bridewell, and Wasylyshyn (2016). Looking at Figure 1, these include image segmenter, object locator, object-file binder, and vstm (which implements visual short-term memory). In the rest of this section, we summarize these components, mention changes to object locator, detail the new components, and discuss the attentional strategy.

Beginning at the bottom of Figure 1, image segmenter polls a sensor that provides one frame of video input each

Figure 2: A: An image with eight objects. B: A priority map in which four of the objects are tracked.
cycle. The component then outputs a set of proto-objects, hypotheses for the locations of objects (Rensink, 2000), based on closed-contour regions in the frame. For protoobjects to lead to object representations, they must receive attention. To this end, a set of highlighters, described later in this section, proposes one or more candidate proto-objects for the focus of attention. If ARCADIA focuses on one of these candidates, then the object file binder constructs an object file, which is based on the ideas of Treisman and Gelade (1980) and is a representation that binds together any visual features found at the proto-object's location (e.g., color profile, size). If that object file receives attention, then the vstm component stores it in memory.

## Improvements to the Parallel Aspects of Tracking

If tracking objects always required attention, then it would take four ARCADIA cycles ( 100 ms ) to go from visual input to representing a single object in vstm. To update that object's location would take the same amount of time. Even accounting for the ability to pipeline parts of the process, two cycles ( 50 ms ) are required for shifting covert attention and representing an object. The timing needed to serially update the location of multiple objects, which is based on evidence from visual search in humans (Wolfe, 2003), is unrealistic. Therefore, the model needs a way to track objects in parallel.

To address this need, the model includes tracking functionality in object locator. In earlier ARCADIA models, this component kept location information up-todate by matching object files in vstm to the proto-objects nearest to each object's last known location. This approach was inspired by Pylyshyn's (1989) proposal that roughly four objects can be tracked in parallel using visual indices and by Dawson's (1991) work that identified a nearestneighbor constraint in apparent motion, which is likely related to tracking.

In this model, we refine object locator to provide an account of Dawson's constraint based on newer results in visual processing. This new implementation generates a two-dimensional priority map (Fecteau \& Munoz, 2006; Bisley \& Goldberg, 2010), with enhanced regions at each tracked object's last known location and suppressed regions around them. Evidence for this treatment of spatial regions

Figure 3. A: An occlusion event. B: Part of a priority map, updated with an attended object's predicted location, shown as the off-center darker red circle.
comes from early work on multifocal attention (Castiello \& Umiltà, 1992) and center-surround suppression (Tsotsos et al., 1995; Desimone \& Duncan, 1995). To track objects in parallel, each object file in vstm is matched to the protoobject that most overlaps its corresponding enhanced region on the priority map. Figure 2 B shows an example of such a map with enhanced red and yellow circles and suppressed outer green rings. Importantly, if two tracked objects are near each other, one object's suppressed region may overlap another object's enhanced region (see the two lower circles in Figure 2B), resulting in a smaller enhanced region and a greater chance of a tracked object being lost. ${ }^{1}$

## Goal-Directed Attention in Tracking

Adopting a goal to track specific moving objects, or targets, alters how attention is deployed. In particular, attention can be drawn to a target when there is a risk that the parallel, tracking mechanisms could fail for that object. For instance, as suggested by Figure 3A, when multiple objects overlap, they look like a single proto-object. After those objects move apart, it is unclear which one, if any, was previously a target. This problem arises because following a target through an occlusion event requires more information than only its previous location. On these occasions, the model uses an attended target's recent motion history to extrapolate its future position in order to track it through occlusions. We conjecture that serial attention is required for this process because it involves binding trajectory information and the corresponding extrapolated position to a particular object file.

Goal-directed deployment of attention is assisted by the highlighters mentioned earlier in this section. Recall that these components propose proto-objects as candidates for attention and therefore determine which objects will be

[^398]stored in vstm and tracked by object locator. There are three highlighters, one of which is task specific and the other two are generally important for tracking. First, color highlighter is used to identify targets and queries about objects in the multiple-object tracking videos, indicated by objects changing color in the videos.

The other two highlighters propose proto-objects corresponding to currently tracked objects. The crowding highlighter proposes each tracked object as a candidate for attention and includes as information the distance from each one to the nearest other proto-object. This value provides a measure of crowding and is based on the finding that tracked objects draw attention when they are visually crowded and in danger of being lost (Iordanescu, Grabowekcy, \& Suzuki, 2009; Zelinsky \& Todor, 2010).

The maintenance highlighter proposes maintaining attention on the object that was last in focus. If attention remains on the same object over a period of time, this component computes its motion trajectory from location changes over a window of two to three cycles. Additionally, maintenance highlighter detects occlusion events, where the focused object is partially or completely occluded by another object (e.g., Figure 3A). When the attended object is occluded, the component predicts the focused object's position based on its recorded trajectory. This information lets object locator update its priority map to enhance the object's predicted location (the off-center, red circle in Figure 3B), improving its ability to continue tracking the object after the occlusion event ends.

The final component, target object guesser, records the model's responses in the multiple-object tracking task. This component reports whether the model considers a probed item to be a target (tracked) or a distractor.

The model's attentional strategy is a priority list over the elements in accessible content. The highest priority is to focus on new object-files for storage in vstm. Below that, the strategy prefers proto-objects, which enables encoding them into object files. The preferences for proto-objects are ordered with color highlighter first, which ensures that targets are initially encoded and that probes are noticed when objects change color. The next highest priority is to maintain attention on a crowded target, one whose distance to the nearest other proto-object has fallen below a crowding distance threshold. The third highest priority is to attend to whichever target is the most crowded-the one with the lowest crowding distance. This ordering enables goaldirected deployment of attention to objects that are in danger of being lost, and it handles competition between simultaneously crowded objects. Once an attended object is endangered, attention will stay on it until the distance to nearby proto-objects exceeds the crowding threshold even if other targets are also in danger.

In summary, the model consists of eight components (Figure 1), four of which are new and one of which was substantially changed. Two components are task specific: target object guesser and color highlighter. The model includes three free parameters, two in object locator ${ }^{1}$ and

Figure 4. Simulated accuracy across conditions. Error bars are standard error. Speeds were calibrated separately for 2 and 4 targets to achieve about $75 \%$ accuracy.
the crowding distance threshold, which indicates when targets are too close to other proto-objects. In the next section, we report an experiment that supports the validity of this model in the context of multiple-object tracking.

## Evaluation

We evaluated the computational model by running it on MOT videos similar to those used in Luu and Howe's (2015) Experiment 1. In that work, participants tracked either two or four targets with either predictable or unpredictable motion trajectories. Luu and Howe's key finding was that people more accurately track objects with predictable trajectories than with unpredictable trajectories, but only in the two target condition. The model in this paper accounts for this effect, showing that goal-directed deployment of attention can be used to predict a target's location from its past trajectory. This ability enables tracking a single target through an occlusion, and when multiple targets are simultaneously crowded, they compete for attention. This competition for resources means that task difficulty increases with the number of targets.

## Experiment

In each trial of Luu and Howe's experiment, two or four out of eight total disks were highlighted in red to indicate that they were the targets. Afterwards, all disks turned black and the disks moved for 5.5 s while participants fixated on a center cross. During this time the disks could occlude (i.e., pass through) each other. At the end, two disks were highlighted in sequence, and participants indicated whether each one was a target. Each highlighted disk had a $50 \%$ chance of being a target, and participants needed to respond correctly on both for the trial to be coded as correct.

There were two movement conditions for the experiment. In the first condition, every disk moved predictably in straight lines and changed direction only after bouncing off the edge of the display. In the second condition, the disks moved similarly, but every $300-600 \mathrm{~ms}$, they would randomly change direction. This unpredictable movement was expected to reduce the reliability of any effort to compute and utilize motion trajectories.

At the beginning of the study, the motion speeds for each participant were calibrated to determine the speed where the participant achieved $75 \%$ accuracy. Calibration occurred separately for two and four targets and used only predictable motions. Afterwards, participants were tested over 120 randomly generated trials, 30 in each condition (number of targets $\times$ motion predictability), with conditions interleaved.

Luu and Howe reported data from 15 participants. Their results found, unsurprisingly, that tracking two targets was easier than tracking four, as indicated by a much higher speed when calibrating for two targets. Importantly, they observed a significant interaction between the number of targets and motion predictability. Pairwise comparisons indicated that predictable motions were easier than unpredictable motions for two targets but not for four targets. Luu and Howe proposed that object tracking is sensitive to motion trajectories for two targets, but less so for four targets, which is in line with findings by Fencsik, Klieger, and Horowitz (2007).

## Model

To evaluate the computational model using Luu and Howe's experiment, we randomly generated 120 trial videos each for 15 virtual "participants" (the model was the same in each case, so only the trial videos varied). The videos matched the description in the paper as closely as possible with five minor exceptions.
(1) There was no fixation cross, but center fixation was enforced in the model.
(2) It was impossible to match to the original study's display size $\left(15^{\circ} \times 15^{\circ}\right)$ because the model does not perceive the display from a quantifiable viewing distance. However, the study's proportion of disk size to display size was maintained.
(3) Videos were constrained to begin and end with all disks at least one radius apart (such constraints are common but were not mentioned in the paper).
(4) To save simulation time, disks were highlighted for a shorter duration.
(5) Disk colors differed from the original, which was incidental.
The model's crowding distance threshold was 1.6 diameters, meaning an attended target would need to be at least this distance away from all other disks before the model could swap attention to another target.

## Results

The calibration phase of the experiment differed slightly from Luu and Howe's approach. Because the model was held constant across virtual participants, we calibrated the speeds only once. We found that to ensure roughly equivalent accuracy close to $75 \%$, the speeds were eight pixels per cycle for two targets and four pixels per cycle for four targets.

Figure 4 displays the results for each condition. A twoway ANOVA with set size (two vs. four targets) and predictability was conducted. There was a significant main
effect of predictability, $\mathrm{F}(1,56)=14.3, \mathrm{p}<.001$, indicating that accuracy was higher with predictable trajectories. There was also a significant interaction between set size and predictability, $\mathrm{F}(1,56)=4.8, \mathrm{p}=.032$, indicating that the effect of predictability was greater for two targets. Unpaired comparisons confirmed that predictability had a significant effect on accuracy for two targets, $\mathrm{M}=79.8 \%$ (predictable) vs. $68.9 \%$ (unpredictable), $\mathrm{t}(28)=3.91, \mathrm{p}<.001$, but not for four targets, $M=75.3 \%$ (predictable) vs. $72.4 \%$ (unpredictable), $\mathrm{t}(28)=1.23, \mathrm{p}=.230$.

## Discussion

The model's results matched the human data, which suggests that the model accounts for two key findings. First, as evidenced in the speed discrepancies during the calibration phase, tracking two targets was easier for the model and for people than tracking four targets. Notably, increasing the number of targets increases both the number of possible occlusion events and the potential for simultaneous crowding. These effects are important for the model, which explains errors as resulting in part from failures to attend to targets during occlusion. As a result, slowing object movement reduces the number of occlusions and contributes to the ability to successfully track targets.

The second and more important finding is that the model more accurately tracked objects that moved predictably than those that moved unpredictably, but only for two targets. To understand this, we have to describe why the model could track some objects through occlusion events when the trajectories were unpredictable. Recall that objects changed direction only every $300-600 \mathrm{~ms}$, or $12-24$ cycles in ARCADIA, and that the model calculates motion trajectories over a 2 cycle window. As long as a target maintains course through the occlusion and the two cycles before it, tracking should work perfectly. In practice, this means that the unpredictable trajectories only disrupt a small proportion of occlusion events.

As an explanation, the model suggests that there are two sources of error: missed occlusion events and unpredictable trajectories for attended occlusions. With four targets there are more missed occlusion events due to simultaneous crowding than with two, so proportionally that has a larger effect on the error rate than the unpredictable trajectories. This difference explains why unpredictable trajectories are more harmful with two targets than with four, and the combination of this with the overall small proportion of occlusion events disrupted by unpredictable trajectories explains the lack of a significant effect with four targets.

## General Discussion

The model demonstrates the critical role of goal-directed visual attention in object tracking. Although attention is not always needed to update target locations, it provides key information to aid in tracking targets that are in danger of being lost due to visual crowding. In the reported model, attention provides a target's motion trajectory, which enables tracking through occlusions.

One explanation for how people track multiple objects is provided by the multifocal view of attention (Cavanagh \& Alvarez, 2005). Proponents of this view have argued for two theoretical limits on attention. First, attention may be a limited resource that must be distributed among targets (Holcombe \& Chen, 2012), which makes tracking more difficult when targets are crowded simultaneously and must compete for attention (Srivastava \& Vul, 2016). Second, attention may be subject to spatial interference between neighboring targets (Franconeri, Jonathan, \& Scimeca, 2010), which makes tracking more difficult when targets are nearer to each other (Shim, Alvarez, \& Jian, 2008; Holcombe, Chen, \& Howe, 2014).

The reported model offers a competing explanation that distinguishes between serial attention to a single object, which is used to bind features and compute motion trajectories; and parallel enhancement of multiple objectlocations, which is used to track objects. These separate mechanisms account for both apparent limits described above. First, tracking difficulty increases when targets are simultaneously crowded because they compete for the serial focus of attention. Second, difficulty increases when targets are near each other because the parallel tracking process uses center-surround suppression, with an enhanced region and a surrounding suppressed region at each target's location. When two targets are close such that one's suppressed region overlaps the other's enhanced region, the enhanced region shrinks and there is a greater chance of losing the target. Additionally, difficulty increases with the number of targets and with object speed (Alvarez \& Franconeri, 2007) because these manipulations increase the frequency of events where targets are simultaneously crowded or targets interfere with each other.

Although there are other computational models that have been applied to MOT, the reported model provides a novel explanation. Oksama and Hyönä (2008) relied solely on serial attention and Kazanovich and Borisyuk (2006) relied entirely on multifocal attention. Srivastava and Vul's (2016) Bayesian, multifocal model is similar to ours in that it distributes attention to visually crowded targets, which lets it predict greater tracking difficulty when targets are crowded simultaneously. However, their model makes no link between attentional distribution and computing motion trajectories. Additionally, the model cannot account for spatial interference between targets. Finally, their model is disconnected from video input, and it abstracts away the underlying correspondence problem.

In this paper, we demonstrated the role that goals may play in object tracking. In particular, the model's implicit goal to track targets enhances its ability by influencing where it attends. That is, selecting an object as a target recruits processes that monitor crowding and maintain focus when that target is endangered. Additionally, we note that the information made available by attending to an object is a form of indirect influence by the goal on visual processing (e.g., during the creation of the priority map). In the future we intend to explore other cases where the goal-directed
deployment of attention interacts with perception and eventually with motor control.

