Social media platforms provide a source for transmitting information that can become widely accepted. However, in this process of transmission, information becomes susceptible to distortion. In this study, we assessed people's semantic (i.e., prior expectations) and recognition memory for pop culture content, as a function of confidence and perceived information source. In Experiment 1, we investigated semantic memory for ubiquitous movie quotes (e.g., the famous Star Wars quote "Luke I am your father"). Notably this quote is incorrect, but we found that a majority of participants accepted these lure quotes as true with high confidence and indicated they had experienced the original source. In Experiment 2, participants viewed the original movie sources before a recognition test of the quotes. We found that while there was some improvement, people still preferred the lure quote with high confidence. We discuss the findings in terms of the strength of people's prior expectations when reconstructing events from memory.

Keywords: Semantic memory, recognition memory, source attribution, pop culture, confidence ratings.

## Introduction

Social media platforms such as Reddit, Facebook, and Twitter are popular outlets to discuss a broad range of topics including people's memories of favorite movies, movie quotes, and scenes. Recently a viral online forum topic focused on people who recalled watching a movie dating back to the '90s called 'Shazaam,' which starred the actor Sinbad playing the role of a genie ("People Claim to Have Seen", 2016). Interestingly, there is no record of a movie called 'Shazaam,' and Sinbad himself denies the movie ever existed. This raises the question: how could so many people feel so strongly about a shared false memory of watching a movie that never was? While misremembering a movie might be harmless, imagine being misinformed about a real-world event-such as falling prey to fake news about politics or terrorist attacks. In this paper, we assess people's semantic (i.e., prior expectations) and recognition memory for pop culture content, as a function of their confidence and perceived information source.

There are a number of cognitive mechanisms that might underpin this behavior. One explanation might be that people are falling victim to "the social contagion of memory", which occurs when one person's recollection of events influences and shapes another person's recollection (Roediger, Meade, \& Bergman, 2001). People integrate the false information with their true source representation. In this case, the contagion becomes exacerbated online as people's personal
recollections are being influenced by the recollections of people from around the world in an instant, thus allowing these false memories to be shared and spread.

Take the game of telephone as an example. It begins with one person whispering a message to the person next to them, and so on. Oftentimes, the last message is significantly different from the original. The transmission for any individual in the chain would become a question of reconstructing the noisy information from memory (Xu \& Griffiths, 2009).

These same factors also have implications for everyday memory such as singing the wrong song lyrics or misquoting common phrases and movie lines. As illustrated by the shared internet memory of 'Shazaam,' many of our memories for ubiquitous and pop culture concepts are not learned through first-hand experience with the original source-such as learning a quote directly from a movie-but rather are the result of information being passed from one person to another. In this case, the information transmitted takes on an abstracted nature.

Such distortion can happen in three different ways: assimilation, leveling, and sharpening (Bartlett, 1932). Assimilation occurs when details of the information are altered in memory to reflect one's own culture. Leveling occurs when information that is deemed non-essential is left out, reflecting a 'gist' representation of the event rather than the details. Sharpening occurs when the order of some details is changed. This illustrates how the reconstructive process can influence the transmission of information, leading to an event being slightly altered with each retelling to reflect the biases of the people participating in the transmission process.

While assimilation, leveling, and sharpening can result unintentionally from either the person transmitting the information or the person encoding the information, it is also possible to intentionally distort the shared information. This has been apparent in many experiments involving eyewitness testimony. Repeated exposure to suggestion, specifically, has been found to alter recall for a previous event (e.g., Loftus \& Palmer, 1974). When shown a video of a car stopped at a stop sign and asked questions containing misinformation, such as "did the car stop at the yield sign," most participants responded in the way suggested by the misleading interview question, rather than what they had witnessed in the video (Loftus, Miller, \& Burns, 1978; Loftus \& Palmer, 1974; Mitchell \& Zaragoza, 1996). It has been suggested that when misleading information is presented, it is introduced into the representation for the event and causes an alteration of that representation (Loftus, Miller, \& Burns, 1978). This
illustrates a reconstructive process similar to that of the telephone game leading to biases in memory.

One possible hypothesis to explain this willingness to accept misinformation as part of the original event is source misattribution, where people incorrectly attribute the source of the memory (e.g., Schacter, 2001). According to the source monitoring framework, participants fall prey to misinformation because they have confused the source of the original information with the source of the misinformation (e.g., Johnson et al., 1993; Lindsay, 1994; Lindsay \& Johnson, 1989).

In addition to confusing the source of information, people tend to express high levels of confidence in their memory, whether it is accurate or not (Bacon, 1979; Mitchell \& Zaragoza, 1996). People are equally confident when reporting false information about an event that they heard from a secondhand source, as when they are correctly recalling the event as they experienced it (Mitchell \& Zaragoza, 1996). Higher confidence has also been reported for more familiar statements (those that have been heard before), regardless of the accuracy of those statements (Hasher, Goldstein, \& Toppino, 1977). This suggests that confidence in memory is not directly related to the accuracy of that memory.

Each of these cases demonstrates how memory is a constructive process, prone to distortions from factors including intrusions from semantic memory, source misattribution, and misinformation. Although there is extensive literature on false memories and source misattribution across a number of domains, one domain that has not been widely studied is memory for ubiquitous concepts, specifically the type that would be prone to influences from popular culture. Therefore, we were interested in evaluating people's semantic memory (i.e. prior expectations) for pop-culture content and how their semantic memory influences recognition memory for this content. We tested semantic and recognition memory for well-known quotes that tend to be misrepresented in popular culture, specifically focusing on how pervasive the misremembering of popular incorrect information is, what source people attribute the information to, and how confident they are in their responses. We compared these ubiquitous quotes to performance on common graphics such as the Apple logo, which are less likely to undergo transmission distortion.

In Experiment 1 we assessed participant's semantic memory and attribution of the source of the information, but we did not test recognition memory given the true source information. In Experiment 2 we investigated recognition memory for the original source of the ubiquitous information, in order to compare it to the semantic memory in Experiment 1. We hypothesized that selections of the incorrect popular lure quote would be made with high confidence, and that the likelihood a selecting the lure quote even after studying the video would be similar to the likelihood of selecting the lure

[^260]quote in Experiment 1. If prior expectations exert a strong influence on memory, it is possible that even after viewing the original source material participants will still recall the misinformation that is pervasive in popular culture.

## Experiment 1

## Method

Participants Sixty-three Rutgers University undergraduate students participated in this study in exchange for course credit.
Materials The stimuli consisted of a brief demographics questionnaire (i.e. age, primary language, major, and media usage), and 273 -alternative forced choice (AFCs) questions: three movie quotes, three famous quotes, four logos (note: the Google logo had six individual test questions, one for each letter ${ }^{1}$, so the total number of logo questions was nine), and 12 distractor questions. See Figure 1 for the set of target stimuli. The 3-AFCs for each question included the correct response, a critical lure (i.e., the quote that has become common usage), and a non-critical lure. We selected the critical lures based on what has circulated on the Internet (e.g. In 2012's "Snow White and the Huntsman," Charlize Theron's character can be heard saying, "Mirror, Mirror, on the wall..."). For the graphics questions, the lures were selected based on one that closely resembled the target and one that did not. Both the demographics questionnaire and the

## Movie Quotes:

Star Wars: "No. I am your father."
Snow White and The Seven Dwarves: "Magic, mirror on the wall, who is the fairest of them all?"
Forrest Gump: "Life was like a box of chocolates."

## Graphics:

Figure 1. Stimuli (movie quotes and graphics) used in Experiments 1 and 2.

Figure 2. First panel: demographic questionnaire; Second panel: sample stimuli.

3-AFC questions were written in Matlab and presented on 23inch Dell monitors
Design Given the types of questions that were asked (e.g. recognition of the Apple logo), participants were instructed to put away all cellphones and other electronic devices before the experiment began. First, participants completed the demographic questionnaire (Figure 2, first panel). Next, participants answered 27 questions, one at a time, which consisted of three parts: 1) participants responded to each question by selecting one of the 3-AFCs from a drop-down menu 2) participants rated their level of confidence in their answer on a seven point Likert scale, with one being not confident at all and seven being very confident 3 ) participants indicated from a drop-down menu if and how they had previously been exposed to the information presented in the question. The options included: "I recently discussed this with a friend", "I have seen the TV show/movie, read the book/play, or heard the song/phrase before", "I have not seen the TV show/movie, read the book/play, or heard the song, but I have seen this referenced elsewhere", "I have never seen or heard of this before", or "Other", which then allowed participants to elaborate on their source of knowledge using the keyboard (Figure 2, second panel). The presentation order of the 27 questions was randomized across participants. On average, it took participants 20 minutes to complete the experiment.

## Results

Because the goal was to compare performance on the ubiquitous movie quotes and graphics between Experiments 1 and 2, only these target questions were used in the analysis. To evaluate whether participants could correctly identify the true quotes/graphics, we computed the response probability for the target, the critical lure, and the non-critical lure for each question (see Figure 3). We found that the preferred response for the movie questions was the critical lure (Star Wars: $95 \%$; Snow White: $95 \%$; Forrest Gump: 92\%). The preferred response for most of the graphic questions was the target (Apple logo: 82\%; American flag: 79\%). However, for the Microsoft logo question, participants were split, with $48 \%$ of participants choosing the target, and $48 \%$ choosing the more closely matching lure.

A series of binomial tests were conducted to assess whether the proportion of correct responses for each question was different from chance. The tests revealed that performance was significantly worse than chance for the movie quote

Table 1: Proportion Correct Compared to Chance

| Question | Exp1 | Exp2 | Chi Square <br> Exp1 \& Exp2 |
| :--- | :--- | :--- | :--- |
| Star Wars | $p<.001^{* *}$ | $p=.08$ | $\chi^{2}=25.04, p<.001^{* *}$ |
| Snow White | $p<.001^{* *}$ | $p=.01^{*}$ | $\chi^{2}=2.39, p=0.12$ |
| Forrest Gump | $p<.001^{* *}$ | $p=.004^{*}$ | $\chi^{2}=4.54, p=0.03^{*}$ |
| Apple Logo | $p<.001^{* *}$ | $p=.08$ | $\chi^{2}=11.22, p<.001^{* *}$ |
| Flag | $p<.001^{* *}$ | $p<.001^{* *}$ | $\chi^{2}=0.09, p=0.77$ |
| Microsoft Logo | $p<.001^{* *}$ | $p=.007^{*}$ | $\chi^{2}=1.34, p=0.25$ |
| ${ }^{*} p<.05 ;{ }^{* *} p<.001$ |  |  |  |

Figure 3: Response probabilities for the target and critical lure for each question in Experiments 1 and 2.
questions and significantly better than chance for the graphics questions (see Table 1).

We then assessed confidence for the preferred response for each question. For the movie related questions, a majority of those who chose the critical lure also responded with high confidence, defined as five or higher (Star Wars: 86\%; Snow White: $92 \%$; Forrest Gump: 77\%). For the graphics questions, a majority of those who chose the target responded with high confidence (Apple logo: 78\%, American flag: 94\%; Microsoft logo, target: $55 \%$, most closely matching lure: $45 \%$ ), see Figure 4. When comparing confidence ratings for targets to critical lures, we found that for most of the movierelated questions, confidence was greater for the critical lure than the target. We report the mean and standard deviation because there were not enough participants who chose the target to conduct a statistical test comparing confidence between target and critical lure (Star Wars: critical lure $M=6.14$, $S D=1.63$, target $M=3.50, S D=3.54$; Snow White, critical lure $M=6.55, S D=0.82$, target $M=3.50, S D=2.12$; Forrest Gump, critical lure $M=5.6, S D=1.6$, no participants chose the target for this question). There was no significant difference in confidence ratings between targets and more closely matching lures for the Apple logo, American flag, and Microsoft logo questions.

For source attribution, we computed the response probability for each possible source conditioned on target and critical lure responses. Here we report the most frequently selected source for the preferred response for each question. Given that a majority of participants responded with the critical lure for the movie related questions, we analyzed which source they attributed their response to and found that they responded "watched the movie" as their direct source of knowledge (Star Wars: 71\%; Snow White: 83\%; Forrest Gump: 84\%), see Figure 5.

Figure 4: Confidence ratings for target and critical lures for movie related and graphic questions in Experiments 1 (top row) and 2 (bottom row).

Figure 5: Source attribution for the movie related questions in Experiment 1 (left column) and Experiment 2 (right column).

## Experiment 2

## Method

Participants Thirty-six Rutgers University undergraduates participated in exchange for course credit.
Materials The demographic questionnaire was identical to Experiment 1. The study stimuli consisted of eight videos corresponding to the movie quotes and graphics, as well as one distractor clip. The video clips were scenes from movies that contained the quotes and commercials that contained the logos that were the basis of the questions in Experiment 1. The clips varied in length from 30 seconds to one minute. The test stimuli consisted of 123 -AFC questions identical to those in Experiment 1, and related to the video clip content (three movie quotes, three logos, and three Google logo related questions ${ }^{2}$ ). The demographics questionnaire and 3-AFC

[^261]questions were administered through Qualtrics Survey System on Dell computers in the lab.
Design After completing the demographic questionnaire, participants viewed seven of the eight video clips, one at a time, wearing a pair of provided headphones. Participants were instructed that they would receive a memory test on the content of the video clips. After viewing all seven target video clips, participants then watched an eighth clip which was unrelated to the memory test. This clip served as a distractor between study and test and lasted for roughly five minutes. After the distractor, participants answered 12 recognition memory questions related to the seven clips they had just viewed. Importantly, these questions were identical to those in Experiment 1 including the 3-AFC (target response, critical lure, and non-critical lure), confidence ratings, and source attribution questions. The recognition
questions were self-paced and took participants 15 minutes, on average, to complete.

## Results

To evaluate whether participants could correctly recognize the target quote and graphic after having viewed the original source, we computed the response probability for the target, critical lure, and non-critical lure for each question (see Figure 3). We found that participants were split for the Star Wars question with $44 \%$ choosing the lure response and $47 \%$ choosing the target response, indicating that performance was substantially better for participants after watching the original source (with $95 \%$ choosing the critical lure in Experiment 1). Interestingly, however, for the other movie related questions the preferred response was still the critical lure (Snow White: 75\%; Forrest Gump: 78\%). Participants were split for the Apple logo question, with $47 \%$ of participants choosing the target, and $33 \%$ choosing the more closely matching lure. It is important to note that more participants responded correctly with the target in Experiment 1 than in Experiment 2. For the other graphic questions, the preferred response remained the target (American flag: 84\%; Microsoft logo: 56\%).

A series of binomial tests were conducted to assess whether the proportion of correct responses for each question was different from chance (see Table 1). The tests revealed no significant difference for the Star Wars question and the Apple logo question. There was a significant difference in performance for the remaining questions, with participants doing significantly worse than chance for the Snow White and Forrest Gump questions, and significantly better than chance for the American flag and Microsoft Logo questions.

In order to further examine whether the introduction of the video clips improved performance, a chi-square test was conducted to compare the proportion of correct responses in Experiment 1 to the proportion of correct responses in Experiment 2 (see Table 1). The test revealed that performance on the Star Wars and Forrest Gump questions were slightly better for those participants who watched the video clips in Experiment 2. For the Star Wars question, there were significantly more people who answered correctly in Experiment $2(47.22 \%)$ compared to Experiment 1 $(3.28 \%)$. For the Forrest Gump question, there were significantly more people who answered correctly in Experiment 2 ( $11.11 \%$ ) compared to Experiment 1 ( $0 \%$ ), indicating that recognition accuracy was higher for those participants who had studied the direct source. However, there was no significant difference in performance between experiments for the Snow White, American flag, or Microsoft logo questions, indicating that for some questions, even for participants who had seen the video clips, recognition performance was no better than for participants in Experiment 1 who had not viewed the direct source. For the Apple Logo question, there were significantly more people who answered correctly in Experiment 1 (81.97\%) compared to Experiment 2 ( $47.22 \%$ ).

We then assessed confidence for the preferred response for each question in Experiment 2. For the movie related
questions, a majority of those choosing the critical lure also responded with high confidence, defined as five or higher (Star Wars: 88\%; Snow White: 81\%; Forrest Gump: 75\%, Apple logo, critical lure: $71 \%$, more closely matching lure: $58 \%$ ). It is important to note that for the Apple Logo question, more people answered with the critical lure in Experiment 2 than in Experiment 1. However, for the remaining graphic questions, a majority of those choosing the target responded with high confidence (American flag: 90\%; Microsoft logo: $55 \%$ ), see Figure 4 . When comparing confidence ratings for targets to critical lures, we found that there was no significant difference in confidence ratings between target and critical lures for any of the questions, indicating that participants who chose the critical lure were just as confident as those who chose the target.

For source attribution, in Experiment 2 we computed the response probability for each possible source conditioned on target and critical lure responses. Here we report the most frequently selected source for the preferred response for each question. We found that a majority of those who chose the critical lure also responded that they had "watched the movie" as their source of knowledge (Star Wars, critical lure: $50 \%$, target: $53 \%$; Snow White, critical lure: $93 \%$; Forrest Gump, critical lure: 82\%), see Figure 5.

## Discussion

The current study investigated people's semantic memory (i.e., prior expectations) and recognition memory for pop culture content, as a function of their confidence and perceived information source. We found that people chose the ubiquitous incorrect (critical) lure for the movie related questions. These results are consistent with the finding that people remember the gist of sources and not most of the details (Sachs, 1967). These responses were given with high confidence, with participants indicating that they had learned this information from the direct source, i.e., the movie. This suggests that people have strong prior expectations for pop culture content frequently circulated through the media even though these expectations are not correct.

We found that in Experiment 2, exposure to original source material did not overwhelm pop-cultural distortions or lead to higher recognition accuracy for all of the movie quotes. Participants were still prone to select the critical lure, and did so with high confidence. This suggests that when prior expectations are strong, even if they are misaligned to the truth, viewing the original source cannot always overcome this inaccuracy.

Although there has been some success in correcting false memories (Brewer, 1977; Fazio \& Marsh, 2010), we did not observe this in our study. Providing the original source material may have been ineffective in our task because we did not explicitly inform our participants to attend to the original source material (movie quotes or graphics). This was purposely done to simulate real world settings where people may passively encode information.

These two findings together present a somewhat dangerous picture of what misinformation can do to episodic memory.

For example, for the Apple logo where semantic memory (Experiment 1) was highly accurate, recognition memory (Experiment 2) faltered. This might be because the somewhat abstract noisy semantic representation is integrated with a noisy episodic representation in the reconstruction process. In contrast, for the pop culture movie quotes, recognition memory was only slightly better than semantic memory. This might be a result of semantic representations exerting a strong influence on the noisy episodic traces in the reconstruction process-consistent with a Bayesian interpretation of memory (e.g., Hemmer \& Steyvers, 2009). In other words, the false semantic representation provides a high baseline contribution to episodic memory that is too strong to overcome even with exposure to the true source.

The implications of these findings as they relate to real world events are far reaching. Much of the "fake news" that was circulated the Internet throughout the 2016 presidential election consisted of fabricated stories posing as professional journalism. These stories were spreading misinformation, and ultimately became a means to influence public opinion. The importance of this issue has grown over time, as more people have reported that they get their news from the Internet (Lee, 2016). If we examine contemporary popular culture and the focus on social network distribution, it is easy to see how information spreads very rapidly through re-posts, re-tweets, or sharing via word of mouth throughout the Internet population, often in ways that the original producers cannot determine or control (Burgess, 2008). So, the next time you share a post on Facebook, or quote a movie, make sure you check your sources.

# A Computational Model for Reasoning About the Paper Folding Task Using Visual Mental Images 

James Ainooson (james.ainooson@ vanderbilt.edu)<br>Maithilee Kunda (mkunda@vanderbilt.edu)<br>Department of Electrical Engineering and Computer Science, PMB 351679<br>2301 Vanderbilt Place, Nashville, TN 37235-1679, USA

#### Abstract

The paper folding task is commonly used for the evaluation of nonverbal, spatial reasoning skills. In this paper, we present a computational model that attempts to use visual-imagerybased representations and operations to solve this task. The model was tested against all problems from the standard paper folding task and achieved a perfect score, illustrating that visual-imagery-based representations and operations are sufficiently expressive to capture at least one successful solution strategy. Although the model does not closely resemble human cognitive processing, and thus should not be considered in its current form to be a plausible psychological model of human task performance, the assumptions made and their implications for our understanding of human cognition on the paper folding task point to fruitful lines of future work towards this goal.

Keywords: artificial intelligence; cognitive assessment; paper folding; spatial skills.

## Introduction

Paper folding tasks are cognitive assessment tools used in the evaluation of spatial, non-verbal reasoning skills. Visuospatial skills in general are thought to be critical to a variety of human endeavors, including scientific discovery (Miller, 1984), art (Arnheim, 1969), engineering (Ferguson, 1994), computer programming (Petre \& Blackwell, 1999), mathematics (Giaquinto, 2007), education (Silverman, 2002), and even feats of memory (Foer, 2011). Visuospatial skills also seem to be areas of intact or even superior performance for certain individuals with developmental conditions such as autism (Soulieres et al., 2011; Kunda \& Goel, 2011) and Prader-Willi syndrome (Verdine et al., 2008).

In research on Science, Technology, Engineering and Mathematics (STEM) education, visuospatial ability is viewed as a key contributor to math learning (National Research Council, 2009) and to pursuing degrees and careers in STEM disciplines (Wai et al., 2009). Studies suggest that visuospatial ability can improve with training (Uttal et al., 2013), and that such training can enhance math performance in children (Cheng \& Mix, 2014).

Thus, there is an urgent need for effective visuospatial assessments as well as training interventions to promote learning outcomes, creative discoveries, effective design work, and more. Understanding the specific cognitive mechanisms that underlie visuospatial ability is a critical step along this path.

Of course, studying visuospatial ability purely through observations of human behavior is challenging because many of the underlying cognitive processes are not directly observable. Even neuroimaging yields only a coarse view of the specific information processing steps that take place as someone is solving a task.

Figure 1: A sample task from the VZ-2 paper folding test. The images on the left of the vertical line depict the stages in a fold. The images on the right of the line are possible choices of how the paper may look when unfolded.

In this paper, we instead adopt the approach of implementing a computational cognitive model that simulates solving the task-the cognitive systems approach of artificial intelligence (AI) (Thagard, 2005). Cognitive systems model how intelligent agents combine different cognitive processes, like learning, reasoning, and memory, to perform a task. By implementing a cognitive system that simulates solving visuospatial tasks, we can look "under the hood" at specific types of information processing mechanisms that might drive visuospatial ability.

In previous work, we have implemented similar models that investigate aspects of visuospatial cognition on other cognitive assessment tasks. Previous work on the Raven's Progressive Matrices intelligence test has examined the role of visual mental representations in solving difficult test problems (Kunda et al., 2013), the contributions of different types of imagery operators (Kunda et al., 2013), the meaning of different patterns of errors (Kunda, Soulières, et al., 2016), and visual mechanisms for maintaining goal-subgoal hierarchies (Kunda, 2015). Previous work on the Block Design task has looked at relationships between internal mental representations and external deployments of visual attention (Kunda, El Banani, \& Rehg, 2016), and previous work on the Embedded Figures task has looked at capacity limits in visuospatial memory, in particular the effects on task performance of internal deployments of visual attention to different parts of a visual mental representation (Kunda \& Ting, 2015).

In this paper, we present initial results from a new computational model of the paper folding task. Although the model does not closely resemble human cognitive processing, and thus should not be considered in its current form to be a plausible psychological model of human task performance, the assumptions made and their implications for our understanding of human cognition on the paper folding task point to fruitful lines of future work towards this goal.

In particular, the model we present can be considered as
an experiment on the sufficiency of certain imagery-based representations and operations for solving paper folding, which is valuable for understanding how different cognitive mechanisms might in theory contribute to visuospatial ability in people, and especially how certain cognitive limitations might affect task performance. Ultimately, we hope that results from this line of work will serve as a basis to suggest routes for how such cognitive limitations might eventually be overcome, i.e., in developing new visuospatial training interventions for use in education.

## About Paper Folding Tasks

Paper folding tasks are usually presented as line-drawings of paper cut-outs or folded pieces of paper. People are then asked to imagine changes that happen when this paper is manipulated in different ways. Several forms of the test exist.

Shepard and Feng (1972) presented a form of the paper folding test which required test subjects to fold a cube out of six connected squares. Two of the squares have arrows that point to an edge and one square is greyed out to show that it is the base of the cube. People are then required to predict whether the arrows align and point to the same edge when the cube is re-constructed. This essentially requires them to mentally reconstruct the cube by imagining folding the paper as though the shape was cut-out of the paper. Lovett and Forbus (2013) developed a computational model developed to reason about this specific case of paper folding tasks. Their model takes the approach of simplifying the task by removing unnecessary details and essentially focusing primarily on the orientation of critical edges to solve the task.

Another form of the paper folding task (which is also called "the punched hole test"), developed by Ekstrom and colleagues (1976), is administered as a 6 minute pencil and paper test in two parts ( 3 minutes for each part). During the test, subjects are presented with a sequence of images showing the stages in folding a square piece of paper. A hole is then punched on this folded piece. Test subjects are also presented with five possible outcomes of how the paper looks when it is unfolded. See Figure 1 for an example of this type of problem. Designed as part of the "Kit of Factor-Referenced Cognitive Tests", this task appears as the second test under the group of tests that evaluate the visualisation cognitive factor (VZ-2).

A number of research studies have used paper folding to evaluate spatial reasoning skills. While testing a hypothesis on learning styles amongst individuals, Mayer and Massa (2003) used this test as part of their measure of spatial skills. Keehner et al. (2004) also used this test as one of their tests of spatial ability while investigating the correlation between spatial ability, experience and skill in laparoscopic surgery. Another example is the study by Silvia (2008) in which the paper folding test was used as part of a measure of fluid intelligence, while investigating relationships between creativity and intelligence.

There is much that is still unknown about the direct cogni-
tive mechanisms involved in paper folding tests. Mental rotations are believed to play a major role (Shepard \& Feng, 1972). In addition to the complexity of the mental rotations, people may have to deal with the additional component of mental folding (Glass et al., 2012) and in the case of a punched hole test, how the holes affect the final output. Wright and colleagues (2008) showed that training on mental rotation tasks improved performance on paper folding tasks, just as training on paper folding tasks improved mental rotations.

Next, we present a computational model that attempts to solve the paper folding task using simulated "mental rotations" in "three dimensions". The exact formulation of the paper folding task we intend to tackle with this model is "The Punched Hole" test (Ekstrom et al., 1976).

Figure 2: A sequence of images sent as input to the model (blue and white), and the corresponding bitmaps that are used by the model after inputs are processed (black and white). The first input row corresponds to the initial "problem" part of a paper folding item. The second input row contains the possible choices the model is presented with.

## The Model

We present a computational model that attempts to solve "The Punched Hole" paper folding task (Ekstrom et al., 1976) using only image based operations. The model is built in the Python programming language and relies extensively on the Pillow fork of the Python Imaging Library (PIL) to perform low level image manipulation.

The main task of the model is to analyze a sequence of images that depict the folding and punching in a problem
of the paper folding task to determine what the paper would look like when unfolded. It achieves this by maintaining a three dimensional representation of the paper which is stored as a stack of two dimensional images. Each image on the stack represents a single level of folding performed in a single time-slice. The actual fold operations are performed with image reflections that provide a simplified simulation of threedimensional rotations.

## Input

Inputs to the model are presented in three stages. The first stage consists of a sequence of images that represent the state of the folded paper in each time-slice. The second stage consists of a single image that represents the state of the folded paper after the hole has been punched. Finally, the third stage presents the possible solutions from which the model could select an answer after it is done predicting a solution.

All the inputs are presented as line drawings with sections that contain paper filled with pixels to ensure the model can properly differentiate between paper and empty space. Before any images are passed on for further processing, they are converted to single colour images. This makes it easy for the model to perform logical bitwise operations between images. Once converted to a single colour image, any pixel that is set to 1 in the image is considered to be an area containing paper, and pixels set to 0 are considered to be empty spaces. See Figure 2 for a sample sequence of input images and their corresponding bitmap representations.

## Strategy

The model's strategy for solving the tasks relies heavily on two stacks. The first stack (which we call the image stack) keeps track of images that represent the layers of folds. The second stack (which we call the operations stack) keeps track of the operations that are performed on the images as folds occur. In predicting the solution, the model utilizes four main operations: Initialize, Fold, Punch and Unfold.

The Initialize operation sets up the model before solving any task. It places an image which has all its bits set to 1 on the images stack. This image is meant to represent the initial piece of unfolded paper on which fold operations will be performed.

The Fold operation receives as input an image of the state of the paper after a given fold has occurred. The model will attempt to use this image and other images on the image stack to find the best estimation of the line along which the fold was made. To accomplish this, the following processing steps are performed on the bitmap representation of the fold input image for every image on the stack, starting from the bottom:

1. The current layer to be processed is retrieved from the image stack. In the case of the first fold operation, this image has all pixels set to 1 .
2. An intersection operation is performed between an inverse of the fold input image and the image retrieved from the stack. This operation is constrained by the bounding box
around the image that was retrieved from the stack. The resulting image is an image of the flap to be folded, as illustrated in Figure 3.

Figure 3: Stages the images go through to generate the folded flap image.
3. Another intersection operation is performed between the fold input and the image retrieved from the stack. This new image replaces the original image on the stack, as shown in Figure 4.

Figure 4: The intersection between the input image and the existing image on the stack to generate a replacement for the image on the stack.
4. In order to determine the line along which the fold would occur, a single pixel border is drawn around both the folded flap image, and the modified image on the stack. This is to make both images larger so they can slightly overlap. An intersection operation is computed between the two new overlapping images to generate an image containing the line along which the fold is to be made. A search for two extreme coordinates of this image is then performed on the pixels in this image. This search is biased towards the pixels that are from the folded flap image. Search results will now contain the coordinates of the fold line. These coordinates are then pushed onto the operations stack.

Figure 5: Intersecting the new overlapping images to determine the fold line.
5. Finally, the folded flap image is reflected across the fold line. This reflection operation is analogous to a $180^{\circ}$ rotation in three dimensional space about the fold line axis. The reflected image is then pushed to the top of the stack to act as one of the base images for any subsequent fold operations. After a series of fold operations is performed, each image on the stack will represent a folded layer.

Figure 6: The final reflection operation of the fold.

Once all fold operations are completed, the Punch operation is performed. This operation takes the punch input, and computes the intersection of this input with all the images on the stack, replacing all the contents on the stack with the results. See Figure 7 for an image depicting all the changes that take place on the stack for fold operations and the punch operation.

Figure 7: The various states of the image stack as inputs are fed to the model.

Unfold is the next operation after the punch has been performed. This operation runs through the operations stack and performs a reverse of all operations. It works by picking the image on top of the stack and the one below the stack. It performs the reverse operation on the image on top of the stack (which will be the folded flap).

It then performs an OR operation between the folded flap and the base image. The new image generated after the OR operation is placed onto a new image stack. The unfold operations are recursively called on the newly generated image stack until the stack contains a single image. This image will represent the model's predicted solution to the problem.

A final solution can be chosen by the model with the last image generated after the unfold operation. A pixel by pixel comparison is performed between the model's prediction and each of the possible solutions. The comparison that yields the largest number of matching pixels is selected as the solution.

Figure 8: The various states of the image stack during the unfold operations.

## Experiments and Observations

We tested the model against all twenty items from "The Punched Hole" test (Ekstrom et al., 1976). Input images (for both the fold stages and answer choices) for this experiment were taken from the original test but redrawn as "clean" versions using the Inkscape Vector Graphics editor. Redrawn vector images were converted to raster images before being passed to the model.

Results for the experiment were a count of the number of items on which the model was able to select the correct answer. When this experiment was performed, the model selected the correct answer on all items in the test-a score of 20 out of 20 .

Looking more carefully at the operation of the model, we observed that a constant number of operations are performed for each fold simulated. Also, the size of the stack grows exponentially with respect to the number of folds performed. For every $n$ folds, there are a total of $2^{n}$ items on the stack.

Interestingly, the set of problems had 1 to 3 fold levels. This meant that the maximum stack size required for the tasks varied from 2 (for single folds) to 8 (for triple folds). If we take the size of the image stack to be analogous to "working memory usage" in our model, the maximum number of items stored while solving any of the paper folding problems is consistent with what is known about visuospatial working memory capacity limits in people (Luck \& Vogel, 1997).

Also, working in the image domain gives the model the ability to operate on arbitrary folding tasks. To test this ability, we ran a "paper snowflake" simulation through the model to evaluate its output. From Figure 9, we can clearly observe that the model generated an output that corresponds to the snowflake folds passed through it.

Figure 9: The model's "solution" to a paper folding problem with arbitrary fold and punch shapes. The top row of images show the input to the model and the bottom row of images showt the output of the model at the various stages of unfolding the snowflake.

## Discussion and Future Work

One current assumption of this model has to do with the comparison technique used to match possible solution choices to the predicted solution. As stated earlier, this operation is performed using a pixel by pixel comparison technique, where pixels on the predicted solution must closely match pixels on a possible solution. For the case of our experiment, these possible solutions were carefully drawn such that holes in both the right and wrong choices were precisely placed.

However, as we have observed in other standardized cognitive assessments (Kunda et al., 2013; Kunda \& Ting, 2015), printed figures in test booklets are not always so precise at the pixel level. (We surmise that many of these tests must have been hand-drafted when they were first created.) On the actual paper folding test by Ekstrom et al. (1976), many of the positions of the punched holes are not necessarily aligned perfectly. However, people are still able to solve these tasks, which suggests that the model should have more robust pattern recognition and processing abilities.

Our model has shown one possible set of cognitive mechanisms, based on visual mental images, that are sufficient for solving the paper folding test. Other strategies undoubtedly exist. What is more interesting, perhaps, is a consideration of why people might fail to solve paper folding items. What mechanism or set of mechanisms might they lack?

One possibility is working memory capacity, simulated in our model as the size of the image stack. Clearly, limiting the size of the stack will immediately reduce the model's ability to successfully solve paper folding problems. However, there are other possibilities as well.

One idea is that people might "forget" where the fold is on a folded up piece of mental paper, and proceed to unfold the paper in the wrong direction. (For example, they might interchange the folded side and the open side of a folded page, at the moment when they are unfolding it.) This is a subtle error that does not have to do with raw capacity but more like a limit on attentional capability, or the accurate persistence
of information in working memory. We speculate that these types of fold-forgetting errors may lead participants to choose some of the distracter answer choices that are provided.

In continued work on the model, we will implement some of these cognitive limitations to see what might lead the model to make particular types of errors. Then, we could compare the errors made by different configurations of the model to the errors made by people, to see if there are suggestive connections between cognitive strategy variations and behavioral error patterns (Kunda, Soulières, et al., 2016).

#### Abstract

In psychology, we tend to follow the general logic of falsificationism: we separate the 'context of discovery' (how we come up with theories) from the 'context of justification' (how we test them). However, when studying human interaction, separating these contexts can lead to theories with low ecological validity that do not generalize well to life outside the lab. We propose borrowing research practices from formal inductive methodologies during the process of discovering new regularities and analyzing natural data without being led by theory. From the perspective of experimental psychology, this approach may appear similar to the 'questionable research practice' of HARKing (Hypothesizing After The Results are Known). We argue that a carefully constructed form of HARKing can be used systematically and transparently during exploratory research and can lead to more robust and ecologically valid theories. Keywords: HARKing; experimental psychology; conversation analysis; methodology; interaction

## Performance-enhancing questionable practices

Most discussions of the current 'replication crisis' in psychology and the social sciences (Pashler \& Harris, 2012; Pashler \& Wagenmakers, 2012) focus on identifying and mitigating the biases and incentives that lead researchers to adopt questionable research practices (QRPs): a range of methods for manipulating experimental results and processes that John, Loewenstein, and Prelec (2012) describe as "the steroids of scientific competition, artificially enhancing performance". But science-at least ideally-is not about competition, and the highest scientific achievements are of benefit to all. It makes sense, therefore, to look at some QRPs and their underlying rationales in more detail: why are they so tempting? What makes them 'safe' or 'unsafe' for science in specific contexts? For example, qualitative, inductive methods often used in cognitive science such as grounded theory (Glaser \& Strauss, 1967) are very useful for exploratory studies in many research areas, but may produce misleading inferences when used to code certain kinds of behavioral phenomena for confirmatory, quantitative research into language and human interaction (Stivers, 2015). However, rather than simply labeling all such methods as QRPs in the context of experimental, confirmatory research, we may be able to borrow from them to enhance our research results without compromising our methodological rigor. In many of the failed replications reported in Open Science Collaboration (2015), it seems that QRPs are used to increase the probability of 'finding' an effect predicted by the stated theory. Theorizing about an interactional phenomenon that has no grounding in interactional reality makes QRPs attractive, simply because they make it more likely that researchers will be able to report significant effects that support their theory. The issue underlying the use
of QRPs in the study of human interaction, then, may be intrinsically related to the broader problem of groundless theorizing, where theories are formulated without being familiar with the situations they theorize about. We suggest that this problem, in turn, stems from some uncritical assumptions about science and human interaction.