Ryan McKay (ryan.mckay@rhul.ac.uk)<br>Department of Psychology, Royal Holloway, University of London<br>Egham, Surrey, TW20 0EX United Kingdom

#### Abstract

From distracted driving, to work focus on a computer, increasing amounts of research is investigating how digital technology influences users' attention. A couple of widely cited studies have found that the mere presence of cell phones interferes with social interactions and cognitive performance, even when not actively in use. These studies have important implications but they have not yet been replicated, and also suffer from methodological shortcomings and lack of established theoretical frameworks to explain the observed effects. We improved the methodology used in a previous study of phone presence and task performance (Thornton, Faires, Robbins, \& Rollins, 2014), while testing an 'opportunity cost' model of mental effort and attention (Kurzban, Duckworth, Kable, \& Myers, 2013). We were unable to replicate Thornton et al.'s finding that presence of cell phones reduces performance in a specific cognitive task (additive digit cancellation). Moreover, contrary to our expectations, we found that participants who used their phones more, and who were more attached to them, found the tasks more fun/exciting and effortless, if they completed them with their phone present.

Keywords: attention; distraction; cell phones; smartphones; effort; task performance

## Introduction

A growing amount of research in the cognitive science of attention studies how workers and students navigate a workspace with ample opportunities for distraction and/or multitasking (Cain \& Mitroff, 2011; Mark, Voida, \& Cardello, 2012; Ophir, Nass, \& Wagner, 2009; Pea et al., 2012; Ralph, Thomson, Cheyne, \& Smilek, 2014). Recently, this strand of research has moved on to how smartphones influence their users' attention. This is an important topic, since more than $72 \%$ of the US population own smartphones (Pew Research Center, 2016), and because it has very real consequences: the US Department of Transportation recently urged mobile companies to develop a simplified 'Driver Mode' for smartphones, due to an alarming rise in traffic accidents related to distracted driving (NTHSA, 2016).

A couple of widely cited studies have reported negative effects of the mere presence of cell phones on social interactions. Przybylski \& Weinstein (2012) varied whether or not a mobile phone was placed next to strangers engaged
in a conversation task and found that participants reported lower relationship quality and partner closeness when a cell phone was present. A follow-up observational study found a similar effect in a coffee-shop setting (Misra, Cheng, Genevie, \& Yuan, 2014). However, the results from these studies are open to a multitude of interpretations (e.g. various meanings of phone presence in a social context).

Our point of departure was a controlled study by Thornton et al. (2014) who in a non-social context investigated effects of cell phone presence on performance in simple cognitive tasks. They varied whether or not a cell phone was present on a participant's table while he/she completed a series of tasks (digit cancellation: searching for and crossing out target numbers among other numbers, or trail making: connecting consecutively numbered or lettered circles displayed in random order). They found that people performed worse in more challenging versions of these tasks (crossing out pairs of target numbers that add up to a specific number; connecting circles so that consecutive numbers and consecutive letters alternate, e.g. 1-A-2-B-3-C$\ldots$..), when a cell phone was present. The authors concluded that the mere presence of a cell phone, even when not in use, can be distracting and cause performance deficits on tasks that require full attention for optimal performance.

The experiments by Thornton et al. have potentially widereaching implications, from distracted driving to performance in schools and workplaces (Thornton et al., 2014). However, no replication studies have been conducted to establish the reliability of their findings. Moreover, their study had limitations: In their first experiment, they manipulated the presence of an experimenter's cell phone rather than the participant's own. In their second experiment, they varied the presence of participants' own phone but did not check whether their procedure for doing so made participants suspicious about the purpose of the experiment. They also did not test any theoretical frameworks that would explain their observed effects.

## The present research

We followed up on Thornton et al.'s study, addressing these limitations: We i) conducted a replication study using their
original stimuli for the digit cancellation task ${ }^{1}$ (responding also to general calls for replication studies, cf. Francis, 2012; Nosek, Spies, \& Motyl, 2012); ii) improved the original procedure to study effects of presence of participants' own smartphones while ruling out suspicion; and iii) tested a new theoretical framework for understanding the effects. In relation to the latter, we applied Kurzban et al.'s 'opportunity cost' model of attention and mental effort (Kurzban et al., 2013). According to this cognitive model, the human mind continuously computes the opportunity costs of our available tasks, i.e. the value of options that one is missing out on by persisting on the current task. The higher the perceived opportunity costs, the more the current task will feel mentally effortful and/or boring, with decreased quality of performance to follow. This model is well suited to predict effects of smartphones: Smartphones give immediate access to a virtual infinity of stimulating and relevant content, from global news to social gossip and video games. Insofar as they therefore afford opportunities for highly rewarding activities other than the task at hand, smartphone presence should increase the current task's opportunity costs. In turn, this might make one's current task feel more boring or effortful, and cause decreased quality of performance. Hence, our predictions were:

Prediction 1 (replication): Average scores in the additive digit cancellation task will be lower when a smartphone is present than when it is absent.

Prediction 2: The digit cancellation tasks will feel more effortful to complete when a smartphone is present than when it is absent.

## Methods

## Participants

53 participants ( 50 female) were recruited at the University of London, Royal Holloway ${ }^{2}$. Mean age was 18.8 years (SD $=1.4$, range 17-27).

## Materials

Digit Cancellation Task Participants completed two versions of a digit cancellation task, using Thornton et al.'s original stimuli. In both tasks, participants were given a piece of paper containing 20 rows of 50 -digit strings. In the 'simple' version, participants cross out every instance of the number specified at the beginning of each row (e.g. 3: $7301638 \ldots$ ). In the 'additive' version, participants cross out

[^399]every instance of two consecutive numbers that, when added, equal the digit specified at the beginning of each row (e.g. 5: 1237814...). In the 'simple' version participants cross out as many numbers as possible in 90 seconds; in the 'additive' version they cross out as many pairs of numbers as possible in 180 seconds.

Effort Measure The participants filled in a brief questionnaire about how effortful they thought each task was to do. Participants indicated a) how boring or exciting the task was ( $1=$ Very boring, $7=$ Very exciting), b) how effortless the task was (1 = Intensely effortful, $2=$ Completely effortless), c) how fun the task was ( $1=$ Not fun at all, 7 = Intensely fun), and d) how difficult the task was ( $1=$ Not difficult at all, $7=$ Intensely difficult). We constructed the questionnaire to probe the experiences mentioned by Kurzban et al. (2013) as dimensions of effort that correspond to perceived opportunity costs.

Individual Difference Questionnaires Following Thornton et al., participants completed a) the Attentional Behaviour Rating Scale (Ponsford \& Kinsella, 1991), a measure of general attentional difficulties, b) a Cell Phone Usage survey (Thornton et al., 2014), a measure of overall cell phone use, c) the Possession Attachment survey (Weller, Shackleford, Dieckmann, \& Slovic, 2013), a measure of how attached participants feel to their phone, and d) general demographics.

## Procedure

Figure 1: Experimental procedure
After signing a consent form, participants were asked to use their phone to photograph one of four objects placed on a desk. After the participant took the photo, an RA asked to
look at it and made a note of the object photographed and the photo's orientation. (What the participant photographed was irrelevant - the purpose of this initial task was to check if the participant had a smartphone, and to give the RA control of the phone's placement without making the purpose of the experiment obvious.) Next, participants were seated. In the phone-present condition, the RA placed the phone face-up near the edge of the table and said "I'll just leave this here, if that's okay". In the phone-absent condition, the RA placed a stack of post-it notes near the edge of the participant's table, and asked the participant to turn off their phone and put it away in their bag. Participants were then given one of the digit cancellation tasks to complete (order was counterbalanced). After completing the task, they filled in an effort measure. Then they completed the second digit cancellation task, and filled in another effort measure. Finally, the participants filled in an openended question about what they thought the purpose of the experiment was, followed by the questionnaires. The procedure is summarized in figure 1.

## Results

No participants reported suspicion that the purpose of the experiment was to study effects of phone presence.

## Prediction 1: Phone presence and cancellation score

In the simple digit cancellation task, there was no significant difference between cancellation scores in the phone-present $(\mathrm{Mdn}=65.0, \mathrm{IQR}=11)$ and phone-absent $(\mathrm{Mdn}=69.5$, $\mathrm{IQR}=14.2$ ) conditions, $\mathrm{W}=348.5, \mathrm{p}=0.30^{3}$. Similarly, in the additive cancellation task there was no significant difference between scores in the phone-present (Mdn = 20.0, $\mathrm{IQR}=4.5$ ) and phone-absent $(\mathrm{Mdn}=18.0, \mathrm{IQR}=6)$ conditions, $\mathrm{W}=259.5, \mathrm{p}=0.62$.

As will be discussed, scores in the additive cancellation task were highly left-skewed, with very few participants obtaining a score higher than 23 (see Fig. 2).

Figure 2: Distribution of scores in the additive cancellation task.

[^400]Table 1: Scores in the individual difference measures

|  | Phone present |  | Phone absent |  |
| :---: | :---: | :---: | :---: | :---: |
|  | Mean | SD | Mean | SD |
| Attentional behaviour | 43.3 | 1.2 | 41.9 | 1.2 |
| Cell phone use | 57.0 | 2.3 | 58.3 | 1.6 |
| Possession attachment | 17.4 | 0.9 | 17.3 | 1.0 |

## Prediction 2: Phone presence and subjective effort

To test effects on subjective effort, we first did a principal component analysis of responses on the effort measure. Scores for the simple cancellation task clustered on a 'fun/excitement' and a 'difficult/effortful' factor, whereas scores for the additive cancellation task clustered on a single factor of 'effortlessness'. We computed a score for each participant on these three factors and used them as our measures of 'effort'.

There was no main effect of phone presence on how effortful participants found the tasks, neither in the simple cancellation task ('fun/excitement': phone-present, Mdn = 4.75, phone-absent: $\mathrm{Mdn}=4.50, \mathrm{~W}=285, \mathrm{p}=0.65$; 'difficult/effortful': phone-present: Mdn $=3.0$, phoneabsent: $\mathrm{Mdn}=3.5, \mathrm{~W}=358.5, \mathrm{p}=0.32$ ) nor the additive cancellation task ('effortlessness': phone-present: Mean = 3.81, $\mathrm{SE}=0.17$, phone-absent: $\mathrm{Mean}=3.48, \mathrm{SE}=0.21$, $t(43.58)=-1.25, \mathrm{p}=0.22) .{ }^{4}$

## Interactions: Effects of personality variables

To explore whether the personality variables interacted with effects of phone presence, we split participants into 'high' and 'low' scoring groups on the questionnaires (Attentional Behaviour, Cell Phone Usage, and Possession Attachment), separating the groups at the median. We conducted factorial ANOVAs for each effort dimension, using 'high'/'low' questionnaire category as predictors. In the simple cancellation task, there was a significant interaction between smartphone presence and Cell Phone Usage, $F(1,41)=$ $5.00, p=0.03$ : When a phone was present, participants high on Cell Phone Usage rated the task as more fun/exciting (Mean $=5.17, \mathrm{SD}=1.05$ ), than did those low on Cell Phone Usage (Mean $=4.47, \mathrm{SD}=0.72$ ), $p=0.039$. In other words, participants who generally use their phones more found the task less boring when they completed it with their phone next to them. See Figure 3.

[^401]

Figure 1: Interaction between phone use and phone presence on 'fun/exciting' ratings for the simple cancellation task. Error bars show standard errors.

Similarly, in the additive cancellation task, there was a significant interaction between smartphone presence and Possession Attachment, $F(1,41)=4.40, p=0.04$. When a phone was present, participants high on Possession Attachment found the task more effortless (Mean $=4.04$, $\mathrm{SD}=0.90$ ), than those less attached to their phones (Mean = $2.94, \mathrm{SD}=1.02$ ), $p=0.10$. In other words, participants more addicted to their phones felt that the task required less effort if they had their phone next to them. See Fig. 4.

Figure 2: Interaction between phone attachment and overall scores on 'effortlessness' in the additive cancellation task.

## Discussion

In terms of task performance, we, similarly to Thornton et al., did not observe any statistically significant effect of phone presence on performance in the simple digit
cancellation task. More importantly, however, we did not replicate Thornton et al.'s central finding that phone presence causes diminished performance on the additive version of the task. Two things should be noted: Even though our sample size was similar to the original study, it may have been too small to reliably detect this effect. We ran a post-hoc power analysis of Thornton et al. and found that their experiments $(\mathrm{n}=54$ and $\mathrm{n}=47)$ only had a power of .65 to detect an effect in a two-tailed $t$-test. Sample size should have been $n=66$ just to obtain a power of .8 . Note, however, that we did not even observe a trend towards replication - in fact, in our study, additive cancellation scores were marginally larger in the phone-present than the phone-absent condition. Moreover, recall that scores in the additive task were left-skewed with very few participants obtaining a score higher than 23 . When we went over Thornton et al.'s stimuli, we discovered that one row of numbers (row nine), located when most participants were running out of time, had no targets at all. Moreover, the two rows before this one contained only one target each, in contrast to the first six rows which contained from two to four targets each. This will have reduced variation in performance between participants in the higher end of the performance distribution. For example, if one participant just managed to cross out the single target in row eight before running out of time, whereas another were ahead and managed to search through also all of row nine, these two participants will still have been given the same score. Hence, the material design is likely to have reduced our power to detect an effect, because it will have masked some of the variation in performance between participants.

Another issue is that in our setup, each participant only completed two versions of the cancellation task, whereas in Thornton et al.'s original study each participant completed two versions of the cancellation task and two versions of the trail making test. Whereas Thornton et al. did not discuss this, it is possible that effects of phone presence on task performance in this particular lab scenario is contingent on some degree of mental fatigue or shift in motivation from performing more tasks (Baumeister, Bratslavsky, Muraven, \& Tice, 1998; Inzlicht, Schmeichel, \& Macrae, 2014). However, we did add an effort measure for participants to complete after each task, which reduced the difference in participant investment between the original study and ours.

In terms of subjective effort, there was also no main effect of smartphone presence. However, we observed an unpredicted effect in which participants using their phones more often, and participants more attached to their phones, found the tasks more fun/exciting and effortless, respectively, if they completed them with their phones next to them. We cannot draw any strong conclusions due to our limited sample size and the post-hoc nature of this analysis, but future studies should test if the relationship replicates.

The interaction ran in the opposite direction from what we had initially predicted from Kurzban et al. (2013)'s 'opportunity cost' framework. Nevertheless, we still expect
this framework to be useful to approach cognitive effects of information communication technologies. From 'fear of missing out' to popular anti-distraction apps like Freedom and SelfControl that people use to restrict the functionality of their own devices, many current phenomena suggest that opportunity cost models remain important to explore. However, if the interaction effect replicates, it might mean that factors like anxiety from separation from one's phone (Cheever, Rosen, Carrier, \& Chavez, 2014) or positive feelings from having more stimulation available (Gazzaley \& Rosen, 2016) provides better explanations than Kurzban et al. (2013)'s opportunity cost model.