## The problem of groundless theorizing

A common assumption about falsificationism, still implicitly or explicitly a major philosophical underpinning of empirical science, is that as long as a theory can be falsified by testing a hypothesis, the scientist is free to theorize any conceivable causal relationship between any measurable variables. There is nothing inherently wrong with this approach if all plausible confounding variables can be controlled, and this theoretical freedom of movement is tremendously powerful. Popper was inspired by how the freedom to theorize raised the stakes for cosmologists such as Einstein, whose entire theory of general relativity could have been falsified if just one of his audacious predictions about electromagnetism and gravitational potential had turned out to be false. However, in the context of human interaction research, it is notoriously difficult to control for confounds because there are many human behaviors that are very difficult if not impossible to emulate in controlled conditions (De Ruiter, 2013; Schegloff, 2006), and just recording or observing people interacting may change the ways they interact in unpredictable ways (Labov, 1972). In this paper we describe a set of pre-theoretical research procedures that interaction researchers can use to constrain their theories to match observable facts within the domain of interest. While this may sound like the questionable research practice of HARKing (Hypothesizing After the Results are Known) (Kerr, 1998), we argue that systematic, inductive methods for analyzing social interaction can provide a principled and effective way to ground theorizing about human interaction, leading to more robust and relevant theories.

## Contexts of discovery and contexts of justification

The 'context of discovery' is the situation in which a phenomenon of interest is discovered. For example, when studying human interaction, a useful context of discovery would be an otherwise naturalistic conversation that happened to be recorded for analysis (Potter, 2002). 'Contexts of justification', in this example, might then include the laboratory, the conference paper, and the academic literature within which the empirical details are reported, analyzed and formulated as a scientific discovery (Bjelic \& Lynch, 1992). These

| Context | Participants' resources | Analysts' resources |
| :--- | :--- | :--- |
| Discovery | Observable actions <br> Observable settings | Observable actions <br> Observable settings |
|  | Knowledge \& experience <br> beyond current interaction | Ability to fast forward, <br> rewind and replay. |
| Justification | Sequential organization of <br> talk \& social actions <br> Self/other correction <br> (repair) | Sequential organization of <br> talk \& social actions <br> Self/other correction <br> (repair) |
|  | Introspection <br> Inductive reasoning | Quantification <br> Deductive analyses |

Figure 1: Interactional resources and methods within participants' or analysts' contexts of discovery and justification.
are important distinctions for what we think of as theoretical grounding: drawing together the contexts of discovery and contexts of justification in order to place principled limits on theorizing about interaction. However, drawing these contexts together in interaction research requires analysts to take account of critical distinctions between what kinds of evidence is available to analysts and the kinds of interactional resources available to participants in the situation itself (Garfinkel, 1964; Lynch, 2012). Figure 1 lists a few key resources participants and analysts can both use when discovering and justifying interactional phenomena, and (underneath, in red) some of the resources for making sense of interaction that are only available from one perspective or the other. Some of these resources are shared, for example, both participants and overlooking analysts can use observable features of the setting and the visible actions of the people within it to discover new phenomena. Both participants and analysts can also observe when these visible actions are contiguous and uninterrupted (Sacks, 1987), and can see if certain actions are routinely matched into patterns of paired or 'adjacent' initiations and responses (Heritage, 1984, p.256). Similarly, both analysts and participants can observe when contiguous flows of initiation and response seem to break down, falter or require repair to re-establish orderliness and ongoing interaction (Schegloff, Jefferson, \& Sacks, 1977). By contrast, many other resources and methods for making sense of the situation are exclusively available to one or another role. For example, analysts can repeatedly listen to a recording, slow it down, speed it up, and can precisely measure, quantify, and deduce cumulative facts that would be unimaginable to participants in the interaction. On the other hand, participants may draw on their store of tacit knowledge and use introspectionoptions which are not necessarily observable for overlooking analysts-to make sense the current state and consequences of the interaction. 'Discovery' for participants, then, is some action or phenomenon observably discovered and treated as mutually relevant with others in the situation. Justification is the interactional work participants do with others in the setting to display and uphold the mutual intelligibility and rationale of their actions: an imperative that Garfinkel (1967)
describes as 'mutual accountability'. For analysts, discovery and justification use as many of the same resources as possible, but are motivated by different concerns i.e. to provide causal explanations for the events and phenomena discovered for the purposes of scientific research, but without the urgent imperatives of mutual accountability. The challenge for analysts wishing to improve their theories by bringing together contexts of discovery and contexts of justification is to constrain themselves to testing theories that deal with resources and methods that are evidently available to both analysts and participants.

## Pre-experimental HARKing for better theories

When we advocate pre-experimental HARKing, it should be clear that this proviso about using interactional resources available to both participants and analysts excludes 'exploratory data analysis' (Jebb, Parrigon, \& Woo, 2016) or other uses of inferential statistics for pre-confirmatory theorizing since this is not something participants would be able to use as a resource within their contexts of discovery or justification. Rather, the research procedures recommended here are inspired by conversation analysis (CA): an approach to interaction research which exemplifies the use of empirical constraints on theorizing (Schegloff, 2007, pp. xii-xiii), and which has tended to avoid engagement with experimental studies that necessarily prioritize theorizing in order to arrive at causal explanations (Kendrick, 2017). The 'theoretical asceticism' (Levinson, 1983, p. 295) of CA's research practices makes them very useful for drawing together contexts of discovery and justification in a principled and coherent way (De Ruiter \& Albert, 2017). In relation to theorizing, we call these practices 'pre-experimental HARKing' to draw attention to the distinction between HARKing as a QRP (after having produced a theory and tested it with an experiment), and CA's "qualitative, inductive, and strictly empirical" (Haddington, Mondada, \& Nevile, 2013, p.7) research processes of systematic observation and ongoing informal peer review that takes place before any theorizing is allowed. One of the ironies of theories and experiments in interaction psychology that use corpora is that the 'results' (i.e. what actually happened in the interaction) usually are known before the hypotheses or research questions are formulated. It therefore makes sense to use these data to develop better theories and operationalizations before having to make key decisions about coding, quantifying and analyzing interactional phenomena. The risk otherwise is that what gets coded, quantified and tested may not turn out to be observably relevant to the participants in the interaction at all (Schegloff, 1993; Stivers, 2015). It should be clear by now that the term HARKing is not used perjoratively here. Since existing data, intuitions, and past results often provide the basis for theorizing at a pre-experimental stage in any case, we advocate using CA's systematic and transparent procedures to constrain and ground those theories empirically.

## Sharing contexts of discovery and justification

A 'result' in the participants' context of discovery can be thought of as the achievement of a reciprocal action in a social situation such as successfully ordering a beer in a bar. This is motivated quite differently from from the 'results' that might be discussed in the analyst's context if the researcher were, for example, designing an experiment to try to figure out what behaviors enable people to obtain beer in bars. Loth, Huth, and De Ruiter (2013) show that going to a bar and systematically observing how beer-ordering is achieved through interaction provides very informative and somewhat surprising results as the basis for formulating new theories. They found that all customers have to do to initiate a successful beerordering interaction is to stand at the bar looking towards the bartender and that any use of the stereotypical ordering-like actions they had anticipated in fact proved to be unnecessary and even potentially disruptive. The first step in drawing together contexts of discovery and justification, then, is to find a setting where participants do observable interactional work to achieve their results (getting a beer in a bar) in ways that are informative for the analyst's results (finding out how people get beer in bars). CA terms this kind of social situation that can be used as a starting point for analysis a 'perspicuous setting' from the Latin perspicio 'to see through', denoting a situation that functions like a microscope that analysts can use to examine the local organization of human affairs. Garfinkel (1992, pp. 184-186) emphasizes that in perspicuous settings participants' affairs are 'locally produced, locally occasioned and locally ordered" and that these function as contexts of discovery and justification of what is relevant for the participants, whose interactions in those contexts are conducted without reference to analyst's concerns. The bar is an obvious choice as a perspicuous setting for exploring beer-ordering, but even if there is no specific domain of inquiry, new questions can also emerge from repeated viewing and 'unmotivated' analysis of data. For example, a corpus of video recordings of guided walking tours has provided a perspicuous setting for discovering questions about how people organize themselves as mobile groups (De Stefani \& Mondada, 2013), about the roles and procedures involved in getting the group to examine something (De Stefani, 2010), and to then coordinate the process of walking away together interactionally (Broth \& Mondada, 2013). The starting point for Legal HARKing, then, is to find a perspicuous setting where participants work together to achieve a given outcome in ways that researchers can then observe and analyze as the basis for formulating more interactionally grounded theories.

## Transcribe interactionally relevant details

Conversational turn-taking is one of the most clearly observable systematic forms of organization in interaction (Sacks, Schegloff, \& Jefferson, 1974). In this sense conversation is a useful example of a context of discovery and justification that is shared between participants and analysts alike. In the context of conversation, participants discover things like
whose turn it is to talk next, and justify their discoveries using a clearly organized protocol for turn-allocation and turntransition. For conversation analysts, the turn-taking system became a foundational context for discovery and justification when Sacks et al. (1974) showed how it could explain systematic features of everyday interaction such as the tendency for minimal gaps and overlaps in natural talk (a discovery that has subsequently been tested experimentally and across multiple languages (Stivers et al., 2009)). CA's transcription system was devised by Gail Jefferson to highlight the systematic patterns of overlap and variations in prosody and intonation (Hepburn \& Bolden, 2012). Although phonetic transcription in IPA notation provides a much higher degree of accuracy than standard orthography, these objective levels of description are not necessarily available to participants themselves, and in any case people in everyday interactions do not usually make an issue of pronunciation. Jeffersonian transcription is relatively simple to read and use, and is optimised to spatialize and represent the features of talk such as speed-ups, stress, stretches, overlaps, and gaps that seem most relevant to participants' contexts of discovery and justification. Most importantly, the activity of hand-transcribing conversational data is a very useful pre-analytical activity in itself through which researchers can become intimately familiar with their data by watching repeatedly while trying to capture the fine details of whatever features are observably relevant to the participants themselves (Bolden, 2015). While all transcription systems introduce the analytic perspectives and assumptions of the analyst doing the transcription (Ochs, 1979), it makes sense to use a system designed specifically to capture the details of talk most demonstrably relevant to how participants maintain the smooth operation of the turn-taking system.

## Use intersubjective review of subjective judgments

Another way to draw together the participants' and analysts' contexts of discovery and justification is to use the interactional aptitudes of the analysts themselves as a heuristic device to explore what is going on in the interaction. This may sound like an overly subjective form of judgment, but since the object of inquiry for analysts is human interaction where we have no better measuring device than our own social intelligence, it makes sense to use our skills as interactants, even if we may not understand how these abilities work. This problems of reliance on subjective intuition can be mitigated through interaction itself. The conversation analytic 'data session' is a research practice where analysts present their data, describe what they see, and have their observations tested against the intuitions and reasoned arguments of other analysts. This is one of the least well-documented aspects of CA, and is barely mentioned in the research or training literature (Sidnell \& Stivers, 2012), although Ten Have (1999, pp. 140-141) provides a brief explanatory description.
"[The data session] often involves playing (a part of) a tape recording and distributing a transcript...The session starts with a period of seeing/hearing and/or read-
ing the data, sometimes preceded by the provision of some background information by the 'owner' of the data. Then the participants are invited to proffer some observations on the data, to select an episode which they find 'interesting' for whatever reason, and formulate their understanding, or puzzlement, regarding that episode. Then anyone can come in to react to these remarks, offering alternatives, raising doubts, or whatever."

The group often consists of both experienced and novice analysts, so there is an element of 'tradecraft' and apprenticeship built into the structure of the data session (Jordan \& Henderson, 1995; Harris, Theobald, Danby, Reynolds, \& Rintel, 2012). Ten Have (1999) in fact attributes his learning CA to having attended data sessions with Gail Jefferson and Emanuel Schegloff, so despite the lack of documentation, the data session has clearly been central to CA from the start. There is a scattering of advice about how to run such sessions in some textbooks, in a few short papers (Hindmarsh, 2012) and even within some reflexive studies that explore CA data sessions as interactional situations in themselves using CA (Antaki, 2008; Harris et al., 2012). These accounts also provide some useful technical advice, for example, Jordan and Henderson (1995) suggest that the 'owner' of the data plays back short clips of up to twenty seconds, then discusses each clip, but limits the discussion to 5 minutes before looking at more data, so that "no single participant can speculate for very long without being called upon to ground her or his argument in the empirical evidence, that is to say, in renewed recourse to the tape." Heath, Hindmarsh, and Luff (2010, pp. 156-157) have some similarly practical advice to limit the session to 20 or fewer people, and not to "cheat and look ahead, or rely on information exogenous to the clip itself": essentially following the rule of thumb to avoid using resources or methods unavailable to participants themselves. Of course the frequent fast forwarding and rewinding of recordings and many of the other analytical methods described here do, nonetheless, rely on resources not necessarily available within the participants' contexts of discovery and justification. However, since the data session is an interactional situation where peers are involved in grounding one another's assumptions about the interaction through interaction, there is also a degree of mutual accountability at work that may compensate for the loosening of CA's strict methodological constraints. Through the data session, theories and assumptions are subjected to open and self-critical debate. Ten Have (1999) sums up this analytic attitude neatly:
"What is most important in these discussions is that the participants are, on the one hand, free to bring in anything they like, but, on the other hand, required to ground their observations in the data at hand, although they may also support them with reference to their own data-based findings or those published in the literature. One often gets, then, a kind of mixture, or coming together,
of substantial observations, methodological discussions, and also theoretical points."

Even after the analyst's painstaking transcripts and observations have run the gauntlet of multiple data sessions where flaws in theory may be identified and discussed, the CA research cycle has just begun by finding candidate phenomena for analysis.

## The analytical phases of pre-experimental HARKing

Having attended multiple data sessions to explore candidate phenomena and findings, there are several further stages required to develop analytically grounded theories about interaction. Conversation analytic primers are now available (Schegloff, 2007; Sidnell \& Stivers, 2012; Ten Have, 1999), so only a summary of analytic procedures is provided here.

After a series of data sessions, analysts collect multiple instances of a target phenomenon each with minor variations in terms of their composition, sequential structure and their range of uses in interaction. Analysts often then work on 'single case analyses' involving an extended study of a few episodes of interaction featuring the target phenomenon in great detail. Over time, the analyst may build up hundreds of cases, organized into 'collections' (Schegloff, 1996), working towards a more complete characterization of the phenomenon and its specialized variations. For example, Schegloff (1968) describes collecting 499 cases of telephone call openings, and considering his collection almost complete and ready to be analyzed. It was the 500th case, however, which provided him with a single 'deviant case' that forced him to re-evaluate his findings about the sequential order of ringing and greeting exchanges in telephone call openings. This example is often cited to demonstrate the difference between these approaches and more conventional case studies. Each single case starts from first (interactional) principles in trying to explore the setting from a vantage point as close to the context of discovery and justification of the participants as possible. For this reason, Schegloff's (1968) example functions as a kind of applied falsificationism: the only way the 500th case could make sense from the analyst's context was to (quite radically) change the theory. Furthermore, long-standing collections of often-analyzed phenomena become theory-like over time, and can be subject to falsification and ongoing modification through contradiction by subsequent CA findings, or through changes in people's patterns of behavior over time. For example, since the mid-2000s the most common telephone call opening sequence has changed significantly due to the prevalence of caller-ID on mobile phones (Raudaskoski, 2009). This process of careful, qualitative analysis is required before CA researchers even consider developing a formal coding scheme (Dingemanse, Kendrick, \& Enfield, 2016; Stivers \& Enfield, 2010) with which to quantify their findings (Stivers, 2015) and run experiments-although these last few steps are still not widely accepted, and remain controversial within CA
(Kendrick, 2017). While this overall procedure is clearly extremely laborious, it does have the reassuring advantage that the phenomena described are guaranteed to have actually occurred in reality, not only in our theoretical imagination.

## Summary: Better theorizing after legal HARKing

This paper argues for researchers of human interaction to devote attention and resources to systematically exploring the context of discovery where their theories will be formulated by extending the falsificationist paradigm. Before we theorize and then test our predictions experimentally, we suggest researchers borrow methods from conversation analysis and other formal inductive methods to enhance the performance of our theories with a kind of pre-experimental 'legal HARKing'. This procedure involves using detailed Jeffersonianstyle transcription, holding data sessions and subjecting our qualitative findings to ongoing, critical analysis before developing theories. By proceeding with our analysis with a sensitivity to the kinds of resources that participants themselves have at hand, we can identify interactional practices that are psychologically relevant and consequential for participants (and not just researchers), and empirically grounded in natural interaction. We expect this kind of grounding to improve the relevance, robustness, and replicability of human interaction research by producing more theoretically grounded hypotheses that we can then test using traditional experimental methods. As long as-at this stage-we pre-register our experiments, we can harness the performance-enhancing benefits of legal HARKing while excluding the dangerous possibility of 'illegal' post-experimental HARKing. More generally, since research practices are seen as 'questionable' in relation to the conventions of a specific methodological framework, we suggest that if we reconsider them at a critical distance from any one methodology, these practices may have many potentially beneficial applications. From the perspective of the experimental research practices that predominate within cognitive science and psychology (Toomela, 2014), for example, the inductive categorizing and coding methods of grounded theory may be seen as 'questionable'. Similarly, from the perspective of generalization-oriented experimental studies, the scope of theories derived from micro-analytic methods such as CA (e.g. about turn-taking) can seem almost trivial (Heritage, 2008). However, taken together the body of work derived from CA's empirical studies constitutes a very broad set of findings about interaction against which generalized theories can be tested (De Ruiter \& Albert, 2017). While different research practices address different problems and questions at different scales, they may also have some useful practical and philosophical intersections. One scientists' 'questionable' research practice can be another's means of rigorous inquiry, and perhaps remaining 'questionable'in the sense of being open to critical review-is something more researchers could aim for in their research practices.

# Segmentation as Retention and Recognition: the R\&R model 

Raquel G. Alhama (rgalhama@uva.nl) Willem Zuidema (zuidema@uva.nl)<br>Institute for Logic, Language and Computation, Science Park 107<br>Amsterdam, 1098XG, The Netherlands

#### Abstract

We present the Retention and Recognition model (R\&R), a probabilistic exemplar model that accounts for segmentation in Artificial Language Learning experiments. We show that R\&R provides an excellent fit to human responses in three segmentation experiments with adults (Frank et al., 2010), outperforming existing models. Additionally, we analyze the results of the simulations and propose alternative explanations for the experimental findings.

Keywords: artificial language learning; segmentation; statistical learning; cognitive modelling

## Introduction

A crucial step in the acquisition of a spoken language is to discover what the building blocks of a speech stream are. Children perform such segmentation by exploiting a variety of statistical and prosodic cues in the input. Understanding the unique ability of humans to acquire speech requires an understanding of the nature of this learning mechanism.

Artificial Language Learning (ALL henceforth) has, over the last 20 years, become a key paradigm to study the nature of learning biases in speech segmentation and rule generalization. In experiments in this paradigm, participants are exposed to artificial stimuli designed to incorporate particular aspects of speech and language, and they are subsequently tested on whether and under which conditions they discover the regularities in such artificial language.

A key result in this tradition is the demonstration that 8 month old infants are sensitive to transition probabilities between syllables, and can segment a speech stream based on these probabilities alone (Saffran, Aslin, and Newport (1996), Aslin, Saffran, and Newport (1998)). This ability to track statistics over concrete fragments of the input, known in the literature as statistical learning, has also been demonstrated in adults (Saffran, Newport, \& Aslin, 1996).

However, these experiments do not reveal whether the underlying cognitive mechanism does operate over transitional probabilities or, instead, it performs computations of an entirely different nature but which can be described as transitional probabilities. In order to reveal the precise underpinnings of such cognitive mechanism, a useful methodology is computational modeling.

There exist several segmentation models in the literature, offering alternative accounts of the nature of this process. Thus, these models need to be compared and analyzed against empirical data to validate their predictions. Possibly the most comprehensive study for the evaluation of computational models in segmentation is presented in Frank et al.
(2010). In that study, the authors evaluate a range of models based on their goodness of fit to three segmentation experiments that involve a great number of different conditions -thus providing a rich dataset for comparing the models.

In this paper we present one model for to account for segmentation experiments in ALL. Our model, called the Retention \& Recognition model (henceforth R\&R), is a novel processing model that explains segmentation based on the retention and recognition of subsequences of the input. Following Frank et al., we test our model against the experimental data from their study, and compare the goodness of fit of our model with those reported in previous studies.

## The R\&R Model

The model we propose, which we call the RetentionRecognition Model (R\&R), takes a sequence of syllables $X=$ $\left\langle x_{o}, x_{1}, x_{2}, \ldots, x_{m}\right\rangle$ as input, and considers all subsequences of length $l=1,2, \ldots, l_{\max }$ as potential segments to be memorized.

The model maintains a memory $M$, which is a set of segment types and their associated counts. The memory is initially empty ( $M_{0}=\emptyset$ ) and it changes with update steps that either add an entry (with count 1) or increase the count of an existing entry:

ADD: $\quad M_{t+1} \leftarrow M_{t} \cup\left\{\left\langle\left\langle x_{j}, \ldots, x_{k}\right\rangle, 1\right\rangle\right\}$

## INCREMENT:

$M_{t+1} \leftarrow M_{t}-\left\{\left\langle\left\langle x_{j}, \ldots, x_{k}\right\rangle, c\right\rangle\right\} \cup\left\{\left\langle\left\langle x_{j}, \ldots, x_{k}\right\rangle, c+1\right\rangle\right\}$
For any candidate segment $s \in S$ (with segments processed in the order they are encountered in the stream), the model checks whether it is stored in memory and, if so, what the count of that segment in memory is (its 'subjective frequency'). The model may (with a probability $p_{1}$ that increases with that count) recognize it (i.e., match it with a segment in memory). If it succeeds, the count is incremented with 1. If it fails to recognize the segment, the model might (with a probability $p_{2}$ that decreases with the length of the segment) still retain it (i.e., add it to memory with initial count of 1 if it was not stored, or in the event that a previously stored segment was not recognized and is retained -very rare in practise- increase the count by 1 as a form of 'late recognition'). In this way, the model builds a memory of segments that have different degrees of familiarity depending on their distribution in the stream. R\&R's flowchart is given in Figure 2.

The key components of the model are the equations for
computing the recognition probability $\left(p_{1}\right)$ and retention probability $\left(p_{2}\right)$. Recognition should become more probable the more often a segment has been recognized, but decrease with the number of segment types in memory $(|M|)$. Hence, we define $p_{1}$ as follows, with $B$ and $D$ free parameters $(0 \leqslant B, D \leqslant 1)$ that can be fitted to the data:

$$
\begin{equation*}
p_{1}(s, M)=\left(1-B^{\operatorname{COUNT}(s, M)}\right) \cdot D^{|M|} \tag{1}
\end{equation*}
$$

If a segment is not recognized, the model considers retaining it with a probability that decreases with the length of the segment $(l(s))$, and which can be boosted if there are additional cues favoring this segment (e.g., a pause preceding it). Hence, we define $p_{2}$ as follows, with $A$ and $\mu$ free parameters $(0 \leqslant A \leqslant 1 ; 0 \leqslant \mu)$ that can be fitted to the data:

$$
p_{2}(s)=A^{\operatorname{length}(s) \cdot \mu} \quad, \text { where } \mu=\left\{\begin{array}{l}
\mu_{w p} \text { after a pause }  \tag{2}\\
\mu_{n p} \text { otherwise }
\end{array}\right.
$$

The $A$ parameter thus describes how quickly the retention probability decreases with the length of a segment. The probability is also affected by the presence of additional cues; in this paper, we consider only the pauses between sentences as additional cues. ${ }^{1}$

Putting everything together, the model can be described in pseudocode as in Figure 1. As can be seen, R\&R is a simple model, but it gives a surprisingly accurate match with empirical data, as we will explore in the next sections, without even taking processes such as forgetting, priming, interference and generalization into account.

## Related Models

There exist several models of segmentation in the literature. We do not have the space to address them all here, but we discuss how our model relates to those to which it has more similarities.

The recognition component of our model yields rich-getricher dynamics (and thus consistently produces very skewed count distributions over segments in memory) similar to that of non-parametric Bayesian models, such as the Bayesian Lexical Model (BLM henceforth) in Goldwater, Griffiths, and Johnson (2009) (adapted for ALL in Frank et al. (2010)). The BLM implements such dynamics with a Dirichlet process. The main assumptions of this process are: (i) the probability of a word in the $i^{\text {th }}$ position is proportional to the number of occurrences of this word in previous positions; (ii) the