Finally, Kurzban et al.'s paper offered a persuasive, but abstract model. The effort measure we developed here is the first attempt to operationalize their opportunity cost model for experimental studies. Despite the present paper's mixed findings, we encourage future studies to apply Kurzban et al.'s model to human-computer interaction research and to test the reliability and validity of our effort measure.

In sum, follow-up research should establish whether Thornton et al.'s finding of a detrimental effect of phone presence on performance in the additive cancellation task is valid, by using larger sample sizes and adjusting the experimental stimuli to better pick up variation between participants. Future studies should also test whether heavy phone users really do feel that tasks are less, rather than more, effortful to complete when they have their phones present. With smartphone use now ubiquitous, it should be a priority in cognitive science research on executive functioning to establish conclusive findings on how smartphones affect users' attention and performance, and why.

#### Abstract

Predicting the effect of persuasion campaigns is difficult, as belief changes may cascade through a network. In recent years, political campaigns have adopted micro-targeting strategies that segment voters into fine-grained clusters for more specific targetting. At present, there is little evidence that explores the efficiency of this method. Through an Agent-Based Model, the current paper provides a novel method for exploring predicted effects of strategic persuasion campaigns. The voters in the model are rational and revise their beliefs in the propositions expounded by the politicians in accordance with Bayesian belief updating through a source credibility model. The model provides a proof of concept and shows strategic advantages of micro-targeted campaigning. Despite having only little voter data allowing crude segmentation, the microtargeted campaign consistently beat stochastic campaigns with the same reach. However, given substantially greater reach, a positively perceived stochastic candidate can nullify or beat a strategic persuasion campaigns.

Keywords: Agent-Based Model; Persuasion; Strategic campaigns; Politics; Voting simulation

## Introduction

Persuasion is paramount in political campaigns, and source credibility is a key component of a successful campaign. It influences a range of human cognitive phenomena related to reasoning, argumentation, and judgement and decisionmaking. It influences the reception of persuasive messages (Petty \& Cacioppo, 1984; Chaiken \& Maheswaran, 1994), plays a vital part in the development of children's perception of the world (Harris \& Corriveau, 2011), impacts juror decision making (Lagnado et al., 2012), increases adherence with persuasion strategies (Cialdini, 2007), and influences how people are seen in social situations (Fiske et al., 2007; Cuddy et al., 2011). The specific normative function of source credibility in argumentation, however, is still debated. For example, the dual-process-based Elaboration-Likelihood Model (Petty, 1981) assigns message source to heuristic rather than analytic cues (Briñol \& Petty, 2009) whilst recent Bayesian models integrate credibility in revising beliefs when given evidence from a
source (Bovens \& Hartmann, 2003; Hahn et al., 2012; Harris et al., 2015).

Trustworthiness is an important factor in politics. It increases public policy compliance (Ayres \& Braithwaite, 1992), influences candidate choice (Citirin \& Muste, 1999), increases intention of voting (Householder \& LaMarre, 2014, though not necessarily actual voting, see Dermody et al., 2010), increases societal cooperation (Fukuyama, 1995), and lack of trust may instigate civic participation (see Levi \& Stoker, 2000 for a discussion of this). The current paper expands upon these findings by showing how source credibility influences the convincingness of an argument for a proposed candidate.

In political literature, credibility factors include integrity, competence, fairness, flip-flopping, honest, equitable, and being responsiveness to public needs (Citrin \& Muste, 1999; Levi \& Stoker, 2000). Collating these, Mayer and colleagues identify credibility as ability, benevolence, and integrity (Mayer et al., 1995; Mayer \& Davis, 1999). Empirical exploration of management corroborates such a definition (Colquitt et al., 2011 for a review) while social psychology partitions reliability in two main spheres: warmth and competence (Fiske et al., 2006; 2007; Cuddy et al., 2011). Further studies in management literature differ in whether they identify two (Jarvenpaa et al., 1998) or three credibility traits (Mayer et al., 1995).

The model employed in the paper is in line with the factors identified in the above studies. Specifically, we divide credibility into two factors: expertise (the capability to provide accurate information) and trustworthiness (the willingness to provide accurate information).

## Micro-targeted campaigns

Political campaigns attempt to persuade voters that they should support and vote for a particular candidate or political position. Unsurprisingly, the competitive nature of electoral campaigns has led to the development of strategies regarding belief updating and behaviour changes, in particular through the use of data and voter segmentation (O'Neil, 2016). Typically, an election campaign is divided into two phases: a persuasion phase that focuses on changing the minds of the voters and a "get-out-the-vote" phase that focuses on making sure the voters do indeed turn out for the election. While the former phase typically lasts
for the duration of the entire campaign, the latter is typically implemented in the final 3-4 days (see Green \& Gerber, 2008). In the current paper, we focus on the element of political campaigns concerned with changing the minds of the voters (i.e. the persuasion phase). Specifically, we explore the potential strategy advantages of knowing the voters' attitudes towards the persuader (the politician).

Companies increasingly accrue data on their customers. Given potential access to and purchase of large-scale data sets about voters, recent years have seen the development of specifically targeted political campaigns, known as microtargeted campaigns (MTCs, see Issenberg, 2012). While traditional campaigns use rough voter segmentation such as by gender, income, or place of habitation, individual voter models allow for fine-grained segmentation (e.g., uppermiddle class, Caucasian, suburban, father, Prius-owner, Seattleite; as well as top-five travel destinations, frequented news sites, etc.). Such data allows for highly specified models of the individual voter concerning political leaning, policy priorities, and voting likelihood. The models allow for targeted political adverts that address specific political issues in a way that is tailored to the individual in question.

There is currently little academic research conducted on the effect and strategic administration of micro-targeted campaigns in elections. First, micro-targeted models are a recent element in election campaigns (Issenberg, 2008). As such, most models actually used in campaigns are subject to non-disclosure agreements and are kept by the responsible companies. Second, it is difficult to assess the quality of campaigns; partly due to the aforementioned secrecy regarding the exact models, and partly due to the complexity of campaigns, given the number of free parameters and the uniqueness of each campaign.

The current paper focuses on changes of electorate beliefs and not on the likelihood of voting (at the end of the simulation (i.e. campaign period), all voters vote with a probability of 1). Election campaigns unfold over time, where campaigns can contact voters and attempt to persuade them. As such, the persuasion attempt of the politician is a successive campaign designed to convince the electorate that the voters should support the persuader in question.

While we do not test specific campaign models, the paper provides a proof concerning the potential effect of micro-targeted campaign strategies through Agent-Based Model simulation of interactions between politicians and voters. We stress the exploratory nature of the study, as the model is necessarily simplified. Rather than testing the predictive power of a specific voter model, we explore the strategic potential of MTCs through a Bayesian source credibility model, which has been developed and tested in previous studies. In the following, we present Agent-Based Models as a technique for exploring the development of aggregate patterns (such as changes in beliefs in a population) across time. Aside from testing the potential effectiveness of MTCs, the paper presents Agent-Based Models (ABMs) as a novel method for simulating the predicted effect of persuasion campaigns.

## A Bayesian source credibility model

Bayesian approaches to reasoning and belief revision take point of departure in subjective, probabilistic degrees of beliefs in propositions where Bayes' theorem captures the posterior degree of belief given a prior belief in the hypothesis and some new evidence (Oaksford \& Chater, 2007). The approach has been applied to argumentation theory (Hahn \& Oaksford, 2006; 2007) where findings suggest that Bayesian reasoning may account for crucial elements of human information integration in practical reasoning. Most relevant to the current model, researchers have used Bayesian approaches to describe how humans integrate uncertain information from more or less reliable sources (Bovens \& Hartmann, 2003). The model has been tested empirically (Harris et al., 2015; Madsen, 2016) and enjoys a good fit with observed responses.

Taking point of departure from the Bayesian source credibility model, credibility is defined as a combination of trustworthiness and expertise (Hahn et al., 2009; Harris et al., 2015; see Fig. 1). In order to implement this model and to facilitate communication between persuaders (politicians) and persuadees (voters) and to capture the desired belief updating process, the members of the electorate have subjectively estimated beliefs about the credibility of each persuader.

Fig. 1: A Bayesian source credibility model ${ }^{l}$
Expertise refers to whether or not the persuader is capable of providing accurate and relevant information. For example, a politician may know the legislative framework connected with a policy proposal (thus increasing the chances of providing legislation that is legal and within constitutional law), a doctor may be more qualified to diagnose an illness compared with a layperson and so forth. Conversely, trustworthiness refers to the intention of providing accurate information. Regardless of the expertise of the source, the speaker might wish to misinform, lie, or otherwise deceive the listener. Expertise and trustworthiness are orthogonal and independent in the model (see Fig. 1) such that a person can be inexpert and yet intend to represent her available information as accurately as possible or a person can be highly expert within a field, but wish to misinform the listener. The source credibility model used in the current paper has previously been tested on appeals to political authority, which suggests that the model captures

[^402]part of how voters update their beliefs when politicians publically endorse or critique a policy (Madsen, 2016).

As explained later, the persuaders in the model contact the voters and provide either a positive or a negative statement concerning a hypothesis. To calculate the expected posterior belief in the likelihood of the hypothesis (e.g. the goodness of the candidate), we apply the source credibility model. The equation used to calculate the posterior is an expanded version of Bayes' theorem that incorporates trustworthiness and expertise within the theorem. It is taken from Harris et al. (2015) and relies on advances made in Bovens and Hartmann (2003) and Hahn et al. (2009) on the concept of source reliability (Hahn et al., 2012).

$$
P(H \mid e)=\frac{P(H) P(e \mid H)}{P(H) P(e \mid H)+P(\neg H) P(e \mid \neg H)}
$$

where $\mathrm{p}(\mathrm{h} \mid$ rep $)$ represents the probability that the hypothesis is true (h) given a confirming statement (rep). $\mathrm{P}(\mathrm{h})$ represents the prior belief in the hypothesis, and p (rep $\mid \mathrm{h}$ ) and $\mathrm{p}(\mathrm{rep} \mid \neg \mathrm{h})$ represent the conditional probability that the source would provide a positive statement if indeed the hypothesis was true or false. Trustworthiness and expertise are integrated within $p(r e p \mid h)$ and $p(r e p \mid \neg h)$ through the combination of these conditionals ${ }^{2}$.

To parameterise the model, $\mathrm{p}(\exp )$ and $\mathrm{p}($ trust ) represent prior beliefs in expertise and trustworthiness. Conditional probabilities (see footnote 1) represent the epistemic relationship between model parameters and the likelihood of providing true or good advice. For example, p(rep|h, exp, trust) refers to the likelihood that a speaker declares a hypothesis to be true when the speaker has complete and perfect knowledge of the topic and is unequivocally trustworthy in a world where the hypothesis happens to be true regardless of the statement of the speaker.

The model allows for parameter-free belief revision such that the agent makes use of its estimation of the persuader's source credibility to update its belief when the persuader contacts the voter with a persuasive statement.

## Agent-Based Modelling

Traditional equation-based models typically take point of departure in cognitive functionality in isolation (e.g. belief revision given new information) or in dyads (e.g. prisoners' dilemma). However, when agents can interact and influence each other through time, across space and between multiple agents, behaviour may become dynamic and adaptive. If this happens, patterns may become computationally intractable, making predictions difficult or impossible with isolated or dyadic models, as the system becomes complex (see Parunak et al., 1998). ABMs allow for simulations of interactions between agents and their environment and between multiple agents (Epstein \& Axtell, 1996). In the

[^403]paper, we use this method to simulate a campaign with interactions between politicians and voters. Each round in an ABM is called a tick. Here, each tick represents a campaign day. For the current model, the ABM requires agents and links between agents.

## Agents

Agents are the actors in the simulated model world. The cognitive make-up of each agent may consist of any rules constrain or enable relevant behaviours within the simulated world. By applying the relevant cognitive rules, agents can revise their beliefs about the model world by interacting with the environment. Further, agents can have physical rules such as metabolism, energy consumption, and age. This allows for simulated life-spans in which agents can live, learn, generate progeny, and die. The physical and cognitive rules allow for heterogeneity, as agents may differ in essential characteristics. This allows for dynamic models of heterogeneous populations.

In the ABM presented in this paper, there are three types of agents: voters, strategic persuaders and stochastic persuaders. The persuaders' aim to convince the voters to support them in an election. Politicians engage with voters by providing a statement, supporting one candidate or the other $(\mathrm{H}=0$ or 1$)$. Voters update their belief in the goodness of each candidate on the basis of the prior beliefs $(\mathrm{p}(\mathrm{h}))$ and their perception of the candidate (using the above Bayesian source credibility model).

## Links

While agents have cognitive rules that apply to agents in isolation, ABMs allow for interactivity. Links represent connections between agents that may be encoded with functional capacities. These can be any and all social links that inform and influence behaviour. Links can be direct (e.g., providing information to another agent, fighting with another agent) or indirect (e.g., some agents might prefer to be in the vicinity of other types of agents). In the current model, only direct links are employed, as the persuaders contact voters directly.

In the current model, politicians establish links by seeking out voters. Stochastic candidates engage randomly with voters while MTC candidates only engage with voter that has a positive attitude towards the candidate (using the 'signal factor' described in the following section). There are no links between voters in the current model. Introducing social structure will be a natural development in future work. Indeed, we strongly suspect that MTC candidates would be more efficient in social structures, as they can target 'community leaders' and important social nodes.

## Simulating Micro-targeted campaign strategies

In order to tentatively explore the effect of MTCs, we simulate the span of an election campaign through an ABM in which the politicians (the persuaders) can interact with the voters (the persuadees). Though exploratory in nature, the model has two aims. First, to our knowledge, although
some models have explored opinion chance in politics (e.g. Duggins, 2016), ABMs have not been used to directly explore campaign strategies. The paper consequently provides a new method for exploring the efficiency of persuasion campaign strategies. Second, by implementing a simplified voter and strategy model, the efficiency of minimal voter knowledge is explored. As the strategic potential of MTCs increases given higher voter complexity (e.g. if voters have prioritised political beliefs), the simplified model explores the efficiency of MTCs in situations where they are expected to be least effective. As such, the model explores a conservative modelling scenario. In the following, we present the Agent-Based Model.