[^262]```
Input: Stream \(X\), and empty memory \(M_{0} \leftarrow 0\).
Output: Memory \(M_{n+1}\).
/* Compute candidate segments: */
\(S \leftarrow\left\langle s_{0}, s_{1}, \ldots, s_{n}\right\rangle\)
/* Process each segment: */
for \(i=0\) to \(n\) :
    /* Compute the recognition probability: */
    \(p_{1}=p_{1}\left(s_{i}, M_{i}\right)\)
    /* Compute the retention probability: */
    \(p_{2}=p_{2}\left(s_{i}, M_{i}\right)\)
    /* Draw two random numbers */
    \(r_{1} \sim \mathcal{U}(0,1)\)
    \(r_{2} \sim \mathcal{U}(0,1)\)
    /* Recognize, retain or ignore: */
    IF \(\left(r_{1}<p_{1}\right)\)
        \(M_{i+1} \leftarrow \operatorname{increment}\left(s_{i}, M_{i}\right)\)
    ELSE IF \(\left(r_{2}<p_{2}\right)\)
        \(M_{i+1} \leftarrow \operatorname{add}\left(s_{i}, M_{i}\right)\)
    ELSE
        \(M_{i+1} \leftarrow M_{i}\)
```

Figure 1: Pseudocode describing the R\&R model.
relative probability for a new word type in the $i^{t h}$ position is inversely correlated with the total number of word tokens, and (iii) a new word type is more probable if it is shorter. Assumption (ii) does not allow for direct comparison, since $R \& R$ is not a generative model, and therefore it does not provide a probability for new types -rather, the incorporation of new types to the memory of the model depends on the retention probability, and it is based on a preference for shorter sequences (an intuition encoded also in assumption (iii) of the Bayesian model). As for assumption (i), the same principle is incorporated in the recognition process in $R \& R$; however, in our model, the counts of the number of occurrences of a word is based on the subjective frequencies resulting from memorization, while in the BLM, these counts are based on absolute frequencies of the current hypothesis. This reflects a fundamental difference between the two approaches, which concerns their level of analysis (Marr, 1982). The Bayesian model is framed at Marr's computational level, and thus, it operates over the whole stimuli, since it does not incorporate perceptual or memory constraints (although some of the extensions in Frank et al. (2010) experiment with limitations on memory capacity, leading to a somewhat hybrid model; we return to this point later). In other words, the BLM is not proposed as a mechanistic explanation of the cognitive processes involved in the experiment; on the contrary, $R \& R$ is a processing model, which postulates that cognitive processes of retention and recognition, and psychological representations of exemplar segments are responsible for segmentation.

An existing model that is also pitched at Marr's processing level is PARSER (Perruchet \& Vinter, 1998). PARSER is a symbolic model, built around basic principles of associative learning and chunking, that shares many similarities with R\&R. Both PARSER and R\&R are exemplar-based models that build a lexicon of segments (exemplars), and use this

Figure 2: R\&R:The Retention-Recognition Model
lexicon of already-memorized segments to decide on further segments to memorize. Each segment in the lexicon is stored together with a score that determines the impact of this segment in the next steps of the segmentation process. Thus, the models are similar in their procedure, but there are notable differences between them. One of them is the probabilistic nature of their components. For PARSER, the stochasticity is limited to the random selection of the size of the next segment to read from the stream. In contrast, $R \& R$ considers all possible subsequences of the stream (up to a maximum length), as inspired by research in Data-Oriented Parsing tradition (Scha (1990), Zuidema (2006)). Additionally, the model is inherently probabilistic in its basic processes of retention and recognition.

There exist other differences in the procedure of these approaches. To begin with, the process of retention in R\&R penalizes longest segments, on the basis that they would require more working memory. However, PARSER is a chunking model, so it implements the opposite principle: whenever several segment candidates are possible, it selects those that are built of the longest units, creating in this way a bias for larger units. As for the process of recognition, it is implicitly implemented in PARSER when it maps the next segment to be read against the units in memory. This process involves a binary threshold: only units with weight above the threshold can be recognized as components of the segment (but those below the threshold are retained). In contrast, the interaction between recognition and retention in $R \& R$ is based on a graded probabilistic choice. Finally, an important difference between the models is that $R \& R$ does not implement any form of forgetting. Although we do not claim that humans are endowed with perfect memory, our results suggest that forgetting does not seem to play a key role in the timecourse of the experiments.

On the other extreme, at Marr's implementational level, we find TRACX (French et al., 2011; French \& Cottrell, 2014), a connectionist proposal that is also based on the recogni-
tion of subsequences. TRACX is an autoencoder model that learns a representation for the input data. The error of the output layer is computed by comparing it with the input, and it serves as an indication of the degree of recognition of the input. The model processes the input stream sequentially, maintaining a context window. After successful recognition of a segment, the internal representation learned by the network is used as the context for the next segment to be presented. In this way, contiguous segments that are successfully recognized are gradually represented as a single chunk, and therefore can be recognized as a unit. This approach shares with R\&R the intuition that words are consolidated in memory after repeated recognition; however, like PARSER, TRACX is a chunking model, that is, it is oriented to the integration of syllables in order to build larger fragments. In contrast, in $R \& R$, words emerge in a process that actually penalizes larger fragments, as a consequence of consolidated memorization of statistically salient segments.

To sum up, R\&R constitutes a new approach to modelling segmentation that offers a processing level explanation of the identification of words in a speech stream, which emerges as a result of the interplay between probabilistic memory processes. We now proceed to validate this model against empirical data.

## Fitting R\&R to Experimental Data

## Experimental Results

Frank et al. investigate how distributional aspects of an artificial language have an effect on the performance of human adults in segmentation. Each of their three experiments involves a range of conditions that vary in one particular dimension: (i) sentence length, (ii) amount of exposure (number of tokens) and (iii) vocabulary size (number of word types).

The stimuli consists of an auditory sequence of sentences, each of which is created from a sample of artificial (unexisting) words. The sentences are separated with a silence gap
of 500 ms , while there is no acoustic nor prosodic cue indicating the separation between words within a sentence. After the participants have been exposed to a sample of sentences thus constructed, they participate in a 2-Alternative-ForcedChoice test (2AFC). The two alternatives in the test consist on one word from the artificial language (a correctly segmented sequence), and one "part-word" (a sequence resulting from incorrect segmentation).

To analyze the results, the mean number of correct choices is computed across participants in each condition. The curves formed by these datapoints (ordered by condition value) is taken as indication of how segmentation performance is affected by the varied dimension. These curves (which are shown in the continuous line in Figure 3) show that: (i) human adults have more difficulty in segmenting words when sentences are longer, presumably because they do not benefit from the extra cue provided by the silence gaps; (ii) when the amount of word tokens is varied, more occurrences of words facilitate the identification of such words, and (iii) the size of the vocabulary seems to cause lower performance in the experiment, with an almost-linear inverse relation.

## Goodness of fit

The study by Frank et al. evaluates a number of segmentation models in terms of their goodness of fit to the curve that describes the average performance of the human subjects. The evaluated models include the ones previously described (BLM, PARSER, and later, also TRACX, reported in French et al. (2011)), and four additional approaches, all of them consisting on normative models: Transitional Probabilities (TP), a Bayesian version of TP (by Frank et al.), Mutual Information (MI), and a version of MI model that identifies words when they exceed a threshold both on MI and raw frequency counts (MI Clustering, Swingley (2005)).

In order to compare the models, Frank and colleagues convert the output of each model to a metric that can be interpreted as behavioural predictions for the 2AFC task. To do so, they employ the Luce Rule (Luce, 1963). Given a pair of sequences $s_{1}$ and $s_{2}$ in test, the Luce Rule defines the probability of choosing $s_{1}$ as can be seen in Equation 3:

$$
\begin{equation*}
P\left(s_{1}\right)=\frac{\operatorname{SubjFreq}\left(s_{1}\right)}{\operatorname{SubjFreq}\left(s_{1}\right)+\operatorname{SubjFreq}\left(s_{2}\right)} \tag{3}
\end{equation*}
$$

Once the scores have been transformed to probabilities, the performance of the models is computed as the mean probability of choosing the correct item, averaged over participants and test trials. These datapoints are arranged in a curve in the same way as with human participants, and the correlation in the shape of these curves -measured with Pearson's r- is taken as an indication of good fit.

Likewise, we run simulations of the three experiments with $R \& R$, transforming its output (the subjective frequencies) into test trials with the Luce Rule. We run a search over the parameter space, in order to find which parameters yield

Figure 3: Curve of performance for all conditions in the experiments in Frank et al. (2010).
best correlation with human performance ${ }^{23}$. The best results are shown in Table 1. As it can be seen, our model outper-

[^263]Table 1: Comparison of model results to human performance. The reported metric is Pearson's r. ${ }^{*}$ Experiment 2 was not reported in French et al. (2011). Therefore, the mean can be taken to be 0.63 (for a Pearson's $r$ of 0.0 in experiment 2) or 0.945 (averaging only over experiments 1 and 3 ).

| 12 | R\&R | $\mathbf{0 . 9 8}$ | $\mathbf{0 . 9 4}$ | $\mathbf{0 . 9 8}$ | $\mathbf{0 . 9 7}$ |

forms all the other models in the three experiments, with a parameter setting that is common to the three experiments ( $A=0.008, B=0.923, D=0.866, \mu_{n p}=1.0, \mu_{w p}=0.234$ ). The curves of the performance of both human adults and R\&R can be see in Figure 3.

When it comes to experiment 1 , one possible explanation for this result is that $R \& R$ is the only model that explicitly models the effect of the silence gaps. By increasing the length of sentences while keeping the number of types and tokens constant, the stimuli necessarily consists of fewer sentences when those are made longer; therefore, the number of silence gaps also decreases. For this reason, the performance of $R \& R$ declines with longer sentences, since it cannot obtain the same benefit from exploiting silence gaps. This explanation for the superior performance can be supported by looking at the values of the $\mu_{w p}$ parameter: the best fit of the model requires a low value for this parameter ( $\mu_{w p}=0.234$ ) , so in the presence of a pause it substantially boosts the otherwise very small $\left(A^{\mu_{n p}}=0.008\right)$ retention probability.

In the second experiment, normative models based on point estimates (those based on TP and MI) do not offer a good fit with the data, since those metrics do not benefit from the accumulation of evidence offered by the increased number of tokens (contrary to humans). Frank et al. suggest that humans may be forgetting much of what they hear, which would explain the increased performance with the number of tokens. However, the extended versions of the BLM that incorporate some form of evidence limitation (with input data restricted to a random $4 \%$ sample) or forgetting exhibit mixed results (rows $8,9,10,11$ on table 1). Moreover, these extensions appear unrealistic from a cognitive perspective (e.g. one of the extensions forgets a random token when the memory capacity is full), and additionally, the resulting models are somewhat difficult to interpret, since after incorporating memory limitations, they are not computational level approaches anymore.

PARSER offers a more intuitive account of forgetting, with modest correlation with human data; however, this model has zero correlation in the other experiments. So this pattern of results suggests that a rich-get-richer form of recognition combined with a process of retention as defined in R\&R seems a more compelling explanation than a process of recognition with forgetting.

Also on experiment 3, the $\mathrm{R} \& \mathrm{R}$ model exhibits the best correlation with human data, followed closely by TRACX. Again, normative models show the opposite trend from humans (rows 1, 2, 3, 6 on table 1), since they do not have any memory limitations, and thus the effect of increasing vocabulary size only has an effect in the distributional properties of the stream, which result in less statistically coherent partwords. This is the case also for PARSER and the BLM. Frank et al. attribute this failure to the lack of forgetting in the models, but the same issues we have discussed above apply to this experiment. Therefore, the more convincing approaches are TRACX and R\&R. But although TRACX naturally reproduces the human results without forgetting, it is difficult to interpret what is the component of the model that is responsible for its success in this experiment. Conversely, R\&R explicitly incorporates a parameter that penalizes recognition based on the number of memorized types. In line with our intuitions, the corresponding parameter value for the best fit amounts to $D=0.86$, which results in a relatively large penalization for recognition ${ }^{4}$. Therefore, in conditions of high number of types, humans have an increased difficulty in recognizing sequences, most likely originating from the process of matching the input segment to one of the many segments stored in memory.

[^264]
## Discussion

With our model, R\&R, we provide a theory of the process of segmentation based on the interaction of two cognitive mechanisms of memorization. We believe that one of the best features of our model is its transparency: pitched at the processing level, and with a very simple formalization that involves clearly identified components, $R \& R$ allows for straightforward interpretation of the results. Even though, for reasons of space, we have not been able to report a thorough analysis of the behaviour of the model under different parameter settings, we have shown a glimpse on how these parameters allow for the identification of the relative importance of each component.

This study shows that our model can fit 2AFC data on human adults with a correlation that is at least on par with that of other models. Even though we consider that the evaluation data and procedure initiated by Frank et al. is one of the most thorough in the ALL modelling literature, in Alhama et al. (2015) we argue that averaging the responses over stimuli classes is likely to mask important differences between otherwise seemingly equivalent models. The work reported in this paper is a necessary first step to confirm that $R \& R$ is comparable to other models, but for future work it is important to move to evaluating models based on response distributions over individual test items (albeit our first attempts to evaluate our model with this procedure are inconclusive), and replace the Luce choice rule and correlation metric with a more cognitively realistic response model.

Finally, segmentation is a fundamental ability for language learners, but any segmentation model must at some point be related to other cognitive mechanisms that operate in natural and artificial language learning. In Alhama and Zuidema (2016) we show that the subjective frequencies computed by R\&R have the necessary distributional properties to explain some of the main results in rule learning in ALL. Future work may explore how the model relates to other linguistic processes (e.g. word learning), so that we can eventually achieve a complete understanding of how segmentation relates to the complete picture of language learning.

## Acknowledgments

This work was developed with Remko Scha, who sadly passed away before the finalization of this paper. We are grateful to Andreea Geambasu, Clara Levelt, Michelle Spierings, Carel ten Cate and Padraic Monaghan for their feedback. This research was funded by a grant from the Netherlands Organisation for Scientific Research (NWO), Division of Humanities, to Levelt, ten Cate and Zuidema (360-70450).

# Phonological features in the bilingual lexicon: Insights from tonal accent in Swedish 

Nadja Althaus<br>University of East Anglia, Norwich, United Kingdom

Allison Wetterlin<br>University of Agder, Kristiansand, Norway<br>Aditi Lahiri<br>University of Oxford, Oxford, United Kingdom

#### Abstract

Scandinavian languages like Swedish employ tonal accent as a lexical phonological feature, where suprasegmental information can be the sole factor differentiating between words. Using cross-modal semantic fragment priming we tested the following: (a) Do monolingual speakers of Swedish use tonal accent information during lexical access? (b) Do bilingual speakers, who grew up with one tonal (Swedish) and one non-tonal language, treat this feature the same way as monolinguals? Our results show that for monolinguals, accent mispronunciations eliminate priming effects, implying that tone is used during lexical access. For bilinguals, by contrast, mispronunciation sensitivity depends on both the accent type and its distribution across the linguistic input, as well as on the lexical neighbourhood.

# Semantic Networks Generated from Early Linguistic Input 

Andrei Amatuni, Elika Bergelson<br>Department of Psychology and Neuroscience, Duke University<br>417 Chapel Dr. Durham, NC 27708 USA<br>\{andrei.amatuni, elika.bergelson\} @duke.edu

#### Abstract

Semantic networks generated from different word corpora show common structural characteristics, including high degrees of clustering, short average path lengths, and scale free degree distributions. Previous research has disagreed about whether these features emerge from internally- or externallydriven properties (i.e. words already in the lexicon vs. regularities in the external world), mapping onto preferential attachment and preferential acquisition accounts, respectively (Steyvers \& Tenenbaum, 2005; Hills, Maouene, Maouene, Sheya, \& Smith, 2009). Such accounts suggest that inherent semantic structure shapes new lexical growth. Here we extend previous work by creating semantic networks using the SEEDLingS corpus, a newly collected corpus of linguistic input to infants. Using a recently developed LSA-like approach (GLoVe vectors), we confirm the presence of previously reported structural characteristics, but only in certain ranges of semantic similarity space. Our results confirm the robustness of certain aspects of network organization, and provide novel evidence in support of preferential acquisition accounts.

Keywords: semantic networks; word learning; preferential acquisition

## Introduction

A word functions as an atomic unit of meaning, in principle carrying independent semantic content. In practice though, it occurs with its fellow words, as humans produce language. From this word-stream, infants begin to understand words by 6-9 months (Bergelson \& Swingley, 2012), and to produce them soon thereafter. Here we aim to shed light on how these semantic atoms are organized in the mental lexicon, and the degree to which this representational structure is reflective of the conceptual order found "out there" in the world.

To explore this, we turn to semantic networks, an idea dating back nearly a century (Trier, 1931). Given that words are related along semantic dimensions, characterizing these relations is a first step towards understanding their representational structure. Previous research on semantic networks generated from word corpora have shown small-world connectivity (i.e. any given word node is not very many nodes away from any other), as well as scale free degree distributions (i.e. a few nodes serve as 'hubs', and node distribution follows a power law such that probability $(k) \approx k^{-\alpha}$, for a node with degree $k$, and scaling parameter $\alpha$ ) (Sigman \& Cecchi, 2002; Steyvers \& Tenenbaum, 2005; Hills et al., 2009). This suggests that semantic information may be inherently structured in nonrandom, clustered, and highly organized ways, which internal representations may mirror or exploit ${ }^{1}$ (Todd, Hills, \& Robbins, 2012). Scale invariance

[^265](here equivalent to scale-free distributions), has been found in many cognitive domains and diverse natural phenomena; it is argued to be a general unifying principle of cognitive organization (Kello et al., 2010).

Barabási and Albert (1999) suggest that graphs with degree distributions that follow power laws imply constraints on the processes which formed them. Their model for generating such networks relies on incremental growth and a process of "preferential attachment" (hereafter PAT), whereby existing nodes with many connections are preferentially "chosen" by new nodes. While their resulting graphs display power law degree distributions, they did not find small world connectivity of the kind found in semantic networks, such as those generated from WordNet and Roget's Thesaurus. Building on this, Steyvers and Tenenbaum (2005) proposed a model for incrementally growing semantic networks similar to Barabási and Albert (1999), which indeed resulted in both small world and scale free structures. Their growth process centered on semantic differentiation, i.e. new words that are more contrastive with existing words are preferentially incorporated into the graph; they include a frequency parameter as well. The resulting semantic graphs showed degree distributions which reflected the relative time at which a particular node was added to the network: age-of-acquisition (AoA) norms for words corresponded to the relative number of connections in these graphs. PAT-based graphs inherently bias nodes which are added earlier to have higher degree.

Steyvers and Tenenbaum (2005) suggest that the structure of internal representations guides the selection process of new words or concepts. In contrast, Hills et al. (2009) propose that the connectivity of words in the external environment plays a guiding role in the acquisition of new words. In this alternative, dubbed preferential acquisition (hereafter PAQ), the relative salience between unlearned words directs new node integration into the lexicon. Under PAQ, the structure of the external semantic ground is itself scale-free, clustered, and small world, leading internal representations to mirror this structure as lexical items are added. This contrasts with PAT, which suggests that the structuring is a consequence of incremental semantic network growth. Under PAQ, the higher a word's contextual variety, the more interactions it has with other elements in the external ground. This results in more neighbors in semantic network space, making it more linguistically salient to the learner. Indeed, evidence by Hills, Maouene, Riordan, and Smith (2010) suggests a role for contextual variety and associative density in noun lexical development in particular. In the present work, we build on these previous results, combining approaches that suggest network
properties arise from incremental generative processes with networks that are definitively non-generative, as a window into how external and internal semantic spaces may influence the growing noun lexicon.

One limitation of previous work concerns operationalizing semantic relatedness, generally achieved through handtagged features or word associations (Steyvers \& Tenenbaum, 2005; Hills et al., 2009). Hand-tagged features may not reflect the underlying semantic organization given that they stem from an overt metalinguistic task. Indeed such features do not produce scale free graphs or predict AoA. Word association data lead to directed networks, which may obscure inherent transitivity between word pairs (unless both words have the other as their associative target). It's not clear whether this directedness is inherent in the lexicon. While asymmetry is conspicuous in human similarity judgments (Tversky, 1977), this may be a function of task rather than underlying semantic representations. In the present work, we rely on neither hand-tagged features nor directed associations in building our semantic graphs.

Given the goal of explaining how semantic structure emerges, a further limitation of previous work lies in the constituent word nodes in the semantic networks, which used e.g. free associations, Roget's Thesaurus, and WordNet, rather than child-directed corpora. In this paper, we make use of a new corpus of words from infant-caretaker interactions. This allows us to examine whether scale free distributions, small world connectivity, and links to lexical development trajectories are limited by corpus origin, and thus whether using a full range of concrete nouns children are exposed to in naturalistic settings renders different results.

Here we extend previous work and begin to address these limitations by building ecologically valid semantic graphs of early linguistic input. We use modern vector space methods to calculate undirected semantic relations, resulting in a gradient of networks parameterized by degree of similarity. We limit network nodes to only those which infants' hear and embed them in a space which approximates a common semantic ground shared by infants and adults alike. We also investigate links between word frequency in the corpus, and connectivity rank in network space.

## Present Study

We generate networks using a new model of semantic relatedness: vectors trained with GloVe (Pennington, Socher, \& Manning, 2014). We first determine whether our networks reproduce previously reported small world structure, and scale invariance (i.e. power law distributions). Such structures are consistent with PAT or PAQ. However, only PAT proposes that such structures arise due to incremental growth mechanisms (Barabási \& Albert, 1999). PAT suggests that words already in the internal lexicon guide new word selection: early words have higher degree than later-added words, i.e. new additions "prefer" to attach to words with higher degree. In contrast, PAQ proposes that external network connectivity drives
node addition, suggesting that internal structures mirrors external structure, which may be scale-free, small-world, or not. Because our networks are built using the GloVe vectors, they are, by definition, non-generative and non-incremental: showing scale free and small world behavior in our networks would suggest this structuring might exist without PAT's assumed incremental generative growth processes.

As a proxy for AoA, we make use of parent-reported vocabulary norms from WordBank (Frank, Braginsky, Yurovsky, \& Marchman, 2016), a compilation of the MacArthur-Bates Communicative Developmental Inventory (CDI.) We assume words known by more infants at a given age have been in the lexicon longer. Here we attempt to replicate network structure and AoA correlations originally presented as evidence for PAT, while violating PATs assumption of incremental growth. If successful, it would imply that scale-free structure does not itself depend on PAT.

We also test for evidence of PAQ, by determining whether words that go from being poorly-known to well-known over time have more connections in the externally-based network than those that remain poorly known over time. That is, we test PAQ's proposal that high degree nodes in networks generated from external linguistic input are acquired earlier than lower degree nodes in those same networks. Notably, PAQ models do not depend on power law distributions or scale free behavior, but rather on children selectively integrating salient (more densely connected) words from all possible lexical items they're exposed to. If adult sampling is also inherently biased to those words which have high degree in semantic network space, then we expect too that highly frequent words have higher connectivity relative to all child-directed words. Because our corpus is generated from a large sample of child-directed speech, we can further compare word frequency statistics with degree distributions generated using the same set of words.

## Method

## Data

The SEEDLingS corpus (Bergelson, 2016a, 2016b) comes from home recordings of 44 infants from upstate New York, followed from 6 to 17 months. Each month, a daylong audio recording and hour-long video recording were collected. All videos and 3-10 hours of each audio recording were manually tagged for concrete nouns directed to and/or attended by the child, creating tags of several thousand hours of naturalistic interactions between infants and caregivers. We exclude utterances made by the child, resulting in a final dataset of 4359 unique noun-types (194204 tokens). Plurals and diminutives were consolidated into a "basic level" proxy for word lemmas for each recording. These nouns were used to generate the SEEDLingS-All graphs. We also generate graphs for 6 month recordings alone (1855 types, 29289 tokens; SEEDLingS-6mo) and a $16 / 17$ month combined set (1708 types, 26969 tokens; SEEDLingS-16+17mo), to contrast networks generated from speech to pre-verbal infants
and speech to newly verbal toddlers; the SEEDLingS networks are our model of the external linguistic environment. We generated an additional network (WordBank), using only the 369 nouns on the CDI; this serves as our internal semantic network, given that it only includes words that (some) 16-30-month-olds produce.

As our measure of relative AoA, we used by-word summary data from the online WordBank repositories (Frank et al., 2016). This data includes productive vocabularies for children aged 16 to 30 months (reported productive vocabulary is generally more reliable than reported receptive vocabulary. ${ }^{2}$ We make the assumption that words said by more children at a given age entered the lexicon earlier. Indeed, the age at which a word is produced by $50 \%$ of children, the AoA metric used by Hills et al. (2010), is significantly inversely correlated with the percentage of production at 16,23 , and 30 months ( $r=-0.78,-0.97$, and -0.88 respectively; all $p<0.005$ ). Furthermore, AoA measures correlate with children's elicited naming rates (Morrison, Chappell, \& Ellis, 1997). We use WordBank norms rather than the SEEDLingS infants' own productions, as an independent and extremely large-n ( $n=5450$, for English) estimate of children's knowledge for each word in our networks, removing potential dependencies in our analyses.

## GloVe Vectors

Since our dataset is not tagged with semantic features, and since results with hand-engineered features have been mixed, we chose to follow a method described by Steyvers and Tenenbaum (2005) and use semantic vector space models to generate edges between any nodes above a given similarity threshold. We build on their use of Latent Semantic Analysis (LSA) vectors. In that work, LSA vectors (which along with other geometric methods, are non-incremental) did not generate scale free networks; this result was used to suggest that such approaches are incompatible with incremental growth and PAT. To generate our graphs, we use pre-trained word vectors produced by GloVe, a recently developed algorithm for word embedding (Pennington et al., 2014). Using this algorithm, we can investigate whether we find scale free and small world graphs; if so, the original failure to do so might be LSA-specific, and not a necessary consequence of PAT, as the authors suggested.

GloVe has been demonstrated to have higher performance on many different word similarity tasks compared to word2vec and matrix factorization methods using SVD. Here, we opted to use vectors trained on the Common Crawl corpus with 42 billion tokens, resulting in 300 dimensional vectors for 1.9 million unique words. ${ }^{3}$ In some sense this 'full' dataset provides word similarity proxy based on the target (i.e. adult) meanings the child is acquiring. Further analyses using vectors trained on CHILDES (MacWhinney, 2000),

[^266]displayed analogous and in some cases even stronger patterns than the current results. ${ }^{4}$ This to us suggests consistency in the linguistic manifestation of word meaning (and perhaps their concomitant cognitive processes) at both largeand narrow-sampling scales.

Similar to LSA, GloVe learns vector representations of words from co-occurrence matrices built from large text corpora. It instantiates the distributional hypothesis of linguistics, famously articulated by Firth (1957): "you shall know a word by the company it keeps". Because the GloVe vectors encode co-occurrence statistics derived from natural language, our similarity measures also indicate the degree to which two words share contextual coherence. I.e., the more connections a word has in the semantic network, the more words it shares this coherence with. Given this high dimensional encoding space, we can use a continuous metric of similarity. Iterating through similarity thresholds, we create a gradient of networks to study.

## Generating Semantic Networks

We generate graphs across a range of similarity thresholds ( $\varepsilon$ ). Our similarity measure is the cosine between two GloVe vectors. The cosine function also normalizes for word frequency (to some degree) since dot products are divided by their vector norms. For each corpus, for each word, we calculate $\cos (\theta)$ between it and every other word in the set.

We give an undirected edge between two words if their cosine is above a threshold $\varepsilon$. Since generating each graph is a quadratic operation we normalize the vectors to unit length before calculating cosines. We iterate $\varepsilon$ from 0 to 0.99 (step size $=0.01$ ), generating a graph for each similarity threshold. Further methods of edge generation are left for future research. Our code and IPython notebooks are on Github ${ }^{5,6}$.

## Results and Discussion

## Correlations Between Node Degree and Production

We generated 100 graphs for each corpus, one for each value of $\varepsilon$. We calculated Spearman's rank correlation coefficients between each word's number of connections and productive vocabulary norm (for the 369 CDI nouns), for each network and similarity threshold, at 16,23 and 30 months. Under both PAT and PAQ, we would expect to see that words with more connectivity have higher CDI production rates. Indeed, we find robust and significant correlations between the degree of a word in the network, and the percent of toddlers who produced it, for a range of $\varepsilon$, across corpora and ages; Fig.1.

More specifically, we find similar behavior across all networks, with a global peak in correlation for $\varepsilon=0.12-0.19$. All peak correlation values had Spearman's $\rho=0.43-0.52$, with $p<10^{-5}$, showing consistent behavior across networks and ages. This suggests that both the parent's word choice given

[^267]a child's age, and the child's responsiveness to external semantic density across time are roughly constant. This range of $\varepsilon$ where the correlation is at a maximum is relatively low, allowing very loose semantic associations to result in edges. In Figure 2 we show a subgraph from the SEEDLingS-All network, centered around the node "baby."

Figure 1: Correlation coefficients ( $\rho$ ) between number of edges and CDI production rate across words, as a function of similarity threshold $\varepsilon$ (all $\rho$ are significant at $p<0.005$ ). Color indicates which corpus created the network, shape indicates which month of CDI norms was used to calculate $\rho$. Vertical lines indicate the range in which we find scale free degree distributions ( $0.6-0.73$ ). (For thresholds $\varepsilon>0.75$ there were very few (or no) edges being created, explaining the discontinuity and lack of points towards the end of the scale.)

Figure 2: "Baby" subgraph from the SEEDLingS-All network at the similarity midpoint $(\varepsilon=.5)$, where "baby" has 40 neighbors.

## Power Law Degree Distributions

Surprisingly, at the values of $\varepsilon$ where the correlation is maximal, we did not find power law distributions. We did however find them at higher thresholds: at $\varepsilon=0.68$ we can fit a power law function with $\alpha=3.2 \pm 0.1$, with a $\log$ likelihood ratio in favor of power law over exponential fit ( $R=$ 115.73, $p=2.337 \times 10^{-21}$ ). Indeed, at $\varepsilon=0.63-0.75$ we find power law distributions ( $\alpha=2.39-3.73$ ) characteristic of scale free
networks. At these higher thresholds a word's neighbors are semantically very close, similar to other semantic graphs which have shown scale free distributions (e.g. Roget's Thesaurus), suggesting this property might depend on connections' high semantic proximity. See Figure 3.

Figure 3: Sample networks showing degree distributions with power law behavior ( $\alpha=3.1-3.2$; $\mathrm{SE}=.1, p<0.001$; similar behavior found across networks for $0.60 \leq \varepsilon \leq 0.73$ ). Distributions are plotted on a log-log scale with logarithmic spacing between points, which represent the edges of bins. Power law distributions appear linear on this scale.

PAT models presuppose power law distributions (indeed, PAT was initially proposed after observing scale free distributions in semantic networks, and arguing that this limits the kinds of mechanism which could have created them). We thus further analyze the range of $\varepsilon$ where our networks display power law behavior. Again, networks showing this distribution are critical for PAT (and thus our CDI-based Wordbank networks' proxie of an internal network), but incidental for PAQ, which makes no claims about power-law distributions.

Limiting our focus to these ranges (between the vertical lines in Figure 1,) we see that the degree of a given word in the SEEDLingS-All network has uniformly higher correlation with productive vocabulary norms compared to that same node in the internal (i.e. WordBank) networks. (To be clear, we can only calculate $\rho$ for words we have CDI norms for, but the SEEDLingS networks contain all the nouns infants heard, while the WordBank networks contain only CDI word nodes). This pattern is consistent with PAQ, where more densely connected words in the environment are preferentially incorporated into the learner's lexicon. The correlation between AoA and node degree for the WordBank networks, along with their scale-free organization, suggest that PAT is not a necessary condition for this behavior, since these graphs were generated using GloVe. The presence of these same correlations for our other networks (which serve as a proxy of an externally-based network) in this same range of $\varepsilon$, are also scale-free, and provide new support for PAQ.

This pattern validates our method of generating graphs using GloVe vectors: both the WordBank and our SEEDLingS networks display behavior consistent with previous accounts (i.e. scale free distributions in internal lexical networks
and node degrees correlated with AoA). If anything, the SEEDLingS networks show the predicted structure more strongly, suggesting the nouns infants actually hear may form a better representation than limiting the space to lexically simple, early-learned nouns alone. Our current analysis suggests that scale-free and small world structure can be produced without an incremental growth process, since our graphs were generated using a vector space model (i.e. GloVe). If words are to be incorporated using PAQ, this external structure would necessarily be mirrored in the internal lexical network. However, it remains possible that PAT and PAQ could both be at play during infant lexical development, perhaps with PAQ supplementing PAT by providing a structured sampling space for new word selection.

## Clustering Coefficients and Path Lengths

We next examined whether our semantic networks, based on natural language to children, exhibited two key small-world properties found in previous research: low average pathlength (L), and high clustering coefficients (C). We found that the SEEDLingS networks generally had lower C and higher L than the WordBank networks. In Table 1 we list $C$ and L of each network at their respective peak from Figure 1. We also generated Erdős-Renyi and Watts-Strogratz graphs for comparison (Watts \& Strogatz, 1998; Erdős \& Rényi, 1960); Erdős-Renyi gives us a baseline measure of a comparably sized graph built using a random process, while WattsStrogatz provides a prototypical example of a small world graph, with low L and high C. The SEEDLingS networks clearly showed higher clustering coefficients and smaller average path lengths compared to the Erdős-Renyi graph, and comparable behavior to the Watts-Strogatz graph. This small world organization is indicative of hub structures in the network, where a few very densely connected nodes establish routes between a large proportion of the graph, keeping the average shortest path length low. This is also a defining feature of networks with power law distributions, even though the networks we've listed in Table 1 do not fit that criteria. This small world organization, even in the absence of power law distributions, ${ }^{7}$ supports previous findings in other semantic networks and suggest that even in child-directed natural language input we see these structures.

## AoA as a Function of Frequency and Connectivity

The SEEDLingS corpus contains word frequency counts, a particularly powerful predictor of word acquisition (Goodman, Dale, \& Li, 2008), allowing us to examine the relationship between word frequency and network connectivity. ${ }^{8}$ A positive relationship would suggest that densely connected words are preferentially sampled in adult speech directed towards children. As shown above, more highly connected words were said by more toddlers, across our networks (at peak $\varepsilon$, all $\rho>.51$, all $p<.0001$; see Fig. 1). Using

[^268]| Corpus | $\varepsilon$ | C | L |
| :--- | :--- | :--- | :--- |
| SEEDLingS All | 0.13 | 0.594 | 1.749 |
| SEEDLingS 6 mo. | 0.16 | 0.669 | 1.739 |
| SEEDLingS 16+17 mo. | 0.12 | 0.726 | 1.534 |
| WordBank | 0.13 | 0.895 | 1.202 |
| Erdős-Renyi | - | 0.049 | 1.950 |
| Watts-Strogatz | - | 0.634 | 3.013 |

Table 1: Clustering coefficients (C) and average shortest path lengths (L) of the largest connected subgraph at peak values from Figure 1. Generated Erdős-Renyi $(\mathrm{n}=6404, \mathrm{p}=0.05)$ and Watts-Strogratz graphs ( $\mathrm{n}=6404, \mathrm{k}=64, \mathrm{p}=0.05$ ) are listed for comparison.
model comparison of simple linear models, we find that including both word frequency and node degree as predictors of word production (at 16,23 , and 30 months) accounts for significantly more variance than either alone (all $p<.01$; interaction term significantly improved model fit for months 23 and 30 only, both $p<.01$ ). ${ }^{9}$

Finally, to better understand whether our semantic networks find support for PAT and PAQ models, we tested one specific prediction of each. For PAT, we tested whether words that had been known longer (i.e. by proxy, were said by more children) had more connections than those that had not. Indeed, conducting a median split on words' production rates at each age (16, 23, and 30 months), we find that better known words have higher degree than less well known words ( $p<0.005$ by Wilcoxon Test). For PAQ, we tested whether the words that went from less-well-known to betterknown over 16-30 months had higher degree than those that remained poorly known. Indeed, for words produced below the median rate at 16 months, those below the median at 30 months had significantly lower degree than those above it ( $p<.005$ by Wilcoxon Test.) This supports PAQ's proposal that high degree nodes in networks generated from external linguistic input are acquired earlier than lower degree nodes in those same networks.

## Conclusions

Our results suggest there is inherent semantic structure present in the early linguistic environment, and that both the caregivers and their children are likely sensitive to this nonuniform distribution of semantic information. Because the SEEDLingS corpus provides a uniquely rich dataset of early linguistic input, we were able to construct ecologically valid networks and study differences in their structure across time for a constant set of infants. Our present findings support previous work addressing semantic network structure. Using a modern semantic vector space model to generate our graphs, we were able to confirm the presence of scale free degree distributions in our networks, as well as high clustering

[^269]coefficients and low average path lengths. This method for generating semantic networks avoids the need for hand engineered features and sidesteps the limits of free-association data, providing a potentially more advanced measure of semantic relatedness compared to the original work on PAQ.

That said, the process that generated the GloVe vectors here is not the same as that generating any human's lexicon; further work is needed to strengthen and test links between these representations. Moreover, the GloVe model does not speak to the origin of token distributions in natural language. It does, however, encode a geometric projection of a meshwork of causal substructures present in the external world. Future research will explore the link between these structures and their grounding in cognitive processes. While we have taken a few steps towards examining network growth over time (finding little difference in our 6 mo . and $16+17 \mathrm{mo}$. SEEDLingS networks, or over 16,23 , and 30 mo . CDI norms), more work is needed to better understand not only whether PAT and/or PAQ-compatible processes are at play, but how the interplay between input and uptake changes as the learner grows.

In their original work, Hills et al. (2009) were not able to produce scale free graphs using their hand made features, but were able to do so using adult free association data. In our own graphs we saw that the scale free property only manifested at relatively high values of $\varepsilon$, where only very closely related words (often synonyms) were connecting to each other. Because our measure of similarity was parameterized, we were able to produce a gradient of networks and study their behavior across a range of thresholds, focusing at different ranges of the scale as needed. By generating scale free networks using a non-incremental procedure, we lend support to the hypothesis that this structuring may be an inherent feature in the external environment, rather than a consequence of how it's integrated into internal representations. Building on Firth: our results suggest that words may indeed become known by the company they keep, and that the relevant neighbors may be both those inside the lexicon, and in the as-yet unknown external world of words.

# Analogical Abstraction in Three-Month-Olds 

Erin M. Anderson (erinanderson2014@u.northwestern.edu) Yin-Juei Chang (alixyj@gmail.com) Susan J. Hespos (hespos@northwestern.edu) Dedre Gentner (gentner@northwestern.edu)<br>Department of Psychology, 2029 Sheridan Rd.<br>Evanston, IL 60208 USA

#### Abstract

This research tests whether analogical processing ability is present in 3-month-old infants. Infants are habituated to a series of analogous pairs, instantiating either same (e.g., AA, BB, etc.) or different (e.g., $\mathrm{AB}, \mathrm{CD}$, etc.), and then tested with further exemplars of the relations. If they can distinguish the familiar relation from the novel relation, even with new objects, this is evidence that for analogical abstraction across the study pairs. In Experiment 1, we did not find evidence of analogical abstraction when 3-month-olds were habituated to six pairs instantiating the relation. However, in Experiment 2, infants showed evidence of analogical abstraction after habituation to two alternating pairs (e.g., AA, BB, AA, BB...). Further, as with older groups, rendering individual objects salient disrupted relational learning. These results demonstrate that 3-month-old infants are capable of analogical comparison and abstraction. Our findings also place limits on the conditions under which these processes are likely to occur. We discuss implications for theories of relational learning.

Keywords: cognitive development, relational processing, infants

## Introduction

Analogical ability - the ability to make relational comparisons between objects, events, or ideas, and to see common relational pattern across different sets of objects - is a cornerstone of higher reasoning abilities. Learning by analogy is a powerful way of acquiring and transferring new information. Equally important, analogical comparison facilitates the formation of abstract categories and rules (Doumas \& Hummel, 2013; Gentner \& Medina, 1998; Gick \& Holyoak, 1983). Indeed, recent theoretical perspectives have asserted that analogical ability is the key capacity supporting higher-order cognition and differentiating human cognitive capacity from that of other primates (Gentner, 2003; 2010; Penn, Holyoak, \& Povinelli, 2008).

The relational abilities of adult humans are astounding. But there are many contributors to the sophistication of adult cognition. Adults have had the benefit of cultural transmission of knowledge - skills, cultural technologies of
various sorts, and symbol systems such as language and mathematics. In addition, adults have broad domain knowledge-another contributor to understanding relations (Gentner, 1988). It is therefore impossible to disentangle the roots/sources of our cognitive power by studying adults. To gain understanding of the nature and origin of our extraordinary relational ability, we must investigate infants who have not yet acquired these resources.

Although little is known about the very early development of human analogical ability, there has been considerable research on the development of analogical ability from preschool to adulthood. Analogical processing shows a relational shift (Gentner, 1988; Gentner \& Toupin, 1986; Halford, 1992; Richland, Morrison, \& Holyoak, 2006) with young children focusing on object matches and older children focusing relational matches and capable of using relational similarity in problem-solving (Chen, 1996). This shift has been attributed to increases in relational knowledge (Gentner \& Rattermann, 1991), to maturational increases in processing capacity (Halford, 1992) and to increases in executive ability, including inhibitory control (Doumas, Hummel, \& Sandhofer, 2008; Richland et al., 2006; Thibaut, French, \& Vezneva, 2010), and it is possible that all three play a role.

This work has also revealed characteristic patterns of relational learning, including factors that support or hinder it. One signature component of relational learning is that the ability to perceive abstract relational matches can be enhanced by comparing different instances of a relation. For example, Gick and Holyoak (1983) found that comparing two stories that had the same causal structure enabled people to transfer that structure to a further situation. Preschool children have shown similar benefits from comparison (e.g., Christie \& Gentner, 2010; Honomichi \& Chen, 2006). These findings are consistent with other research suggesting that the act of comparison entails a structural alignment process that highlights the relational commonalities between the compared items (Markman \& Gentner, 1993). The influence of structural alignment is a defining characteristic of analogical reasoning in adults (Doumas \& Hummel, 2013; Gentner, Holyoak, \& Kokinov, 2001), and the evidence of its influence in children as young as 3 years of age suggests that there may be continuity in the signature components of
relational learning through human development.
A second signature component of relational learning is that attention to individual objects can interfere with relational processing. Preschool children perform far worse on relational matching tasks when competing object matches are present (Gentner \& Toupin, 1986; Richland et al., 2006), especially if the objects involved are rich and distinctive (Gentner \& Rattermann, 1991; Paik \& Mix, 2006). The finding that attention to objects can overshadow attention to relations extends to very young age groups (Casasola, 2005; Maguire, Hirsh-Pasek, Golinkoff, \& Brandone, 2008).

The following experiments aim to trace the development of relational learning processes in infants. We focused on the same-different relation because it is among the simplest and most basic relations in the human repertoire. Additionally, Ferry, Hespos, \& Gentner (2015) found that 7- and 9-month infants can learn same-different relations from four exemplars of same or different toy pairs (e.g., $\mathrm{AA}, \mathrm{BB}, \mathrm{CC}$, DD or $\mathrm{AB}, \mathrm{CD}, \mathrm{BC}, \mathrm{DA}$ ). The key finding was that infants discriminated between the relation they had experienced and the novel relation, even when both were instantiated with new objects. Further, infants failed to discriminate between the learned relations when the test pairs contained objects that have been rendered individually salient prior to habituation. This was consistent with the findings among older children, for whom object salience interferes with analogical comparison (Gentner \& Toupin, 1986; Richland et al., 2006). These findings suggest that by 7 months, infants show the basic characteristics of analogical learning. In the present research, we took this investigation to even younger infants.

## Experiment 1

To fully understand the ontogenetic development of relational processes, we need to test for relational abstraction at the earliest age possible. This will this provide evidence as to when in development relational processing becomes possible. Further, it will serve as a base for capturing developmental changes in the learning process across age groups.

The key dependent measure in this study is whether infants can differentiate the familiar relation (e.g., same if habituated to same) from the unfamiliar one (different) when they see test pairs composed of new objects. The specific predictions are that if infants are learning via structural alignment, then (a) relational encoding and abstraction should benefit from comparing a series of exemplars and (b) relational encoding should be hampered for pairs that contain a highly salient object (based on findings that object focus interferes with relational encoding (Gentner \& Toupin, 1986; Richland et al., 2006)).

Participants. The participants were 31 healthy, full-term 3-month-old infants ( 17 male and 14 female) with an average age of 3 months, 2 days. Sixteen infants were assigned to the same condition and 15 to the different condition. Seventeen additional infants were tested but eliminated from the final analysis for fussiness (defined as fussy or crying on 4 or more test trials by two independent coders), breaks longer than 8 minutes, or because they looked the maximum amount of time on 7 out of 8 test trials, making their data uninterpretable.
Materials and Procedure. Coding and analysis procedure was closely modeled on Ferry et al. (2015). In Experiment 1, infants received training on either same or different relations. During test trials, infants saw pairs of objects instantiating the same and different relations (See Figure 1). The key question was whether infants would differentiate the familiar relation from the novel relation at test. Each infant saw four types of test trials, composing a $2 \times 2$ within-subject design. The first type consisted of entirely new objects (New). These trials tested the main prediction: whether infants had abstracted the relation across the habituation pairs and applied this relation to new instances. The second test type consisted of objects that had been rendered individually salient in the waiting room prior to habituation, but not shown in habituation trials (Object Experience only). These trials investigated whether object salience would disrupt relational processing. The third type was made up of objects that had been rendered individually salient in the waiting room and had subsequently appeared as part of pairs during the habituation trials (Object Experience + Pair Habituation). These trials tested whether repeated alignment across pairs would overcome initial object salience. The fourth test trial type was made of objects that were not seen in the waiting room, but were viewed in pairs during habituation trials (Pair Habituation only). These trials provided a check on whether infants recognized identical pairs. If infants failed to discriminate between a pair that they had seen in habituation and a novel pair, this would suggest failure to learn the exemplars even at a concrete level.

A small camera captured video of the infant's face while they watched an experimenter raise, lower and tilt a pair of objects in tandem on the stage. Two research assistants in a separate room viewed the image, each pressing a button when the infant attended to events on stage and releasing the button when the infant looked away. A software program recorded the looking times. Each trial ended when the software signaled that the infant had looked away from the stage for more than two consecutive seconds. If coder agreement was less than $90 \%$, recordings of the trials were re-coded by two new coders.

## Methods

Figure 1. Schematic of events in Experiment 1. A) In the waiting room before the experiment, infants were shown a subset of individual objects used in the experiment. (B) During habituation trials, infants were either shown pairs of same objects or pairs of different objects. (C) during test trials, infants saw pair of objects presented sequentially. There were four types of test trials that systematically varied the infants' object experience with the objects to measure the influence on performance. To give a sense of the variation across the stimuli, three sets of same and different pairs are shown in Figure 2.

Figure 2 Examples of the same and different pairs.
Pair habituation trials. When the screen was raised at the start of every trial, a pair of objects rested on the cardboard tray on the stage. To engage infants' attention, in both habituation and test trials, the experimenter grasped one object in each hand and raised the objects, tilted them to the left and right, then paused on the tray. This 8-s cycle repeated continuously until the trial ended.

Test trials. Infants viewed eight test trials. In each test trial, infants viewed one pair of objects, presented in the same motion pattern as in the habituation trials, while their looking time was recorded. Each infant received test trials with both same and different pairs of objects, presented in alternation, with order counterbalanced across infants.

Figure 3. Test trial looking times for Experiment 1. Looking durations to novel and familiar pairs for each test type were collapsed across same and different conditions. The
diamonds represent the mean. The horizontal line inside the rectangle represents the median. The area above and below the median represents the 1 st and 3rd quartiles respectively.

## Results

The results depicted in Figure 3 show no evidence of generalization to new pairs: infants did not distinguish novel from familiar relations on the test pairs with new objects. An

ANOVA testing the between-subject factor of habituation condition (same or different), and the within-subject factor of relation (novel or familiar) failed to show a significant effect of relation across all test trials, $F(1,30)=.967, p=.333$.

Critically, there was no evidence that either group-same or different-had abstracted the relation, because they showed no difference in looking time between novel and familiar relations when the relations were composed of new objects, $\mathrm{t}(30)<1, \mathrm{p}=.628$. This pattern suggests that infants recognized pairs they had seen previously, but did not generalize the relation.

## Discussion

Given infants' failure to generalize the relation to the novel objects in Experiment 1, there are at least three possible interpretations. First, three months-old infants may not yet be able to engage in analogical learning. Second, they may not be able to form abstract relations like same and different. However, a third possibility is that these young infants do already possess the relational learning processes, but that the training set used in Experiment 1 (i.e., six unique pairs of exemplars) was not adequate. For example, the range of exemplars given in habituation may have been too limited. Perhaps these very young infants need more variation and more exemplars to abstract the relation. This would be consistent with the standard assumption in learning theories that high variability in training enhances transfer, and with evidence that generalization improves when the number and
range of examples increases (e.g. Gerken, 2006; Quinn \& Bhatt, 2005; Xu \& Tenenbaum, 2007). The six exemplars we showed in Experiment 1, though, is already a larger training set than the four exemplars 7 - and 9 -month-olds saw in Ferry, et al. (2015). This larger set did not appear to benefit the 3-month-olds.

A second route-the one we pursued-is to show infants fewer pairs during habituation. Although this choice may seem counterintuitive, there is evidence that in early learning, fewer exemplars of a relation can lead to better learning of the relation. For example, Casasola (2005a) found that infants were better able to learn and generalize the spatial category of support when they were given two alternating exemplars of the relation than when they were given six exemplars of the relation (see also Maguire, et al., 2008). This pattern can be understood in terms of the general finding that relational alignment can be impeded by attention to objects (Gentner \& Medina, 1998; Gentner \& Toupin, 1986; Paik \& Mix, 2006)-particularly when the objects are rich and distinctive (Casasola \& Park, 2013).

## Experiment 2

In Experiment 2, we presented infants with only two pairs during habituation---either two same pairs (alternating between $A A$ and $B B$ ) or two different pairs ( AB and CD ). The idea is that alternating between just two pairs could allow that infants to become familiar enough with the objects to be able to attend to the relation between them. As in our previous studies, prior to habituation we showed the infants some of the objects (singly, not in pairs) in order to render those objects individually salient. This serves as a test of whether object salience disrupts relational learning in 3-month-olds. Thus, this study tests whether 3-month-old infants can abstract the same-different relation and generalize it to new test pairs and whether their ability to do so will be impeded for pairs containing high-salient objects (see Figure 4).

## Methods

Participants. The participants were 32 healthy, full-term, 3-month-old infants ( 19 male and 13 female) average age 3 months and 16 days, ranging from 2 months 10 days to 4 months 15 days. Half of the infants were assigned to the same condition; the other half, to the different condition. Ten additional infants were tested but eliminated from the final analyses (using the same criteria as Experiment 1). Procedure. As in Experiment 1, there were three types of test trials, varied according to infants' experience with the objects. Because fewer objects were used in habituation, we reduced the number of test trial types from four to three, dropping the Pair Habituation only trials (see Figure 4). The remaining test trial types were as in Experiment 1.

Figure 4. Schematic of events in Experiment 1. A) In the waiting room before the experiment, infants were shown a subset of individual objects used. (B) During habituation trials, infants were shown either alternating pairs of either same or different objects. (C) During test trials, infants saw six pairs of objects, presented sequentially.

## Results

The results (Figure 5) fit the predictions of an analogical learning account. First, infants looked significantly longer at the novel relation than at the familiar relation during test. Critically, this novelty preference held for test pairs containing new objects, demonstrating that the infants had abstracted the relation and could apply it to objects they had not seen before, $t(29)=3.616, p<.001$. Second, as predicted, prior experience with individual objects interfered with noticing the relation: there was no significant difference in looking time between the novel and familiar relations for pairs containing objects seen in the waiting room. This was true whether these salient objects appeared only in test or in pair habituation as well as test.

Figure 5. Test trial looking times for Experiment 2. Looking durations to novel and familiar pairs for each test
type collapsed across same and different conditions. The diamonds represent the mean. The horizontal line inside the rectangle represents the median. The area above and below the median represents the 1 st and 3rd quartiles respectively. The * indicates $p<.01$.

## Discussion

The findings in Experiment 2 are evidence for early relational learning. Critically, infants were able to distinguish the familiar relation from the novel relation even on pairs composed of new objects-the gold standard for testing whether infants abstracted the same and different relations. Consistent with other findings on analogical learning, infants performed significantly worse on test trials containing objects that had been seen prior to habituation. These findings show that the key signatures of analogical learning are already present by 3 months of age.

At the same time, the knowledge of the specific relations same and different in 3-month-olds appears to be learned: Experiments $1 \& 2$ show strong limits to the situations in which they could generalize these relations. Infants performed best with fewer exemplars. Even then, the infants did not discriminate between novel and familiar relations when they saw pairs that contained salient objects. Unlike with 7-month-olds in Ferry et al. (2015), 3-month-olds failed to overcome their object focus even after seeing the waiting room objects in pairs during habituation.

## General Discussion

There are two key findings. First, the results show that analogical learning processes are present in 3-month old infants. In Experiment 2, the infants showed two key signatures of analogical learning: (a) the ability to abstract a common relation across a sequence of pairs and (b) the detrimental effects of individual object salience. These findings suggest that the ability to abstract relations is an innate mechanism in human infants. If so, then analogical processing would join association and other domain-general processes as part of the core cognitive apparatus of humans.

The second key finding is that these young infants showed more learning when given just two pairs during habituation than when given six distinct pairs.
This pattern runs counter to the general finding that increasing the variability within a set of training stimuli increases learners' level of abstraction and therefore the range of transfer (Gerken, 2006; Gómez, 2002; Quinn \& Bhatt, 2005).

However, there is precedent for this kind of "less is more" finding (Casasola, 2005; Casasola \& Park, 2013; Maguire et al., 2008). What these studies have in common is that the objects participating in the relations are of high salience. Under these conditions, a participant given a series of different exemplars may attend only to the novel objects in each pair, and fail to attend to the relations. In this case,
reducing the range of instances so that a small set of exemplars is seen repeatedly may lead to better relational learning. As Casasola and Park (2013) note, although increasing the range of exemplars can help learners to isolate the relevant structures, "... the need for fewer exemplars arises when the relevant features, such as a spatial relation, risk becoming obscured by [...] the objects depicting that relation."

The finding then raises the question of when this pattern holds. As discussed earlier, many developmental studies have found better learning with more exemplars than with fewer (e.g., Bulf \& Johnson, 2011; Casasola \& Park 2013; Gerken 2006). Further, in our previous studies we found that 7- and 9 -month-olds successfully abstracted same and different relations when given four repeated exemplars (Ferry et al., 2015). Clearly, a goal for future research will be to understand the range of exemplar variability that best supports early relational learning across development.
Implications for learning theories. As noted above, a surprising finding is that in order for 3-month-old infants to learn the relations, they needed comparison across two repeating pairs rather than comparison across a greater variety of pairs. How do we square this finding with the many findings that greater variability during training leads to greater abstraction and transfer? We think that the key is that the current studies focus on relational learning. When the desired abstraction is at the level of overall exemplar similarity (e.g., learning a basic-level category such as dog, or learning a distribution of line lengths), then increasing the range of exemplars in learning should increase the level of generalization. However, if the desired generalization is a relational pattern, then it is crucial that the learner be able to compare and align the exemplars (Christie \& Gentner, 2010). In this case, whether the learner can align the exemplars may matter more than the amount of information potentially available. This leads us to suggest an amended learning principle: in relational learning, breadth of alignable training predicts breadth of transfer.
Summary. Together, the evidence from our experiments points neither to core knowledge of same or different nor to a process that arises entirely from experience, but to structural alignment as an early learning mechanism that becomes elaborated over development and with increases in language and domain knowledge.

## Acknowledgements

This research was supported by NSF Grant BCS-1423917 to Susan J. Hespos, NSF SLC Grant SBE-0541957 awarded to the Spatial Intelligence and Learning Center (SILC), and by ONR Grant N00014-92-J-1098 to Dedre Gentner. We are indebted to parents whose infants participated in the research. We thank members of the Infant Cognition Lab for help with data collection, and Ruxue Shao, Christian de Hoyos and Christine Schlaug for their insightful comments.

#### Abstract

A preliminary meta-analysis using the p-curve method (Simonsohn, Nelson, \& Simmons, 2014) was performed on a subset of the learned categorical perception literature to explore the robustness of the phenomenon. Only studies using novel visual categories and behavioral measures were included. The results strongly suggest that the phenomenon is robust but that the studies are somewhat underpowered. We argue that this is problematic because it renders both statistically significant and nonsignificant results very difficult to interpret, which impedes progress in understanding the learned CP phenomenon, for example, why expansion vs. compression is observed, or boundary vs. dimensional effects. Fortunately, there is a clear solution: conduct studies with greater statistical power.

Keywords: categorical perception; categorization; learning; p-curve; statistical power; expansion; compression; dimensional modulation

## Introduction

Learned categorical perception (CP) is a phenomenon whereby learning to place objects into categories alters some aspect of the way those objects are judged (for a review, see Goldstone \& Hendrickson, 2009). The classic patterns of change in judgments are that items placed in different categories become more distinguishable, sometimes called expansion, and/or that items placed in the same category become less distinguishable, sometimes called compression. These are category boundary effects, but other versions of learned CP are increased sensitivity to dimensions relevant to the category distinction and/or decreased sensitivity to dimensions irrelevant to the category distinction.

There has been a great deal of research on learned CP, but this paper will focus on visual categories learned in a laboratory setting. This is motivated mainly by our own interest in learned visual CP and the recognition that there may be important differences between CP in different
modalities that would make it inappropriate to group those studies together for this meta-analysis. Thus the large body of research on auditory CP, in particular for speech sound distinctions that are acquired in the lengthy process of learning a natural language, will not be considered here. It is notable that laboratory-induced learned CP effects are obtained with very little training compared to the kind of exposure that is usually given in real category learning, e.g., learning color categories. This makes the phenomenon appear to be pervasive and basic, but there are several important questions that need to be addressed.

First, in light of the recent attention given to failures to replicate (Open Science Collaboration, 2015), p-hacking (Head, Holman, Lanfear, Kahn, \& Jennions, 2015), the file drawer problem (Rosenthal, 1979), lack of sufficient statistical power (Button, Ioannidis, Mokrysz, Nosek, Flint, Robinson, \& Munafò, 2013), and so forth, we believe that it is essential to assess whether the published learned CP literature demonstrates convincing evidence for the effect. Like many, perhaps most, areas of research in cognitive science, the phenomenon of learned CP allows researchers many degrees of freedom that may, unintentionally no doubt, inflate the appearance of real effects. For example, within a single study, there are often a variety of different ways in which the data can be analyzed to look for evidence of learned CP effects. Researchers can investigate accuracy and/or response time data - both have been used as evidence of CP in the literature - in a multitude of combinations due to the many different possible behavioral patterns that count as learned CP. Furthermore, different potential criteria for what counts as successful learning (a precondition for testing for learned CP effects) can be used, leading to additional choices that can unintentionally bias the analysis. In short, this is exactly the kind of situation where preregistration is important to avoid mistaking the noise in the data for signal. To our knowledge, very little if any learned CP research has been preregistered as of yet, for replication purposes or otherwise.

One reason this is important is the current controversy over whether there are really any genuine top-down effects of cognition on perception, of which learned CP could potentially be one type. Firestone and Scholl (2016) argue that none of the vast amount of research claiming to have demonstrated such effects has actually successfully done so. It seems to us that before we can effectively debate whether learned CP provides evidence for such effects that is immune from Firestone and Scholl's criticisms, we must first establish that there is credible evidence that the effects themselves actually exist.

The optimist might point to the dozens of studies on CP that report significant results as compelling evidence that these effects are real. The problem with this approach is that it ignores the existence of publication bias in favor of statistically significant results. If learned CP turned out to not be replicable, it would not be the first example of a widely reported phenomenon that did not reliably replicate (e.g., Lurquin et al., 2016; Papesh, 2015; Shanks et al., 2013; Simmons \& Simonsohn, in press).

The purpose of this paper was to do a preliminary evaluation of published learned CP effects by using a pcurve analysis (Simonsohn, Nelson, \& Simmons, 2014). A p-curve is a meta-analytic technique that looks at the distribution of statistically significant $p$-values in a set of related studies. An advantage of the p-curve approach is that it nicely handles the file-drawer problem by looking only at statistically significant $p$-values. If the results come from a collection of well-powered studies investigating a real
effect, most of the p-values should be very small (well below .05). However, if many of the results are due to falsepositives, either because of a lack of statistical power or because the phenomenon being studied is not real, then the distribution of significant $p$-values will be flat, in the case of a null effect, or close to flat, in the case of low statistical power. (In extreme cases, the presence of substantial phacking can generate a p-curve with left skew.) Furthermore, the p-curve can reliably estimate the average statistical power of a set of studies because the distribution of observed p -values is directly related to statistical power when the null hypothesis is false. This estimation of power is an average estimate assuming that all studies are investigating the same basic effect.

In the analyses presented below, we calculate p-curves for a set of studies from the visual learned CP literature, but we caution that this analysis is preliminary. We expect that enlarging the scope of the search for relevant sources would yield many additional studies of learned CP that could be included in the analysis, though our sample size is large enough to likely be informative.

## Method and Results

The articles used in the analysis were selected by conducting a Scopus search of all articles citing Goldstone (1994) that had "CP" or "categorical perception" in the title, abstract, or key words and were deemed relevant (i.e., reported original empirical results in detail; used visual

Table 1. Articles used in the p-curve meta-analysis of learned categorical perception research.

| Authors | Year of publication | \# experiments included | \# analyses <br> included | Learned CP measure | Type of measure ${ }^{\text {a }}$ |

${ }^{\mathrm{a}} \mathrm{O}=$ objective, $\mathrm{S}=$ subjective

Note: The observed p-curve includes 33 statistically significant ( $p<.05$ ) results, of which 26 are p<. 025 .

Figure 1: P-curve for all relevant results in the articles listed in Table 1. The solid blue line shows the observed distribution of significant p-values. The dotted red line shows what the expected distribution of p -values would be if the null hypothesis were true. The right skew tests, for both the full set of p-values (all p-values $<.05$ ) and half set of p-values (all p-values $<$ .025 ), indicate that the p-values are more right skewed than would be expected if the null were true. The dashed green line represents the expected distribution of p-values if the set of studies had $33 \%$ power. The flat tests test if the observed distribution is flatter than the distribution that would be observed if the studies had $33 \%$ power.
stimuli, unfamiliar categories, and behavioral measures; and focused on learned CP). This yielded 14 articles; in addition, we included two conference papers meeting the same criteria for a total of 16 sources (see Table 1). Within those 16 sources were a total of 30 experiments reporting 42 distinct relevant statistical results. (For example, statistical results pertaining to the learning of the categories per se were not relevant.) Of these 42 statistical results, 33 were statistically significant in the predicted direction and these results were input to the p-curve app version 4.05 (http://www.p-curve.com/app4/) to produce the p-curve shown in Figure 1. Note that the p-curve analysis only considers the distribution of p -values below the 0.05 threshold.

In addition, separate p-curves were generated for the subset of results obtained using objective measures of learned CP, such as accuracy of same-different judgments, and the subset of results obtained using subjective measures such as similarity judgments. These are shown in Figures 2 and 3.

The p-curves shown in Figures 1-3 display the distribution of $p$-values that fall into five bins. For a real
effect with high power samples, most of the p -values should be in the leftmost bin ( $\mathrm{p}<0.01$ ). Shown in the figures are what the distribution would look like with a set of studies powered at $33 \%$ (green dashed line) and a set of studies testing a null effect (red dotted line). Note that because the distribution of p -values is determined by statistical power when investigating a real effect, the average power of the studies can be estimated from the observed distribution of p values.

The results of the overall p-curve meta-analysis show a curve that is right-skewed, which strongly suggests that the research has evidential value and is not the result of worrisome p-hacking (which produces a left-skewed curve). ${ }^{1}$ This is welcome news. However, the estimated power is only $62 \%$ ( $90 \%$ confidence interval is $41-78 \%$ ) which is not very high. If this estimate were correct, it would mean that only 6 in 10 studies of learned CP will detect an effect. We explain why this is a significant

[^270]problem for advancing our theory of learned CP in the discussion.

We conducted a separate analysis for objective and subjective measures of CP for two reasons. The first is that some researchers have suggested based on neural evidence that learned CP is not a genuinely perceptual effect but occurs at a higher, post-perceptual level (e.g., Clifford, Franklin, Holmes, Drivonikou, Özgen, \& Davies, 2012; but see Zhong, Li, Li, Xu, \& Mo, 2015 for counterevidence). We reasoned that if this were the case, studies employing more subjective measures of learned CP , such as ratings of similarity or typicality, should show stronger effects. The second is that there is a worry that learned CP effects could be the result of demand effects (Goldstone, Lippa, \& Shiffrin, 2001). That is, participants in these experiments may indicate that two items are subjectively more similar (dissimilar) to each other precisely because the experiment trains them that the two objects belong to the same category (different categories), and not because of any perceived change in similarity of the visual objects. If this is a contributing factor, then we would expect studies with subjective measures to have higher power, because this demand effect will only contribute for subjective measures of CP.

Figure 2: P-curve for learned CP results based on objective measures.

These ideas received some support from the p-curve patterns based on studies using subjective vs. objective learned CP measures, with a generally stronger pattern and higher power estimate for the subjective measure studies (79\%) than objective measure studies (52\%). However, given the preliminary nature of this analysis and the small set of results included, particularly for those using subjective measures, it is premature to draw any conclusions about this yet (note that the confidence intervals for the power estimates overlap substantially). Furthermore, we
can't distinguish between the two possible explanations of this result without directly investigating the matter.

Figure 3: P-curve for learned CP results based on subjective measures.

## Discussion

The literature for learned visual categorical perception contains evidentiary value, according to this meta-analysis. We can be reasonably confident that the studies reported are in general not reporting on a null effect. However, the relatively low statistical power shown by this analysis for the overall set of findings has important implications for how our theoretical understanding of learned CP is informed by these studies, and future studies with similar statistical power. We argue here that the statistical power of learned CP research must be improved in order to make robust advances in theory.

Several debates in learned CP research (e.g., to what degree is CP a perceptual or decision-making process; what kinds of judgments are changed by learning categories; is CP the result of demand effects) currently hinge on the observation of CP in some experimental contexts but not others. However, the overall lack of statistical power makes the pattern of significant and non-significant results difficult to interpret. Low power may well explain the occurrence of non-significant results. Low power also increases the likelihood that significant results are actually false positives. It follows from these two facts that when studies of learned CP are underpowered, the noise in the data makes it very difficult to distinguish among specific theoretical variants of what learned CP is. For example, it is difficult to distinguish among the different types of learned CP , of which there are at least four, as noted in the introduction (the boundary effects of compression and/or expansion and dimensional sensitization and desensitization based on category relevance). Since null results are impossible to interpret when statistical power is low (and using traditional
statistical methods), and patterns in statistically significant results may be just noise, it is correspondingly impossible to use the data to figure out under what conditions each of the types of learned CP do and do not occur. Yet this is essential to do in order to determine the nature of learned CP mechanisms and their purpose.

To understand the problem that this causes for our theoretical understanding of learned CP , it is important to keep in mind that the articles included in our analysis are not a set of direct replications, but rather a body of scientific evidence. Experiments in this set of results aim to build on the contributions of prior work to refine our theory of learned CP. Thus, we often rely on the pattern of findings within individual studies, or between small sets of studies, to constrain theorizing. But, as noted, with low statistical power comes the increased probability of false negatives and the increased probability that significant results are false positives. This leaves the theorist in a tough position. Are we improving our theoretical understanding with a new set of data, or merely reading the tea leaves of statistical noise?

Recent work in our lab provides an illustration of this problem (de Leeuw, Andrews, Livingston, \& Chin, 2016). We were primarily interested in why some learned CP studies had shown compression while others showed expansion. There seemed to be a relationship between both the type of learned CP measure (similarity vs. samedifferent judgment accuracy) and stimulus discriminability, on the one hand, and the pattern of learned CP on the other. Initial studies in our lab seemed to confirm variations of this kind but the patterns were somewhat bewildering. Only when we conducted a large scale study ( $\mathrm{N}>550$ ) simultaneously incorporating multiple measures and levels of stimulus discriminability and used Bayesian data analysis did a clear picture emerge: learned CP effects occurred (in fact, three of the four possible patterns occurred), but this pattern of effects did not differ systematically according to either of those variables. ${ }^{2}$

It is important to note a related set of problems with learned CP research that also presented a challenge for conducting the p-curve analysis. (1) Learned CP studies often don't test for more than one or two of the four possible types of effect, and the statistical analysis used may test for different effects separately or lump them together. Furthermore, there are methodological ambiguities in many of the studies that make separating out which effects occurred impossible. ${ }^{3}$ We therefore could not classify the pvalues according to which aspect of learned CP they

[^271]corresponded to, even though we would have liked to be able to do this. (2) Predictions are often vague in regard to the nature of a two-way interaction in an ANOVA, for example. But different results should be used for the pcurve for attenuation and reversal interaction predictions (just the overall interaction for attenuation and just the simple effects for reversal). Since we were limited to the information available in the articles, most of which did not predict a specific pattern of interaction, power may be overestimated by the p-curve. (3) A final caveat regarding our analysis is that our p-curve results could potentially be somewhat misleading if in fact certain learned CP effects (e.g., dimensional effects) are much stronger than others (e.g., boundary effects), which would mean that they are not really the same kind of effect as assumed by a combined pcurve analysis. If this were the case, it would suggest that power could be higher than our estimate for some aspects of learned CP, but lower for others. This would only further exacerbate the problem of drawing theoretical conclusions about the nature of learned CP , as the studies of certain kinds of effects that are deeply relevant to the theory would have even lower power.

The preliminary meta-analysis we report here strongly suggests that learned CP effects are real but also that our current knowledge of them is highly ambiguous and destined to remain so if we do not change the way we do research. In our view, only by conducting future studies with sufficient statistical power will we make significant progress understanding the phenomenon of learned CP.

#### Abstract

A reading skill test to diagnose basic language skills is introduced. The test is designed to measure six component skills relevant to reading in comparison with those of state-of-the-art natural language processing technologies. The results of the first large-scale experiments using the test are reported. Surprisingly, almost half of Japanese junior high school students do no better than machines in dependency analysis. More than half of $7^{\text {th }}$ grade students do no better than making random choices on questions involving inferences and definition understanding.

Keywords: Reading Skills, Language Comprehension, Test Theory

## 1. Introduction

Artificial intelligence (A.I.) armed with machine learning technologies often surprises us by demonstrating its power. Arai et al. developed A.I. systems that were capable of passing the entrance examinations of more than half the universities in Japan (Arai \& Matsuzaki, 2014). On the other hand, teachers are facing the problem that many students come into their classrooms without the requisite knowledge, skills, or disposition to read and comprehend the materials placed before them (RAND, 2002).
This situation raises a natural question. Will there be any economic returns to education when A.I. is smart enough to "learn" better than most of us? Do we have to set different goals for education in the age of A.I.?
Before jumping to any conclusions, we must carefully study the performance of human beings in comparison with those of machines, especially of the skills and expertise that are believed to be acquired only through education. Reading comprehension is, of course, one such example.
In this paper, we introduce a new reading skill test (RST) for assessing an examinee's basic language skills involved in the comprehension of texts consisting of sentences taken from junior high and high school textbooks and dictionaries. It is a major version-up from the prototype developed in (Fujita et al., 2016). A unique feature of the RST is that it is designed to analyze language skills of both human beings
and machines. Consequently, the test results will tell us not only an examinee's language skills relative to others, but also to machines. It will also reveal what kinds of sentences (i.e. lexical, structural, thematic) are harder than others to comprehend (process) for human beings (for machines).
The RST contains six different types of question. The first two types are designed to measure an examinee's ability to analyze intra- and inter-sentential relations among words: dependency analysis and anaphora resolution. Statistical algorithms often achieve precisions around $80 \%-90 \%$ in parsing sentences and $60 \%-70 \%$ in anaphora resolution (Nivre et al., 2007; Pradhan et al., 2012), which indicates that not only examinees but also A.I. may be able to perform syntactic analysis of a sentence without understanding its meaning. The second two are designed to measure an examinee's inferential skills based on appropriate amounts of vocabulary and common sense. They are closely related to tasks called textural entailment recognition or synonymy recognition in the field of natural language processing, and both of them are known to be very hard (Dagan et al., 2013). The last two are designed to measure how examinees can map texts into meanings. They require high-level symbol grounding and abstract thinking, and neither a practical algorithm to solve them nor a theory to formalize them has been proposed yet.
If an examinee does equally well on the six different types of question, we can assume that he/she reads differently from machines. On the other hand, we had better doubt that an examinee reads like a machine if he/she does well on the first two types of question: he/she appears to understand the meaning of the texts, but actually may not. In other words, human-machine comparison and error analysis of machines may allow us to diagnose why many readers read poorly.
The results of the first large-scale investigation involving 1758 students from six public junior high schools are reported. Surprisingly, in a country like Japan where education is compulsory up to the end of junior high school, and which is among the top countries in PISA tests (OECD, 2016), more than half of the $7^{\text {th }}$ grade students did no better
than random choice on the third two types of question. These results lend support to the concerns expressed in (RAND, 2002). The performance of a popular Japanese dependency structure analyzer on dependency analysis questions is also reported for comparison.

## 2. Design of RST

2.1 Six Component Skills and their Measurement We define six component skills relevant to reading. Each skill is measured separately in the RST. We do not claim that basic language skills consist exclusively of these six. We plan to add new types as necessary.

1. Dependency Analysis (DEP): The skill of recognizing the dependency relations between words and phrases in a given sentence.

2 Anaphora Resolution (ANA): The skill of anaphora resolution. ANA is comprised of two elements: Demonstrative Anaphora Recognition (DANA) and Zero Anaphora Restoration (ZANA).

DANA: The skill of recognizing the anaphoric relation between a demonstrative pronoun in a sentence and its antecedent.

ZANA: The skill of restoring and recognizing a noun phrase implicitly omitted in a context.
3. Paraphrasing (PARA): The skill of recognizing that a sentence is the same in meaning as another one. PARA is comprised of three elements which are Lexical Paraphrasing (LeP), Structural Paraphrasing (SP), and Logical Paraphrasing (LoP). The participant reads two sentences and judges whether they are synonymous. The examinees are asked to choose "Yes" or "No".

LeP: The skill of recognizing the synonymy between words or short phrases.

SP: The skill of recognizing the synonymy between two sentences written in different voices (active/passive).

LoP: The skill of recognizing logical equivalency of two sentences.
4. Logical inference (INF): The skill of reading a sentence and determining what can be inferred from a proposition in the sentence, what conflicts with it, and what does not relate to it. Here, two sentences are presented to the examinees. The instruction asks the examinees whether the proposition in the second sentence (task sentence) can be inferred from the proposition in the first sentence (presented sentence). The examinees are asked to choose "Yes" if the sentence can be inferred, "No" if the first and the second propositions cannot hold true at the same time, and "Not known" if the propositions are not related to each other.
5. Representation (REP): The skill to represent an image (figure or table) by comprehending a sentence of the textbook. The participant reads a sentence and chooses the images correctly representing the sentence out of four (multiple responses).
6. Instantiation (INST): The skill to understand how to use a term correctly according to a given definition of the term. The participant reads a definition sentence and
chooses correct usages from four sentences (multiple responses).
2.2 Test settings Each RST question requires a considerable amount of concentration. We designed the RST so that examinees would not get confused or become exhausted. As a result, each examinee randomly takes three of six types of questions in the current setting. After answering two sample questions of a type, examinees are asked to answer questions randomly chosen from an item pool as precisely and quickly as possible in four minutes.

We intend to change the design of the test so that he/she takes all six types when we are ready to calculate $b$, the difficulties of the questions, and $\theta$, the ability of the examinee in Item Response Theory (IRT; Lord \& Novick, 1968; Hambleton \& Swaminathan, 1985) with fewer questions.
2.3 Interface RST is conducted as a Computer Based Test (CBT) or Paper Based Test (PBT). Figure 1 shows a screenshot of an REP question. For the details of the design, the reader should refer to (Fujita et al., 2016).

Figure 1: Question REP 39 shown in CBT
2.4 Materials We created all of the questions, except for the INST questions, on the basis of textbooks that have been approved by the Ministry of Education, Culture, Sports, Science and Technology and are being used in Japanese junior high and high schools. The INST questions were created using terms and definitions appearing either in the textbooks or in Japanese dictionaries.

## 3. Psychometric Properties of RST

An examinee's score is usually assessed by the sum score of all items to which he/she responded. However, because in the setting of RST, each examinee responds to different items, the sum score is not appropriate for an examinee's assessment. That is, the sum score is "item dependent", which means that the assessment result depends on the difficulties of the items that the examinee responded to as well as the examinee's characteristics.

Therefore, in this project, IRT is used for each examinee's assessment. One of the distinctive features of IRT is that it
is not item dependent. The reason is that an item's difficulty and an examinee's characteristics are treated as different parameters. An item $j$ 's difficulty parameter is denoted as $b_{j}$. The higher $b_{j}$ is, the more difficult the item is. An examinees $i$ 's characteristic is denoted as $\theta_{i}$. The higher $\theta_{i}$ is, the better the examinee's characteristic is, which is reading skill in this study. For the details of IRT, the reader is referred to the above references.

In the near future, we will start computerized adaptive testing (CAT, van der Linden and Glas, 2010). In CAT, each examinee answers items shown on a PC display or tablet. If the examinee correctly answers an item, the next item is more difficult, whereas if he/she incorrectly answers an item, the next item is easier. Note that CAT requires an item pool, which is a set of items whose item parameters have already been estimated. In CAT, an appropriate item for each examinee is selected from the item pool. Therefore, IRT is suitable for the CAT framework. This is another reason why IRT is used in the analysis.