Agents The model consists of three types of agents: Voters, Micro-target persuader (MTC), and stochastic persuader (non-MTC). The physical space plays no role in the current model (as the interactions between the persuader and the persuadee may be likened to sending out pamphlets or generating cold-calls). Consequently, voters are randomly distributed across simulation space. All voters were outfitted with the Bayesian source credibility model to inform their belief revision process. To operationalise the model, each voter generates an expertise and trustworthy score for each candidate from a normal distribution (as described later, we manipulate the means in the two simulations, such that mean $=0.5$ or $=0.6, S D=0.25$ ). To fully parameterize the model, agents are given conditional probabilities:

| $\mathbf{H}$ | $\mathbf{H}$ | $\mathbf{H}$ | $\mathbf{H}$ | $\neg \mathbf{H}$ | $\neg \mathbf{H}$ | $\neg \mathbf{H}$ | $\neg \mathbf{H}$ |
| :--- | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| $\mathbf{T}, \mathbf{E}$ | $\mathbf{T}, \neg \mathbf{E}$ | $\neg \mathbf{T}, \mathbf{E}$ | $\neg \mathbf{T}, \neg \mathbf{E}$ | $\mathbf{T}, \mathbf{E}$ | $\mathbf{T}, \neg \mathbf{E}$ | $\neg \mathbf{T}, \mathbf{E}$ | $\neg \mathbf{T}, \neg \mathbf{E}$ |
| 80.38 | 58.21 | 34.63 | 18.04 | 22.59 | 42.3 | 59.90 | 71.26 |

Table 1: Conditional probability table
These are taken from Madsen (2016), as this study applies the model to political belief revision. This allows for belief revision given persuader statements (with no free parameters) and further allows for agent heterogeneity, as some agents will rate one candidate highly while another will rate the same candidate poorly.

To provide a 'signaling' factor for the MTC candidate, voters average trustworthiness and expertise scores to generate a 'credibility score'. Each voter generates a prior belief from a normal distribution (mean $=0.5, S D=0.25$, bounded between 0.01 and 1 ), representing a voter's initial (prior) likelihood of voting for either candidate. This introduces the eventual decision (voting) rule: If a voter has p (candidate) $<0.5$, it favours the non-MTC candidate; if p (candidate) $>0.5$, it favours the MTC candidate. The campaign runs for 50 days ( 50 ticks). At the end of the simulation, voters vote for their favoured candidate. There are 10,000 voters in the simulation.

Both persuaders' aim to persuade voters to shift their p (candidate) towards their own position. In order to do so, they establish connection with voters and make opposite claims. In accordance with the source credibility model, the non-MTC candidate represents $p$ (candidate $)=1$ while the MTC candidate represents $p$ (candidate $)=0$. This gives full implementation of the Bayesian source credibility model
where the voter updates the prior belief given representation by a (more or less) credible source. After each connection, the contacted voter takes P (candidate|rep) - i.e. the posterior - as their new value for p (candidate) ${ }^{3}$.

For each tick, the candidate can establish contact with X voters, defined as 'candidate reach'. In the simulations, the MTC candidate has a reach of 20 while we manipulate the reach of the non-MTC candidate to test the efficiency of the MTC strategy. In Fig. 2 below, the reach ratio is the reach of the non-MTC divided by the reach of the MTC.

Central to the model, the MTC and non-MTC campaigns differ in their contact selectivity. The non-MTC is fully stochastic and thereby corresponds to a blind campaign that distributes leaflets or conducts cold-calls with no knowledge of the electorate. The MTC segments voters and will only contact voters with a favourable impression of the credibility of the candidate (voters with a signaling factor > 0.5 ). This selection process does not take into account the voter's prior belief in the candidate. As such, the underlying source credibility factors determine whether the voter is "open" to the candidate's message (i.e. will update in the desired manner). Of the sub-group of (desirable) voters who fit this criterion, a random selection (the amount based on "reach") are selected for contacting. Both campaigns may contact the same voter multiple times during the simulation, but not more than once on a single "day".

In sum, voters entertain prior beliefs about each candidate, rate each candidate for trustworthiness and expertise, and have a signaling factor. When a candidate contacts the voter, the voter updates the belief in p (candidate) in accordance with the Bayesian source credibility model. Candidates are either stochastic (non-MTC) or use the signaling factor to identify favourably disposed voters. Each candidate can reach a fixed number of voters each click. There are 10.000 voters and 2 candidates, and the campaign lasts for 50 days (ticks). At the end of each simulation, voters cast their vote for the candidate they find most favourable.

## Main findings

We conduct two main manipulations. First, we manipulate the mean credibility rating of each candidate by altering voter perception of candidate trust and expertise (mean $=.5$ or mean $=.6, S D=.25$ ), providing a $2 \times 2$ simulation. Second, for each of the credibility combinations, the reach ratio of the non-MTC is between 1-10 (1 represents simulations where the non-MTC and MTC have identical reach; 10 represents simulations where the non-MTC can reach 10 times as many voters per tick). The reach of the MTC candidate is always 20 . Fig. 2 illustrates the percentage of voters who supported the non-MTC on the $y$ axis and the reach ratio of the non-MTC on the x -axis.

[^404]

Fig. 2: Election outcome $(p($ cred $)=.5 ; p($ cred $)=.6)$
The simulations point to two main conclusions. First, a nonMTC with mean credibility rating of .5 is inefficient when run stochastically. As opinions about the candidate are equally divided, a stochastic strategy will necessarily engage with an equal number of supporters and adversaries. As such, blind strategies only work in when the campaign expect general voter estimation of the candidate to be $>.5$. If the candidate is seen as distrustful, a blind campaign will be ineffective or detrimental and will be beaten by campaigns with simple winnowing strategies.

Second, though MTCs provide a distinct advantage in terms of persuasion strategies, the stochastic campaign can beat the strategic campaign through brute force if the average $p$ (cred) of the stochastic candidate is $>0.5$. If the reach of the non-MTC is roughly double, the effect of the MTC is cancelled out. If the reach ratio $>2$, the non-MTC edges out the strategic campaign. This is an interesting finding, as the MTC is effective, but can be beaten. Given the possibility of simulating and calculating a tipping point where a stochastic candidate (with credibility rating > . 5 among the voters) beat strategic campaigns, it is possible to conduct cost-benefit analyses to determine the best available strategy given a limited campaign budget. In general, though highly simplified, the simulations show that it is methodologically possible to estimate the expected effect of a strategic (or stochastic) persuasion campaign by applying cognitive rules to the persuaders and persuadees in a dynamic environment.

## Discussion and future developments

The current model provides an important proof of concept that MTCs have a non-trivial advantage in a limited world where the voters revise their beliefs in the same manner and where the candidates can only advocate their position in a simplified way. We believe the paper provides a novel method for simulating and analysing electoral strategies using Agent-Based Models. However, as a proof of concept, this leaves room for further model developments.

First, real-life voters may exhibit individual differences concerning moral foundation (Haidt, 2012) or reasoning strategies (Lodge \& Taber, 2013). Voters in the current model are cognitively homogenous (though epistemically heterogenous) who revise their beliefs by the same process. Future work could integrate cognitive voter heterogeneity,
which would allow for exploration of strategic choices. Adding personality profiles would make the model more realistic and interesting in terms of testing election strategies for actual elections. Further, real-life campaigners do not have a perfect signal from each voter. Consequently, noise needed to be added to voter signalling.

Second, in the model, voters consider one proposition whereas elections often consist of a multitude of attitudes, beliefs, and desires. The present framework may easily be extended to include multiple policy beliefs, preference rankings, and multiple candidates.

Third, the MTC only considers the favourability of the candidate. Given additional data about complex voters (e.g., policy preference, personality, etc.), a sophisticated MTC may target voters more strategically. For example, an MTC could differentiate between swing and secure voters. Additionally, some voters are more likely than others to vote regardless of their political conviction. This is essential for strategic implementation of get-out-the-vote strategies.

Fourth, in the model, voters cannot communicate with each other. To allow for greater belief diffusion and for a more dynamic simulation of an electorate, it is reasonable to assume voter interaction where voters can share beliefs and persuade each other through their individual networks. Models that explore the role of hierarchy in opinion dynamics would be particularly relevant to explore this function (see e.g., Quattrociocchi et al 2014; Watts \& Dodds, 2007). Some voters might be communal leaders and have more impact than others. Given weighted network structures of the electorate, it would be possible to simulate complex persuasion strategies. This would simulate the relative efficiency of MTCs in highly complex, highly dynamic, and highly adaptive elections.
We predict that models with more complex voter belief systems, individual voter differences, and with interaction between voters will yield much higher benefits to MTCs. That is, we predict a positive correlation between available electorate data and the efficiency of an MTC. Concurrently, we also predict a positive correlation between the complexity of the electorate and the cost of running an MTC, as complex segmentation requires more data and sophisticated models.

By applying a cognitive updating rule in an Agent-Based Model, the paper presents a new methodology for simulating dynamic persuasion campaigns and for estimating their expected effect. We show a strategic advantage of MTCs. In the simulations, non-MTCs require double reach to cancel out this advantage. Despite having only simple voter data that allows for crude segmentation and a very crude selection strategy, the MTC consistently bested stochastic a candidate with the same reach (even when the opponent had a greater average credibility). However, given greater reach, a positively perceived stochastic candidate can beat a strategic candidate.

#### Abstract

Conspiracy theories cover topics from politicians to world events. Frequently, proponents of conspiracies hold these beliefs strongly despite available evidence that may challenge or disprove them. Therefore, conspiratorial reasoning has often been described as illegitimate or flawed. In the paper, we explore the possibility of growing a rational (Bayesian) conspiracy theorist through an Agent-Based Model. The agent has reasonable constraints on access to the total information as well its access to the global population. The model shows that network structures are central to maintain objectively mistaken beliefs. Increasing the size of the available network yielded increased confidence in mistaken beliefs and subsequent network pruning, allowing for belief purism. Rather than ameliorating and correcting mistaken beliefs (where agents move toward the correct mean), large networks appear to maintain and strengthen them. As such, large networks may increase the potential for belief polarization, extreme beliefs, and conspiratorial thinking - even amongst Bayesian agents.

Keywords: Conspiratorial thinking; Extreme beliefs; AgentBased Models; Bayesian updating

## Introduction

Truth is the shattered mirror strewn in myriad bits; while each believe his little bit the whole to own
Richard Burton (The Kasîdah of Hâjî Abdû El-Yezdî)
In recent years, scientists, scholars, and commentators have remarked upon the apparent rise of epistemic echo chambers (see e.g., Bakshy et al., 2016) and increasing political polarization. Echo chambers refer to communities, online or otherwise, that interact predominantly with themselves and who rarely, if ever, seek information aside from the information available within the chamber. Whether endogenously created (such as cults) or exogenously created (such as living on an island with no contact to the outside world), the emergence and maintenance of epistemically enclosed systems and their consequences is interesting and worth studying. The current paper explores the possibility of generating, maintaining and strengthening encapsulated belief communities through an Agent-Based Model (Gilbert,
2008) where every agent is rational (here, Bayesian) and where information is potentially available to challenge the viewpoint of the agent.

Specifically, we are interested in exploring the possibility of generating conspiratorial beliefs. That is, beliefs that are maintained despite being objectively false and there being available evidence to challenge or disprove the theory in question. Proponents of such beliefs frequently hold these positions strongly. We explore whether it is possible to strengthen confidence in objectively mistaken beliefs through a rational process given imperfect knowledge about the world. Rather than assuming illegitimate updating processes or special cognitive functionality, the model tests if, in principle, a Bayesian conspiracy theorist can emerge and be maintained. That is, the model explores whether or not individual differences are a necessary requirement for the emergence and maintenance of extreme beliefs.

The Burton quote at the top of the introduction can be seen as foundational for the paper. It suggests that beliefs can be generated and maintained as a fragment of a larger, and often very different, picture. Further, it intimates that humans generate inferences about the world on the back of the evidence available to us at any given time in our lives. This information may come through first-hand experience or through other sources such as parents, peers, media outlets, and experts.

In order to set the scene for the Agent-Based Model, we briefly consider how conspiratorial thinking has previously been approached in the literature.

## Conspiratorial thinking

Conspiracy theories can be loosely defined as beliefs that are held strongly when evidence is broadly available to challenge or entirely refute the theory. Yet, proponents maintain (and might even strengthen) their belief in the theory despite the availability of this evidence. However, in order to adequately simulate emerging conspiracy theories, we need to employ a more stringent definition of conspiratorial thinking.

According to Barkun (2003), conspiracy theories are characterized by three traits. First, conspiracy theories operate under the assumption that nothing happens by accident. From a cognitive perspective, this may be described as causal oversensitivity where the reasoner generates causal links between disparate and supposedly separate pieces of information, leading to over-connection. Second, Barkun argues that for conspiracy theorists, nothing is really what it appears to be on the surface (i.e. the 'real' causal mechanisms between pieces of information is covered up(?) by any official story). This element, too, suggests a cognitive agent who over-weights and overgenerates causal links between independent pieces of information. For example, some proponents of the moon landing conspiracy theory believes the director of A Space Oddysey: 2001, Stanley Kubrick, to be involved in producing faked photography because Kubrick hired crew for 2001 who used to work for NASA (Frederick Orway and harry Lange). Finally, Barkun argues that conspiracy theorists tend to believe things to be highly connected. To this end, Barkun argues that conspiracy theories eventually become enclosed systems that are falsifiable if confronted with additional evidence and therefore "a matter of faith rather than proof". Presumably, this entails that conspiracy theorists might stop seeking new information and instead assume their beliefs to be a priori true. As evident from these definitions, the operationalizing of conspiracy theories usually involves special cognitive make-up and a heuristic process that treat information related to the conspiracy theory as qualitatively different from 'normal' belief updating. The current model explores whether these are valid assumptions.

Indeed, Birchall (2006) describes conspiratorial thinking as illegitimate updating and belief maintenance (as opposed to normative, legitimate reasoning). In general, conspiratorial thinking is typically conceived as an abnormal and potentially fallacious (or illegitimate) reasoning process, which relies heavily on cognitively biased heuristics such as over-generation of causal links, erroneous attribution of motives, and mistaken perception of interconnectivity. Commonly, these conspiratorial thinking accounts assume conspiracies are a product of mistaken or misguided reasoning.

In this paper, we provide a proof of concept that conspiratorial thinking can emerge from Bayesian rational paradigms given access to a subset of evidence and the possibility of interacting with other like-minded agents. As will be argued later, we believe both of these assumptions to be realistic and grounded in psychological findings. As will be explained further in the paper, we show that conspiratorial agents do not require special cognitive abilities or predispositions in order to be supremely confident in their (objectively mistaken) belief. This approach is reminiscent of work conceptualizing supposed reasoning flaws through cognitively reasonable processes. This work includes, but is not limited to, Bayesian accounts of argument fallacies (e.g., Corner et al., 2011; Harris et al.,
2012), a Bayesian model of appeals to authority (e.g. Hahn et al., 209; Harris et al., 2015), and skepticism in climate change (Cook \& Lewandoswky, 2016). Further, Bayesian agents represent a rational process of integrating new information with prior beliefs pertaining to that hypthesis. For this reason, Bayesian agents have been used previously to explore belief diffusion in networks (see e.g. Jern et al., 2009; Olsson, 2013; Denrell \& Le Mens, 2017).

While the current work builds on similar Bayesian accounts of belief updating, we provide a novel contribution to the field by implementing a computational, Agent-Based Model that allows for interaction between agents across time.