The R software (version 3.1.0) was used to fit the IRT model. Estimations were performed for each component. Therefore, if an examinee took all six different types of tests, he/she would have six $\theta$ values.

Before going to the next analysis where $\theta$ is used, inappropriate items were detected and deleted and the IRT analysis was done once more. Inappropriate items were detected using item analysis, in particular, a trace line plot.

Figure 2 shows trace line plots of appropriate (left) and inappropriate (right) items. The horizontal axis of this figure is $\theta$. All the examinees who responded to these items were divided into four groups in accordance with $\theta$. The vertical axis of the figure is the ratio of the examinees who selected options 1 to 4 for each $\theta$ group. For both items, option 2 (bold line) is the correct one. Note that " $s$ " in this figure means 'skipped the item'.

The left item is appropriate because the higher $\theta$ is, the higher is the rate of the examinees correctly answering the item. This item will be examined in detail in the Results section. On the other hand, the right item is inappropriate because the higher $\theta$ is, the lower is the rate of the examinees correctly answering the item. Therefore, the right item was deleted.

Figure 2: Two trace plots
The three deletion criteria described below were applied to items responded by more than one hundred examinees. Items applied to more than one criterion were deleted.

1. The rate of the selecting correct option is almost one hundred percent for all of the four $\theta$ groups.
2. The higher $\theta$ groups do not have higher rates of selecting the correct option (right of Figure 2).
3 . The highest $\theta$ group is most likely to select an incorrect option (right of Figure 2).

Table 1 shows the numbers of deleted items and the numbers of remaining items.

Table 1: The number of deleted and the number of remaining items

|  | DEP | ANA | PARA | INF | REP | INST |
| :--- | ---: | ---: | ---: | ---: | ---: | ---: |
| Deleted | 13 | 0 | 0 | 1 | 10 | 28 |
| Remained | 121 | 37 | 36 | 34 | 35 | 85 |

To examine the validity, reliability, and onedimensionality of each test, correlations between the six $\theta \mathrm{s}$, $\omega$ coefficients (McDonald, 1999) and the factor loadings in categorical factor analysis were estimated. Table 2 shows the results. Most of the correlations between the six $\theta$ s are above 0.5 , which means that the six tests all measured different aspects the same trait (reading skill). This shows that the tests have enough validity. Moreover, all six $\omega$ coefficients are very high, which shows that the tests have enough reliability. Finally, the means of the factor loadings are not small, which shows the one-dimensionality of each test, which is required in IRT.

Table 2: Correlations, omega coefficients, and mean of the

|  | factor loadings |  |  |  |  |  |
| :--- | ---: | ---: | ---: | ---: | ---: | ---: |
|  | DEP | ANA | PARA | INF | REP | INST |
| ANA | 0.657 |  |  |  |  |  |
| PARA | 0.652 | 0.455 |  |  |  |  |
| INF | 0.541 | 0.575 | 0.541 |  |  |  |
| REP | 0.515 | 0.534 | NA | 0.620 |  |  |
| INST | 0.178 | 0.354 | 0.607 | 0.126 | NA |  |
| $\omega$ | 0.990 | 0.963 | 0.962 | 0.967 | 0.927 | 0.964 |
| mean loadings | 0.644 | 0.620 | 0.610 | 0.421 | 0.489 | 0.589 |

Note: NA means that the correlation could not be calculated because there was no examinee who took the two tests.

## 4. Related work in cognitive science

To answer the RST items, examinees need to parse sentences with unfamiliar content. In this situation, the literature suggests that human parsers tend to make errors with ambiguous sentences (Frazier \& Rayner, 1982). On the other hand, readers can construct coherence between sentences through automatic inferences (McKoon \& Ratcliff, 1992). However, studies on the human parsing process are mainly based on data collected from adult readers. Some studies suggest that there are different characteristics in the sentence processing of younger children (Otsu, 1994) and older adults (Baota et al., 2001), but there seems to be no evidence on sentence processing of young students. Moreover, despite that some school teachers recognize the possibility that the difficulties in parsing and building coherence between sentences are larger
than expected, achievement tests remain mainly concerned with higher levels of discourse.

## 5. Results of junior high school students

5.1 The appropriateness of RST Response data from six public junior high schools' students were analyzed, to show the appropriateness of the RST. These schools are in City A, whose schools are known to perform well (the best in the prefecture in 2016) in national standardized achievement tests. The responded included 613 students in grade 7, 537 in grade 8 , and 608 in grade 9 . The students responded to questions (items) taken from sentences from junior high and high school textbooks and from Japanese dictionaries.

The analyses calculated two statistics: the Correct Answer Rate (CAR) and the Rate of Students who may respond by Guessing (RSG). CAR is the percentage of items that a student correctly answered, while RSG is the rate of students who were not statistically significant in a one-sided hypothesis test assessing whether each student's correct answer rate is greater than that by guessing (null hypothesis). For example, in the PARA test, whose items have two alternatives, the expected correct answer rate by guessing is 0.5 .

First, we calculated CARs for each student in the six component tests. Although each examinee responded to different items as noted above, because these items were selected randomly, the CARs can be assumed to be comparable. The mean CAR was calculated for each grade (Table 3).

Table 3: CAR means of each grade in the six component tests

| Grade | DEP | ANA | PARA | INF | REP | INST |
| :--- | :--- | :--- | :--- | :--- | :--- | :--- |
| 7 | 0.613 | 0.611 | 0.728 | 0.548 | 0.278 | 0.247 |
| 8 | 0.646 | 0.653 | 0.746 | 0.576 | 0.303 | 0.281 |
| 9 | 0.703 | 0.739 | 0.798 | 0.621 | 0.384 | 0.383 |

Table 3 indicates that in all the component tests, as the grade goes up, the mean CAR also increases. Generally speaking, reading skills improve as the grade goes up.

Table 4: Means of $\theta$ and RSG of each component skill

| in each grade |  |  |  |  |  |  |
| :--- | :--- | :--- | :--- | :--- | :--- | :--- |
| Skills | grade 7 | grade 8 | grade 9 | grade 7 | grade 8 | grade 9 |
| DEP | -0.595 | -0.502 | -0.295 | 0.376 | 0.302 | 0.188 |
| ANA | -0.558 | -0.425 | -0.106 | 0.365 | 0.260 | 0.110 |
| PARA | -0.551 | -0.440 | -0.228 | 0.107 | 0.069 | 0.020 |
| INF | -0.470 | -0.443 | -0.200 | 0.660 | 0.531 | 0.423 |
| REP | -0.450 | -0.436 | -0.103 | 0.522 | 0.339 | 0.255 |
| INST | -0.154 | -0.072 | 0.232 | 0.583 | 0.505 | 0.312 |

Next, to examine the relationships between the six component skills and grades, the means of six $\theta$ s in each grade and the RSGs for each grade were calculated (Table 4). Including city A's, we collected responses from more
than 13000 participants, which are elementary-school students to adults. The $\theta$ s were estimated using the responses of all the examinees and the mean of the $\theta$ s was set to 0 for all six components. The means of the six $\theta$ s for the junior high school students therefore tend to be negative in this table. The table shows that like CARs, for all component skills, as the grade goes up, the means of $\theta$ also increase and the RSGs decrease.

Finally, to determine whether the relationships between six component skills, RSGs, and grades differ among schools, we calculated the means of the six $\theta \mathrm{s}$ and the RSGs of each grade in the six schools. The results indicate that the six junior high schools showed almost all the same tendencies as Table 4. That is, in all schools, as the grade goes up, the means of the six $\theta$ s tended to increase and the RSGs of the tests decreased.

All these results are evidence of the validity of the test.

### 5.2 Assessment of students' reading skills

It is a good sign that RSGs decrease as the grade goes up. However, the RSGs of the $7^{\text {th }}$ grade students on INF, REP and IST exceeded $50 \%$. In other words, more than half of them failed to make inferences correctly based on the knowledge given in the textbooks, map the texts into the correct images, or understand the definitions. Our statistics show that at least one fourth of students graduate from junior high school without the ability to read and comprehend textbooks at a level better than guessing. As far as we know, this is the first large-scale investigation revealing this inconvenient fact.
Read the following sentence.
Buddhism spread mainly to Southeast Asia and East Asia, Christianity
to Europe, North and South America and Oceania, and Islam to North
Africa, West Asia, Central Asia and Southeast Asia.
Choose the most appropriate answer from the given choices that correctly fill
the blank in the following sentence.
( ) has spread to Oceania.
Hinduism
Islam

Figure 3: Question DEP 103
Now, let us examine three items as to whether or not the items were tricky or too difficult for them to answer (Table 5). In DEP 103, given in Figure 3, one can choose the correct answer, Christianity, without knowledge of the four religions. Figure 2 shows the trace plot of DEP103. It shows the item was neither tricky nor inappropriate. Still, about $40 \%$ of $7^{\text {th }}$ graders, $50 \%$ of $8^{\text {th }}$ graders, and $33 \%$ of $9^{\text {th }}$ graders were not able to choose the correct answer.

Table 5: Percentage of correct answers to the three questions for each grade

| Question | grade 7 | grade 8 | grade 9 |
| :--- | :--- | :--- | :--- |
| DEP103 | 0.609 | 0.516 | 0.676 |
| REP39 | 0.070 | 0.281 | 0.298 |
| REP38 | 0.250 | 0.419 | 0.492 |

Moreover, all the $8^{\text {th }}$ grade students had learned the words appearing in REP39, in Figure 1, (i.e., circle, origin, x-axis, tangent to) in the $7^{\text {th }}$ grade. The gap between the CARs of the $7^{\text {th }}$ and $8^{\text {th }}$ grades (0.070: 0.281 ) might be explained by the unfamiliarity of these words to the $7^{\text {th }}$ graders. Then, how can we explain that only 28.1 percent of the $8^{\text {th }}$ grade students were able to choose the correct image of the text?

One may explain that unskillful readers fail to monitor when they are checking more than one condition. Here, we asked the following simpler question as REP38: "The circle passes through the origin O". The gap between CARs of REP 38 and 39 of the $8^{\text {th }}$ and $9^{\text {th }}$ grades might be explained by monitoring failure. Still half of the $9^{\text {th }}$ grade students failed to answer correctly. We could not find relevant literature to explain this phenomenon.
5.3 Correlation with schools' characteristics We calculated correlations between these statistics and the schools' characteristics; Distances from the nearest station (Dis), the Number of Students (NS), and Rates of Students receiving Financial Help for school attendance (RSFH) in each grade (Table 6).

Table 6: Correlations of means of $\theta$ and RSG with school characteristics

| Means of $\theta$ |  |  |  |  |  |  |
| :--- | :--- | :--- | :--- | :--- | :--- | :--- |
| Rkills | Dis | NS | RSFH | Dis | NS | RSFH |
| DEP | -0.534 | 0.302 | -0.540 | 0.434 | -0.324 | 0.491 |
| ANA | -0.315 | 0.104 | -0.451 | 0.098 | 0.018 | 0.359 |
| PARA | -0.294 | 0.101 | -0.313 | 0.236 | -0.105 | 0.412 |
| INF | -0.262 | 0.251 | -0.288 | -0.001 | -0.114 | -0.016 |
| REP | -0.235 | 0.143 | -0.291 | 0.347 | -0.209 | 0.408 |
| INST | -0.156 | 0.279 | -0.310 | 0.160 | -0.345 | 0.237 |

Table 6 shows that in all the tests, the correlations of the means of $\theta$ with Dis and RSFH are negative, but positive with NS, and that in almost all of the tests, the correlations of RSG with Dis and RSFH are positive, but negative with NS. These results imply that students whose schools are near a station, are large, and offer less financial support tend to have higher component skills and therefore may respond to items not by guessing. We will continue to investigate these findings.

We asked examinees to answer a questionnaire including items on their attitudes toward reading and likes and dislikes of school subjects. City A conducts standardized achievement tests every year. We are planning to assess the relationship between the results of the RST, the responses to questionnaires and the scores of the achievement tests.

## 6. Comparison of performances with automatic dependency structure analyzer

We processed the test sentences of the RST dependency analysis questions (DEP) with the CaboCha parser (Kudo \& Matsumoto, 2002) and analyzed the errors. We hoped that
the analysis of errors made by a machine would help us to understand the human errors. CaboCha is a dependency parser based on Support Vector Machine. It was trained only on a news corpus, and its accuracy on news text is around $90 \%$ at the dependency relation level and $50 \%$ at the sentence level. The comparison with the human responses provided here is hence preliminary in that we expect the parser's accuracy will improve by retraining it on textbook data.

We analyzed the items on which we collected the responses from more than 100 students. DEP is a set of multiple-choice questions that ask for a phrase that stands in a certain grammatical relation to a phrase in a test sentence. We chose the answer based on CaboCha's output. The rate of correct answers by CaboCha was $66 \%$. For example, CaboCha parsed DEP103 (Figure 3) correctly.

Figure 4: DEP $\theta$ value of humans and CaboCha
Figure 4 shows the distribution of human $\theta$ and the estimated $\theta$ of CaboCha on the DEP questions. It reveals the mode of human $\theta$ is only slightly above that of CaboCha.

The most common error types made by CaboCha were as follows (the numbers in parentheses are the fractions of the errors of these types).

1. When the test sentence includes a phrase inside parentheses (7\%)
2. When the sentence is long ( $11 \%$ )
3. Unusual use of a comma or no use of comma (2\%)
4. Choice of the attachment site of a subordinate or parallel verb phrase ( $60 \%$ ): CaboCha made mistakes most frequently on the sentences including more than one subordinate or parallel verb phrase (VP). It corresponds to a sentence in the form of "... Verb ... VP1 ... VP2 ..." in English, where VP2 has two possible attachment sites, Verb (matrix verb) and VP1 (another subordinate VP), as in:

Adaptive immunity [verb includes] humoral immunity in which B cells [vP1 form proteins called antibodies] [vP2 to remove extracellular pathogens], and ...(snip).

There is no syntactic clue to choose between the two possibilities. Thus, it should be judged by meaning, and hence, it is difficult for CaboCha.
5. Wrong word segmentation (5\%)

In Japanese, words are not separated by whitespaces as in English. CaboCha often fails to segment technical terms correctly.

The errors of type 1, 3, and 5 would be reduced by retraining the parser on textbook data. On the other hand, the errors of type 4 require context and meaning to fix them. Table 7 lists the rate of correct answers by the human examinees on the questions on which CaboCha made mistakes. It suggests the choice of subordinate or parallel VP attachment is also difficult for humans. While Table 3 indicates that students gradually acquire the skill and knowledge to do it, it would remain a hard problem for an automatic parser since it requires some understanding of the meaning and context of a sentence.

We would like to confirm and extend these findings by examining more diverse samples collected through RST. Of special interest is a further analysis of the errors of human and automatic parsers on the basis of the cognitive studies on sentence processing (Mitchel 1994) such as the gardenpath theory (Frazier \& Fodor, 1978; Frazier \& Rayner, 1982) and minimalist hypothesis (McKoon \& Ratcliff, 1992).

Table 7: Human CARs on the questions on which the automatic analyzer made mistakes

| Error type of CaboCha | Human CAR |
| :--- | :---: |
| Parenthesized phrase | 0.584 |
| Long sentence | 0.572 |

## 7. Conclusion

We developed a new reading skill test (RST) to measure six component skills relevant to reading. By analyzing the responses to the RST, we confirmed that it has enough reliability and validity. In addition, we analyzed response data of Japanese junior high school students to the RST, and the results implied that, surprisingly, the six component skills might be lower than expected. Finally, we compared the performances of the students with those of a Japanese dependency parser. The results implied that students do no better than a machine in dependency analysis.

#### Abstract

Students cheating on an exam in an academic setting creates an environment where one person (the student) must reason about the perception of another (the teacher). In exploring the student's mindset, trends concerning how humans make decisions based on their understanding of another human's intentions and knowledge can be uncovered. In this work, we study human cheating behavior through simulated examinations in virtual reality, showing that the teacher's animacy and orientation plays a large part in the student's reasoning of the teacher's awareness. By utilizing a virtual classroom setting and accurately tracking a users behavior (through head tracking, eye movement, etc.), we have also demonstrated how a novel virtual reality approach can be used for such experiments involving human behavioral observations, which can be further explored in other cognitive science research experiments.

Keywords: deceptive behavior; behavior modeling; virtual reality; game experimentation; human vision; Theory of Mind

## Introduction

Imagine you are a teacher surveying your classroom of students who are taking a final exam. You know that the exam is very difficult and you expect that some students may attempt to cheat. Perhaps you find yourself scanning the room for signs of cheating behavior. But, what do such signs look like? A student looking around the room could simply be in the process of managing their thoughts. If a student is looking straight at you for a while, are they waiting for you to look away or are they wondering if they should ask you a question? How can you determine which students are simply feigning innocence while planning a cheating attempt? What if you have a large classroom of students; how would you be able to keep an eye on all of them at once?

Cheating remains a common problem in examinations, which creates an interesting scenario for cognitive psychology research in its need to have one person relying upon their perceptions of the intentions of another person to behave. In a classroom, the student must rely upon the teacher's actions and movements in order to determine when the best window to cheat off of another student's exam is. How the student reasons about a teacher's intentions, formulates the right time to cheat, and performs certain behaviors to "trick" the teacher are areas that have yet to be explored in a way that does not simply rely on asking students how they cheat. Discovering how a cheater successfully accomplishes his or her task is related to the cognitive science concept of the Theory of Mind, defined as "a mechanism that helps [one] to make sense of the behaviour of others in specific contexts and to predict their next action" (Dias, Aylett, Paiva, \& Reis, 2013). In the situation of cheating during an examination, the student must predict what the teacher is perceiving in order to gauge the success of their cheating attempt.

In this work, we study the signs and visual behaviors of cheating through virtual reality. Having actual students in real life to participate in our experiments and produce the cheating data gives us a realistic dataset to visualize and analyze how university students may actually cheat on classroom examinations. We recreate the cheating situations captured in

(a) Cheating in a real classroom

(b) Our game

Figure 1: (a) Cheating in a real classroom during an exam. (b) A screenshot of our game that mimics the settings of a real exam. The player cheats during a simulated examination in virtual reality while avoiding getting caught by the teacher similar to a real-life situation.
virtual reality to establish ecological validity and track various factors of the participants' behavior with respect to the state of the teacher.

Figure 1(b) shows a screenshot of our game. Our game premise is inspired by Sunken Places' virtual reality game "Classroom Aquatic". In their game, the player is asked to complete their multiple-choice examination within a time limit by cheating off of other students' examinations, avoiding the teacher's and students' gazes, and using objects as distractions to answer the questions correctly. This premise takes an ordinary situation and recreates it in virtual reality, encouraging players to use deceptive behavior to complete a task. From a cognitive science standpoint, such a game setting is interesting as it provides a good scenario for studying how humans exhibit cheating behavior and for understanding how humans judge the actions of others to be deceptive.

The major contributions of our work include the following:

- Analyzing how students cheat on classroom exams based on their behavior within a virtual setting.
- Demonstrating that virtual reality environments can produce a way to objectively gather data on human behavior.

## Hypothesis

Through our experiments, we seek to answer the question of how students use information of a teacher's movements to perceive the teacher's intent (i.e. how does the teacher's movement and placement in the room affect the student's judgment on when it is "safe" to cheat?). This question contributes to the discussion of the Theory of Mind and how humans process information of others' behaviors to make judgments. Inspired by the previous research on animacy and how that influences a human's decision-making process, we hypothesize that (1) players will cheat most often when the teacher is completely turned away from them. For this hypothesis, we believe that players will assume that the teacher will keep walking in the same direction, away from them, for a long enough time for them to safely cheat. As for how the players will choose to cheat, we also make the hypothesis that (2) the players will not look directly at another students' exam, and will instead cheat while employing their peripheral
vision in order to appear innocent to the teacher and also to keep an eye on the teacher as much as they can.

## Related Work

Common Cheating Behavior in Exams. Prior methods used to prevent cheating and to catch potential cheaters are common in research literature on the topic of student cheating. The factors behind why students cheat is welldocumented and analyzes how certain variables affect the students' likeliness to cheat including gender, GPA, parental pressure, etc. (Batool, Abbas, \& Naeemi, 2011). Although such findings are useful, their applications in preventing cheating are difficult to place given that one may not be able to generalize which students are likely to cheat based on their personal life (such as parental pressure) as well as the fact that some of these variables may not be accessible by an educational institution. An examination of classrooms and learning environments that are best able to dissuade cheating has been performed in prior research (Cizek, 2003), which found that students tend to cheat less often when (a) classes are smaller; (b) classroom conditions (both physical and instructional) are established that are conducive to learning; (c) instruction, assignments, and examinations are clear, welldesigned, meaningful, and relevant; (d) teachers take reasonable steps to prevent cheating. While (a) is an issue that is generally assumed to be handled by the educational institution, and (b) and (c) are obvious goals that any class setting should aim to achieve, it is (d) that we are most interested in cultivating by finding out how students actually cheat.

Many of the methods used to discover how cheating is conducted is qualitative and frequently relies upon students' readily answering questions on the matter (e.g., (Batool et al., 2011; Shon, 2006; Yee \& MacKown, 2009)). Relying upon student responses alone is problematic for the obvious reason that students could easily lie and fail to realize their exact behavioral habits when trying to be deceptive. By taking data from "cheaters" in a quantitative way through automatically tracking their actions throughout a cheating session, this problem would be resolved. Previous attempts to automate detection have applied text-mining based approaches, which only evaluate cheating after the fact and is limited to open-ended exams (Cavalcanti, Pires, Cavalcanti, Pires, et al., 2012). We are more interested in studying the cheating behavior at the instant it occurs, which forces the student to rely upon his or her reasoning of the teacher's perception, as it is highly relevant to the Theory of Mind.
Prior Cognitive Science Studies on Deceptive Behavior. According to previous studies, students cheat by first "qualifying the professor": determining how likely they could get away with cheating based on evaluating the teacher's behavior (Batool et al., 2011). This is an area that we would like to explore further as it is an extension of a human's Theory of Mind, defined as the ability to infer the full range of epistemic mental states of others, i.e., beliefs, desires, intentions and knowledge (Dias et al., 2013). This is a mechanism that helps to make sense of the behavior of others in specific contexts and to predict their next action. Through our experiments and analysis, we investigate the Theory of Mind in that we are trying to find out how people figure out whether or not the teacher is catching on to them and, based on the teacher's behavior, when it is safe to cheat.

In a recent study, (Dias et al., 2013) established a game in which different artificial intelligence models with varying levels of Theory of Mind were set to perform deceptive behaviors in a game setting, finding that those with higher levels of Theory of Mind (and thus a greater ability to reason and make inferences on others' behaviors) were more successful in deceiving, showing how frequently deception is founded when making judgments upon the actions of others. In our experiments, we examine the behaviors of the human players against the actions of a virtual teacher to discover how humans may similarly reason about the teacher's behavior in order to be successfully deceitful.

Gao's et al. (Gao, Newman, \& Scholl, 2009) research concerning how animacy is involved in a person's reasoning on intent provides a possible explanation for what we are observing in our players' behavior. Their study found that humans rely on the direction and orientation of an object to perceive its animacy, movement, and intent. Subjects were more likely to reason that a wolf shape was "chasing" a sheep shape if orientation was present. Therefore, animacy and orientation of movement may be influential when humans apply the Theory of Mind. In our experiment, we will observe to what extent the player will use the teacher's animacy and movements in making their decision of what time is best to cheat.

Investigating how humans reason about their game opponents in game settings is well-documented and is helpful to those in game-development who are concerned with realistic AI mechanisms. Prior research in turn-taking games follows a similar setup in exploring the Theory of Mind and looks into "which rules govern human strategic thinking" (Halder, Sharma, Ghosh, \& Verbrugge, 2015). Such findings inspired us to determine which aspects of human behavior we should track and record, taking note to include timing and duration of actions (such as cheating) in our own experiments. However, unlike such studies, we are dealing with continuous gameplay and so we cannot delineate a player's choices in a clearcut manner as we would in a turn-taking game. Having a continuous gameplay setup serves our purpose in mirroring a situation that would take place in everyday life.
Using Games for Cognitive Science Research. The involvement of videogames into academic research has an established, albeit relatively new, presence in academic research. Previous branches of research involving videogames in the fields of Cognitive and Social Psychology have studied the effect of entertaining games on basic cognitive skills while another has researched the success of educational gaming (Killingsworth \& Clark, 2013). Instead of contributing to either of these branches, our experiment seeks to instead use a videogame format in order to observe human behavior, which is an ability afforded to us through the use of virtual environments that are now even more immersive with the aid of a suitable virtual reality headset.

Previous research studies have used virtual reality technology to recreate real-life situations and examine human behavior in such instances (Kozlov \& Johansen, 2010; Olivier, Bruneau, Cirio, \& Pettré, 2014; Li, Liang, Quigley, Zhao, \& Yu, 2017; Rovira, Swapp, Spanlang, \& Slater, 2009). These studies have found that virtual scenarios are a good fit in measuring human responses to real events due to the close correspondence in human behavior between the two environments

Figure 2: Experiment setup. The participants performed the examinations using (a) an Oculus Rift virtual reality headset and (b) a Microsoft Xbox 360 game controller.
as well as the fact that the virtual reality settings can be finetuned by the researchers (Rovira et al., 2009). If the virtual setting is close enough to pass as its material counterpart, it is safe to claim that observations made on participants are valid.

## Approach

Overview. To study how students cheat, we seek to gather information on how players cheat on exams within a game session that models the real-life situation. In our experiments, the player takes on the role of a student taking a multiplechoice paper exam. The player is immersed in a virtual classroom environment and is asked to achieve two objectives: (1) answer as many questions on the examination correctly as possible by cheating off of other students' exams and (2) avoid detection of the teacher. If the teacher is able to catch the student in the act of cheating, the player will fail the task and that round will end.
User Interaction. Figure 2 depicts the experiment setup for the game sessions. We decided to use an Oculus Rift DK2 as our virtual reality hardware setup due to its ability to conduct the sessions in a small space and immerse players within the game setting. A Microsoft Xbox 360 wireless controller is used as the primary controller for which the player cheats and answers questions with. The player can change his viewpoint and shift his gaze as he would in reality with the use of the virtual reality headset. Other primary modes of interaction will be the act of cheating, which is triggered when the Left/Right Bumper Button is held down by the player (the answer retrieved from the examination paper of the classmate sitting on the left or right will be displayed); and the abilities to switch through and answer examination questions, which are respectively achieved by pressing Left/Right on the directional pad and either $\mathrm{A} / \mathrm{B} / \mathrm{Y} / \mathrm{X}$.
Virtual Environment Design. We designed a 3D virtual environment in the form of a classroom in which the player is a student surrounded by other students at individual desks, much like how most classrooms are set up at colleges today. The classroom objects, the teacher, the player character, and the other 3D student models were found at the Unity Asset Store. The design of the classroom is not flashy nor distracting so that players can focus on the task at hand.
Gameplay. The exams of the students to the left and right sides of the player will contain a correct answer to one of the questions on the exams; these answers will change in a preset interval every 5 seconds so that all answers can be obtained by cheating. The teacher moves along a preset path to hit certain points along the classroom, rotates about every six seconds, and seems to be checking over the room for signs of potential cheating. The path of the teacher is shown in

Figure 3: The path of the teacher during the game. Walking through the path once takes about 80 seconds and the teacher cycles through the path until the player finishes his exam in the round, which usually takes about $100-200$ seconds. Arrow directions correspond to the orientations of the teacher.

Figure 3. The questions that show up on the player's exams are derived from the website "Trivia Country" (Trivia Country, 2016). We chose questions from this website due to their specificity and very low chance that participants would know the correct answers. For example, one question we ask participants on the exam is: The Philadelphia mint started putting a 'P' mint mark on quarters in which year? Answer Choices: a)1980; b)1960; c)1950; d)never. We give the participants an incentive to cheat by telling them that the number of correct responses they answer is important to getting the maximum amount of money. Since the multiple-choice questions are derived from random, factual knowledge that the participants will most likely not know the answer to, cheating becomes a necessity to gathering the correct answers. Furthermore, we give an incentive for the players to cheat wisely by telling them that, if they are caught cheating, their potential to gather the maximum amount of points per round will be cut short. The player is also told that the teacher is powered by an advanced artificial intelligence and a human vision model so that he can perceive the environment like a real human, so that the player treats the teacher's actions with severity. In actuality, the teacher has a limited, cone-shaped range of vision that functions as a spotlight to detect cheating if the player is within the cone of vision and holding down the cheat button at the same time.

Data Collection. In order to gather data through the game session playthroughs, we constantly track the position and orientation of the teacher model. The position and orientations of the the teacher's head and the player's head movements are recorded during gameplay for later analysis. We measure the user's visual attention through game scripts that track an approximation of the player's gaze by creating a ray at a point where the player is looking, as well as taking note of at what time the player is cheating and which paper the player is cheating off of (either the left or right exam). During the player sessions, we also record a video of the gameplay, from both the teacher's and the student's point of view. Refer to our supplementary video which showcases some of this footage.

Figure 4: Human's field of vision.

## Experiments

Subjects. 25 participants were recruited to conduct this study with 22 being college students and the rest in high school and middle school. The subjects were recruited through emails sent out to the Computer Science department at UMass Boston as well as through word of mouth. About $60 \%$ of the subjects were of a Computer Science background. None of the students had played the aforementioned Classroom Aquatic game. Of all the subjects, there were 14 males and 11 females. Each player session consisted of 3 rounds. The participants participated individually for approximately 10 minutes for each player session and so completed each round in about 3 minutes. Participants were paid $\$ 10$ for their time upon completion of their experiments.
Implementation. The virtual reality program was run on a desktop computer installed with an AMD FX 8350 EightCore Processor $(4.00 \mathrm{GHz}), 16 \mathrm{~GB}$ memory (RAM) and a MSI Radeon R9 390 8GB Graphics Card. Participants were given a Xbox 360 wireless controller and an Oculus Rift DK2 headset to play the game created using the Unity game engine.

Briefing. Participants were given instructions on how the controls of the game functioned through a short tutorial session. This tutorial session allowed players to understand how to answer exam questions, how to cheat, as well as to become accustomed to the game surroundings. The virtual teacher was not introduced in the tutorial session. The players were then told the following message before the start of the game session:

You are a student looking to get a decent grade on an inclass, multiple-choice exam. The answers to the questions correspond to the $A-B-Y-X$ buttons on your controller. To gain a good score, you can cheat off of the exams of the students to the left and right of you. Hold down the left or right bumper to cheat off of their exams, which will have a correct answer to a question on the exam and will change answers in a set time interval. There will be three rounds with five questions on an exam each. You gain a point for each question that you correctly answer. You can earn up to 10 dollars depending on how many points you have at the end of the three rounds. The teacher in this game is wearing a blue suit and is designed with advanced AI and vision capabilities such that they can perceive the world like real humans can. If the teacher catches you teaching, it's game over for that round and you will go on to the next round.

Figure 5: The angles by which players cheated off of the left or right exam.

## Results and Analysis

Using the data we have gathered during the game experiments, we plot several different variables against each other to draw conclusions on students' cheating behavior. We ignore the first round of data for each participant as the latter two rounds are far more likely to contain the players' intent and are not marred by first-time errors.A total of 255 cheating attempts were recorded (not counting the first round).
Peripheral Vision. We first examine the player's use of peripheral vision in order to cheat by inspecting the angle between the player's estimated gaze and the exam they are cheating off of (either the left or the right exam). The angles at which the player cheated off of the exams are shown in Figure 5. The number of cheating attempts made off of the left exam were 117 while the right exam had 138 in total. We refer to the human's field of vision (Bhise, 2011) depicted in Figure 4 to compare the angle between the player's central ray and the left or right exam to this diagram in order to determine which area of their vision the participants used to cheat.

For those who cheated on the left exam, a mere $2 \%$ cheated using their central vision. $24 \%$ of participants utilized their near-peripheral vision. The majority of the left attempts, $70 \%$, cheated within the angle range considered to be midperipheral vision. The remaining $4 \%$ of these cheating attempts were conducted at an angle greater than 60 degrees. Similar results were found for the cheating attempts done on the right exam. $0 \%$ used their central vision on this side while $38 \%$ relied upon their near-peripheral vision. The remaining $62 \%$ all took place under the player's mid-peripheral vision.

Instead of staring directly at the other students' exams, the subjects chose to keep the exam they were cheating off of to the side of their vision. The reason for this result could be the effect of the player exhibiting signs of "sneaky" behavior. The player's cheating status is turned off or on simply by holding down the cheating buttons, which was made clear to the participants during the tutorial. Therefore, looking directly at another exam or not has no bearing on how quickly one can "stop" cheating. Because of this, we can say that the reason for this behavior is due to the player constantly keeping in mind the teacher, as the player exhibits signs of feeling wary of the teacher. By only "sneaking" glances at a nearby exam they are cheating off of, the student is trying not to be too "obvious" in their cheating. This action reveals that the

Figure 6: Appearances of the teacher at different relative orientations with the player.
student is letting their perception of the teacher's perception shape their own actions. The students exemplify the Theory of Mind: they are reasoning and making inferences on another's perception based on that person's behavior and are changing their own behavior accordingly (Dias et al., 2013).
Teacher's Orientation. The teacher in our experiment, in his pre-figured path around the room, pauses about every six seconds to rotate back and forth (as if he is scanning the room for signs of cheating) and turns his body like a normal person walking around a room would. Figure 6 shows the teacher's appearances at different orientations. We examine when
 tween the teacher's teacher's orientation relative to the player by noting the angle $\theta$ by which the teacher sees the student (depicted in Figure 7).

According to Figure 8, students mostly cheated during the moments where the teacher was farther away from the student and when the student was on the outskirts of the teacher's perceived vision. Out of 255 recorded cheating attempts, only $7 \%$ of attempts were undergone when participants were within the teacher's central range of vision (and got caught by the teacher during these attempts). $12 \%$ of cheating attempts were done under the teacher's near-peripheral range of vision and $9 \%$ under the teacher's mid-peripheral range. The majority of cheating was split between when the student was within the teacher's far-peripheral range of vision (the dark purple points, taking up $34 \%$ of all cheating attempts) or when he was not facing the student at all (the black points, which make up $38 \%$ ). When the teacher can see the student only with his far-peripheral vision or not at all, the player was able to be more certain that the teacher was not paying attention to him and therefore cheated the most during those moments.
Teacher's Position. Figure 8 also shows that more than half of all cheating attempts took place when the teacher's distance exceeded 3 meters, attesting to the player's feeling that, the farther away the teacher is, the "safer" the cheater is. Figure 9 shows further that students chose to initiate cheating when the teacher was located in areas that were farther away from them and did not feel safe enough to cheat when the teacher was not in sight. The moments in the teacher's path with the most frequent cheating attempts, at around $32 \%$ of all cheating instances, were located close to Area A, where the teacher was within the student's sight, was not relatively close to the student, and was moving in a clear path towards the back of the room. At this point, the student was able to cheat off of the left exam and keep the teacher within their line of sight. The least amount of cheating occurred around Area B, where the teacher was completely out of the student's range of vision. We see a brief peak in cheating when the

Figure 8: Each dot refers to an occurrence of cheating, plotted against the distance between the player and the teacher, and the angle by which the teacher saw the student.
teacher was close by but had his back turned to the player, in Area C. The player might assume they were safe at this point, thinking that the teacher would continue to walk away from them. However, the teacher turned around shortly after and walked by them again, moving back towards the front of the room. Cheating instances only became more frequent again, with around $9 \%$ of all cheating attempts happening, when the teacher had traveled a farther distance away in Area D.

The players' cheating patterns here reveal that students rely upon their perception of the teacher's perception to make judgments on the teacher's ability to spot them cheating. This explains why they choose to cheat only when they are able to see the teacher. It is also clear that the players used the animacy of the teacher to make predictions of the teacher's perception and behavior as they were more likely to cheat when he had his back turned or was walking away.

## Discussion

Feedback and Observations. We asked the participants how they felt about the experiment after receiving their compensation. The general feedback from the players was that the game was "fun" and "interesting". They claimed that, during the game, they felt slightly afraid of the teacher model. From our observations, we noted that, during the start of the first round, the participants would be reluctant to look away from their paper at all once they saw the teacher. Only after we reiterated the rules of the game (that the student is not cheating unless the corresponding button is held down) did the players feel comfortable looking around the room. However, even still, very few players turned completely around to see where the teacher was when he was behind the student, even though they could have done so with no penalty. In reality, few students would turn all the way around to spot the teacher as this might appear suspicious. This attests to the participants taking the game seriously and that they performed as they would in an actual classroom.
Limitations. The participants' experience with virtual reality and computer games may affect their performance in our experiments. Most of our participants were students from the Computer Science major. Many CS majors are exposed to and regularly enjoy computer games, so they may have had a slight advantage in escaping cheating during the game sessions, compared to participants from a non-CS background. Furthermore, virtual reality headsets affected different partic-

Figure 9: Cheating frequencies when teacher was at different locations along his path. Redness corresponds to the cheating frequency. Most cheating occurs when the teacher was at the far left. Refer to text for detailed description of the observations.
ipants differently, especially when some were wearing glasses or were just using a virtual reality device for the first time. As a result, some might have experienced slight discomfort with the virtual reality headset, perhaps leading to less ease in playing the game. We are also limited by the teacher's lack of realistic head movement. The teacher's torso and head move in the same direction throughout the game, which the player may or may not have realized as they were playing. Because of this, the results may be slightly varied from a reallife classroom setting.
Conclusion. In this study, we have verified our hypothesis about deceptive human behavior during an exam as the players (1) cheated most frequently when the teacher was turned completely away from them and (2) used their peripheral vision frequently to cheat off of other exams, showing that the teacher's animacy and orientation play a significant role in the student's likeliness to cheat and that their own judgment about "appearing" suspicious affected how they decided to cheat. By utilizing a virtual classroom setting and accurately tracking a user's behavior, we have also demonstrated how a novel virtual reality approach can be used for such experiments involving human behavioral observations, which can be further explored in other cognitive science research experiments. An interesting venue for future work is to use the human behavior data collected from virtual environments to train a realistic, human-like AI that can exhibit human deceptive behaviors. The application of new virtual reality devices that can accurately measure eye-tracking to this experiment would lend itself to the peripheral vision analysis as well. Furthermore, because students often cheat in collaboration with other students, our extension of this work will include a cooperative mode that allows two players to help each other cheat. We are also developing a quantitative method analysis of the player's cheating by establishing a metric to estimate the amount of visual attention the student is receiving from the teacher at any given point in time.

# Against the group actor assumption in joint action research 

Ed Baggs (e.baggs@ucl.ac.uk)<br>Bartlett School of Architecture, University College London, 22 Gordon Street, London WC1H 0QB<br>Department of Psychology, University of Cincinnati, Cincinnati, Ohio 45221

#### Abstract

A central assumption in joint action research is that in order to explain how individuals act as part of a group, we must first explain how the group comes into existence. This assumption has led to an unnecessarily narrow research programme: research has focussed largely on interpersonal coordination mechanisms. I outline an alternative approach predicated on a dynamic conception of the ecosystem. On this view, there is no need to assume that actors must first constitute a group agent with their fellows before entering into coordinated action. Such coordination can be more efficiently explained by recognizing that all actions perturb the structure of the ecosystem itself in a manner that can alter the action possibilities available to neighbouring actors. This move allows us to overcome entrenched debates over the nature of shared intentionality, and to instead focus on practical interventions in multiactor settings.

Keywords: joint action; shared intentionality; ecosystems; ecological psychology

## Introduction: The group actor assumption

The group actor assumption is not a commonly-used term; it is a term I introduce here to characterize the way that researchers working in the joint action tradition typically understand their project (Sebanz, Bekkering, \& Knoblich, 2006). The assumption might be analysed into the following four claims:

## 1. the basic form of action is individual action

2. the group is to be understood as a set of constraints and structures placed on individual action (the tactic here might be to reduce joint action to structures in individual minds, or, alternatively, it might be claimed that the group itself is an emergent structure that constrains the individual components)
3. the existence of the group must be explained in terms of the nature of the individuals involved, and the coordination activities they engage in
4. the group must come into existence first before a joint action can be implemented

I do not, however, wish to make a fetish out of these four items. So let us immediately simplify this analysis by replacing it with the following statement:

## 'The group actor assumptions reifies the group'

That is to say, under the group actor assumption, it is understood that the study of activity involving multiple actors requires a special mode of analysis. The group actor assumption says that the group is a real entity, and, furthermore, it
asserts that this groupness will play a crucial role in explaining whatever it is that we wish to explain about some phenomenon of interest. The group actor assumption invites us to divide the world, a priori, into individual actions and joint actions, and says that the latter type requires an additional layer of explanation over and above what is required for the former.

I will provide evidence for all of these claims below. But first it will be useful to consider a specific example of the kind of joint action that we might want to study. I will use this to argue that the group actor assumption leads to an unnecessarily narrow research programme. In the second half of the paper, I outline an alternative approach which avoids the problems identified, appealing to the concept of the ecosystem.

## Case study 1: Children's soccer training

When young children, say around age five, are first corralled onto a soccer pitch they can easily enough be divided into two teams and encouraged to act out a soccer game. What one will notice, however, is that these teams exhibit a striking absence of structure. The ball will be propelled in some direction, whereupon the children will chase the ball en masse, and then different children will try to coordinate the necessary limb movements in order to make some decisive connection with the ball. At the end of this process, the ball is propelled in some new direction, and the cycle begins again. What is going on here? Here is a succinct explanation: 'A child's basic urge is to run and chase the ball' (Quinn \& Carr, 2006). The children's chasing-urge, coupled with the quasi-random trajectory of the ball at a given moment, produces a situation in which all of the action appears to be reactive to the current spatial configuration; indeed, the ball itself almost appears to be driving the action.

Contrast this with an accomplished team performance played to a high degree of skill. Take the goal scored by Esteban Cambiasso for Argentina against Serbia and Montenegro at the 2006 World Cup. This is a famous goal because it came after the team had completed a sequence of 24 uninterrupted passes, and it thus serves as an object lesson in dominant possession-based soccer. But let's consider just the last four passes here. For each of these passes the player receiving the ball is already on the move and the passing player, detecting this movement, plays the ball into the space just in front of where the recipient is going to be. The whole sequence of four passes goes off in a fluid, continuous fashion. In contrast to the five-year-olds' game, we are no longer tempted to claim that the ball is driving the action. The ball is still central, of course, but it has now come under the control of a
disciplined, structured team.
The question is: What has changed between these two soccer games? How does one get from the five-year-olds' skill level to something approaching that of the Argentinian players? What does the learning process look like? How can we understand the skilled version of the game in a way that allows us to do useful things like come up with effective training interventions?

It would be reasonable to expect that research on joint action should give us something to say about such matters. A joint action research programme worth the name ought to provide us with some guidance about how to go about formulating and answering appropriate questions. Does it?

## From the study of the individual to the study of the group: Where did the action go?

Joint action research has its origins in attempts to expand the traditional, individualistic cognitivist research programme to encompass the study of interpersonal phenomena, such as discourse-level activities in spoken language. For the sake of clarity, here is a definition of that individualistic research programme: 'Cognitivism in psychology and philosophy is roughly the position that intelligent behavior can (only) be explained by appeal to internal "cognitive processes," that is, rational thought in a very broad sense' (Haugeland, 1978).

This immediately raises a problem. Any attempt to deal with multi-actor activities within cognitivism runs straight into an apparent contradiction: how can we appeal exclusively to internal processes when the 'inside' is distributed across multiple individuals? The way that researchers have typically dealt with this is through accepting the group actor assumption.

In perhaps the most widely-cited paper on the topic in recent years, Sebanz et al. (2006) frame the problem thus: 'As a working definition, joint action can be regarded as any form of social interaction whereby two or more individuals coordinate their actions in space and time to bring about a change in the environment.' Gilbert (1990) discusses the case of two people going for a walk, and insists that 'in order to go for a walk together, each of the parties must express willingness to constitute with the other a plural subject of the goal that they walk along in one another's company.' Bratman (1992) identifies as one of the characteristic features of joint activity that each actor has an 'appropriate commitment' to the joint activity. Marsh, Johnston, Richardson, and Schmidt (2009), who are not themselves cognitivists, go as far as to describe the group as a hybrid organism or 'chimera', an entity 'that has an implausible wholeness, despite the disparateness of the parts that compose it.' Searle (1990) provides a clear-eyed analysis of the problems associated with appealing to intentionality in the group setting, but he also posits a version of the group actor assumption: 'Intuitively, in the collective case the individual intentionality, expressed by "I am doing act A," is derivative from the collective intentionality, "We are doing act A."'

What can be seen in all of these statements is an acceptance of the view that the group must be understood as a real entity-a set of constraints or structures which are imposed on individual action and which must come into existence first before the joint action can be implemented. Debate within the joint action tradition can largely be read as a series of disagreements about what we should expect these constraints and structures to look like. ${ }^{1}$

In practice, this has led to the most intense research effort being directed at the question of interpersonal coordination (Vesper et al., 2017): How is it that a dispersed set of individual actors becomes a group? The ancillary assumption driving such investigations is that we should be able to identify a single, general mechanism which applies in all cases and which allows multiple individuals to coordinate with one another, no matter the activity they are actually engaging in.
In this vein, Tomasello et al. (2005) attribute the set of behaviours they consider to be uniquely human, such as language and culture, to an entity they call 'shared intentionality'. Tomasello notes at the end of his 2014 book that a 'particularly big' open question remains concerning 'the nature of the jointness or collectivity or "we-ness" that characterizes all forms of shared intentionality.' He favours an appeal to recursive mind-reading of the he-thinks-that-she-think-that-he-thinks variety, a solution similarly favoured by other researchers (e.g., Clark, 1996). On this account, a joint action can proceed only when all participants to the action understand themselves to be participating in the action as part of the group. The group exists in the minds of its members.

The most common alternative to recursive mind-reading hypotheses are contagion-based theories which posit that the group comes into existence automatically, as a result of lowlevel synchronization phenomena (e.g., Pickering \& Garrod, 2004; Marsh, Richardson, Baron, \& Schmidt, 2006). On such accounts, joint action is made possible-the group is able to act-because the individuals have already, spontaneously, become organized into a coordinated unit. The group exists precisely in the coordination of its members.
But notice that, in its pursuit of general mechanisms driving interpersonal coordination, the joint action research programme has indefinitely postponed the study of any particular action phenomenon as an instance of what it says it is: action. Nowhere does the group actor assumption lead researchers to ask the kinds of questions suggested above, about how to understand the movements of skilled soccer players, or how to come up with useful training interventions. The research programme appears to be misnamed, because what is actually being studied-interpersonal coordination-is understood only as a prerequisite to the real action. Where did the action go?

[^272]
## Case study 2: Group hunting in wolves and chimpanzees

In the wild, wolves are observed to hunt in packs, chasing large prey such as buffalo. A buffalo is a dangerous animal for a wolf: it has horns and powerful legs, which the wolf must avoid. Rather than attack the buffalo directly, the wolves chase the prey animal until it tires and collapses, whereupon the wolves will surround the prey on all sides, cutting off potential escape routes. Muro, Escobedo, Spector, and Coppinger (2011) were able to reproduce this behaviour in a computer simulation, modeling the wolves as agents following two rules: 1) get as close as possible to the buffalo without putting yourself directly in its path (i.e., avoid being trampled on or skewered), and 2) maximize your distance from neighbouring wolves.

Now, we might be tempted to conclude from this that the wolves are literally following a couple of simple rules. But the rules here are written as they are only because this is a computer simulation and it therefore requires explicit, symbolic rules in order to produce any output. In reality, the wolves cannot be following rules; the action must be driven by perception. What an individual wolf sees is a vista containing a potential prey animal along with a number of other wolves, all of which are already moving. The whole scene is perceived as a set of threats and opportunities which are continually rearranged as the situation unfolds. The question is, what aspects of this whole structure must a wolf learn to attend to and to exploit in order to successfully act?

A somewhat more structured type of group hunting behaviour has been observed in chimpanzees, who hunt monkeys (Boesch \& Boesch, 1989). It is attested that one chimpanzee will instigate the hunt, chasing the monkey from some direction, whereupon further chimpanzees will join in from the sides, driving the monkey into a space where eventually an ambushing chimpanzee will be in a position to catch and kill the monkey.

Boesch (2002) posits that the chimpanzees are able to coordinate this behaviour because they each adopt a specific 'role'. He identifies four roles: chimpanzees can act as driver, chaser, blocker, or ambusher. The suggestion is that these roles have some normative significance: a chimpanzee's role determines the share of the meat that they are entitled to. If this is the case, then some form of mind-reading must be involved, as each chimp would need to know what role the other chimps are playing.

Tomasello (2014) disputes this description, arguing that, in fact, each individual chimp's behaviour can be explained by selfish motives: 'chimpanzees in a group hunt are engaged in a kind of co-action in which each individual is pursuing his own individual goal of capturing the monkey'.

For Boesch, then, the group is reified as a set of normative role assignations. For Tomasello, the group simply does not exist because for it to exist the chimpanzees would have to have a human-like understanding of themselves and their fellows-the very idea is anathema.

But seeking to explain these hunting behaviours in terms of the reified group (or the absence of a group) draws our attention away from the actual action. It draws our attention away from the physical structures, movements, events, and reconfigurations that must necessarily be invoked in a description of the hunting behaviours: the chase, the closing in from the sides that narrows the monkey's escape possibilities, the space where the ambush can occur. In other words, the group actor assumption causes us to overlook the world itself. So let us reformulate our earlier critique:

## 'The group actor assumptions reifies the group while neglecting the world'

Perhaps 'the world' is too imprecise a term here. Below, it will be replaced with the concept of the ecosystem.

## The late appearance of the individual in evolution and development: from public action to private action

So far, we have left untouched the special position of individual action, generally understood as action in its most basic form. This assumption, too, must be challenged.

When we take a historical perspective on cognition, we note that the individual, as self-aware, symbol-using actor, is in fact a rather late achievement, in evolutionary terms as well as in terms of development within the human lifespan. Indeed, the notion that the individual should be treated as a given is only a self-evident truth when the matter is considered from within the cognitivist research programme.

One approach to psychology which rejects this progression from individual to joint action is that developed by Vygotsky and his followers. According to Vygotsky (1978), the child develops into a competent language-using being not by silently contemplating the actions and utterances of others, but by actually engaging in action: 'Prior to mastering his own behavior, the child begins to master his surroundings with the help of speech. This produces new relations with the environment in addition to the new organization of behavior itself.' Through the repetition of actions that were initially directed outwards, the child eventually starts to direct his actions inwards, at himself. Lake (2012) gives the example of a child speaking to himself as he looks at paint: 'I need the green paint.' Here, the speech is performed 'out loud' but is directed at regulating the child's own behaviour, not directed outwards to an audience.

Through continued practice, the child will eventually learn to regulate his behaviour without needing to say the words out loud. His private, self-directed speech becomes inner speech. This process is what Vygotsky referred to as 'internalization'. It should be noted that what has been internalized here is not some arbitrary symbol, or some Platonic notion of greenness, but the self-regulatory action. What was an action when it was carried out publicly remains an action when it is directed inwards and carried out privately: 'internalization reflects not "content" poured into a person's psychological structure, it is
how that structure is formed' (Lake, 2012). In other words, it is only through the mastery of externally-oriented actions that the individual arises.

But here we are talking about the development of speech. What does this have to do with joint action?

The difficulty is that as adult humans we are inescabably also language-users. Think back to the two soccer teams described above. While the five-year-olds have a limited vocabulary for explaining to themselves what they are doing, this is not the case for skilled adult players. Soccer players are barked at repeatedly on the training pitch year after year: "keep the ball moving", "give your teammates options", "don't get caught ball-watching", etc. The public behaviour of skilled soccer players is modified and channeled through private self-regulating actions and instructions.

The point here is that private action need not be taken as the starting point for the activity of groups. If action in its basic form is a public activity, directed outwards at the world and having immediate effects in changing the structure of that world itself, then perhaps the central contradiction driving joint action research-the contradiction which drives researchers to accept the group actor assumption-need never arise. The problem of explaining group action in terms of internal processes can be dissolved by recognizing that those internal processes do not arise until late in evolution and development. Private, self-directed behaviour is the consequence of public action, not a prerequisite for it.

## An ecosystems view of action: Reinstating space and movement

At the level of biology, an ecosystem is thought of as a rather slow-moving thing: a stable configuration of species, niches, soil types, atmospheric conditions, and so on that exist in some sort of equilibrium (Sarkar, 2016). At the level of psychology, the ecosystem must be thought of as a dynamic system, one in which every public action made by an animal alters, or perturbs, the configuration of the ecosystem itself. Moreover, because the ecosystem contains multiple actors, all public actions are inherently social, in the sense that the action changes the whole system in a manner which may be relevant to other animals: it may create new opportunities, erase previously existing ones, reveal threats, etc.

Consider the wolves again. After the pursuit of the buffalo the wolves surround their prey. Now, at this point any movement that a given wolf makes-an anti-clockwise rotation around the buffalo, say-alters the layout of opportunities for the neighbouring wolves, just as it changes the shape of the potential escape gaps for the buffalo. The second wolf may respond to the first movement in any number of ways. In no sense, though, would this response require an 'understanding' of what the first wolf was doing. It is enough to point out that the spatial configuration has changed. If we wish to understand the wolf's behaviour we should investigate what is going on in the relationship between the animal and its surroundings-that is, at the level of public action.

Does this mean that the wolf has direct perceptual access to the ecosystem? It does not. An ecosystem is not the kind of thing that can be perceived. Here it is necessary to make a distinction between the ecosystem and the environment.

James Gibson (1979) developed a psychology of perception that has as a central claim that perception cannot be thought of as something that an animal does on it own, merely in response to an environment; perception must instead be thought of as a process enacted within an animal-environment system. The animal's environment is already structured. If it is to survive, the animal must learn to make use of this structure in adaptive ways. Moving forwards creates an optic flow pattern which can be used to direct locomotion. This pattern only exists when the action is implemented and useable structure is present in the environment-the pattern does not exist for an animal that has never moved, nor is it present for an animal whose environment is filled with thick fog. For the pattern to exist requires both the animal and the environment to be in a certain relation, hence the animal-environment system.

An under-appreciated implication of this view is that it requires us to adopt a view of the environment as animalspecific. That is, it requires us to conclude that there are precisely as many environments in the world as there are animals (for a related argument about the concept of information see van Dijk, Withagen, \& Bongers, 2015). At the very start of his 1979 book, Gibson says the following about the animal and its environment:
[I]t is often neglected that the words animal and environment make an inseparable pair. Each term implies the other. No animal could exist without an environment surrounding it. Equally, although not so obvious, an environment implies an animal (or at least an organism) to be surrounded. This means that the surface of the earth, millions of years ago before life developed on it, was not an environment, properly speaking. The earth was a physical reality, a part of the universe, and the subject matter of geology. [...] We might agree to call it a world, but it was not an environment.

So what can we say about what the wolf sees? What it sees is a perspective on the ecosystem. But this is only to say that what is seen is a partial view of the structure that exists in the world. If an environment is the complement of an animal, then an environment it is what is experienced from a first-person perspective. An ecosystem, by contrast, is an analyst's label. It is a tool for capturing some of the structure in the world in a manner that can guide our investigation of certain phenomena of interest.

In the case of joint action research, the ecosystems concept is a tool that allows us to understand how multiple actors are able to negotiate a space that is populated with other actors. It allows us to move beyond the interpersonal coordination paradigm by making clear that such coordination is not necessarily something the animals must do. A basic level of

Figure 1: A pedestrian, represented by the black circle, waits to cross the road. In (a) the crossing will take 15 s , and the pedestrian must be attentive to potential threats 200 m down the road. In (b) the task difficulty is drastically diminished: with the crossing reduced to 5 s , the pedestrian now only needs to be aware of potential vehicles up to 67 m away.
coordination is already present by virtue of the fact that the animals already exist within a single ecosystem, whose structure is instantiated in just so many first-person perspectives.

The real question, though is whether the ecosystems view of action actually has any value in terms of its ability to generate practical research. I believe that it does. One example is in its potential application to the design of spaces for multiple actors, such as urban streetscapes.

## Case study 3: Pedestrian road crossing

Navigating an urban environment entails continuously coordinating with other actors. An urban design approach that has been popular in Europe in recent years, the shared space approach, argues that interpersonal coordination can be not only necessary but sufficient for managing urban traffic flows. This reasoning has led the UK government to publish design guidelines encouraging the removal of formal infrastructure elements such as kerbs and traffic signs, with the aim of forcing drivers to be more attentive to their immediate surroundings (Department for Transport, 2011). This approach has been criticized because it often renders these spaces less accessible for elderly and visually impaired pedestrians (Moody \& Melia, 2014). To see why this is the case, it is useful to adopt an ecosystems perspective on the activities of the road users. Here we will consider a simple instance in which a pedestrian wishes to cross a road that carries vehicle traffic. We will focus only on the pedestrian's task. ${ }^{2}$

[^273]The first thing to notice is that while this is an interpersonal coordination phenomenon, it is an asymmetrical one. Should a collision occur here, it is likely to be more disastrous for the pedestrian than for the driver of the car. The pedestrian thus has an immediate interest in being especially cautious.

The pedestrian's task here involves prospective control: it requires the pedestrian to be attentive to ongoing, or unfolding, movements in her environment (Von Hofsten, 1993). This is illustrated in Fig. 1. In order to decide whether to begin crossing, the pedestrian needs to take into account the movements of vehicles in the road that are on course to intercept her path. This decision task is made easier or harder depending on a number of factors, which include: how wide the road is, how fast the pedestrian is able to cross it, and the speed of the traffic. If the pedestrian can only move slowly (or has far to cross), as in (a), then that pedestrian must be aware of vehicles that are much further away compared to a pedestrian who is able to cross quickly (b). The difficulty of the decision-making task (how far the pedestrian has to look down the road) is proportional to the pedestrian's time-to-cross. Prospective control refers to the organization of behaviour with reference to perceived future movement, i.e. with reference to where objects are going to be, as the action unfolds. Older, slower-moving pedestrians have particular difficulty in crossing roads (Langlois et al., 1997), and Fig. 1 makes clear why this is the case: the slower one is able to move, the further one has to be able to see in order to control one's movements. In practice, for very wide roads or for very slow pedestrians it becomes impossible to perceive safe crossing opportunities.

From the fact that the crossing time is proportional to the distance one has to be able to see down the street, we can immediately derive a general design principle: for the road to be crossable by a given pedestrian, the crossing width, in seconds, can be no longer than the time it will take for a car to appear from beyond the horizon of visible space to intersect the pedestrian's path. In practical terms, this means that in order to make a road accessible to the widest possible range of pedestrians the crossing width should be kept to a minimum, and visibility maximized. This gives theoretical grounding to recent traffic design manuals that recommend just these measures (e.g., World Health Organization, 2013).

While the activity of crossing a road can certainly be described as an interpersonal coordination phenomenon, this is not all that it is. The ecosystems perspective allows us to reach a deeper understanding of the space in terms of: 1) the first-person perspective of the road users (pedestrians and drivers); 2) the movement capabilities, and vulnerabilities, of these actors; 3) the time-extended quality of the action; 4) the actual layout of the street. Some promising potential areas

[^274]of application are in designing roads to be inclusive for people of diverse capabilities and in redesigning 'accident black spots', which are spaces that are inherently unsafe.

## Implications for joint action research

The group actor assumption has restricted research on multiactor activities to the study of an unnecessarily narrow range of interpersonal coordination phenomena. Rejecting it is a liberating move: it frees researchers from having to address unsolvable questions about shared intentionality. The adoption of an ecosystems perspective, meanwhile, enables an investigation of multi-actor activities for what they are: instances of action. It gives us tools for addressing real-world problems in practical ways. There are some pitfalls to be avoided. I have barely touched on issues of language-use here, but human actions are inherently language-involving. For now, let us restate that internal language use is a kind of private action, and it is derived from public action. This public-private distinction is more useful, and less misleading, than the traditional individual-joint distinction. And let us restate also the ecosystem-environment distinction. The latter is a first-person perspective on the former, which itself is the setting of all social activity.

#### Abstract

Emotional state influences nearly every aspect of human cognition. However, coding emotional state is a costly process that relies on proprietary software or the subjective judgments of trained raters, highlighting the need for a reliable, automatic method of recognizing and labeling emotional expression. We demonstrate that machine learning methods can approach nearhuman levels for categorization of facial expression in naturalistic experiments. Our results show relative success of models on highly controlled stimuli and relative failure on less controlled images, emphasizing the need for real-world data for application to real-world experiments. We then test the potential of combining multiple freely available datasets to broadly categorize faces that vary across age, race, gender and photographic quality.

Keywords: Classification, machine learning, computer vision, support vector machines, emotion and cognition, facial recognition

## Introduction

Emotions are widely assumed to play a causal role in nearly every aspect of cognition (e.g., Pessoa, 2008), and yet many studies in cognitive science (and developmental science in particular) neglect to measure emotion because current measures are either expensive, tedious, or inaccurate. Consequently, many standard practices in the field have turned to indirect measures of affect. One prevalent example is the association of infant looking time with vastly different emotions depending on the researchers' theoretical stance, including preference (e.g., to positive emotional expressions; LaBarbera, Izard, Vietze, and Parisi, 1976), interest (e.g., to animate stimuli; Csibra, 2008), or surprise (e.g., to violations of belief; Baillargeon, Scott, and He, 2010). Another example is the notable lack of emotional state measures in studies on attention, learning and memory, even though the field has acknowledged the impact of emotion on these functions for over 50 years (Easterbrook, 1959). Rather than inferring the role of emotions, future studies could measure it efficiently using facial recognition algorithms. The advent of elegant machinelearning algorithms offers a free, reliable, non-invasive and easily implemented method that may be able to measure affective state in real-world settings at levels that meet or exceed trained human raters.

Here, we demonstrate automatic classification of emotional faces using three different datasets. We concentrate on young populations, as developmental science is particularly interested and constrained by hand-coding, but also demonstrate that methods are easily extended to adult populations. We also concentrate on relatively simple machine learning algorithms that may be flexibly implemented for a variety of
psychological studies. In doing so, we highlight the need for real-world data to solve real-world problems, as models based on well-curated training images that are common in the field often fail to accurately categorize messy, uncontrolled images. We further show how a single, large dataset that leverages controlled and uncontrolled images can improve generalization to real-world stimuli.

Recognition of facial expressions is a useful, non-invasive method of reasoning about another's thoughts. The seeming universality of emotional expressions further underscores their importance (Ekman \& Friesen, 1971). However, to understand how emotion influences cognition, researchers must be able to categorize facial expressions in continuous time and no existing measure can do this without great expense of time or money. Participant surveys lack temporal resolution and fall prey to metacognitive errors. Physiological methods require expensive or invasive apparatus such as galvanic skin response monitors or cortisol measurements Picard, Vyzas, and Healey, 2001. Even the gold-standard method of the Facial Action Coding System (FACS; Ekman and Rosenberg, 1997) requires hours of effort by trained technicians or prohibitively expensive proprietary software. As the demand for ecological experimentation increases, so too does the volume of video data for researchers (or more often their students) to scrutinize and label, frame by frame. The relatively constrained problems of identifying, labeling and categorizing facial features over thousands of datapoints is a prime opportunity for a machine learning solution.

Advances in data science and machine learning offer an affordable and accurate measure of participant emotional state using only filmed recordings. Computer scientists have demonstrated the uncanny accuracy of basic algorithms to classify highly controlled emotional images (e.g., Cohn, Zlochower, Lien, and Kanade, 1999; Littlewort, Bartlett, Fasel, Susskind, and Movellan, 2006), and recent efforts to categorize emotion "in the wild" (Yao, Shao, Ma, \& Chen, 2015) have the problem to unsupervised learning for less controlled images. Here we are interested in applying machine-learning to the varied contexts typical of cognitive science experiments. Laboratory settings offer more control than streaming surveillance footage, but less control than posed photography. We approximate this by comparing human performance to an algorithm trained on three datasets with unique attributes, each of which could reasonably be applied to experimental settings. We demonstrate the need for large amounts of highly varied data to consistently and accurately categorize human facial expressions. Furthermore, we present a model
trained on images that vary by age, ethnicity, gender and photographic conditions that nonetheless approaches human rater performance. It is worth noting that our goal is not to model human performance or develop new machine-learning methods; rather, we wish to explore the kinds of data required to approximate human-level emotion coding for cognitive experiments.

We begin by introducing several datasets with unique attributes of in interest to different applications. We define the methods required to use open-source libraries to create a simple machine-learning classifier. Applying this model to the datasets reveals that highly controlled training stimuli are more easily categorized, and that noisier, real-world stimuli are unsurprisingly more difficult. We discuss the tradeoff between accuracy and generality by amalgamating three datasets into a comprehensive model that is more robust to noisy input.

## General Methods

## Databases

Machine learning requires a large number of samples for reliable classification. However, the type of input can greatly affect the generalizability of the model. For instance, a model trained on only children's faces might not perform well with adult faces. Likewise, a model trained on highly controlled images might not perform well on naturalistic stimuli. We drew from three sources for training, each with a particular strength that could improve performance in a given setting. A "face" was defined as a front-facing image containing two eyes and no obstructions to facial features.

The CAFE dataset. Most face databases for psychology and machine learning focus on adults. However, a recent effort by LoBue and Thrasher (2015) documented the facial expressions of young children for applications in developmental psychology. Although stimulus sets exist for older children (aged 8-17, Egger et al., 2011) and adults (Cohn et al., 1999), the Child Affective Facial Expression (CAFE) set is the only collection featuring young children. The set contains photographs of 154 racially and ethnically diverse 2 - to 8 -yearold children posing for six emotional facial expressions (angry, disgusted, fearful, happy, sad, and surprised) as well as a resting neutral expression. Facial expressions were further labeled for "open" or "closed" mouths for angry, fearful, happy, sad and neutral faces. Disgust expressions were uniquely coded as with or without a protruding tongue. The CAFE set features multiple emotional faces for each child, though not every child demonstrated every subcategory of emotion. Altogether, the set contains 1192 images. Children's facial features offer a great deal of variability, and the ethnic diversity of the participant sample approximates the demographics of the United States.

The CAFE set was validated by a group of 100 independent adult raters, who viewed each image and labeled it with one of the seven emotions. Importantly, the images are labeled by the expression the child was asked to give, and not by
the labels most often generated by the raters. This variability makes the CAFE useful to compare to computer models, as we can test the model's success on "difficult" or "easy" faces compared to human performance.

The CK+ dataset. One method of producing cleaner data for machine learning is to extract images with tightly controlled visual features. Although our focus is on developmental populations, the CAFE set is the only publicly available database of children's faces. We therefore included a dataset comprised only of extensively vetted faces: the CohnKanade AU-Coded Expression Database, Version 2 (Lucey et al., 2010). The Cohn-Kande dataset (CK+) consists of over 11,000 image sequences of 120 adult models as they changed from neutral resting faces to peak emotional expression from 7 categories (the same as the CAFE expressions, with the addition of contempt). It is currently unknown whether training images from an adult dataset would improve performance on child facial categorization. Given the abundance of adult datasets, any improvement on child facial classification would expand the available training data for future models.

Machine vision researchers often use the CK+ dataset as a benchmark for performance of an algorithm (e.g., Littlewort et al., 2006). For our purposes, training the algorithm on the CK+ dataset allows us to test the best case scenario of facial classification, as it contains only highly controlled images with little cross-category variability. This comes at a cost to ecological validity, as all faces are of adults aged 18 to 30 , and less than $18 \%$ were minorities. Additionally, whereas items in the CAFE set were validated using subjective judgments from adult raters, the peak faces from the CK+ database were validated using the Facial Action Coding System (FACS). Briefly, FACS categorizes faces into emotional categories using reliable expressions of specific facial motor groups, or action units (Ekman \& Rosenberg, 1997). Lucey et al. (2010) validated the emotional labels given to each peak face using a linear support vector classifier trained on action units. Selecting these initial and peak faces generated 308 emotional expressions from the 6 emotional categories with a corresponding neutral face for each. A single neutral face was randomly selected for each participant to prevent over-fitting of neutral faces, leaving 120 neutral faces and a total of 428 faces.

Google image search by category. The CAFE and CK+ sets feature images taken under ideal lighting and camera positions, with labels that have been rigorously validated. However, real-world use of a facial expression classifier would necessarily include less-than-ideal photographic circumstances. To approximate the noisiness of real-world stimuli, we extracted images from a Google image search with the search term "X child face", where X was an emotional category of interest. Images were selected by research assistants, with the criteria that each image featured an individual human child's face (approximately aged 3-10) without obstruction on the face area.

Research assistants terminated the collection of images if the total number of collected images exceeded 100 exemplars or if the search returned more than 20 images in a row without a viable exemplar. This produced only 2 neutral exemplars, so an additional search was conducted using "calm" and "serious" as additional terms for neutral. This produced a total of 609 faces from all seven categories

## Face Extraction

Images from all datasets contained extraneous information, including body parts (e.g., hair and shoulders) or photographic artifacts (e.g., serial numbers in the CAFE and CK+ datasets, miscellaneous objects in the Google dataset). All images were passed through a facial recognition algorithm ${ }^{1}$ and reduced to a $300 \times 300$ pixel rectangle centered on the identified face.

Facial recognition was conducted using Haar Featurebased Cascade Classifiers. Generally, the cascade classifier breaks an image into clusters of pixels and excludes clusters that do not resemble facial features from later analysis. The process is then repeated until only clusters that resemble facial features remain. For methodological details and validation, see Viola and Jones (2001). The end result is a computationally efficient method for identifying facial regions.

A trained cascade classifier was obtained from the OpenCV website (Itseez, 2016). All faces from all datasets were passed through the classifier and cropped. A member of the research team then examined each extracted face and discarded false positives on non-face objects. This method produced 1187 faces ( 5 removed) from the CAFE set, 427 faces ( 1 removed) from the CK+ dataset, and 477 faces (132 removed) from the Google dataset.

## Human Validation

Image category labels for the CAFE and CK+ datasets were validated using adult human raters. To ensure that all images were of equal quality when training the classifier, we validated the Google dataset using 87 adult human raters recruited via Amazon Mechanical Turk. This was necessary to compare classifier and human performance for images that more closely resemble the real world.

Raters (median age: 31; 61 females, 41 college graduates, 28 parents) labeled a representative subset of the Google faces (between 47 and 49 images, evenly distributed across categories) into one of seven emotional categories. Raters also labeled a subset of the CAFE dataset (42 images, 6 from each category). The CAFE faces were evenly distributed by difficulty according to the CAFE set's previous validation metrics. This was done to compare the performance of in-person (live) and online raters.

[^275]

Figure 1: Validation of the CAFE and Google datasets by "online" human raters via Mechanical Turk vs in-person, "live" raters.

We first confirmed that Mechanical Turk raters performed comparably to live human raters (Figure 1). Overall accuracy of ratings for CAFE set images between live and online raters was significantly positively correlated ( $r=.783, t_{412}=$ $25.53, p<.0001$ ). Furthermore, accuracy of online and live raters were further correlated for all emotional categories (lowest $r_{\text {surprise }}=.410, t_{55}=3.340, p=.001$; highest $r_{\text {sad }}=$ $.820, t_{57}=10.807, p<.0001$ ), with the exception of happy expressions ( $r=.22, t_{57}=1.742, p=.08$ ), which likely had a reduced correlation due to ceiling effects. These results support the use of Mechanical Turk raters to validate the Google dataset.

We then confirmed that the human categorization performance for the novel Google images were comparable to the CAFE images. A two-way ANOVA modeling mean online rater categorization performance by dataset and emotional label found significant differences in categorization accuracy by dataset $\left(F_{1,877}=8.753, p=.003, \eta^{2}=.086\right)$ and emotion $\left(F_{6,877}=89.504, p<.0001, \eta^{2}=.881\right)$. There was also a significant interaction $\left(F_{6,877}=2.366, p=.028, \eta^{2}=.023\right)$, indicating no significant difference between online and live raters for angry, happy, neutral, sad and surprised expressions (highest $t_{877}[\mathrm{sad}]=.9694, p=.167$ ), and significantly poorer performance by online raters for disgusted and fearful expressions (lowest $t_{877}$ [disgust] $=2.134, p<.017, d=$ .144). These results suggest that the Google dataset is comparable to the CAFE set for five of seven emotions and follows the same trends for sadness and disgust, making the Google set ideal for testing an algorithm on ecological images.

## The Machine Learning Algorithm

Whole research communities are dedicated to the application of machine learning to emotional recognition, using both supervised and unsupervised algorithms for still image, video, audio or multimedia data (e.g., the EmotiW challenge at the annual ACM ICMI conference). Although there have been re-
cent successes modeling dynamic features (Littlewort et al., 2006), We opted to analyze still images to simplify implementation for the target demographic of psychologists, and used a supervised learning approach due to the relatively few training images available. We therefore selected a Support Vector Machine (SVM) algorithm, as SVMs are ideal for use by non-computer scientists for their simple implementation and ease of interpretation. SVMs have a long and successful history in image recognition (Tong \& Chang, 2001), particularly with facial recognition (Osuna, Freund, \& Girosit, 1997). An SVM is a type of supervised learning in which the algorithm identifies the optimal boundary between labeled data points. The boundary is defined by the support vectors, the subset of the data that define the boundary between classes. This boundary can then be used to infer, based on observed features, which category a novel image (or novel images) best fit. We recommend Cristianini and Shawe-Taylor (2000) for an in-depth overview.

We trained an SVM for each dataset, as well as on a comprehensive dataset containing training images from all three datasets. We used an open-source SVM classifier available through the scikit-learn database (Pedregosa et al., 2011). SVMs require the user to choose a similarity function, called a kernel, that governs the complexity of the possible boundaries between classes. There are many standard options for kernels including linear, polynomial, and radial basis function (RBF; aka Gaussian). Each computes similarity somewhat differently and they consequently differ in the kinds of classification boundaries they admit; as one might expect, a linear kernel gives a linear boundary and polynomial and RBF kernels allow non-linear boundaries. While these non-linear methods offer increased expressiveness, they also increase the risk of overfitting.

Additionally, there are two parameters that must be set and affect outcomes: the regularization parameter $C$ and kernel coefficient $\gamma . C$ is a regularization parameter which, when set to higher values, allows more complex solutions. The kernel coefficients $\gamma$ affect the influence of specific specific supports. When $\gamma$ is small, a support has broad influence on classification decisions, whereas when $\gamma$ is large the influence of each support is localized to the area near the supporting data point. A grid search for kernels, \{linear, polynomial, radial basis function (RBF) \}, penalty parameters, $C=(.001, .01, .1,1,10,100)$, and kernel coefficients, $\gamma=(.0001, .001, .01, .1,1,10,100,1000)$, yielded the optimal combination of a polynomial kernel with a $C=1$ and a $\gamma=.0001$, as assessed via cross-validation.

Although SVM classifiers are often used for facial recognition, training a classifier for emotional features offers unique problems. The classifier might divide faces by other similarities; emotional expressions are but a subset of the considerable variability between faces. For example, say a classifier is trained on two stimuli: Child A with an angry expression and Child B with a happy expression. When presented with a test image of Child A making a happy expression, the SVM

Figure 2: Classification of test images improved as a function of training data. The top line denotes average human accuracy across live and online human validation; the lower line denotes chance.
may be more likely to categorize the test image by the stable facial similarities of Child A than to the desired similarities in emotional expression of Child B. One solution might be to randomly select only one face per child participant in the CAFE and CK+ sets. This is not ideal, as it would greatly reduce the training set. Instead, we trained the SVM on all faces for a proportion of participants and tested on all faces for the withheld subset of participants. This eliminated the possibility that a test image might be paired with a training image of the same child, while also maximizing the richness of the dataset.

Another issue unique to emotional classification is the breadth of expression. For instance, the CAFE set makes a distinction between faces with open and closed mouths, and both the CAFE and Google sets contain exemplars that were difficult to label by human raters. We opted to include all instances under the basic emotional category, regardless of subordinate labels or validation score, so as to maximize training data with the greatest possible variation between features.

## Results

The algorithm was trained on incrementally increasing sizes of training data from all three datasets individually and a comprehensive dataset trained from all sources. Each sample size by dataset was repeated 40 times with a new random selection of training and test data to approximate error.

The primary goal of these analyses was to demonstrate machine-learning categorization on different training data versus human raters. Figure 2 illustrates overall performance by sample size for each of the datasets. An ANCOVA modeling dataset by training sample size revealed a significant effect of dataset $\left(F_{3,1512}=1412.39, p<.0001, \eta^{2}=\right.$ $.540)$ and training sample size $\left(F_{1,1512}=1103.76, p<\right.$ $\left..0001, \eta^{2}=.422\right)$, with a significant interaction $\left(F_{3,1512}=\right.$ 96.91, $p=.0001, \eta^{2}=.037$ ). Paired comparisons revealed that performance on within-dataset models increased faster than the comprehensive dataset as a function of training size (CAFE: $t_{1512}=12.246, p<.0001, d=.629$; Google:

Figure 3: Classification by source of testing data. Accuracy on uncurated Google images improved with the comprehensive model.
$t_{1512}=3.705, p<.0001, d=.191 ; \mathrm{CK}+: t_{1512}=11.886, p<$ $.0001, d=.611)$. Altogether, performance on all datasets improved as a function of training data, but performance on within-dataset models increased faster than the comprehensive model.