For the purpose of this paper, we take conspiratorial thinking to be strongly held beliefs that depart from the objective mean where evidence is available to challenge or refute the theory. Barkun and Birchall argue that these beliefs arise from mistaken or flawed heuristics and/or illegitimate reasoning processes that bias proponents of conspiracy theories toward connectivity, attribution of hidden intentions and over-generation of causal structures. Further, Grimes (2016) argues that conspiratorial beliefs are untenable with larger network structures, as the available information to challenge erroneous views increases. As discussed below, there are some potential challenges for conspiracy accounts that assume special cognitive functions such as oversensitivity toward causal connections as the default cognitive foundation.

## Challenges for traditional accounts

The traditional perspectives on conspiratorial thinking may be challenged on at least two grounds. First, it is potentially problematic to ascribe different cognitive functions to the emergence of conspiratorial thinking for two reasons. For one, it is unclear whether this type of reasoning would permeate all beliefs held by that individual (e.g. would a conspiracy theorist also be prone to over-generate causal structures in billiards or snooker). If it were not systemic, it would (insufficiently) appear to be a post hoc account of a particular belief that happens to exhibit such properties. For another, it would not represent a process account of conspiratorial thinking. Rather, it would assume differences and apply these to arrive at the conclusion. Instead, we explore whether it is possible to generate objectively mistaken beliefs from the same cognitive processes that generate objectively true beliefs. Both of these would remove the expectancy of abnormality on the part of the conspiracy theorist.

Second, traditional accounts tend to focus on the cognitive function of the isolated individual, rather than on systemic belief diffusion as a result of interactions with other people. As discussed in the following, studies and simulations have shown that aggregate behavioral patterns might not be reducible to the components in isolation if the components can interact with each other in meaningful ways (see e.g. Johnson, 2001; Ball, 2005) given complex and dynamic environments (Johnson, 2009). Faced with the problem of
epistemic isolation, we apply Agent-Based Modeling to explore the potential of growing a Bayesian conspiracy theorist without adding special cognitive functions to the agent in question.

## Agent-Based Modeling

In order to circumvent the problems caused by traditional individual-based accounts of cognition, we employ AgentBased Modeling, which allows for simulations of belief networks populated by Bayesian agents. This further allows for introduction of heterogeneity, as will be discussed later (here, initial sampling allows agents to gather and evaluate data individually, which provides heterogeneous priors). Agent-Based Models (ABMs) are computer simulated multi-agent systems that describe the behavior of and interactions between individual agents, who operate in synthetic environments (Gilbert, 2008; Bandini et al., 2009). Agents are encoded on a computational basis, and may implement and explore models of cognitive function. They allow for complex, dynamic and adaptive systems to emerge through interactions between agents and with the environment as well as across time (Miller \& Page, 2007). ABMs may be described in terms of their three fundamental components: Agents, Links, and Patches.

Agents are the nodes representing the active cognitive entities of the system. They can make decisions and make use of information in any way that is formally expressible. These functions include, but are in no way limited to, utility valuations, Bayesian belief inferences, stock market engagement, and so forth. The agents may reproduce (e.g. give birth to a new agent), move around the simulated space, and make new (and potentially more relevant) decisions as they learn more about the environment. In order to engage with the environment, agents will have specified rules for agent-environment interactions such as fishing, purchasing a house, moving around the simulated space and so forth. These behaviors and inferences may yield dynamic and adaptive aggregate behavioral patterns. For example, if all agents harvest simultaneously, Tragedy of the Commons type problems (Ostrom, 2012) can emerge. In the present model, we allow for Bayesian belief updating as the agents encounter new information or talk with other agents via links.

Links represent rules for possible interactions between agents. Links can be any interactivity that can be expressed formally. The interaction may be direct (e.g. communication between two agents or sales structure between agents, see Epstein \& Axtell, 1996) or indirect (e.g. social attraction or repulsion or emotional feedback, see Schelling, 2006; Epstein, 2013). Interactions allow for feedback loops to emerge, which in turn may generate aggregate behavioral patterns that are irreducible to the components in isolation.

Patches represent the simulated environment in which agents exist. They can have any and all properties that are formally describable. If consumable (such as grass for sheep, fish for fishers), they may give the agent energy, money, or other affordances. Patches may be dynamic such
that they might regrow or migrate. Further, patches may facilitate or restrict movement of agents in the simulated space. The patches provide the foundational and potentially dynamic environment in which the agents live and act. In the model we present, the environment restricts interaction between agents if the search potential is low.

Compared with traditional methods, ABMs are capable of simulating dynamic and adaptive decision-making in changeable environments (Miller \& Page, 2007). This allows for agents to self-organize without hard-wiring expected aggregate behavioral patterns such as emergent echo chambers. Rather, ABMs allow for these properties to emerge, or, in the terminology of Epstein and Axtell (1996), to grow. ABMs further allow for agent and environmental heterogeneity (i.e. agents with different cognitive capabilities).

## Growing a Bayesian conspiracy theorist

The aim of the current model is to test a proof of principle that conspiracy theorists can emerge through entirely rational processes without providing any special cognitive functions, heuristic strategies, or access to unique information. In order to do so, we generate an Agent-Based Model where agents can sample information, communicate with one another, and update their beliefs about the world.

Given this initial proof of concept, we simplify the epistemic challenge and consider only one abstract belief. The true probability of the Gaussian distribution from which the agents sample is 0.5 . The standard deviation can be manipulated to represent greater or lesser noise in the information environment. In the present paper, the standard deviation is set to 0.2 . For the sake of understanding, the probability may represent the belief in the fairness of a coin. If the coin is fair, the distribution of tosses is trivially 50-50 between heads and tails. However, if the coin is not fair, the distribution can be skewed in the direction of either heads or tails. Understood in this way, the agents try to understand if they are in a world in which the coin is fair (uncovering, as it were, the true, underlying probabilities) or if they are in a world where the coin is rigged to either side (arriving at an objectively mistaken belief).
If agents are able to generate, maintain and possibly strengthen a mistaken belief in the epistemic state of the belief, the agent will have exhibited conspiratorial traits, as this fulfills the criterion for the definition in the above: a potentially strongly held, yet objectively mistaken belief, availability of information to challenge or refute the theory, and access to that information. The literature review uncovered two central positions that we explore here. One, we explore Grimes' (2016) argument that conspiratorial thinking is untenable in a large network structure. If this is true, we should see a global regression towards the objectively true mean given larger networks (that is, fewer agents who believe they are in a rigged coin world). Two, we explore Barkun and Birchall's arguments that conspiratorial thinking relies on illegitimate reasoning and biased heuristics. As will be described below, the agents in
the model are perfect Bayesian reasoners. If conspiratorial thinking requires special cognitive properties, we should not expect the Bayesian agents to generate strong and mistaken beliefs about the world. The model implements six key elements: generation of prior beliefs, constrained search, network generation, communication between agents, belief updating, and network pruning.

In order to generate a subjective prior belief, agents are born onto the world and sample randomly generated data from a Gaussian distribution ( $\mu=0.5, \sigma=0.2$ ). In a frequentist manner, these are used to calculate a perceived mean and probability density. The sampling represents the worldview of each particular agent before they are able to communicate with other agents.

Having generated a prior belief for each agent (and thus introduced sampling heterogeneity), the model relies on four additional assumptions and mechanisms. First, agents cannot sample all available data in the simulated world. This means that they do not have access to all data sampling that other agents have encountered unless they communicate with the other agent in order to learn the beliefs of that agent. As such, agents do not have perfect and complete knowledge about the world in which they live. We believe this is a reasonable assumption, as humans do not have perfect knowledge in real life. Second, although all other agents are hypothetically available, agents cannot communicate to every other agent in the simulated world. Rather, each agent randomly generates the amount of possible communication links. Like the first assumption, we believe this is a reasonable assumption, as humans in the real world cannot communicate with every other person on the planet, but has to settle for a subset of all living persons.

Third, in order to make the agents rational, they update their beliefs about the world in a Bayesian manner. Bayesian updating represents the rational integration of prior beliefs with new evidence to generate posterior belief in the hypothesis. This approach has been applied to a host of related phenomena such as argumentation (Hahn \& Oaksford, 2006; 2007), source credibility (Bovens and Hartmann, 2003; Harris et al., 2015), and reasoning and decision-making (Oaksford \& Chater, 2007). The integration is formally expressed through Bayes' theorem

$$
P(h \mid e)=\frac{P(h) P(e \mid h)}{P(e)}
$$

where $\mathrm{p}(\mathrm{h} \mid \mathrm{e})$ denotes the posterior belief in the hypothesis (h) given the evidence (e). As such, agents treat each new encounter as a data point to be integrated within their subjective probability density function. Bayesian updating ensures that the agents are fully rational in their belief revision when encountering new evidence.

Finally, several studies on confirmation bias, selectivity bias, and in-group behavior strongly suggest that agents are not entirely stochastic and non-directed in their information search. Taking inspiration from segregation studies (e.g., Schelling, 2006), we introduce a mild preference for people who remotely share their beliefs about the world. The agents
are relatively tolerant and will engage in conversation with any other agent who is within $\pm 1.5$ standard deviations of its own perception of the world. Given Gaussian distributions, this means that the agent will speak to $86.6 \%$ of people within its belief distribution. Thus, they are willing to talk to and integrate information from agents who have different viewpoints than their own. However, if they are confident in their belief, they will engage with less diverging viewpoints, as their probability density narrows. As an analogy, this means that an agent might be willing to discuss political questions with people with different points of view, but would refuse to engage in discussion with people who believe that fair coin-flips are 60-40 rather than $50-50$ in cases where they are absolutely certain about the latter and less certain about the former.
In sum, the agent is born into the world by sampling randomly generated pieces of information related to the hypothesis in question. This informs the mean and standard deviation of their prior. Second, the agents generate networks with other agents within their network radius (which may be limited or encompass the full system). Having set up the model, the agents will communicate freely and honestly (i.e. representing their belief in the hypothesis to the best of their ability), which enables Bayesian belief updating. Agents will maintain communication networks with other agents who are within 1.5 standard deviation of their subjective understanding of the world (i.e. their belief in the hypothesis). If agents within the network fall outside of those boundaries, the agent deactivates the network contact with that particular agent. If agents cannot find any suitable agents within their range, they decrease confidence (simulating negative feedback) and thus expand acceptable search parameters for the following tick. This allows for dynamic network pruning (Ngampruetikorn \& Stephens, 2015).

## Main findings: Limited and extended networks

We implemented the above model in NetLogo (5.2.1) and manipulated the model in terms of the size of the network. For limited networks, agents had a search range of 10 of 100 (as a product of their geographical location). Extended networks, on the other hand, had a search range of 80 of 100. Agents could connect to and sample randomly from other agents within agent search range who fall within their network criteria. Figs 1 a and 1 b show the extent to which search capability influences network generation.

Figures $1 a$ and 1 : Limited and extensive networks
The overall belief structure did not differ significantly between limited and extended networks. Some, but not all agents regressed towards toward the mean while some agents retained their objectively mistaken belief (see Fig. 2a and 2 b , which are histograms where number of believers are
on the y axis and agent belief is on the x axis), we observe differences in belief confidence. As seen in Figs. 3a and 3b, extended networks allowed for interactions with increasingly like-minded agents, which in turn increased belief confidence. This is true both for agents who obtain objectively true and false beliefs. As agents become increasingly confident, their probability density narrows, meaning that they are less willing to engage with agents with differing beliefs. Extended networks allow them to form and maintain contact with agents who share their specific beliefs such that they increase their confidence in that particular view of the world. This means purification of beliefs and purification of networks, i.e. the emergence of epistemic echo chambers.

Figures $2 a$ and $2 b$ : Limited and extended belief structures

Figures $3 a$ and 3b: Limited and extended confidence (0-1)
Overall, the model shows that fully rational agents can maintain and potentially strengthen objectively mistaken beliefs. Further, given a mild preference for interaction with like-minded agents, we observe the rise echo chambers. This effect is strengthened with the size of the network. Rather than making extreme beliefs untenable as predicted by Grimes, we show that large networks, here quantified in terms of the number of reachable agents for any given agent, can engender extreme belief maintenance and belief purism.

## Discussion and concluding remarks

The Agent-Based Model in the paper provides a theoretical proof of concept that a Bayesian agent can become an ardent conspiracy theorist under three main assumptions. One, the agent does not have perfect and full access to all available information that exists in the world, but can only sample a sub-set of that information. This means that the agent does not rely on perfect knowledge of the system. Depending on the practical conceptualization of information accessibility, the agent may have access to very limited or more extended amounts of information. Two, the agent cannot talk to every other person in the world, but can only talk to a sub-set of all existing agents. Similar to assumption one, this means the agent cannot converse with all other agents and learn their subjective access to information. In the current model, information after prior sampling is
gleaned through interactions with other agents. Consequently, by limiting the amount of other agents with whom an agent can engage, the model naturally also limits the access to available information. Principles one and two are concerned with the degree to which the agent can sample information and learn about the world. Three, agents search for and interact with other agents on the basis of their current worldview. They are willing to communicate with most other agents, but avoid other agents with whom they radically disagree about the nature of the world.

## The Rise of Echo Chambers

Together, these three (we believe reasonable) assumptions show that larger networks do not yield belief amelioration (as was postulated by some theoreticians who believed the Internet to facilitate greater communication between people and thereby allow a global regression towards the mean). Rather, the model shows that extended networks, given plausible constraints to exposure, lead to the growth of echo chambers and eventual belief purism, whereby agents increasingly discard those who do not share their specific beliefs about the world.

One might compare this increasing belief purism to development of political ideologies. In a limited network structure (e.g., a small village), the model suggests that leftleaning voters are willing to communicate with other leftleaning voters (and some right-winged voters depending on the mean and probability density function of the specific voter, mutatis mutandis for right-winged voters). However, in an extended network structure (such as a metropolis or Facebook), the model suggests that voters will have access to other voters who have more similar worldviews. This allows for emergence of political echo chambers where extreme voters have access to other extreme voters. From this, greater belief confidence grows and network pruning increases, as belief purism emerges. We therefore expect increases in network structures will facilitate rather than hinder belief extremism and confidence in worldviews.

The model presented in the current paper allows for this dynamic adaption. In the beginning, agents cluster around people with whom they share general beliefs about the world. However, as they increase in confidence, their probability densities narrow, meaning that fewer agents will fit within the $\pm 1.5$ standard deviations of the perceived mean. As the agent becomes increasingly confident in its own reading of the world, it will be decreasingly inclined to engage with agents who entertain different viewpoints. This allows for belief communities to fracture and radical and supremely confident cells to emerge. The emergent echo chambers function as cyclical maintenance of a peculiar belief.

This finding is interesting because larger networks did not yield belief amelioration, but rather belief solidification. It opens up for a novel way to approach and model epistemic communities that maintain strong beliefs despite available data challenging their beliefs (e.g., creationists, climate skeptics, and radicalized or discriminatory beliefs).

## Emergence of reasonably mistaken views

Central to the model, the agents do not have full and perfect knowledge of the world and can only talk to a sub-set of other existing humans. Given the fact that agents update their beliefs in a Bayesian manner, their cognitive system can be described as rational and entirely reasonable. Yet, given incomplete access to data and given the network properties, the model shows that the agents can become entirely confident in objectively mistaken views. As such, we show that extreme beliefs such as conspiracies could emerge through entirely rational processes. While this does not preclude heuristic strategies or special cognitive functions, the model shows that these are not necessary for strongly held mistaken beliefs to emerge. Aside from emerging, mistaken beliefs are also able to survive (and even strengthen) in such an environment rather than being swallowed by mainstream beliefs.

Further, agents had a mild preference for communicating with like-minded agents. Rather than making extreme beliefs untenable, the model suggests that increasing the size of the network intensifies the process of radicalization and augments the confidence even in an objectively mistaken belief. In the age of the Internet, this finding is worth considering seriously and exploring further

In conclusion, we have provided a proof of concept that shows the impact of network structures in generating and maintaining extreme beliefs such as conspiratorial thinking. A Bayesian agent can generate and even increase its confidence in objectively mistaken beliefs.

#### Abstract

The dilution effect occurs when the introduction of nondiagnostic information lessens the impact on reasoning of diagnostic information despite having no relevance to the hypothesis in question. While the effect has been reproduced in several studies, the psychological basis of the effect remains unclear. Some believe it to be conversational while others believe it to be cognitive and social.

The paper tests the conversational basis of the effect by minimising pragmatic, conversational influence. To this end, it makes use of a legal setting with witness testimonies. The studies replicate the dilution effect, which suggests that the basis of the results in the original studies is not conversational. However, the credibility of the source strongly influences whether or not the effect occurs. If reliable sources provide the non-diagnostic information, the effect lessens. Conversely, if unreliable sources provide the non-diagnostic information, we observe a stronger dilution effect.

Keywords: Dilution effect; legal reasoning; source credibility; witness testimonies

## Introduction

Most information that humans gain throughout their lives comes from other sources. It may come from friends and colleagues, from professionals such as weather forecasters or news anchors, or it may come through de-personalised sources such as the Associated Press. However, information comes in various guises. Concerning the evidence itself, information may be highly diagnostic and related to a particular hypothesis at stake in the context or entirely unrelated and non-diagnostic. If, for example, an athlete is tested for doping before a race, the subsequent outcome of the test will be highly relevant in determining whether or not the athlete should be allowed to compete. The colour of the athlete's trousers worn during the drug test, however, should not. In addition, the information may be more or less noisy for a variety of reasons. This noise may be due to degradations in the access to information relating to the hypothesis (such as faulty equipment or poor visibility) or it
may be due to the reliability of the person who delivers the information.

The aim of the current paper is threefold. First, as discussed in the following section, it has been suggested that the dilution effect (see next section) is a conversational rather than a social or a cognitive effect. In the original studies, it is the experimenter himself who presented the participants with diagnostic and non-diagnostic information. If participants believe that the experimenter has chosen the non-diagnostic information for a reason, it may prompt them to try and interpret the information as somehow diagnostic. By removing the experimenter as the source of the diagnostic and non-diagnostic information, we test this possibility. We offer a possible control of this by placing the information in a legal setting and by having witnesses provide the testimonies. Second, as the role of the source of the information has been suggested as an influential element in reasoning, we manipulate the reliability of the source such that the source is either highly reliable or entirely unreliable. Third, from the literature, it is unclear how participants conceptualise non-diagnostic information. In particular, it is unclear whether or not the participants expect the dilution effect to occur if they were put in an observer role. To test this, study 2 allows participants to provide qualitative replies. Here, they are asked to imagine how a jury would react to the information and whether they believe it would make a difference to include the nondiagnostic information with the diagnostic.

## The dilution effect: A conversational explanation?

The dilution effect has been reported in several studies (e.g. Nisbett et al., 1981; Hilton \& Fein, 1981; Krueger \& Rothbart, 1988; Tetlock \& Boettger, 1989, see also Troutman \& Shanteau, 1977). However, aside from a few notable exceptions (e.g. Waller \& Zimbelman, 2003), the effect has received relatively little attention in recent years compared with more prominent cognitive influences on reasoning such as the confirmation bias (e.g. Frost et al.,
2015). In particular, the basis of the effect has remained under-explored.

One question, though, has been raised about the dilution effect, namely whether the effect has a conversational, pragmatic basis rather than a social perceptual basis (see Igou \& Bless, 2005; Kemmelmeier, 2007; Igou, 2007). It is well-known in the field of pragmatics that conversational expectations and extra-linguistic content can influence the interpretation of an utterance (see e.g. Sperber \& Wilson, 1995; Carston, 2002; Katsos, 2008; 2009). If the nondiagnostic information was somehow perceived as relevant given the inclusion by the experimenter, it is plausible that the participants could generate interpretations that make the information more relevant than the experimenter intended.

It is possible that the methodology of the experiments prompts participants to treat all information given to them as relevant, as the experimenter provides it to them. If the participants approach non-diagnostic evidence as potentially diagnostic in some way that they did not understand given the fact that the information was chosen by the experimenter, this may introduce noise into belief revision, which should make judgments less extreme. That is, given an increase in the noise of the data, a participant would be expected to update in a more tempered manner. Kemmelmeier (2007) describes this position (which he criticises) thusly: "The mere fact that the information is provided in the experiment suggests to participants that the experimenter considers this information relevant and wants participants to use it in making their judgments." (p. 49)

The above studies aimed at testing the conversational basis of the dilution effect by trying to manipulate the relevance of the information provided, but kept using the main methodology where the information is provided by the experimenter, and the task had generally to do with social judgment. One way of manipulating the relevance was by explicitly warning participants that the information might not be relevant. For example, Igou and Bless (2005) state, "prior to the sales scenario, half of the participants were informed that some of the presented information might not be relevant to their task". This is a methodological attempt to prepare the participant for the fact that they may encounter irrelevant information.

Kemmelmeier, who argues against the conversational account of the dilution effect, claims that the alleged evidence in favour of the conversational basis is not proving anything. Kemmelmeier concludes:
"Last, there is a very mundane reason to suspect that the dilution effect is not the product of conversational dynamics. The dilution effect occurs as much inside the psychological laboratory as outside of it (see Waller \& Zimbelman, 2003, for a review). Often there are no specific individuals who can be identified as the source of non-diagnostic information, or one even has to assume that one's communication partner is potentially deceptive, as in the case of an accounting audit (Waller \& Zimbelman, 2003). Because the dilution effect occurs regardless of whether non-diagnostic information can be assumed to be part of a meaningful communication, it seems highly questionable that the dilution effect has a conversational basis." (Kemmelmeier, 2007, p. 58)

In order to test the potential influence of the experimenter and to lessen the influence of social context, the current studies are set in a legal setting where the information is presented as a summarised court case concerning a murder in Paris. The existence of identified witnesses (with certain characteristics) attempts to alleviate the methodological problem of the experimenter providing 'irrelevant' information, as witnesses may provide more or less relevant statements during a trial. In order to manipulate the relevance of the statements, we manipulate the witness condition. As discussed in the following section, several studies have shown the influence of source credibility in reasoning tasks.

## The dilution effect and source credibility

As the dilution effect has mainly been explored with the information being provided by the experimenter, little is known about the relationship between the effect and the credibility of the source.

Source credibility has been shown to influence several cognitive phenomena related to reasoning, argumentation, and decision-making. It influences the reception of persuasive messages (Petty \& Cacioppo, 1984; Chaiken \& Maheswaran, 1994; Tormala \& Clarkson, 2007), is integral to the development of children's perception of the world (Harris \& Corriveau, 2011), influences candidate choice (Hetherington, 1999; Citirin \& Muste, 1999), increases adherence with persuasion strategies (Cialdini, 2007), and influences how people judge the quality of evidence from others in social situations (Fiske et al., 2007; Cuddy et al., 2011). The normative function of source credibility in reasoning and argumentation remains contentious. The dual-process-based Elaboration-Likelihood Model (Petty, 1981) describes reliance on the source of the message as a heuristic and shallow cue (Petty \& Cacioppo, 1984; Briñol \& Petty, 2009). Comparatively, Bayesian models integrate credibility in beliefs revision when a source provides information (Bovens \& Hartmann, 2003; Hahn et al., 2012; Harris et al., 2015; Madsen, 2016).

According to the dilution effect, participants who are faced with non-diagnostic information in addition to the diagnostic information provided will become less extreme in their degree of belief in the overall proposition. Given the findings in the literature, we predict that testimonies from reliable witnesses will be seen as more persuasive than testimonies from unreliable witnesses.

## The case study: Murder in Paris ${ }^{1}$

In order to make the experimental setting seem realistic, we made use of simplified version of a court case that happened recently in Paris. In the court case, the defendant, Siem, was accused of assaulting the victim, Tommy, which caused Tommy's fall to the ground. Further, they were told that

[^405]the impact of the ground caused the brain injury, which led to Tommy's death.

The participants were told that they would read an excerpt from a court case in Paris, France. They were further told that the names of the people involved had been changed and that the story had been abbreviated significantly. The participants were then instructed to read the summary of the court case thoroughly as if they were a member of the jury in the trial. Specifically, they were asked to pay attention to what had happened and whether or not the defendant was likely to be guilty or innocent.

## Study 1

Study 1 aims to replicate the dilution effect. To test the potential pragmatic basis of the dilution effect, the study was set in the legal context of a trial with all information provided by witnesses rather than by the experimenter. By using a realistic court case and witness testimonies rather than instructions from the experimenter, the design lessens the likelihood that the experimenter influenced the participants. The dilution effect predicts that participants should decrease their belief in the likelihood of the defendant being guilty when a non-diagnostic testimony was added to the diagnostic witness testimony.

The study was a $2 \times 2$ between-subjects design. To explore the influence of source credibility on belief revision and on the dilution effect, participants in the 'no witness' condition were told that the statements were 'information added to the initial enquiry'. As such, the information was provided with no specific source. In the 'witness' condition, a reliable witness presented the diagnostic testimony while an unreliable witness provided the non-diagnostic testimony ${ }^{2}$.

To test if the dilution effect was replicable, half of participants saw only the diagnostic information while the other half saw the diagnostic and the non-diagnostic information. Diagnostic statements read: "There was a dispute about drugs between Siem and Tommy, and Siem had threatened Tommy several times. Siem was heard several times saying 'he will be dealt with soon, this fucking Caribbean!" Non-diagnostic statements read: "When walking, Siem always took great and long strides. Siem used to wear funny clothes. In particular, he liked to wear bright colours".

Participants: 200 participants were recruited from MTurk (see Paolacci et al., 2010 for validation of MTurk as a tool for data collection in social sciences). All participants had to be native English speakers and aged 18 or above.

Procedure: Having read the background story (see appendix), participants provided their degree of belief in the likelihood that Siem had assaulted Tommy on a gradient scale from $0-1$, with 0 representing complete certainty that Siem did not assault Tommy and 1 representing complete certainty that Siem did assault Tommy. This elicited their

[^406]belief in the likelihood of guilt prior to hearing witness testimonies.

After providing their prior belief in the likelihood of guilt, participants read the testimonies. Having read the testimonies (witness statements or additional information // diagnostic or diagnostic as well as non-diagnostic information), participants were asked to indicate their posterior degree of belief in the likelihood of guilt on an identical sliding scale from 0-1. Diagnostic evidence was presented before non-diagnostic evidence. In order to test the dilution effect, we compare the changes in beliefs from prior to posterior belief between conditions.

Results: As the study was carried out online via MTurk, we eliminated any participants who carried out the study in less than 120 seconds, as the study could not be completed in seriousness in such short time. In total, this eliminated 15 participants, leaving 185 participants.

To test the dilution effect, paired-sample t-tests show a significant difference between prior and posterior degrees of beliefs in both diagnostic groups (No witness condition: $t=$ $3.105, \mathrm{p}=0.003$ (df, 42); Witness condition: $\mathrm{t}=2.890, \mathrm{p}=$ .006 , df (45)) while we observe no difference in degree of belief when non-diagnostic information is provided alongside the diagnostic (No witness condition: $\mathrm{t}=1.839$, p $=0.072$ (df, 48); Witness condition: $\mathrm{t}=.459, \mathrm{p}=.648$, df (46)), see Fig. 1 for means and standard deviations.

| Condition | Prior belief | Posterior belief |
| :---: | :---: | :---: |
| Diagnostic, no witness | $60.67(21.49)$ | $69.93(18.43)$ |
| Non-diagnostic, no witness | $64.36(17.88)$ | $69.18(17.94)$ |
| Diagnostic, witness | $58.97(18.87)$ | $66.32(19.38)$ |
| Non-diagnostic, witness | $62.68(22.24)$ | $61.29(22.27)$ |

Table 1: Prior and posterior beliefs
Tentatively, it looks as if the witness condition yields different patterns in the non-diagnostic condition (as the no witness condition is borderline significant). To test the influence of witnesses, we calculate a change score by subtracting the prior belief from the posterior. Having done this, we run a $2 \times 2$ ANOVA to test the influence of the inclusion of a witness. We find an effect of diagnosticity ( $p$ $=.019, \mathrm{~F}=5.556$ ), but no effect of the witness condition ( p $=.149, \mathrm{~F}=2.105)$.

Testing for influence of gender and age yielded no significant results, as p's were between .103 (influence of age on posterior degree of belief in the likelihood of guilt) and .881 (influence of gender on prior beliefs).

## Study 2

Study 1 suggests that the dilution effect was replicated in an experimental design aimed to lessen the experimenter's role and thereby reduced the potential for conversational effects. However, while the results of study 1 replicated the dilution effect, tentative evidence suggested that the reliability of the witness might have an impact on the relative strength of the effect. For one, the reliable witness always presented
condition the diagnostic information and the unreliable witness always presented the non-diagnostic information.

To test the potential influence of source reliability on the perception of evidence, half of the participants read the diagnostic testimony from the reliable witness and the nondiagnostic testimony from the unreliable witness whilst the other half were presented with the opposite source-message matrix.

While study 1 tested a specific question concerning the conversational basis for the dilution effect, study 2 is more exploratory, as the relationship between source credibility and the dilution effect has, to our knowledge, not been explored in detail (although, see Harkins \& Petty, 1987). As a consequence of the exploratory nature, participants were given the opportunity to provide qualitative feedback.

Importantly, study 2 used a different dependent variable: In study 1, as participants in the previous study were asked to provide their own degree of belief in the likelihood of guilt; in the present study, the participants were asked to provide their personal estimation of how convinced a member of a jury would be if confronted by the diagnostic information in isolation or by the inclusion of the nondiagnostic statement. As such, they were asked to provide an estimation of the strategic potential of including or omitting the non-diagnostic statement. Consequently, all participants read the diagnostic and the non-diagnostic statements. Thus, only two participant groups emerged in the present study: diagnostic (reliable witness) and nondiagnostic (unreliable witness) or diagnostic (unreliable witness) and non-diagnostic (reliable witness).