The bold dotted line on Figure 2 denotes average human categorization performance for the CAFE and Google sets, although it should be noted that no item-wise validation metrics were available for the $\mathrm{CK}+$ set. T-tests revealed that maximum training sizes on the CK+ dataset exceeded human performance ( $t_{40}=6.00, p<.0001, d=1.90$ ). Classifier performance was significantly below human performance for the CAFE ( $t_{40}=-3.62, p=.0006, d=1.145$ ), Google ( $t_{40}=-38.65, p<.0001, d=9.92$ ), and comprehensive datasets ( $t_{40}=-39.51, p<.0001, d=10.68$ ). Interestingly, human performance was not significantly correlated with classifier performance at maximum training sample size for any dataset (CK+: $r=-.031, p=.837$; CAFE: $r=.260, p=.105$; Google: $r=-.030, p=.869$; Comprehensive: $r=.240, p=.135$ ), suggesting that the basis on which categorization decisions were made by the algorithm differed from human judgments.

It is crucial for future applications that a classifier not only categorizes within a training dataset, but can also generalize beyond that set. A common method of gauging generalizability is to train models for each dataset and test on the other datasets. However, all of the present datasets, particularly the CK+ dataset, have unequal numbers of exemplars for each emotional category. As classifier performance is directly related to the amount of training data, we would have to hold training data constant to the minimum possible value across all emotional categories and datasets, which in this case would be only 25 exemplars per category (the number of exemplars for "fear" in the CK+ dataset), for a training set of only 175 images. Instead, we tested how well a single comprehensive model performs against maximally trained mod-

Figure 4: The comprehensive model from all three datasets paralleled human performance.
els for each individual dataset (the within-set models). This comparison demonstrates how the addition of training images outside the dataset improves performance. An ANOVA comparing accuracy by model type (within-dataset or comprehensive) and source of test images revealed a no effect of model $\left(F_{1,234}=0.001, p=.973, \eta^{2}<.001\right)$ but a significant effect of test image source $\left(F_{2,234}=1175.71, p<.0001, \eta^{2}=\right.$ .961) as well as a significant interaction ( $F_{3,234}=47.13, p<$ $.0001, \eta^{2}=.039$ ). Accuracy for the comprehensive model was significantly greater than the within-set model for Google ( $t_{234}=6.03, p<.0001, d=.792$ ), not significantly different for CK+ test images $\left(t_{234}=1.09, p=.140, d=.142\right)$ and significantly less for CAFE test images ( $t_{234}=6.50, p<$ $.0001, d=.849$ ). Comparing Figure 2 and Figure 3, the overall performance deficit of the comprehensive model relative to the CK+ and CAFE sets in Figure 2 are due to the high proportion of training images in the comprehensive model that come from the CAFE set (57.9\%). Importantly, these results show that a comprehensive dataset from multiple curated sources improves classification of more realistic and uncontrolled Google set.

Finally, it is worthwhile to see how a comprehensive dataset compares to human raters. Figure 4 compares human and comprehensive model performance by emotional category. An ANOVA modeling emotion by rating type (human vs the comprehensive algorithm) revealed than human raters were significantly more accurate than the classifier ( $F_{1,546}=1450.24, p<.0001, \eta^{2}=.567$ ). There were significant differences by emotion ( $F_{6,546}=1021.81, p<$ $\left..0001, \eta^{2}=.400\right)$ as well as a significant interaction $\left(F_{6,546}=\right.$ $\left.84.51, p<.0001, \eta^{2}=.048\right)$.

Overall, these results suggests that the comprehensive dataset follows similar trends as human raters. Sampling from multiple datasets improves performance on the highly uncontrolled Google stimuli and the highly controlled CK+ stimuli; although performance drops for the CAFE stimuli, it
likely stems from the high proportion of images in the comprehensive dataset that are sampled from the CAFE. These results suggest that models comprised of more training data may approach human performance on varied images.

## Discussion

Psychological theories emphasize the causal role of emotions across a variety of phenomena including learning, memory, and attention. However, emotion is rarely measured in such studies due to the cost, inefficiency and tediousness of modern methods. Widely available and accessible methods for coding emotion would greatly reduce barriers to advancing theory by allowing dense measurement of emotion in continuous time. Using a standard machine learning method, we explored the types of training data one would need to approach human-level coding of the big 7 emotional categories. These included curated image sets developed by psychological researchers and uncontrolled images drawn from Google with crowdsourced labels. We find that comprehensive models generated from multiple datasets improve classification of uncurated images. Overall model performance follows the same trends as human performance, and the inclusion of additional datasets promises to further approach human accuracy.

Cognitive science, and developmental science in particular, are greatly limited by the methods of the day. A typical developmental experiment takes place with one child and one experimenter for fifteen minutes. Such tight controls have led to important insights at the cost of ecological validity. The past 20 years have seen incredible improvements to computational theory and processing power that permit a more flexible study of human behavior. With machine-learning methods, scientists are no longer bound to brief interventions or constrained to discrete conditions. Rather, we can now continuously monitor affect and behavior as a response to the real world. Instead of inferring surprise from an infant's looking times, these models provide a method to measure a reliable indicator of emotion. Instead of assuming a role of affect in student outcomes, we can incorporate emotional expression with an intervention in real time.

This paper represents an effort toward integrating computational methods with cognitive science with the goal of actively measuring all features that support cognition. For now, we have demonstrated the feasibility of using publicly available software and data to code images in minutes rather than days. We have not yet reached human-level performance, but we have shown that the curated datasets that have traditionally been collected improve performance over training on naturalistic uncontrolled images. This marks the first step towards building theories that explain how emotion interacts with cognition in real-world learning scenarios.

#### Abstract

Does the ability to reason well make one less likely to engage in motivated reasoning? Following a paradigm used by Kahan, Peters, Dawson, and Slovic (2013), this study aims to replicate, extend, and explain the surprising finding that those most likely to process politicized data in a biased manner are those who score highest on a measure of numerical proficiency. Although our study found general effects of motivated reasoning, we failed to replicate Kahan et al.'s "motivated numeracy effect". However, our study did find that, when forced to consider competing statistical interpretations of the data before responding, highly numerate participants were more likely than less numerate ones to choose a correct but belief-contradicting interpretation of data. These results suggest that while numerate participants were biased when generating responses, they were not when evaluating reasons to justify their responses.

Keywords: reasoning; motivated reasoning; decision making, science communication; inference; intelligence; rationality

## Introduction

When science becomes politicized, who can we trust to maintain objectivity? Conventional wisdom tells us that when it comes to assessing politically-charged data, those most capable of seeing past their biases and recognizing "the facts" are those most proficient in quantitative reasoning. If that's the case, then people high in numeracy-a measure of the disposition and capacity to engage with quantitative information-ought to process information more objectively and therefore exhibit less bias in assessing it. However, a body of research suggests not only that polarization increases with numeracy, but also that highly numerate people process politicized data in a more biased manner (Kahan, Peters, Wittlin, Slovic, Ouellette, Braman, \& Mandel, 2012; Kahan, Peters, Dawson, \& Slovic, 2013; Kahan, Jenkins-Smith, \& Braman, 2010).

In one of these studies (Kahan et al., 2013), participants were faced with a problem that tested their "ability to draw valid causal inferences from empirical data." Participants all saw the same two-by-two data table, but the data were framed either as the results of a pharmaceutical study of a new rash cream or the results of a study of the effects of gun control on crime rates. Correctly interpreting the results required participants to detect covariance between the relevant intervention and two outcomes, and the numbers in each cell of the table were chosen such that a conclusion drawn using
one of two known "heuristic strategies" (comparing either the absolute value of positive outcomes or the difference in positive and negative outcomes between the two groups) did not agree with a conclusion correctly drawn using the "covariance strategy" (comparing the ratio of positive to negative outcomes between the two groups). Unsurprisingly, the authors found that participants highest in numeracy were most likely to give the correct response in the politicallyneutral rash cream version of the problem. But in the politically-sensitive gun control version, highly numerate participants only performed better than their low numeracy counterparts in cases where using the covariance strategy would lead to a conclusion that aligned with their political beliefs.

This "motivated numeracy effect" fits with a large body of literature on motivated reasoning. In her comprehensive review, Kunda (1990) writes that while "people are more likely to arrive at conclusions that they want to arrive at... their ability to do so is constrained by their ability to construct seemingly reasonable justifications for these conclusions". In many cases, such a "reasonable justification" will take the form of a processing strategy biased towards a favorable outcome (Giner-Sorolla \& Chaiken, 1997). If the information is quantitative in nature, this processing strategy may be a statistical heuristic (Ginossar \& Trope, 1987; Petty \& Cacioppo, 1986). Taken together, these studies predict that if a sophisticated strategy like covariance detection is required to arrive at a favorable conclusion, then people low in numeracy will be limited in their ability to engage in motivated reasoning. On the flip side, just because highly numerate people possess both a heuristic and normative strategy does not mean that their application of these strategies will be unbiased. To this point, Stanovich and West (2008) found that studies in which correlations were found between cognitive ability and unbiased processing supplied cues which signaled that unbiased processing was requiredmost often, these studies employed a within-subjects design where the conflict between a normative and heuristic rule was transparent. When this conflict was obscured, Stanovich, West, and Toplak (2013) found the degree of "myside bias"-the tendency to evaluate evidence, generate evidence, and test hypotheses in a manner biased towards one's priors-to be uncorrelated with measures of cognitive ability.

If the motivated numeracy effect depends crucially on both the salience and availability of heuristic and normative statistical strategies, what would happen if participants were to respond to Kahan et al.'s problems with both strategies at
hand? If motivated participants are inexorably biased in their selection of statistical strategies (as Kahan et al. suggest in their discussion), then providing "reasons" that describe each strategy before participants make their final judgement should infect the responses of those low in numeracy with the same bias exhibited by those high in numeracy. Alternatively, if motivation only obscures the need for heuristic override, then providing reasons may reduce bias in one of two ways. Assuming both low and highly numerate participants are equally cued by the reasons, performance should improve for all participants, regardless of whether the data they encounter are belief-affirming or belief-contradicting. However, if those high in numeracy are better able to recognize and respond to a conflict between normative and heuristic rules, then providing all participants with reasons should only benefit those high in numeracy.

## Study

This study examined the effect of reasons on the motivated numeracy effect, and attempted to replicate and generalize Kahan et al.'s (2013) results.

## Method

Participants Seventy-six undergraduates at Brown University participated in the study for course credit. Each participant attended one of four identical group sessions (excluding one who completed the survey during an individual session). All participants completed the study on personal computers.

Procedure Each participant was randomly assigned either to the "no reasons" or "reasons" condition. In both conditions, nine fictional experiments were described and the observed results were presented in the form of either a table, a scatterplot, or a histogram (three of each in total). Six of these data analysis problems dealt with politicized issues and three of the problems dealt with non-politicized issues.

In the "no reasons" condition, participants saw the results of the experiment and, on the same page, were asked to indicate which conclusion the described experiment supported. To respond, participants could select either between one of two opposing conclusions or could select "Other" and fill in a response. In the "reasons" condition, participants saw the results and, on the same page, were asked to select "the interpretation that best explains the data". Then, on a separate page, participants saw the data again and were asked to respond just as participants in the "no reasons" condition did.

Immediately following the study, participants completed a nine-item numeracy scale and were asked to report their political outlook (5-point Likert scale), political affiliation (7point Likert scale), and prior beliefs about each of the politicized issues presented in the study (7-point Likert scales). In a final series of questions, participants shared their
suspicions, confusions, and any other thoughts concerning the study.

Stimuli The six motivated problems looked at (1) the effect of gun control measures on crime rates, (2) the effect of mandatory anti-bias training on the number of minority civilians shot by police, (3) the effect of affirmative action on company profitability, (4) the effect of undocumented immigrant populations on violent crime rates, (5) the effect of stop-and-frisk practices on crime rates, and (6) the effect of taxing coal on unemployment rates. The three neutral problems looked at (1) the effectiveness of a rash cream, (2) the effectiveness of a fertilizer, and (3) the relationship between a property's distance from a city and the real estate commission earned on that property. For each problem, the conclusion that the data supported was randomized for each participant by switching column or axis labels.

Of the nine problems, three presented results in table form (gun control, affirmative action, and rash cream), three in the form of a scatterplot (stop-and-frisk, immigration, and property), and three in the form of a histogram (anti-bias, coal, and fertilizer). A random sequence of three blocks of table-scatterplot-histogram was generated, and the order in which the nine problems appeared was then counterbalanced using a Latin square. Selecting the correct answer in case of a table or a histogram required participants to detect covariance, just as in Kahan et al.'s (2013) original study. Selecting the correct answer in case of a scatterplot required participants to notice an overall positive (about 0.40 ) or overall negative (about -0.40 ) correlation rather than extreme outliers.

For tables and histograms, the interpretations presented in the "reasons" condition appealed to one of the two known "heuristic" responses first described by Wasserman, Dorner, and Kao (1990) or to covariance (a total of three reasons plus a fill-in-the-blank, "Other" response option). For scatterplots, the reasons drew attention to either overall correlation or outliers (a total of two reasons plus a fill-in-the-blank, "Other" response option).

Table 1: Reasons Provided for Gun Control Problems

| Heuristic A-C | Heuristic A-B | Covariance |
| :---: | :---: | :---: |
| The group that did ban carrying concealed handguns in public has more cities who saw an [increase/decrease] in crime than does the group that did not ban carrying concealed handguns in public. | Comparing the number of cities that saw crime <br> [increase/decrease] to the number of cities that saw crime [decrease/increase], there is a greater difference for the group that did ban carrying concealed handguns in public. | The ratio of cities that saw crime <br> [decrease/increase] to cities that saw crime [increase/decrease] is larger for the group that did ban carrying concealed handguns in public than for the group that did not. |

The numeracy scale used included five questions adapted from Weller et al. (2013) and four CRT questions-three
from Toplak, West, and Stanovich (2014) and one from Frederick (2005).

## Results

Participants performed at ceiling on problems in which the results were presented in the form of a scatterplot ( $M_{\text {stop-and- }}$ frisk $=0.95, M_{\text {immigration }}=0.91, M_{\text {property }}=0.99$ ), so responses to these problems were excluded from the analysis. Responses to the coal problem were also excluded, as the mean extremity of priors reported at the end of the study indicated that, for this group of participants, the issue was not a motivated one. On the coal issue, participants reported priors that averaged 0.64 points from "No opinion", compared to $1.6,2.1$, and 2.3 points on affirmative action, gun control, and bias, respectively. That left responses to three motivated problems (gun control, anti-bias, affirmative action) and two neutral problems (rash cream, fertilizer) from each participant for analysis- 228 responses in total.

Bias and Priors Participants were predominantly liberaldemocratic. In terms of outlook, $1 \%$ identified as "conservative" or "very conservative on a five-point scale. In terms of affiliation, 5\% identified as Republican leaning, Republican, or strong Republican on a seven-point scale. On all three motivated issues, participants reported substantial bias consistent with their liberal leanings-on a seven-point scale, $5 \%$ did not support gun control, $1 \%$ did not support mandatory anti-bias training in police departments, and 5\% did not support affirmative action. No significant difference in reported priors was found between HN participants and LN participants on gun-control $(t(72.99)=-0.26, p=0.80)$, antibias training $(t(64.47)=0.49, p=0.62)$, or affirmative action $(t(72.39)=-0.14, p=0.89)$. To simplify the analysis, problems that supported the conclusion that gun control lead to a decrease in crime, that anti-bias training lead to a decrease in the number of minority civilians shot by police, or that affirmative action lead to an increase in company profit are labeled as "motivated affirming". Problems that supported the conclusion that gun control lead to an increase in crime, that anti-bias training lead to an increase in the number of minority civilians shot by police, or that affirmative action lead to a decrease in company profit are labeled as "motivated contradicting".

Numeracy Average numeracy was 6.25 out of nine. Numeracy classes were assigned by a median split, with "high numeracy" (HN) referring to participants with numeracy scores of 7 or above and "low numeracy" (LN) referring to participants with numeracy scores of 6 or below. The sizes of the resulting groups were 36 and 40 , respectively. Numeracy scores were higher in the "reasons" condition ( $M=6.58, S D=2.39$ ) than in the "no reasons" condition ( $M=5.92, S D=1.75$ ), though not significantly so; $t(67.74), p=0.175$. The difference can be attributed to CRT items: Though not significant, the two groups differed in performance on the four CRT items, $t(71.24)=-1.50, p=$
0.14 , while performance on the other five numeracy items was the same, $t(71.31)=-0.79, p=0.43$.

Motivated Reasoning and the Effect of Numeracy After excluding 21 participants who did not encounter at least one problem of each valence (i.e. neutral, motivated affirming, and motivated contradicting), a repeated measures analysis of variance (ANOVA) revealed a significant effect of problem valence on performance, $F(2,102)=4.99, p=0.008, \eta_{G}{ }^{2}=$ 0.041 . This analysis also revealed a significant effect of numeracy on performance, $F(1,51)=20.01, p<0.001, \eta_{G}{ }^{2}=$ 0.18 , with highly numerate participants more likely to respond correctly than their low numeracy counterparts.

Unlike Kahan et al. (2013), in our "no reasons" condition, we found no significant difference in performance between HN and LN participants on neutral $(t(17.75)=1.59, p=0.13)$ motivated affirming $(t(21.90)=1.50, p=0.15)$, and motivated contradicting problems $(t(22.36)=0.64, p=0.53)$. After excluding the 21 participants, we also failed to find a significant interaction between numeracy and problem valence, $F(2,50)=0.058, p=0.944, \eta_{G}^{2}<0.001$. While participants clearly exhibit motivated reasoning, we failed to find a significant effect of motivated numeracy.

Figure 1: Performance in "No Reasons" and "Reasons" Conditions

The Effect of Reasons The analysis did reveal a significant interaction between numeracy and reasons, $F(1,51)=6.20, p$ $=0.016, \eta_{G}{ }^{2}=0.064$. HN participants performed significantly better in the "reasons" condition than in the "no reasons" condition, $\left(M_{\text {reasons }}=0.68, M_{\text {no reasons }}=0.43, t(55.52)=2.34\right.$, $p=0.023$ ), while LN participants performed significantly worse with reasons ( $M_{\text {reasons }}=0.13, M_{\text {no reasons }}=0.28, t(88)=$ $2.15, p=0.034)$. Note, however, that for both groups of participants, the "reasons" manipulation served to reduce bias, as measured by the difference in performance on motivated affirming and motivated contradicting problems (Figure 1). For HN participants, Bias $_{\text {no reasons }}=0.25$, while Bias $_{\text {reasons }}=0.03$. For LN participants Bias $_{\text {no reasons }}=0.26$, while Bias $_{\text {reasons }}=0.11$.

## General Discussion

While reasons served to reduce bias in all participants, those high in numeracy were better able to make use of those reasons to improve their performance. These data suggest that, in the presence of motivation, reasoners are not inexorably biased in their selection of statistical strategiescomparatively evaluating reasons can serve to block the effects of motivation, but only if one is able to understand those reasons. Motivation may encourage less reflective reasoning, but this effect is not irreparable.

Though we failed to find a significant effect of motivated numeracy, it is important to note that Kahan et al.'s (2013) original study analyzed 1111 observations from 1111 participants, while our study analyzed 206 observations from 55 participants ( 55 after the 21 participants who didn't encounter problems of each valence were excluded). As Kahan et al. note, in this paradigm, the "strength of inferences drawn from 'null' findings depends heavily on statistical power", and our sample may have been too small to detect the effect of motivated numeracy those researchers found. If Kahan et al.'s original findings are valid, these results support the hypothesis that the motivated numeracy effect results from belief bias obscuring the need for heuristic override. While motivation biased HN participants in their selection of an appropriate statistical strategy, they could appreciate the correct strategy when it was presented (and when the conflict between normative and heuristic strategies was apparent). But in any case, whether polarization increases with numeracy or whether it remains constant, our results suggest that evaluating reasons can reduce the effect of this polarization on reasoning.

If reasons served to block the effects of motivated reasoning, in virtue of what did they do so? The data suggest that evaluating reasons may have encouraged reflectiveness. To this point, not only were CRT scores higher in the "reasons" condition, but considered together, our four CRT items were the best predictor of a correct response on motivated contradicting, motivated affirming, and neutral problems. Recall that numeracy scales were completed after responding to the data analysis problems, suggesting that
evaluating reasons may have elicited a more analytic frame of mind.

Table 2: Correlations Between Numeracy Scale Items and Task Performance

| Numeracy Scale Item | Performance on <br> Motivated Tasks | Performance on <br> Neutral Tasks |
| :--- | :--- | :--- |
|  |  |  |
| N1 | -0.03 | 0.17 |
| N2 | 0.11 | 0.11 |
| N3 | 0.07 | 0.20 |
| N4 | 0.07 | 0.17 |
| N5 | 0.22 | 0.10 |
| CRT1 | 0.43 | 0.31 |
| CRT2 | 0.29 | 0.33 |
| CRT3 | 0.32 | 0.32 |
| CRT4 | 0.44 | 0.39 |
|  |  |  |
| NUMERACY-CRT | 0.17 | 0.24 |
| NUMERACY (incl. CRT) | 0.42 | 0.43 |
| CRT | 0.52 | 0.47 |

These results additionally suggest that CRT is not just a measure of numeracy, a position debated in the literature (Liberali, Reyna, Furlan, Stein, \& Pardo, 2012); the CRT scale was always a better predictor of performance on the covariance detection task than the numeracy scale considered without the CRT items. While there was a ceiling effect for three of the numeracy items ( $\mathrm{N} 1, \mathrm{~N} 2, \mathrm{~N} 4$ ), the two items for which this effect was absent still showed a lower correlation with performance compared to the CRT. Out of the non-CRT items, only N5 (a Bayes's rule problem) showed a correlation comparable to any of the CRT items. However, unlike N1N4, N5 may be more of a measure of reflectiveness than quantitative ability, per se-even with a frequency chart, the majority of people fail to attend to base-rates in problems like N5 (Bar-Hillel, 1980; Gigerenzer \& Hoffrage, 1995), and this base-rate neglect is correlated with low CRT scores (Hoppe \& Dusterer, 2011).

That said, considering that those low in numeracy generally performed worse with reasons, what appears to be a decrease in bias may not be the result of increased reflectiveness. To this point, unlike their highly numerate counterparts, LN participants in the "reasons" condition performed worse on CRT items (average scores of 0.94 ) than they did in the "no reasons" condition (average score of 1.25). Why might this have been the case? One hypothesis is that those low in numeracy had trouble understanding the reasons provided. But the number of LN participants who reported experiencing some confusion during the study (12\%) was comparable to the number of HN participants who reported experiencing confusion ( $9 \%$ ). What's more likely is that those low in numeracy were unable to appreciate and make use of the covariance strategy when it was presented as a reason.

There are three alternative explanations for our results that are important to consider. First, the difference in CRT scores between the "reasons" and "no reasons" condition may
not have reflected an effect of reasons on reflectiveness, but only an unfortunate selection confound. However, it's not clear how the presence of such a confound would affect our conclusions. As our analyses conditioned on numeracy, selection bias would only affect sample sizes, not mean performance scores.

It might also be suggested that the effect of reasons resulted from a task demand. Because in the "reasons" condition, participants saw similar reasons presented with both neutral and motivated versions of the problem, they may have come to suspect that the study was testing their bias. This may have been the case with HN participants in the "reasons" condition, $32 \%$ of whom reported suspicions about the study (e.g. "I thought that this study was probably testing how our beliefs influence our abilities to analyze the data"). Fewer LN participants ( $19 \%$ ) reported suspicions about the experiment, suggesting that if such a task demand was present, HN participants were better at picking up on (as well as responding to) it. The crucial point, though, is that even if HN participants were responding to a task demand, they could only supply responses that they thought experimenters wanted to hear if they could determine what those responses were. The fact that their responses were so often correct is consistent with our conclusion that HN participants were better at recognizing a correct response.

Third and most importantly, it could be argued that our results support an alternative explanation of Kahan et al.'s motivated numeracy effect: namely, that HN participants were more motivated because they had stronger priors. Here, we found no difference in the extremity of priors between low and highly numerate participants, and we also failed to find a significant motivated numeracy effect. Ultimately, while it is not clear how the alternative explanation could explain the effect of reasons, this is a pressing question for future research.

The implications of these results for science communication complicate Kahan et al.'s (2013) conclusions. While Kahan et al. concluded that "improving public understanding of science and propagating critical reason skills... cannot be expected to dissipate persistent public conflict over decision-relevant science", our study indicates that understanding and being able to make use of normatively correct interpretational strategies can make people more responsive to debiasing efforts, at least when those efforts encourage reflective processing.

## Conclusion

These data suggest that providing reasons can block the effects of motivated reasoning, and that such intervention is most successful for those high in numeracy. Though highly numerate people are more able to recognize when a sophisticated statistical strategy is appropriate, this recognition is impaired when a more immediate, heuristic strategy points to their desired conclusion. Making the need for heuristic override salient improves performance for those
high in numeracy, but is not enough to affect those low in numeracy.

# Belief Updating and Argument Evaluation 

Megan D Bardolph (mbardolph@ucsd.edu)<br>Department of Cognitive Science (0515), 9500 Gilman Drive<br>La Jolla, CA 92093 USA<br>Seana Coulson (scoulson@ucsd.edu)<br>Department of Cognitive Science (0515), 9500 Gilman Drive<br>La Jolla, CA 92093 USA

#### Abstract

Studies of how evidence affects beliefs sometimes show belief polarization in response to mixed evidence. However, the nature of the mental processes leading to change in opinion is up for debate. Different accounts of how people process evidence and then update their beliefs make different predictions, especially about one-sided evidence, which is rarely examined. We presented subjects with multiple text arguments regarding socio-political topics as one-sided or mixed evidence. Participants rated arguments differently according to their extant beliefs, which is consistent with accounts of motivated reasoning. They did not polarize afterward, instead showing evidence of belief updating according to Bayesian principles: belief change is sensitive to prior opinions and to the direction and quality of the evidence presented. These data support rethinking some of the mental processes underlying incorporation of evidence into a personal belief structure.

## Introduction

As people navigate a world filled with information, they must make decisions in order to accomplish various goals. The beliefs that individuals hold provide a structure in which new information is evaluated and potentially integrated with existing beliefs. Different models explain how people evaluate information and use that information to update their beliefs, leading to potentially different implications about human rationality (Oaksford \& Chater, 2007; Klayman \& Ha, 1987).

Information from the world can be thought of as data, or evidence, supporting or disconfirming a hypothesis. The evidence may be accepted without examination or it may be judged before it is used to update one's beliefs, or a hypothesis (Nisbett \& Ross, 1980; Pyszczynski \& Greenberg, 1987). From a Bayesian perspective, evidence is judged according to existing hypotheses about the world along with data that has already been observed. Bayes' rule provides a general model for constructing a posterior probability, $P$ (hypothesis $\mid$ data), as a function of prior beliefs and observed evidence: $P($ hypothesis $) * P($ data $\mid$ hypothesis $)$.

People's prior hypotheses about the world may differ depending on the data they have observed. Furthermore, the nature of people's hypothesis space for a given topic is not always easy to define (Tenenbaum, Kemp, Griffiths, \& Goodman, 2011; Jern, Chang, \& Kemp, 2014). Accounts of Bayesian updating explicitly allow for evidence to be treated differently depending on whether it is in agreement with one's prior beliefs (Gerber \& Green, 1999). However, unless there
is reason to suspect the source or validity of the evidence, Bayesian normative accounts still require that people update their prior beliefs in the direction of the evidence. This updating can be small, but it cannot be in the opposite direction. If such a shift occurs, it should be viewed as a violation of normative updating under this model.

Alternatively, differential rating of information (evidence) may be due to motivated, or hot cognition processes (Kunda, 1990; Ditto \& Lopez, 1992). Under motivated accounts, evidence compatible with an extant opinion is accepted, while incompatible evidence creates negative emotions and is therefore critically examined and judged more negatively because of its incompatibility. This difference in judgement can lead to attitude polarization, or belief polarization.

Lord, Ross, and Lepper (1979) suggested that attitude polarization occurs because people with opposing views can come to opposite conclusions from the very same set of evidence. In a classic study, the authors queried participants about their views on capital punishment, and then revealed the results of two studies, one which suggested the death penalty deters crime, and one which suggested the opposite conclusion. Participants were asked to rate the quality of each study, and then to recharacterize their views on the death penalty. The authors found that proponents of capital punishment rated the study showing the deterrent effect of the death penalty to be superior to that showing that the death penalty did not affect crime levels, and subsequently adjusted their beliefs to more strongly favor capital punishment. By contrast, opponents of capital punishment favored the study that showed the death penalty had little effect on crime, and subsequently adjusted their beliefs to more strongly oppose capital punishment. So-called biased assimilation is the phenomenon by which participants' prior beliefs impact the way they evaluate novel evidence, and it would seem to undermine the possibility of achieving consensus (Lord, Ross, \& Lepper, 1979).

Taber and Lodge (2006) suggest that "primacy and automaticity of affect kick-start the processes that spark motivated biases when citizens encounter attitudinally contrary information." Taber and colleagues (2009) found evidence of an attitude congruency bias, where people evaluate arguments and evidence that supports their prior opinions as stronger than nonsupporting information; and attitude polarization, where this bias leads to polarization with exposure to the same set of information.

The present study aims to clarify the differences between processing compatible and incompatible evidence, separating the effects of the two types of evidence. To do this, we will examine evidence rating for both mixed evidence (as used in prior studies) and one-sided evidence (previously missing from much of the literature). Studies using mixed evidence imply that participants process congruent and incongruent information using different processes; for example, readily accepting compatible arguments while spending more time and mental resources to undermine incompatible arguments (Edwards \& Smith, 1996; Taber, Cann, \& Kucsova, 2009). It is not clear whether compatible and incompatible arguments must be presented together to activate these processes or whether they apply to congruent and incongruent arguments due to the nature of the evidence alone. The inclusion of mixed and non-mixed (one-sided) evidence allows for examination of potential differences.

This study further aims to examine whether belief updating behavior supports a motivated reasoning account or a Bayesian account of belief updating. This will be assessed by testing whether participants' beliefs change as a function of biased assimilation of the evidence, dependent on their prior beliefs, or whether belief change depends on the direction and/or merits of the evidence.

## Methods

## Participants

Participants were 124 students ( 75 female) enrolled in Psychology, Linguistics, or Cognitive Science courses at the University of California, San Diego (UCSD) participating as part of a course requirement. All participants provided informed consent, and procedures were approved by the Institutional Review Board (IRB) at UCSD. Participants were between 18 and 35 years old, with a mean age of 21 . An additional two participants completed the survey, but their results were not included, either because their responses suggested they did not understand the rating scale $(\mathrm{n}=1)$, or because their age was greater than 35 years $(\mathrm{n}=1)$.

## Materials

The study concerned six socio-political issues: abortion, animal testing, assisted suicide, climate change, the death penalty, and school uniforms. These issues were among the most popular topics covered on two debate websites, www.procon.org and idebate.org.

Attitude measurements: For each issue, a single policy statement was chosen for participants to rate in terms of how much they agree or disagree (e.g., "Animal testing should be banned."). This was followed by four position statements for each issue selected from two headings under "Points for" on the idebate.org archive, and two from "Points against." Participants responded to all five of these position statements, and these responses formed the initial attitude measurement. After the experimental treatment, participants again responded to five position statements per issue to form the subsequent
attitude measurement.
Strength measurements: For each issue, participants were given four questions with a 9-point Likert scale to indicate how much they cared about, and had thought about, that issue. These four questions were combined to form a measure of strength of conviction.

Arguments: Using text from the websites, 6 supporting (Pro) and 6 opposing (Con) arguments were selected for each issue. Arguments were generally matched for content (i.e., if a Pro and a Con argument addressed the same point, both arguments were usually selected), and for length (mean argument length $=120$ words, $s d=11$ ). To create arguments of similar length, portions of longer arguments were omitted.

## Procedure

The study included three phases: initial collection of attitude and conviction strength measurements, the presentation and rating of arguments, and the subsequent collection of attitude and strength measurements.

Initial collection of attitude and strength measurements proceeded one issue at a time, as participants first rated their attitude on the issue, and then responded to the questions regarding the strength of their convictions on that issue. The presentation order of the six issues was randomly determined.

Following the collection of attitude and strength measurements, each participant was asked to read and rate arguments for three randomly chosen issues from the original set of six. For these three issues, one was randomly designated as the Pro condition, such that the participant read and rated six arguments in support of the original position; one was randomly designated as the Con condition, such that the participant read and rated six arguments against the original position; and one was randomly designated as the Mix condition, such that the participant read and rated three arguments in support of the original position, and three arguments against. The order of the issues was randomized, as was the order of the arguments presented within each issue. Treatment thus included four treatment conditions: Pro, Con, Mix, and None, with the None condition comprising four issues for which participants were not presented any argument text.

After reading all arguments, participants were again asked to rate their positions on all six issues. Next, participants completed a brief political knowledge quiz to assess their political sophistication, and two questions to assess openmindedness. Finally, they read a debriefing page that explained the goal of the study and provided links to the websites used for the argument texts.

## Analysis

Opinions were scaled from -5 to 5 , with -5 representing the opinion most against the issue and 5 representing the opinion most in favor of the issue (each issue is framed as a statement, e.g. "The death penalty should be banned."). Items where participants spent too long reading the argument text (more than 153 seconds, 3 standard deviations from the mean) were removed from analysis (28 items out of 2232).

Participants' prior opinions and strength of conviction were analyzed to ensure uniform representation across conditions, since within each issue, experimental conditions (Pro, Con, Mix, or None) were varied between subjects. A linear model of prior opinion as a function of treatment condition and issue showed that although opinions varied by issue, there were no significant differences among conditions (Pro, Con, Mix, None), nor was there any interaction of issue and condition. Similarly, strength of conviction did not vary as a function of treatment condition.

Models of argument rating were analyzed with a linear mixed effects regression (LMER) model using the lme4 package in R (Bates, Maechler, Bolker, Walker, et al., 2014; R Core Team, 2015). All experimental factors were allowed to interact initially; more complex models were compared with more parsimonious models using model ANOVA in R. Models were fit with random intercepts for subjects and items (viz. arguments). The reported models are those that included statistically significant predictors of argument rating and are not statistically different from more complex models (using cutoff $\mathrm{p}<.01$ ).

Models of belief updating were analzed with a linear model in R. Again, all experimental factors were allowed to interact initially; more complex models were compared with more parsimonious models using model ANOVA in R. This is equivalent to selecting all predictors with a significant p value ( $\mathrm{p}<.01$ ) in the model ANOVA.

## Results

The present study was designed (i) to replicate patterns of argument evaluation shown in other studies (Lord et al., 1979; Edwards \& Smith, 1996; Taber et al., 2009) and (ii) to critically examine whether biased argument rating leads to belief updating, as suggested by a motivated account of reasoning, or whether belief change can be better explained by a Bayesian account in which participants are sensitive to the merits of the evidence.

The motivated cognition account explains attitude polarization as resulting from a biased assimilation of the evidence, such that evidence compatible with participants' initial positions is weighted more heavily than incompatible evidence, and consequently has a disproportionate impact on the way participants update their beliefs. We first assessed whether participants evaluated the arguments in a biased manner by analyzing whether their ratings of these arguments differed systematically as a function of their prior beliefs. Next, we assessed the factors that influenced belief change in response to these arguments.

## Argument Rating

As noted above, our first question was whether participants rated evidence differentially as a function of its compatibility with their initial attitudes about the relevant issue. To examine this question, we began by modeling participants' argument ratings with a linear mixed effects model with predictors of treatment condition (Pro, Con, or Mix), argument po-

Figure 1: Average argument rating as a function of prior opinion ( -5 most opposed, 5 most in favor of the issue). Green lines represent Pro arguments presented in the Pro and Mix conditions; Red lines represent Con arguments presented in the Con and Mix conditions.
larity (Pro or Con), prior opinion, strength of conviction, issue, and political sophistication. Argument polarity is coded separately from Condition and represents Pro and Con arguments irrespective of which experimental condition they were presented in. The goal of this variable coding procedure was to separate potential effects of experimental condition from effects of argument polarity.

Our model selection procedure revealed that experimental condition per se was irrelevant. The best model predicts argument rating as a function of prior opinion and argument polarity only. There was a trending further interaction with strength of conviction, with the slope of the rating x prior opinion line being steeper for participants with high strength of conviction ( $\mathrm{p}=.015$ for the 3 -way interaction). Other experimental variables did not show main effects or interact with experimental variables. The mixed effects linear model includes random subject intercepts and individual argument intercepts. See Equation 1 and Table 1 for model results.

Argument rating $\sim$ prior opinion $*$ argument polarity

Table 1: Model results for Equation 1.

| Factor | df | F value |
| :--- | :---: | :---: |
| Prior opinion | 1 | 1.5 |
| Argument polarity | 1 | 0.3 |
| Prior x Argument polarity | 1 | 125.1 |

Figure 1 shows how argument ratings differ as a function of participants' prior opinions, with separate green regression lines shown for supporting arguments presented in the Pro condition and in the Mix condition, and separate red regression lines for opposing arguments presented in the Con condition and in the Mix condition. The positive slope of both green lines reflects the fact that the more participants support the issue, the higher they rate the Pro arguments compatible with their position. The similarity in the slope of the Mix and the Non-Mix line indicates that participants' ratings of these arguments were similar, regardless of whether they were presented in the context of other Pro arguments, or with a mixture of Pro and Con arguments. Likewise, the negative slope of both red lines reflects systematic bias in the ratings of opposing arguments, with opponents ( -5 on the $x$-axis) rating those arguments higher than supporters ( +5 on the $x$-axis), irrespective of whether opposing arguments were presented in a Con or a Mix block.

## Belief Updating

We are interested in what factors lead to belief updating, or opinion change, after participants read and rate the arguments. Specifically, experimental condition might interact with participants' prior opinions, showing that belief updating due to different types of evidence (i.e., that presented in the Pro, Con, and Mixed conditions) differs as a function of their original position regarding that issue. Strength of conviction may also influence opinion change if participants whose beliefs are stronger are either more motivated to defend their position or rely on a greater body of knowledge to form their prior opinion. Because participants may change their opinions differently by issue, issue is also included as a predictor. Finally, we included a measure of political sophistication because previous studies have suggested that sophisticated individuals are more likely to engage in motivated reasoning (Taber et al., 2009).

Opinion change was modeled as a function of treatment condition (Pro/Con/Mix), prior opinion, strength of conviction, issue, and political sophistication. Linear models as described in the Analysis section were created to investigate the effects of these factors on opinion change. The best model to predict opinion change is shown in Equation 2.

$$
\text { Opinion change } \sim \text { condition }+ \text { prior opinion } * \text { strength }
$$

Table 2: Model results for Equation 2.

| Factor | df | Estimate | F value | p value |
| :--- | :---: | :---: | :---: | :---: |
| Condition | 2 |  | 19.4 | $<.001$ |
| Prior opinion | 1 | -.41 | 96.2 | $<.001$ |
| Strength | 1 | -0.02 | 0.78 | .38 |
| Prior x Strength | 1 | 0.03 | 7.55 | $<.01$ |

The effect of experimental condition on opinion change is shown in Figure 2. On average, independent of prior beliefs,

Figure 2: Average opinion change for each treatment condition. Lines represent standard error.
participants' opinions were more in favor of an issue after viewing and rating arguments in the Pro condition; more opposed to the issue after viewing and rating arguments in the Con condition; and unchanged after viewing arguments in the Mix condition.

Overall, participants shifted their opinion toward a more moderate point of view (and also in the direction of the evidence), with participants more in favor of an issue changing their opinion to be less in favor, and those opposed changing their opinion to be more in favor. This center-trending behavior is represented in the negative coefficient of prior opinion in the model. Prior opinion further interacts with strength of conviction such that participants with lower strength show more center-trending than do those with higher strength of conviction.

The prior opinion x strength interaction is shown in Figure 3. Values for opinion change were baseline corrected by subtracting prior opinion $*$ opinion change slope for the None condition to show how much opinion changed when participants viewed and rated arguments. This visually removes the overall center-trending pattern observed for all conditions. Participants with high strength of conviction did not show a difference in opinion change compared to baseline. Those with low strength of conviction show an additional centertrending pattern, with participants more in favor of an issue changing to be more opposed, and participants more opposed to an issue becoming more in favor.

Finally, we were interested in whether participants' argument ratings would influence their beliefs in addition to the other factors. Motivated cognition accounts would predict that participants who exhibit biased rating behavior will be more likely to polarize, updating their beliefs in the direction

Figure 3: Interaction of prior opinion and strength. The blue line represents participants with low strength of conviction for a given issue, and the pink line represents those with high strength of conviction. Values have been corrected to remove the center-trending slope of the None condition to show their difference from baseline.
of their initial opinion. By contrast, Bayesian updating predicts that participants will rely only on the evidence. Consequently, they will either move in the direction of the evidence (irrespective of their prior beliefs), or maintain their original point of view.

Model comparison revealed that when participants’ average argument rating was included as a predictor, the most parsimonious account of opinion change is given by the factors in Equation 3. As in Equation 2, the main effect of treatment condition and the interaction between prior opinion and strength of conviction were present. In addition to the previous predictors, opinion change is further predicted by an interaction of argument polarity and argument rating. As shown in Figure 4, this interaction term results because participants' opinions on average change to be more congruent with the position of those arguments that participants rated highly. The higher a given participant rated Pro arguments, the more their opinion changed in the positive direction. The higher they rated Con arguments, the more their opinion changed in the negative direction.

$$
\begin{array}{r}
\text { Opinion change } \sim \text { condition }+ \text { prior opinion } * \text { strength } \\
+ \text { argument polarity } * \text { argument rating } \tag{3}
\end{array}
$$

Figure 4 shows this interaction of argument rating x argument polarity (Pro/Con). The occurrence of prior opinion and argument ratings in separate, additive terms in Equation

Opinion change by argument rating

Figure 4: Interaction of argument rating and argument polarity. The red line represents average opinion change for Con arguments in the Con or Mix condition; the green line represents average opinion change for Pro arguments.

3 suggests that the relationship between argument rating and opinion change was independent of participants prior beliefs. That is, whether or not participants initially agreed with the policy embraced in a given argument, they changed their positions to be more congruent with the arguments, especially for highly rated arguments.

## Discussion

## Argument rating

Participants rated arguments that were compatible with their prior policy opinions as objectively better than arguments that were incompatible with those opinions. Moreover, this bias scaled linearly with participants' prior opinions, as those at either end of the scale showed the greatest bias in argument ratings. This argument rating bias is consistent with previous findings, potentially supporting the motivated reasoning account. However, these findings are also consistent with a Bayesian reasoning account in which participants at the ends of the scale are assumed to assign a high prior probability to their own position, and naturally assess the likelihood of congruent evidence to be higher than that of incongruent evidence. To dissociate motivated from Bayesian reasoning, it is necessary to examine the opinion change data.

## Belief updating

The belief updating data provide support for a Bayesian account and show that even in the presence of biased argument ratings, participants changed their beliefs in response to the evidence. The final model of opinion change suggested that
for any given issue, participants' beliefs at the end of the experiment depended on three independent factors: treatment condition, an interaction between prior opinion and strength of conviction, and an interaction between argument polarity and argument rating. Whereas a motivated reasoning account predicts that treatment condition will interact with prior opinion, we instead found that condition had an independent effect. Participants who read Pro arguments adjusted their beliefs in a positive direction, those who read Con arguments adjusted their beliefs in a negative direction, and those in the Mix condition made almost no adjustment to their beliefs.

Further, while prior opinion was highly relevant for belief change, we found no evidence for the polarization phenomenon predicted by motivated reasoning. In fact, participants with weaker convictions moved a small amount away from their original positions, while those with strong convictions tended to maintain their existing beliefs.

Finally, the relationship between argument ratings and belief change was more consistent with a Bayesian account than the biased assimilation process predicted by motivated reasoning. That is, with motivated reasoning we would expect both highly-rated congruent arguments and low-rated incongruent ones to lead to opinion change in the direction of participants' prior opinions. Instead, we saw that highly-rated arguments, regardless of their congruency with participants' prior beliefs, were associated with movement in the direction of the arguments themselves. This is strong evidence in favor of a Bayesian account and shows that even in the presence of biased argument rating, belief change seems to be based on the quality of the evidence itself.

#### Abstract

Nowadays, several of the situations in which we have to make decisions are in digital form. In a first experiment ( $\mathrm{N}=1010$ ) we showed that people's moral judgments depend on the Digital Context (Smartphone vs. PC) in which a dilemma is presented, becoming more utilitarian (vs. deontological) when using Smartphones. To provide additional evidence, we ran a second $(\mathrm{N}=250)$ and a third experiment $(\mathrm{N}=300)$, where we introduced time constraints and we manipulated time instructions. Our results provide an extended perspective on Dual-Process Models of Moral Judgment, as we showed that the use of smartphones, often assumed to be hurried which would be consistent with gut-feeling decision-making, increased the likelihood of utilitarian responses and decreased deontological ones. This is the first study to look at the impact of the digital age on moral judgments and the results presented have consequences for understanding moral choice in our increasingly virtualized world.

Keywords: Moral Judgment; Behavioural Ethics; DecisionMaking, Human-Computer Interaction.

## Introduction

In this digital age, we spend a lot of time interacting with computer screens, smartphones and other digital gadgets. We buy online, work on the cloud, our social relationships are sometimes online-based, etc. Thus, the contexts where we typically face ethical decisions and are asked to engage in moral behaviour have changed. Nowadays, moral dilemmas are often presented digitally, that is, relevant information is presented through and decisions are made on a technological device.

A key distinction regarding moral judgments concerns deontological versus utilitarian decisions (Singer, 1991). Recent dual-process accounts of moral judgment contrast deontological judgments, which are generally driven by automatic/unreflective/intuitive responses, prompted by the emotional content of a given dilemma, with utilitarian responses, which are the result of unemotional/rational/controlled reflection, driven by conscious evaluation of the potential outcomes (Greene et al., 2001; Greene \& Haidt, 2002). In this account, an individual's ethical mind-set (rule-based vs. outcome-based, Barque-Duran et al., 2015) can play a central role. A deontological perspective evaluates an act based on its conformity to a moral norm (Kant, 1785/1959) or perhaps just a rule (such a law). By contrast a consequentialist/utilitarian perspective evaluates an act depending on its consequences (Mill, 1861/1998).

People often believe that judgments about "right" and "wrong" should be consistent and unaffected by irrelevant aspects of a moral dilemma or by its context. However, studies have shown, for example, that manipulations of the language (foreign vs. mother tongue) in which a moral scenario is presented can affect moral judgments through increasing psychological distance from the situation, and so inducing utilitarianism (Costa et al, 2014). The choice of deontological versus utilitarian judgments can vary depending on the emotional reactivity triggered by the dilemma (Valdesolo \& DeSteno, 2006). As such, establishing which conditions favor each of these two influences is fundamental to understanding the psychology of moral choice.

Construal Level Theory (CLT) provides a framework of considerable potential relevance by linking mental representations to moral judgment. Individuals' judgments, decisions, and behaviours can differ as a function of construal levels. CLT proposes that the same event or object can be represented at multiple levels of abstraction (see Trope \& Liberman, 2010, for a review). More weight is given to global, abstract features at high-level construal, whereas local, concrete features are more influential at lowlevel construal. According to CLT, psychological distance is a major determinant of what level of construal is activated. Distancing a target on any dimension of psychological distance (i.e., time, space, social, and hypotheticality) leads to greater activation of high-level construal (directing attention to end states) than low-level construal. Crucially, high-level construal is often assumed to align with more utilitarian decision-making (Gong, Iliev, \& Sachdeva, 2012; Aguilar, Brussino, \& Fernández-Dols, 2013).

The present study explores whether a Digital Context (i.e. using a different digital device such a Smartphone or a PC, as hundreds of millions of individuals do every day) can have a systematic impact on these processes. Could Digital Contexts induce different construal levels (through psychological distance)?

There is evidence that people experience a so called "narrowing effect" when using smartphones in decisionmaking, which means that they channel or tunnel their focus toward a main task and ignore or filter out certain cues (Ariely, 2016). A narrowing effect is consistent with the idea that devices such as smartphones would increase psychological distance giving rise to an abstract representation of actions. In other words, the narrowing effect would seem to be aligned with a more utilitarian/ outcome-based mind-set, instead of a more emotional/
deontological one. For this reason we asked ourselves whether Digital Context, smartphone vs. PC, might influence the relation between different levels of construal (psychological distance), thus affecting the likelihood of utilitarian vs. deontological judgments.

To summarize, we hypothesize that Smartphones (vs. PCs) have the effect of channeling or tunneling the focus toward a main task at the expense of certain cues. This should induce high construal, increase psychological distance and give rise to an abstract representation of actions, thus biasing towards more utilitarian judgments.
We first tested this prediction using three versions of the well-known Trolley Problem (Switch, Fat Man, Balanced; Thomson, 1985; see Methods sections). To provide additional support we also ran a second and a third experiment where we introduced a Time Constraint (10 seconds vs. Unlimited Time to respond) and where we manipulated Time Instruction, relating to how participants were given information about the time constraints for reaching a decision (Instructing Unlimited Time vs. No Time Instruction).

## Experiment 1

The objective was to explore whether a manipulation of the Digital Context (Smartphone vs. PC) can have an impact on moral judgment. Specifically, we wanted to test if making moral judgments using a Smartphone increased the number of utilitarian responses in comparison to when using a PC.

## Participants

A total of 1010 participants, all US residents, were recruited on-line and received $\$ 1$ for doing the task ( 482 women, 528 men; mean age $=31.7$ years, $S D=9.6$ ). Sample sizes were based on extant research (Suter \& Hertwig, 2011).

## Materials and Procedure

The study was designed in Qualtrics, run on Amazon Mechanical Turk and lasted approximately 10-15 minutes. Digital Context (Smartphone vs. PC) ${ }^{1}$ and Version of the Trolley Problem (Switch vs. Fat Man vs. Balanced) were manipulated between participants. We used the frequency of Utilitarian vs. Deontological Responses as the dependent measure.

Participants were randomly told to switch to a Smartphone or a PC after reading and agreeing the general instructions on Amazon Mechanical Turk. Having a smartphone was a pre-requisite to participate in the experiment. Participants in the Smartphone condition had to respond to all questions from their smartphone devices. As a manipulation check for this condition, we tracked and verified through Qualtrics that the responses were indeed

[^276]made from an iPhone, Android, Windows Phone or Blackberry. Participants were randomly allocated to one of these six conditions: (1) Smartphone/Switch; (2) Smartphone/Fat Man; (3) Smartphone/Balanced; (4) PC/Switch; (5) PC/Fat Man; (6) PC/Balanced. One third of the participants (327 Participants) on each Digital condition were presented with the Fat Man version of the Trolley dilemma, where one imagines standing on a footbridge overlooking a train track. A small incoming train is about to kill five people and the only way to stop it is to push a heavy man off the footbridge in front of the train. This will kill him, but save the five people. A utilitarian analysis dictates sacrificing one to save five; but this would violate the moral prohibition against killing. Imagining physically pushing the man is emotionally difficult and therefore people typically avoid this choice (Thomson, 1985). According to our hypotheses, participants would be more likely to opt for sacrificing one man to save five when dealing with such moral dilemma using a smartphone in comparison to a PC, since this would induce high construal, increase psychological distance and give rise to an abstract representation of actions, which is aligned with more utilitarian judgments under time pressure; or would induce psychological closeness due to the link between low-level construal and a focus on means, which is also hypothesized to align with more utilitarian judgments, under conditions of no time pressure. Another third of participants (313 Participants) were presented with the Switch dilemma, where the trolley is headed towards the five men, but you can switch it with a lever to another track, where it would kill only one man. People are more willing to sacrifice the one man by pulling the switch than by pushing him off the footbridge and the extensively supported explanation is that pulling the switch is less emotionally aversive. The last third of participants (314 Participants) were presented with the Balanced version of the Trolley Problem. The Balanced dilemma had a setting similar to that in the Fat Man version, but with a different number of people one could save (15 instead of 5), so that utilitarian choice would increase. All participants first completed a filler task (10 trivia questions) before responding to one of the versions of the Trolley Problem. A "catch question" was introduced in the experiment, to control for attention during the task (i.e. "If you are paying attention to this question please select answer ' 36 ' from the options below"). Then, participants were presented with one of the three moral scenarios (Switch, Fat Man or Balanced) where they had to choose between Choice A (utilitarian) or Choice B (deontological). In all cases the dilemma was presented with both text and an illustration. Subsequently, participants completed another filler task (10 trivia questions). Finally, participants were asked to complete The Big Five Inventory (John et al., 1991) questionnaire, which is considered a quick (44-items), reliable, and accurate measure of the five dimensions of personality. We considered that the impact of digital content on moral choice could also interact with personality characteristics (Ozer \& Benet-Martínez, 2006) but the
results did not lead to firm conclusions and therefore will not be reported further.

## Results Experiment 1

We excluded participants whose first language was not English, as Costa et al., (2014) showed that the use of a foreign language (instead of a mother tongue) in a moral scenario increases psychological distance and induces utilitarianism when making moral judgments. We also excluded those participants who did not answer the catch question correctly. A total of 56 participants out of 1010 were thus excluded.

We first compared the percentage of Utilitarian Responses for the two Digital Contexts (Smartphone vs. PC) on each of the three Versions of the Trolley Problem that were employed (Switch vs. Fat Man vs. Balanced; Figure 1).

Figure 1: A) The experimental paradigm used in the Smartphone condition in Experiment 1. B) The illustrations used in each of the three moral conditions. C) Percentage of Utilitarian Responses for both Digital Contexts (Smartphone vs. PC) on each of the three versions of the Trolley problem
(Switch vs. Fat Man vs. Balanced). Error bars represent standard errors.

As expected, in the Fat Man dilemma more participants avoided the act of pushing the heavy man off the footbridge in front of the train, presumably because of the emotional burden of this choice. More importantly, participants were more likely to opt for sacrificing the Fat Man (utilitarian response) to save five men when using a Smartphone (33.5\%) than when using a PC ( $22.3 \%$ ). A $2 \times 2$ chi-square test of independence was performed to examine the frequency of Utilitarian vs. Deontological Responses against Digital Context in the Fat Man condition and this
revealed a significant association between the variables, $\chi 2$ $(1, \mathrm{~N}=327)=5.15, \mathrm{p}=.023$. This result supports our hypothesis that moral judgments in Smartphones increase utilitarian decision-making, than when using a PC.

We then analyzed the frequency of Utilitarian vs. Deontological Responses, across the two Digital Contexts, in the Switch condition. Slightly more participants decided to sacrifice one man by pulling the switch than to do nothing and let five people die ( $80.9 \%$ for the Smartphone users; $76.9 \%$ for the PC users), but there was no evidence for an association between the two variables, $\chi 2$ ( $1, \mathrm{~N}=313$ ) $=.741, \mathrm{p}=.389$. This result supports our expectation that in less emotional scenarios, such as the Switch dilemma, there is a reduced effect of Digital Context. That is, there is no difference in participants' moral judgments when using a Smartphone or a PC if the moral scenario is already highly utilitarian.

Finally, we examined the frequency of Utilitarian vs. Deontological Responses in the Balanced condition. Note, this condition was designed so that, in the PC condition at least, there would be fairly equivalent utilitarian and deontological influences, and this was approximately the case. Regarding the manipulation of interest, $40.4 \%$ of participants decided to push the heavy man off the footbridge in the PC and $36.7 \%$ in the Smartphone conditions. Nevertheless, a chi-square test of independence showed that the relation between these variables was not significant, $\chi 2(1, \mathrm{~N}=314)=.448, \mathrm{p}=.503$. The (tentative) conclusion from this experiment is that using a Smartphone ${ }^{2}$ rather than a PC has a reliable impact on moral judgments only when dilemmas or scenarios have high emotional content.

## Experiment 2a and 2b

The objective of Experiment 2a was to provide additional evidence for the increased number of utilitarian responses using a Smartphone by manipulating the amount of time available to form a moral judgment. We wanted to explore Digital Context (Smartphone vs. PC) and Time Constraint (10 seconds vs. Unlimited time to respond) on moral judgments. It is possible that the effect of Digital Context is independent from that of Time Constraint, in which case we cannot explain the former in terms of (just) the latter. Alternatively, Time Constraint may provide a bias on moral decision making opposite to the effect of Digital Context (e.g., a decrease of utilitarian responses, in the fat man scenario, when participants are using a Smartphone), which will create a complex picture regarding how using Smartphones in everyday moral judgments biases for and against utilitarian responses. In Experiment 2b, we addressed the challenge to explain the difference in the Fat Man condition of Experiment 1 and in the Unlimited Time

[^277]condition in Experiment 2a (where the effect of Digital Context had disappeared) by manipulating directly the Time Instruction to either specify that there was unlimited time available for a moral judgment, or not mentioning time at all (Instructing Unlimited Time vs. No Time Instruction). The key difference between these two conditions was that in Experiment 1 participants were not told anything regarding time, while in Experiment 2a, in the equivalent conditions, participants were specifically told they had unlimited time. We also measured participants' affective reaction with the Self Assessment Manikin test (Bradley and Lang, 1994).

## Participants

A total of 550 participants ( $250 \operatorname{Exp} 2 \mathrm{a}$ and $300 \operatorname{Exp} 2 b$ ), all of whom were US residents, were recruited on-line and received $\$ 0.80$ for doing the task ( 234 women, 316 men; mean age $=32.5$ years, $S D=9$ ).

## Materials and Procedure

The studies were designed in Qualtrics, run on Amazon Mechanical Turk and lasted less than 10 minutes. Digital Context (Smartphone vs. PC), Version of the Trolley Problem (Switch vs. Fat Man) and Time Constraint (10 seconds vs. Unlimited Time to respond) were manipulated between participants in Experiment 2a. There were therefore eight conditions. We used the frequency of Utilitarian vs. Deontological Responses as the dependent measure.

All participants followed a similar procedure as in Experiment 1. They first completed a filler task (10 trivia questions) including a catch question, as in Experiment 1. Then, participants were presented with one of the two moral scenarios (Switch or Fat Man). In all cases the dilemma was presented with both text and an illustration. Participants were alerted of the available time for responding depending on their condition (i.e. "You will only have 10 seconds to answer the question in the next screen" vs. "You will have unlimited time to answer the question in the next screen"). After the presentation of the scenario, in the " 10 seconds" condition participants had to choose between Choice A (utilitarian) or Choice B (deontological), while a countdown timer appeared at the top of their screen (both Smartphone and PC). In contrast, in the "Unlimited Time" condition, participants were explicitly told that they had to make their judgment taking as much time as they wanted. Finally, participants were asked to complete the Self Assessment Manikin test (Bradley and Lang, 1994), which is a technique that directly measures the pleasure, arousal and dominance associated with a person's affective reaction.

In Experiment 2b, Digital Context (Smartphone vs. PC) and Time Instruction (Instructing Unlimited Time vs. No Time Instruction) were manipulated between participants, using the Fat Man scenario. Time Instruction was manipulated in the following way. Half the participants were given the instructions as in the Experiment 2 a Unlimited Time condition. The other half did not have any
indication of the time they had to spend making their judgment (same procedure as in Experiment 1).

## Results across all Experiments 1, 2a and 2b

In this section we report the results of Experiment 2a, $2 b$ and then bring together the results from all experiments focusing on the Fat Man scenario (Figure 2).

First, we summarize the results from Experiment 2 a . We excluded a total of 10 participants out of 250 following the same criteria as in Experiment 1. As a manipulation check, we first examined the amount of time that participants took to finish the experiment ( 5 min 10 s in the Unlimited Time condition; 4 min 32 s in the 10 s condition).

We examined the differences in the percentage of Utilitarian Responses for the two Digital Contexts (Smartphone vs. PC) on each of the two versions of the Trolley Problem (Switch vs. Fat Man) and with or without time pressure ( 10 s vs. Unlimited Time).

In the time pressure (10s), Switch condition, slightly more participants decided to sacrifice one man by pulling the switch than to do nothing and let five people die, when using a Smartphone (79.31\%) than when using a PC ( $66.67 \%$ ), but this difference was not reliable, $\chi 2(1, N=65)$ $=1.282, \mathrm{p}=.257$.

Regarding the Unlimited Time condition, in the Switch condition, Digital Context also did not appear to play a role in moral judgments ( $85.71 \%$ and $83.87 \%$ for Smartphone and PC, respectively); regardless of Digital Context, we observed highly utilitarian responses. Thus, as before, the results in the Switch dilemma indicate that Digital Context and (as it seems) Time Constraint have a reliable impact on moral judgments only when dilemmas or scenarios have high emotional content. This result also supports our assumption that in less emotional scenarios, such as the Switch dilemma, any effect of either Digital Context or Time Constraint does not result in a reliable increase in utilitarian responding.

In the time pressure (10s), Fat Man condition, participants were more likely to opt for sacrificing the Fat Man (utilitarian response) to save five when using a Smartphone $(45.7 \%)$ than when using a PC (20.0\%), $\chi^{2}(1, \mathrm{~N}=60)=$ $4.239, \mathrm{p}=.04$. At face value, these results challenge the assumption that hurried responses necessarily lead to deontological moral judgments.

Then, we examined participant's responses in the Unlimited Time, Fat Man condition. The results here appear to conflict with our conclusion from Experiment 1, in that there was no difference in Utilitarian vs. Deontological responses, between the Smartphone and PC conditions ( $27.58 \%$ and $29.63 \%$, respectively, $\chi 2(1, \mathrm{~N}=64)=2.224$, $\mathrm{p}=.136$ ). In other words, when participants were specifically told to spend unlimited time to resolve the dilemma (Unlimited Time condition), the Digital Context effect vanished. We return to this finding in Experiment 2b.

We also considered whether the impact of Digital Content on moral choice could interact with the perceived emotionality of the scenario/context or affective reactions,
but the results did not lead us to firm conclusions and therefore will not be reported further.

Second, we summarize the results from Experiment 2b. In this experiment we excluded a total of 141 participants out of 300 following the same criteria as in Experiment 1 and 2a. One participant was rejected because she/he answered incorrectly to the catch question and one because English was not his/her first language. Additionally, 139 participants were eliminated because they said they had come across a moral choice in the context of the Trolley Problem before. The pattern of results does not change qualitatively if these participants are included, but we decided not to do so.

In this experiment we measured Response Time for the particular moral judgment, though we note that, as the experiment was run over the internet, the accuracy of these measurements is lower than in the lab. Did participants in the Instructing Unlimited Time condition take longer to respond than ones in the No Time Instruction one? There was no evidence that this was the case ( $2 \times 2$ ANOVA with Digital Context and Time Instruction, $\mathrm{F}<1$ for all effects). We suggest that the effects from Time Constraint and Time Instruction seen in Experiments 2a, 2b could result in a change of the participants' mind-set and approach to the problems, without corresponding clear differences in Response Time.

Figure 2: Summary of the relevant results from Experiments $1,2 \mathrm{a}$ and 2 b for the Fat Man problem. The vertical axis shows percentage of utilitarian responses and the horizontal axis the conditions of interest. Error bars represent standard errors.

The two leftmost bar clusters in Figure 2 show the results of Experiment 2b. Interestingly, using the data from Experiment 2b, we replicated the finding from Experiment 2a, that the mere fact of "nudging" participants to use unlimited time resulted in utilitarian responses that were not influenced by Digital Context. A $2 \times 2$ chi-square test with frequency of Utilitarian vs. Deontological Responses against Time Instruction (Instructing Unlimited Time vs. No Time Instruction) confirmed this conclusion, $\chi 2(1)=5.509$, $\mathrm{p}=.018$.

We next considered whether the results from Experiments 2b replicated the effect from Experiments 1 and 2a regarding Digital Context. The pattern of results from the

No Time Instruction condition in Experiment 2b closely matched the corresponding results in Experiment 1. In Experiment 2b, as expected, participants were more likely to opt for sacrificing the Fat Man (utilitarian response) to save five when using a Smartphone (28.6\%) than when using a PC ( $19 \%$ ). Even though the trend was as expected, a 2 x 2 chi-square test with frequency of Utilitarian vs. Deontological Responses against Digital Context (Smartphone vs. PC) was not significant, $\chi 2(1, \mathrm{~N}=70)=$ $0.864, \mathrm{p}=.35$. However, after collapsing the data (for the identical Fat Man, No Time Instruction conditions) from Experiments 1 and 2b, we obtained a significant association between frequency of Utilitarian vs. Deontological Responses and Digital Context (Smartphone vs. PC), $\chi 2$ (1, $\mathrm{N}=397)=6.27, \mathrm{p}=.012$. This result supports our hypothesis that moral judgments in Smartphones increase utilitarian decision-making, compared to when using a PC, when no information about time is provided.

Importantly, the results from Experiments 1, 2a and 2b put together indicate that under conditions of no time information and time pressure there is indeed a utilitarian bias. The only Time Instruction in which the utilitarian bias was eliminated was the Unlimited Time condition, in which participants were specifically told to take as long as they needed to respond. This finding has a plausible interpretation that, in the Unlimited Time condition, participants took into account the information they have been ignoring so far (which would include emotional cues) and this made the utilitarian bias disappear. Thus, the results so far support the hypothesis that, under most conditions, smartphones (vs. PC) are associated with more utilitarian decision-making (vs. deontological). An additional interesting finding is that utilitarian judgments emerge in both the No Time Instruction condition and the Time Pressure condition.

## Discussion

This is the first study to look at the impact of digital context in moral judgments. We considered whether the increasing tendency for our judgments to be mediated through the use of technological gadgets might be changing our approach to moral dilemmas. We have shown that people's moral judgments become more utilitarian (vs. deontological) when using Smartphones as opposed to PCs, under a variety of time-related manipulations (but not all). The present work was motivated by the idea Digital Context might impact the relation between different levels of construal (psychological distance) thus affecting utilitarian vs. deontological judgments. While our results are consistent with such a view, clearly further research is needed.

We first consider the implications of these results for the Dual-Process Models of Moral Judgment (Greene et al., 2001; Greene \& Haidt, 2002). A standard assumption is that moral dilemmas resolved in fast, gut-feeling conditions engage a deontological mode of responding, while utilitarian responses are typically the result of longer consideration and involve cognitive control. Instead, we
showed that participants under time pressure were more likely to opt for sacrificing the "fat man" to "save five" (utilitarian response) when using a Smartphone than when using a PC. That is, some digital contexts (i.e. Smartphones) can trigger utilitarian decision-making under time pressure, even though time pressure has traditionally been associated with deontological responding in moral choice. Dual route models have received extensive support and no doubt they are valid under most circumstances. Our results indicate a need to perhaps augment the available routes for utilitarian biases in such models.

Other research has provided a more complex picture regarding the impact of time on deontological vs. utilitarian judgments. Specifically, Suter and Hertwig (2011) showed that participants in a time-pressure condition (associated with fast, gut-feeling conditions), relative to a no-timepressure condition (associated with longer consideration and higher cognitive control), were more likely to give deontological responses only in high-conflict dilemmas. By contrast, in low-conflict and in impersonal dilemmas, the proportion of deontological responses did not differ between conditions. The results from the present experiments partly support these differences between high-low conflict dilemmas. In less emotional scenarios (Switch), neither Digital Context nor Time Constraint resulted in a reliable increase in utilitarian responding. By contrast, in more emotional scenarios (Fat Man), our results question the well-established assumption (from Suter \& Hertwig, 2011, amongst others) that hurried decisions enhance deontology, since we showed that moral judgments under a time constraint and in a specific Digital context (Smartphones) seem to make utilitarian judgments more common.

Clearly, more work is required to disentangle possible explanations for the exact effect of the different instructions concerning timing, especially regarding the possibility that keeping track of time may result in reduced cognitive resources. But the crucial point regarding the present study is that our conclusion considering Digital Context and moral judgments appears mostly independent of such considerations.

Our hypotheses regarding Digital Context and moral decision-making was largely motivated from the effects and implications from Construal Level Theory. According to CLT, psychological distance can vary on at least four dimensions: temporal, spatial, social and hypotheticality (i.e. probability for a scenario to become reality; Trope \& Liberman, 2010). Can we localize the particular effect of distance in considering responding using a smartphone vs. a PC? In further studies we will attempt to measure psychological distance directly. More generally, our results were inconclusive regarding the idea that the psychological distance elicited by a smartphone decreased the intensity of people's affective reactions. It is possible that smartphones induce a greater distance in other respects. For example, it might be the case that the use of digital devices interacts with/mediates the hypotheticality dimension.

Overall, the present work reveals a need for the further systematic study of how Digital Context affects moral choice, all the more so given that, increasingly, governments, charities and other institutions engage in intense campaigns over digital media to encourage moral choices for important aspects of our way of life.

# Exploring Functions of Working Memory Related to Fluid Intelligence: Coordination and Relational Integration 

Joel E. Bateman (jbat2136@uni.sydney.edu.au) ${ }^{1}$<br>Damian P. Birney (damian.birney@sydney.edu.au) ${ }^{1}$<br>Vanessa Loh (vanessa.loh@sydney.edu.au) ${ }^{1}$<br>${ }^{1}$ School of Psychology, University of Sydney<br>Sydney, NSW, 2006, Australia

#### Abstract

Two hypothesized functions of working memory coordination (ability to maintain unrelated storage loads during processing) and integration (ability to integrate multiple elements into a relation) - were explored and compared to fluid intelligence. In Experiment 1, 130 participants completed a modified Latin-Square Task (LST) which experimentally added or reduced storage load. Results suggested that pure integration (with no storage load) could predict Gf, but no difference was found between coordination and integration. Experiment 2 employed the Arithmetic Chain Task (ACT), again with modifications to storage load. Results support replication of LST findings, though a distinction was found between coordination and integration when storage material could not be easily rehearsed. Findings from both experiments support a distinction between coordination and integration tasks in understanding the WM-Gf association.

Keywords: working memory; fluid intelligence; relational integration

## Introduction

Working memory ( $W M$ ) has consistently been linked to fluid intelligence $(G f)$, yet the intricacies underlying this relationship are not fully understood. This is in part because neither $W M$ nor $G f$ reflect a single cognitive process. Rather, $W M$ is a complex system responsible for processing and maintaining information, attention, and multi-tasking. Gf is similarly multi-dimensional, variously reflecting reasoning and the capacity to deal with novelty. Many $W M$ tasks (such as complex-span tasks; CSPANs) draw on coordination, in that information from one aspect of the task must be maintained in storage while performing a simultaneous but unrelated processing task. Conversely, many prototypical Gf tasks require relational integration (henceforth 'integration'; Halford, Wilson, \& Philips, 1998). Integration entails the ability to combine multiple representations and is critical to reasoning. In this report, we argue that advances in understanding the $W M-G f$ link have been slowed by the overrepresentation of coordination in $W M$ tasks, and the failure to consider integration as a component of $W M$.

We aim to redress this using two experiments. In Experiment 1, we modify the integration-based Latin-Square Task (LST; Birney, Halford, \& Andrews, 2006) by adding or removing storage load. In Experiment 2, we investigate the same processes in an arithmetic task (Oberauer, Demmrich, Mayr, \& Kliegl, 2001). We begin with an exposition of coordination and integration.

## Two Functions of Working Memory

Coordination $W M$ tasks typically involve some combination of processing and storage, reflecting the two components of $W M$. Coordination can be defined as the ability to coordinate stored elements with unrelated processing. CSPANs, such as the operation span, are examples of coordination tasks, because storage capacity is the primary outcome (e.g., the number of words that can be recalled) and processing (e.g., verifying the veracity of a math operation) is included to fulfil the simultaneous processing-storage conceptualization of WM (Baddeley \& Hitch, 1974). While a failure of either component does not represent a failure of the other, if both components are not given equal priority, the extent that CSPAN measures $W M$ is brought into question. However, even when processing is ensured (e.g., with an $85 \%$ threshold for operation verifications), the only measure indexing $W M$ is the recall. Because the processing is somewhat trivialized, it tells us little about how processing ability influences performance on $W M$ tasks. This does not, however, take away from the fact that coordination tasks are excellent for linking $W M$ and $G f$ (Ackerman, Beier, \& Boyle, 2005).

Integration Process-oriented accounts of $W M$ have led to the development of tasks that measure the ability to integrate representations into higher-order relational structures (Oberauer Süß, Wilhelm, and Wittman, 2008). All processing subtasks typically require some form of integration (e.g., integrating two digits to derive a sum), though some researchers have attempted to provide formalized accounts of processing tasks. Oberauer et al. (2008) employed the finding squares task, where participants monitored a 10 x 10 grid filled with 10 dots. Every few seconds, some dots would change position. The task was to monitor the dots and respond if a collective set of dots formed a square. Although tasks such as these have no storage requirements, they are still good predictors of $G f$ (Oberauer et al., 2008). This has led to the suggestion that integration forms the core of $W M$ (Oberauer, Süß, Wilhelm, \& Sander, 2007); and that rather than a 'storage capacity' limiting $W M$, constraints are instead dictated by the strength of bindings between integrated representations.

Halford and colleagues provide an alternate processoriented account of $W M$ limitations in terms of relational complexity (Halford et al., 1998), that formalizes individual
capacity for integration. $W M$ is framed not as a limitation in the number of elements, but by the complexity of relations between elements to-be-integrated. Complexity metrics have been shown to capture constraints in processing capacity (Birney et al., 2006).

Aims There is evidence that both coordination and integration can be implicated in the $W M-G f$ association. However, it is difficult to directly compare these functions, as they are typically operationalised in different tasks. The current research aims to compare coordination and integration within single tasks, experimentally.

## Experiment 1

One way to explore coordination and integration within a task is to consider a variant of a typical processing task, with reduced or additional storage load requirements. If the reduced storage load condition still associates with $G f$, it would suggest a role of pure integration within the $W M-G f$ link, as only the processing remains. Conversely, if the additional storage load condition associates with $G f$, it would suggest a role of coordination. This is the approach we used in Experiment 1, employing the LST as a processing task.

The LST was designed following the principles of relational complexity theory (Birney et al., 2006). The LST presents participants with an incomplete matrix of $4 \times 4$ cells with the governing rule that each row and column may contain only one element from a set of 4 elements. Complexity is manipulated by the number of rows and columns that must be considered in order to deduce a target cell (see Figure 1). In some items, participants must also solve interim cells, using information from those cells to solve the target. Thus, although the task is processingfocused, there is some storage costs associated with holding interim cell information. Birney et al. (2006) found that complexity captures $64 \%$ of variability in item difficulty, while the number of interim cells captures $16 \%$. Thus, $80 \%$ of difficulty variance is from identified processing and storage demands.

Figure 1. Example LST items

Because we were employing a variance-partitioning approach, it was possible to more directly compare the coordination condition with integration by varying whether the additional storage was processing-contingent or not. By partitioning out variance associated with the baseline task, we could derive variance associated solely with a coordination load and compare it to variance associated with an integration load, that were equivalent in task format and (potentially) difficulty. Thus, our four conditions for the LST were: basic, reduced storage, additional storage (coordination), and additional storage (integration); which were crossed with the standard manipulations of complexity and steps.

We hypothesized that the reduced storage condition would reduce the difficulty of the task, but maintain the association with $G f$, because pure integration was still required of the baseline task. We also hypothesized that the additional storage conditions would increase the difficulty of the task to similar degrees, and each would represent a unique contribution to predicting $G f$, as they represent the two functions of coordination and integration.

## Method

Participants and Procedure In total 130 first-year students (83 females) at the University of Sydney participated in exchange for course credit. The mean age was 19.04 ( $\mathrm{SD}=$ 1.6) years. Participants were tested in groups in 60 m sessions.

Measures Three LST sets, each with 12 unique items equally distributed across complexity ( $2 / 3 / 4$ ) and steps ( $1 / 2$ ), were adapted from Birney and Bowman (2009). Thus, all sets included an equal distribution of complexity and steps. The basic set consisted of 12 standard items (as in Figure 1).

The dynamic-completion (DC) set consisted of 12 items which allowed participants to insert interim solutions. Instead of simply selecting an answer, participants could place shapes into empty cells of the matrix, before placing a shape into the target cell to indicate their overall response. In this way, participants were able to work through the problem, offloading storage demands associated with interim cells.

The final set was additional load, consisting of 12 items. Participants were randomly allocated to coordination or integration items for this set. The actual items were identical, but the procedures were different.

For coordination items, there was a 5 s memory phase where participants viewed the matrix without the target indicated. During this phase, two shape-filled clue cells were coloured to indicate that they must be remembered. After this phase and a 2000 ms interlude, the typical test phase began with the target indicated. After responding to the item, the recall phase began. In this phase, there was first a five-second downtime with a black screen stating to "recall the cells". After this, a blank probe matrix appeared and the participant had to indicate the shapes and locations associated with the two marked cells (thus requiring coordination of stored elements and unrelated processing).

For integration items, a similar procedure was employed for coordination items except that the two marked cells during the memory phase were removed during the test phase. In this way, if the participants forgot the shapes in these cells, they would not be able to solve the problem (thus requiring integration of stored elements with related processing).

After the LST, participants completed a 20 -item Raven's Advanced Progressive Matrices (Raven, 1941; APM; odd items + items 34 and 36). The use of a single task does define $G f$ narrowly, because we cannot be certain that correlations between the LST and APM are due to an overlap in WM functions or due to task-specific factors, such as modality. However, there is a large comparative literature base to draw on to understand implications of this limitation.

## Results

Difficulty Effects Descriptive results are presented in Table 1. The overall LST-APM correlation was $r=.47, p<.001$, replicating prior work (Birney et al., 2012). Using a repeated measures ANCOVA, a complexity effect was investigated with APM entered as a moderator (covariate). Consistent with prior research (Birney \& Bowman, 2009), complexity was a significant predictor of performance $\left(\mathrm{F}_{2,256}=94.73\right.$, $m s e=0.485, \mathrm{p}<.001$, partial $-\eta^{2}=.425$ ), but APM did not moderate the effect, suggesting increases in complexity does not result in increased demand on $G f$-like resources.

A set (basic/DC/load) by complexity ( $2 / 3 / 4 \mathrm{D}$ ) repeatedmeasures ANOVA was conducted to determine whether set affected performance. There was a significant main effect of set $\left(F_{2,242}=43.17\right.$, mse $=0.56, p<.001$, partial $\left.-\eta^{2}=.26\right)$. As hypothesized, DC items were significantly easier ( $F_{1,121}=$ 35.14, $m s e=0.76, p<.001$ ) and load items were significantly more difficult $\left(F_{1,121}=14.66\right.$, mse $\left.=1.48, p<.001\right)$. A significant set-complexity interaction $\left(F_{4,484}=13.28\right.$, $m s e=$ $0.36, p<.001$, partial- $\eta^{2}=.10$ ) suggests complexity moderates the set effects. Simple-effect analyses suggest the difference between conditions, particularly the DC condition ( DC vs basic x quadratic complexity effect: $F_{1,121}=4.69, p=$ .03), is more pronounced for more complex items. Finally, separate analyses suggest that integration $(M=3.12)$ and coordination ( $\mathrm{M}=3.31$ ) conditions were not significantly different, $F_{1,128}=2.81, p=.10$. Although this was as hypothesized, there was a trend towards integration items being more difficult.

The results of these tests indicate the LST sets were performing as expected. That is, the DC condition was aiding participants and the load conditions were burdening. The next set of analyses sought to test the hypotheses on the links of set to predicting $G f$.

LST-Gf A series of multiple regressions were performed, regressing APM on LST set performance. Our first hypothesis was that DC should maintain the association with $G f$, despite having reduced storage demands.

When basic and DC items were entered together, $14.2 \%$ of variability in APM performance was accounted for $\left(R^{2}=\right.$ $\left..142, \mathrm{~F}_{2,127}=10.49, \mathrm{p}<.001\right)$. DC items explained $8 \%$ unique

Table 1. LST and APM Descriptives

| Scale (Total Scores) | Mean | (SD) | Range |
| :--- | :---: | :---: | :---: |
| LST combined | 31.17 | $(3.42)$ | $17-36$