Participants: 100 participants were recruited from MTurk. All participants had to be native English speakers and be aged 18 or above.

Procedure: Prior belief elicitations were identical to study 1, as participants read the court case and provided their initial estimation of the likelihood of guilt. After the initial case presentation, participants read both the diagnostic and the non-diagnostic statements and were asked to evaluate the degree to which they believed a jury would believe the defendant to be guilty if the diagnostic information was presented in isolation or in conjunction with the nondiagnostic statement. As such, each participant provided one prior degree of belief and two posterior degrees of belief: diagnostic and non-diagnostic.

Results: Initial paired-sample t-tests were conducted between prior and posterior degrees of belief to test the influence of the source on the likelihood that a jury would find the defendant guilty. In accordance with expectations from studies on source credibility in argumentation (e.g. Harris et al., 2015), participants who were presented with diagnostic incriminating evidence from the unreliable source either significantly or borderline significantly decreased their posterior degree of belief in the likelihood of guilt (diagnostic: $\mathrm{t}=2.812$, df (50), $\mathrm{p}=.034$; nondiagnostic: $\mathrm{t}=1.799$, $\mathrm{df}(50), \mathrm{p}=.078$ ). Comparing the diagnostic and non-diagnostic posteriors, we observe no significant difference $(\mathrm{t}=.893$, $\mathrm{df}(50), \mathrm{p}=.376)$. This
suggests that testimonies from an unreliable source might decrease adherence with the proposition despite being diagnostic. It further suggests that no dilution effect was observed when the witness was reliable. See table 2 for means and standard deviations for both conditions.

In the condition where the reliable witness provides the diagnostic evidence, we observe a significant or borderline significant increase in the degree of belief in the likelihood of guilt (diagnostic: $\mathrm{t}=4.848$, df (49), $\mathrm{p}<.001$; nondiagnostic: $\mathrm{t}=1861$, df (49), $\mathrm{p}=.069$ ). While we did not find support for the dilution effect when the reliable witness presented the non-diagnostic information, we observe a significant difference in the condition where unreliable witness presents the non-diagnostic information $(\mathrm{t}=2.983$, df (49), $\mathrm{p}=.004$ ). That is, compared with the condition in which the reliable witness presented diagnostic evidence, the condition where the reliable diagnostic testimony was followed by an unreliable non-diagnostic testimony decreased the overall estimation of guilt.

Comparing the two conditions, this suggests the reliability of the source that provides the non-diagnostic information influences whether the dilution effect occurs or not. As we did not have a clear hypothesis as to the direction of the influence, qualitative replies were also collected. In the following, we examine these replies.

| Condition | Prior belief | Posterior <br> belief <br> (diagnostic) | Posterior <br> belief (non- <br> diagnostic) |
| :---: | :---: | :---: | :---: |
| Unreliable- <br> reliable | 64.19 <br> $(17.18)$ | $56.09(22.31)$ | $58.57(23.66)$ |
| Reliable- <br> unreliable | $57.4(22.25)$ | $71.60(18.33)$ | $63.82(23.82)$ |

Table 2: Prior and posterior beliefs
Qualitative replies By analysing the qualitative responses, we can get a tentative impression of the differences between reliability conditions and between participants themselves. In the unreliable-reliable condition, 25 participants provided qualitative feedback. In the reliable-unreliable condition, 30 participants provided feedback.

Participants in the condition where the unreliable witness presented the diagnostic information did not make specific comments about the persuasive advantage or disadvantage of presenting the non-diagnostic information (despite the fact that it was presented by the reliable witness). Rather, in line with expectations, they provided character-related comments for the unreliable witness and content-related comments for the reliable witness (e.g. "I'm not sure what Mrs. Lanavan's statement had to do with the case. And the fact that Ms. Harry is unstable would reduce her credibility" and "I think the first is incredible due to her personal history and the second's testimony really is irrelevant to the incident").

In the condition where the reliable witness presented the diagnostic information, comments were more mixed. 11 participants directly stated that including the non-diagnostic witness would not make a difference (e.g. "I don't see how

Ms. Harry changes anything. Her testimony doesn't really say anything useful" and "I think the jury would react the same way"). Comparatively, 13 participants stated that it would make a difference to include the unreliable witness (e.g. "The statement by Ms. Harry doesn't prove or disprove anything, but it takes away from the validity of the first witness, IMO", "Tough call- the statement of Ms. Harry would irritate the jury and would lean the jury to the more credible witness", and "I think maybe the prosecution loses some credibility if they put someone on the stand who gives testimony that doesn't seem substantive"). One participant argued that the inclusion would boost the probability of getting Siem convicted ("more witnesses the more weight the testimony will get I imagine, also the woman is more convincing").

Given the limited population size, the above comment should be taken with extreme caution. However, it suggests that participants may entertain two very different ideas of the reasoning of jurors. While the sample is too small for statistical analysis, the participants appear to entertain realistic approximations of their estimations of the reactions of jury members concerning the inclusion of the nondiagnostic information. The 11 participants who stated it would make no difference report no difference between the prior and the posterior.

## Concluding remarks

The paper set out to explore three different aspects of the dilution effect. First, given the debate concerning the basis for the dilution effect (whether it is conversational, cognitive, or social), study 1 used a legal setting to lessen or alleviate the potential influence of the experimenter and present the information as a court case with witness testimonies. Study 1 replicated the dilution effect.

Study 1 suggested that the credibility of the source might influence the strength of the dilution effect. Consequently, , study 2 manipulated the reliability of the witnesses who provided the diagnostic and the non-diagnostic information. Argumentation studies in source credibility suggest that the degree of belief in a proposition can be negatively influenced despite a diagnostic statement in cases where the source is unreliable or distrusted (see Madsen, 2016). In line with these findings, study 2 found that diagnostic statements from an unreliable source decreased participants' degree of belief in the likelihood of guilt while the same statement from a reliable source increased participants' degree of belief. Further, study 2 suggests that the dilution effect does not occur in situations where the non-diagnostic information is provided by a reliable source while we observe a strong dilution effect when an unreliable source presents nondiagnostic information. Future studies should look at the function of and relationship between source credibility and diagnosticity in more detail.

Study 2 gave participants the opportunity to provide qualitative feedback. Of particular interest, we noted a tendency for two strategy approximations to occur when the reliable source presented the diagnostic evidence and the
unreliable source presented the non-diagnostic statement. 11 (of 50 ) participants believed it would make no difference to the minds of a jury while 13 (of 50 ) believed it would have a negative effect. Their posterior belief revisions were in line with these estimations. This suggests that participants might entertain different perceptions of persuasion strategies and of the effect of evidence. However, as the current study is exploratory, we cannot draw any strong conclusions from these reports. We hope that future studies will explore the role of persuasion strategies and the dilution effect in more detail.

## Appendix: Background story and witness descriptions

## Background story

On the 31st of December 2010, around 7:30pm, the body of a man was found on the Place de Stalingrad, in Paris. The man was later identified as M. Tommy Tessel, a homeless drug-addict from Martinique. He died a few hours later, in the hospital.

A local police inquiry was conducted. All the people questioned in the neighbourhood initially denied having seen anything directly.
Some of them reported having heard that the victim had fallen after having been punched by a third party. The case was initially treated as an accident. No crime scene inspection was performed; no trace of blood was found.

On the 5th of January 2011 ( 5 days after the event), a person, who wanted to remain anonymous, reported to the police that a drug-addict often hanging around near the Rotonde (the rotunda of the Place de Stalingrad), of Senegalese descent, in his fifties, had punched the victim in the face and the victim had fallen heavily on the ground.

On the 8th of January, a crime investigation was opened. The criminal investigation department asked the local police for the victim's clothes so as to perform a DNA test. But it appeared that they were thrown away on the 5th of January for hygienic reasons.

An autopsy was performed on the deceased. The victim death's was directly caused by the brain injury resulting from the shock of his skull on the ground, probably due to a fall.

Reliable witness: Mrs. Rose Lanavan (55, social worker)
Mrs. Lanavan was employed as a cleaner in a pharmacy for around 20 years, after which she decided to enroll in a training programme for adults to become a social worker. She now works with drugaddicts and homeless people, helping them with any administrative procedures in relation to health, lodging, and judicial issues.

She is unanimously reported as a trustworthy and caring person. She works and lives in the area of Stalingrad, and knows well the people living there.

Unreliable witness: Ms. Edith Harry (26, no occupation)
Ms. Edith Harry is a drug-addict, often lurking in the area. She has tried a rehab several times, but always went back to smoking crack. She is reported to be psychologically unstable (she is reported to suffer from a serious personality disorder - labeled 'paranoid-delusional').

#### Abstract

This study focuses on the infuence of a three-dimensional (3D) graphic image and a 3D-printed object on the spatial reasoning of experts and novices in the medical field. The spatial reasoning task of this study required doctors specializing in digestive surgery to infer cross sections of a liver with a 3D image and a 3D-printed object in a situation where liver resection surgery was simulated. The task performance was compared with that of university students who conducted the same task in Maehigashi et al. (2016). The results of the analysis indicated that the doctors showed the same task performance when using the 3D image and the 3D-printed object. However, the university students learned faster and inferred the inside of a liver structure more accurately with the 3D-printed object than with the 3D image, and they performed equally to the professional doctors. Our results are then discussed in relation to previous studies.

Keywords: Spatial reasoning; Spatial mental model; Expertise; External representation; 3D printer

## Introduction

## Spatial reasoning and 3D-printed object

Spatial reasoning refers to the inference of an object's shape and structure and the physical relationship between objects by using spatial information (Byrne \& Johnson-Laird, 1989). Spatial reasoning is ubiquitous in daily activities such as planning routes, inferring a road's slope angle, or even arranging furniture in a room.

When people engage in spatial reasoning, they form spatial mental models in their minds. Spatial mental models are internal representations of the spatial relations among elements, and it is considered that they allow people to do perspective taking, reorientation and spatial inferences (Tversky, 1993). Spatial mental models are strongly influenced by the types of external resources that are referred to for its formation. Tversky (1991) experimentally showed that route searches were more accurate when the route information was displayed on a map rather than text. Moreover, John, Cowen, Smallman, and Oonk (2001) indicated that the understanding of a geometric structure was more accurate with a three-dimensional (3D) graphic image rather than with a
two-dimensional (2D). They explained that using 3D images is more effective because they integrate the multiple perspectives expressed by 2D images into a single viewpoint, provide supplementary depth cues, and display object features that would be invisible in 2D images.

Recently, the prevalence of 3D printers has made it possible for people to replicate objects. 3D printers offer an unprecedented means to express information and are being used in various fields such as education, industrial manufacturing, and medicine. However, very few studies have investigated the influence of 3D-printed objects on spatial reasoning.

Some studies experimentally investigated human understanding of molecular structures using concrete models (Barrett, Stull, Hsu, \& Hegarty, 2015; Stull, Barrett, \& Hegarty, 2013). The results of these experiments demonstrated no difference in task accuracy between the use of 3D images and concrete models. However, in their experiments, task accuracy rate was very high. Therefore, further investigations that consider situations requiring people to understand more complex structures with physical object models are necessary.

Maehigashi et al. (2016) experimentally investigated spatial reasoning of human organ structure using 3D-printed organs. As a result, they found that the understanding of a human organ's structure was more rapid and accurate when examined with a 3D-printed object rather than with a 3D graphic image. Their study indicated the possibility that using 3D-printed objects might reduce both the cognitive load and the cost of information access in forming and manipulating spatial mental models. In addition, based on ethnographical research, Maehigashi et al. (2015) investigated the influence of using a 3D-printed human liver on doctors in real liver resection surgeries. Their results showed that using such objects enhanced the formation of elaborate spatial mental models of a patient's liver. It also enhanced the mental simulation of liver resections and the formation of shared spatial mental models of a patient's liver among doctors.

## Expertise

Experts in various fields use chunking strategy for encoding, storing, and manipulating spatial information. Chase and Simon (1973) showed that chess masters could encode and store multiple positions of chess pieces in a game situation in a single chunk. Also, Busey, Yu, Wyatte, and Vanderkolk (2013) compared the eye movements of experts with those of novices in fingerprint matching. Their results indicated that experts were able to match wider regions of two fingerprints in a single instance than novices, and they could encode and store the various characteristics of fingerprint structures as a single unit. Moreover, an experiment by Hegarty, Keehner, Khooshabeh, and Montello (2009) revealed that fourth year dentistry students inferred the anatomical structure of teeth more accurately than first year students and could encode, store, and manipulate the various characteristics of teeth structures as a single chunk.

Hegarty et al. (2009) proposed that the fourth year dentistry students developed spatial mental models of teeth based on their anatomical knowledge of teeth and their experiences of learning operative skills for dentistry, and such mental models would facilitate chunking strategy. Some studies have shown the similar concepts. For example, Woods (1999) stated that radiologists have developed organized mental matrixes which integrate radiological characteristics, and therefore, they are highly adept in visual management and able to synthesize the characteristics of diseases. Also, Gobet and Simon (1998) demonstrated how chess masters developed mental templates of chess positions based on their prior experiences, enabling them to encode large and multiple quantities of information.

Related to such discussions, some studies have investigated the relationship between an expert's spatial abilities and spatial reasoning. Spatial ability is the capability to mentally store and manipulate spatial representations accurately (Hegarty \& Waller, 2005). An experiment by Hegarty et al. (2009) demonstrated that the spatial abilities of experts influence their performance of spatial reasoning. Conversely, Ackerman (1988) investigated the relationship between expertise and various cognitive abilities and indicated that the development of domain specific knowledge actually decreases the influence of spatial ability on task performance.

The purpose of this study was to investigate the influences of the use of 3D images and 3D-printed objects on the spatial reasoning of both experts and novices. The relationship between the spatial abilities of experts and their performances in spatial reasoning was also examined.

## Experimental task

In this study, we used a spatial reasoning task in a situation where actual liver resection surgery was simulated. The participants inferred the positions of a tumor within a liver and also the veins on cross sections of a liver by referring to its internal structure as displayed in a 3D image and a 3D-printed object.

## Materials

The materials in this study were exactly the same as those used by Maehigashi et al. (2016). Two desks, a primary and a secondary desk, were used in the experiment. The primary desk was set in front of a participant, and the secondary desk was set by the right side of the participant. The primary and secondary desks represented an operating table and tool stand as used in a surgical setting. Three boxes were placed on the primary desk. Each box contained a 3D-printed object of a liver (target) which represented a patient's liver and an answer sheet. Placed on the secondary desk was either a computer displaying a liver's 3D image or a box containing a 3Dprinted object that displayed the inside structure of a liver. Figure 1 shows a 3D image, a 3D-printed object, and a target.

Figure 1: (a) 3D image, (b) 3D-printed object, and (c) target
The 3D image was created by using Pluto, a computeraided diagnosis system developed at Nagoya University's Graduate School of Information Science. It was created based on data from a patient's liver measured by computed tomography (CT) (Figure 1a). In the 3D image, the thickest vein, an inferior vena cava (IVC), and five veins branching from the IVC were represented in blue. A tumor was represented in white. The participants could rotate and zoom in and out of the image by using a mouse.

The 3D-printed object and the three targets were created by using a 3D printer with the same CT liver data as the 3D image (Figure 1b, 1c). The 3D-printed object shows a liver's inside structure. In contrast, the target's surface was colored light gray, and the liver's inside structure was invisible just as a patient's liver would be in real-life surgery. A line was drawn around each of the three targets. Each line was sketched in a different location. Also, on each target the letters " $A$ " and " $B$ " were written to indicate the two separated areas based on the drawn line. Two sets of 3D images, 3Dprinted objects, and three targets were created from different CT liver datum.

## Vein and tumor location tests

The tests used in this study were exactly the same as those used by Maehigashi et al. (2016). The experiment employed a spatial reasoning task. Participants were required to take a vein and tumor location test for each target while referring to either the 3D image or the 3D-printed object. In the vein location test, participants were required to indicate the location of the veins that appeared on the cross section by cutting the target along the drawn line. Specifically, participants were required to mark "O" for the IVC and "X" for the branching
vein on the cross section's outer contour printed on the answer sheet (Figure 2). In the tumor location test, participants were asked to identify the area of the liver, either A or B, where the tumor had occurred.

Figure 2: Vein location test. (a) Contour of cross section of liver, (b) cross section of liver, and (c) participant's answer. (a) shows the outer contour of a liver's cross section printed on the answer sheet. (b) shows an actual cross section of a liver. (c) shows a participant's answer, which provides the number of IVCs, Os, and the branching veins, Xs, (drawn correctly here).

## Experiment

## Method

Participants and Factorial design Twenty-two doctors specializing in digestive surgery participated in this experiment. Their work experience ranged from eight to 22 years ( $M=10.57$ ). The experiment had a single-factor within participants design. The factor was the external representation (image and object).

Procedure The experimental procedure was generally the same as those of Maehigashi et al. (2016). First, the participants took a spatial ability test produced by Guay and McDaniels (1976). It comprised 24 questions that required mental rotations. The participants were required to answer as many questions as possible within three minutes. Next, all of the participants performed practice and experimental tasks with the 3D image in the image condition and the 3D-printed object in the object condition. In the practice task, the 3D image or the 3D-printed object, which represented one IVC and three branching veins, were used. First, the participants observed and learned about the inside structure using either the 3D image or the 3D-printed object for one to three minutes. Following on, they took the vein and tumor location tests for one target, referring to the image or the object.

After the practice, all participants conducted the experimental task. During the learning period, participants observed the inner liver structure for three to five minutes using either the 3D image or the 3D-printed object. When the participants deemed themselves ready after three minutes had passed, or when five minutes passed, the tests began. Participants took out the target and answer sheet from one of the three boxes on the primary desk and attempted to complete the vein and tumor location tests. During the task, participants were allowed to refer to either the 3D image or the 3D-printed object freely.

After the participants completed the tests for one target, they returned it together with the answer sheet back into the box and took a different set from another box. The task was completed when they had finished the tests for all three targets. After the experimental task was completed in one condition, the participants took a five-minute break and performed the practice and experimental tasks in the other condition.

For the image and object conditions, the 3D image and the 3D-printed object created by the different CT liver datum were used. The order of the task conditions and the combinations of CT liver datum were counterbalanced between the participants. Three sets of targets and answer sheets were randomly placed inside the boxes on the primary desk. Participants were instructed to perform the tasks as accurately as possible. Furthermore, removing the target from the primary desk was forbidden during the experiment, as it would be impossible for doctors to remove a patients liver from the operating table in a real-life surgical operation. However, removing the 3D-printed object from the secondary desk was permitted because in a surgical operation, doctors can place a 3D-printed liver right beside a patient's liver to confirm its interior structure (Maehigashi et al., 2015).

## Results

The participants of this study were doctors with anatomical and medical knowledge as well as first hand medical experience. Therefore, the data of this study was treated as an expert's performance data. We compared our data to that of Maehigashi et al. (2016) which examined the exact same tasks under the same conditions on 48 university students who did not possess any anatomical and medical knowledge.

We conducted 2(Expertise: expert and novice) $\times 2$ (External representation: image and object) analysis of variance (ANOVA) on the dependent variables. Since the external representation factor (image and object) was a betweenparticipants factor in the study by Maehigashi et al. (2016), we conducted a two-way between participants ANOVA in our analyses.

First, the learning time was the mean time taken by the participants to observe the inner structure of either the 3D image or the 3D-printed object before attempting the tests in each condition (Figure 3). The results of the analysis showed a significant interaction $(F(1,88)=4.75, p<.05)$. The analysis of the simple main effect showed that in the image condition, the learning time was significantly shorter for the expert condition than for the novice condition $(F(1,88)=14.84, p<$ .001 ). However, in the object condition, there was no significant simple main effect on the expertise factor $(F(1,88)=$ $0.60, p=.44$ ). Also, in the novice condition, the learning time was significantly shorter for the object condition than for the image condition $(F(1,88)=15.70, p<.001)$. However, in the expert condition, there was no significant simple main effect on the external representation factor $(F(1,88)=$ $0.78, p=.38$ ). In addition, there were significant main effects on both the expertise factor $(F(1,88)=10.67, p<.01)$ and the external resource factor $(F(1,88)=11.74, p<.001)$.

Figure 3: Learning time. The error bars indicate the standard error.

Following on, the task completion time was calculated as the mean time from when the first target was pulled out until the third target was returned to the box in each condition (Figure 4). The results of the analysis showed no significant interaction $(F(1,88)=0.10, p=.76)$. There was, however, a significant main effect on the expertise factor as the task completion time was shorter for the novice condition than for the expert condition $(F(1,88)=21.84, p<.001)$. Also, there was no significant main effect on the external resource factor $(F(1,88)=2.08, p=.15)$.

Figure 4: Task completion time. The error bars indicate the standard error.

In the vein location test score, we calculated the mean absolute difference value between the correct number of veins in the stimuli and the number of veins drawn on the answer sheet for the IVC and the branching veins in each condition (Figure 5). If the score is closer to zero, the number of drawn veins is more accurate.

For the IVC, all participants in the expertise condition correctly drew the veins, making the mean absolute difference value zero. On the other hand, for the branching veins, there
was a significant interaction $(F(1,88)=5.23, p<.05)$. The results of the simple main effect analysis showed that in the image condition, there was a significant simple main effect on the expertise factor; in other words, participants in the expert condition drew the number of veins more accurately than those in the novice condition $(F(1,88)=25.45, p<$ .001 ). However, in the object condition, there was no significant simple main effect of the expertise factor $(F(1,88)=$ $3.28, p=.07$ ). Also, in the novice condition, there was a significant simple main effect on the external representation factor, highlighting that more veins were accurately drawn in the object condition than in the image condition $(F(1,88)=9.80, p<.01)$. However, in the expert condition, there was no significant simple main effect on the external representation factor $(F(1,88)=0.01, p=.92)$. In addition, there were significant main effects in both the expertise factor $(F(1,88)=23.50, p<.001)$ and the external resource factor $(F(1,88)=4.58 . p<.05)$.

Figure 5: Absolute difference value. The error bars indicate the standard error.

In each tumor location test, a score of one was assigned if the tumor location was correctly answered. The tumor location test score was the mean total of the test results for the three targets in each condition (Figure 6). In other words, the higher the score, the more accurate is the answer. The results showed a significant interaction $(F(1,88)=$ $4.64, p<.05$ ). The analysis of the simple main effect indicated that in the image condition, the score was significantly higher for the expert condition than for the novice condition $(F(1,88)=5.96, p<.05)$. However, in the object condition, there was no significant simple main effect on the expertise factor $(F(1,88)=0.37, p=.55)$. Also, in the novice condition, the score was significantly higher for the object condition than for the image condition $(F(1,88)=$ $24.27, p<.001$ ). However, in the expert condition, there was no significant simple main effect on the external representation factor $(F(1,88)=3.54, p=.06)$. Additionally, there was a significant main effect on the external resource factor $(F(1,88)=4.64, p<.05)$, but no significant main effect on
the expertise factor $(F(1,88)=1.69, p=.20)$.

Figure 6: Tumor location test score. The error bars indicate the standard error.

Furthermore, correlation analyses were conducted on the relationship between the spatial ability test scores of the experts and their task performance, learning time, task completion time, absolute difference value for branching veins, and tumor location test score, in the image and object conditions. However, there was no significant correlation.

Finally, a t-test was conducted on the test scores for spatial ability in both the expert and novice conditions. The score was higher in the expert condition $(M=10.86)$ than in the novice condition $(M=8.48)(t(68)=2.20, p<.05)$. These results did not confirm the homogeneity of the spatial abilities between the experts and the novices. However, the results of the correlation analyses indicated that the experts did not use the advantage of their spatial ability to conduct the task.

## Discussion

## Accuracy of spatial reasoning

The results of the vein and tumor location tests revealed that the university students inferred a liver's inner structure more accurately with the 3D-printed object than with the 3D image and performed it to a standard equal to that of the professional doctors.

The university students formed spatial mental models of livers probably for the first time. Since the real world offers more depth cues than the virtual 3D environment (Kemeny \& Panerai, 2003), using the 3D image might require more cognitive load in order to form spatial mental models than using the 3D-printed object. The university students who used the 3D image apparently needed to mentally complement or modify spatial information, temporarily storing such information in their memory and mentally resizing it in order to map the information to the target. However, the students with the 3D-printed object were assumedly able to store the spatial information temporarily in their memory as they perceived it
and mapped the information from the 3D-printed object directly to the target without having to internally modify or resize it. Therefore, the university students with the 3D-printed object were assumed to have a smaller cognitive load, and, consequently, make fewer errors from the internal manipulation of spatial information and, therefore, able to show test performances equal to that of doctors.

It is also possible that the university students with the 3Dprinted object experienced lower information accessing costs than those who used the 3D image. Information accessing cost is incurred when acquiring information (Gray, Sims, Fu, \& Schoelles, 2006). Participants with the 3D image had to manipulate a computer mouse in order to acquire the required information. However, participants with the 3D-printed object had only to pick up and physically rotate a 3D-printed object. Thus, accessing information with a 3D-printed object was considered easier and less prone to errors or omissions than working with a 3D image.

However, the doctors showed the same task performance when using the 3D image and the 3D-printed object. It is inferred that the experts obtain spatial mental models developed by their prior knowledge and experiences (Hegarty et al., 2009). The doctors who participated in this study might be in possession of developed rigid spatial mental models of livers, and they were therefore able to modify their mental models based on the information displayed on both the 3D image and the 3D-printed object respectively. As a result, even though the 3D image is not as in-depth as the 3D-printed object, the doctors could still manage to create an equally accurate spatial mental model for the tests by depending on their already developed spatial mental models.

## Learning and task completion time

Analysis of the learning time revealed that the doctors showed the same task performance when using the 3D image and the 3D-printed object. However, the university students with the 3D-printed object finished their period of learning quicker than those with the 3D image and performed equally to the doctors.

As explained above, by using the 3D-printed objects, the university students were assumed to be able to reduce their cognitive load and information accessing cost. Therefore, they might be able to facilitate the formation of spatial mental models and perform equally to the doctors. Also as written above, the doctors were considered to have developed mental models. By modifying these mental models accordingly, they might be able to form spatial mental models with the 3D image as quickly as when they used the 3D-printed objects.

The results of the task completion time indicated that the university students performed the task faster than the doctors either with the 3D image or with the 3D-printed object. Some previous studies also experimentally showed that experts took a longer time to complete tasks than novices (Busey et al., 2013; Krupinski, 1996). One possibility is that since experts could access the related information by recalling and utilizing their existing knowledge, this process might cause
a longer task completion time. Previous studies showed that chess masters focused their eyes on the empty spaces more than novices when pieces on the board were being memorized (Charness, Reingold, Pomplun, \& Stampe, 2001; Reingold, Charness, Pomplun, \& Stampe, 2001). The chess masters were thought to be processing the related information stored in their long term memory. Another possibility is that experts could be more careful than novices. Previous studies showed that fingerprint experts were more skeptical than novices, and it therefore took them longer to match fingerprints (Busey et al., 2013).

## Experts' spatial ability and spatial reasoning performance

When the university students used the 3D image, there was a significant relationship between their spatial abilities and spatial reasoning performance (Maehigashi et al., 2016). In particular, high ability students demonstrated longer learning times and a more accurate inference to the positions of branching veins. On the other hand, in this study, whenever the doctors used the 3D image or the 3D-printed object, there was no relationship between their spatial abilities and spatial reasoning performance.

These results are different to that of Hegarty et al. (2009). The main difference between the previous study and this study can be related to the participants' degrees of expertise. The experts in Hegarty et al. (2009) were fourth year dentistry students. In contrast, the experts in this study were doctors with many years of work experience, and they therefore had many more years of expertise in the specialized field than the experts in Hegarty et al. (2009). Therefore, in this study, the spatial ability of experts did not influence spatial reasoning performance as indicated in Ackerman (1988).

#### Abstract

The development of symbolic algebra transformed civilization. Since algebra is a recent cultural invention, however, algebraic reasoning must build on a foundation of more basic capacities. Past work suggests that spatial representations of number may be part of that foundation, but recent studies have failed to find relations between spatial-numerical associations and higher mathematical skills. One possible explanation of this failure is that spatial representations of number are not activated during complex mathematics. We tested this possibility by collecting dense behavioral recordings while participants manipulated equations. When interacting with an equation's greatest [/least] number, participants' movements were deflected upward [/downward] and rightward [/leftward]. This occurred even when the task was purely algebraic and could thus be solved without attending to magnitude (although the deflection was reduced). This is the first evidence that spatial representations of number are activated during algebra. Algebraic reasoning may require coordinating a variety of spatial processes.

Keywords: algebra; number and space; notations; mousetracking.

## Introduction

The invention of symbolic algebra transformed human civilization. Algebraic notation allows for accomplishments as mundane as buying paint for a new fence and as fantastic as discovering antimatter. But symbolic algebra is a recent cultural invention. Thus, it cannot rely on devoted neural machinery that evolved specifically for that purpose - an innate 'algebra module.' Instead, our capacity for symbolic algebra must be cobbled together from other cognitive capacities. But which?
One proposal is that higher mathematics, including symbolic algebra, builds on a foundation of space (e.g., Lakoff \& Núñez, 2000; Sella et al, 2016). On this proposal, our evolutionarily ancient spatial abilities have been coopted by culture to reason about abstract mathematical entities and relations. Indeed, early spatial abilities are known to predict life-long mathematical performance, from grades in elementary school to the choice of a mathematicsheavy college major.
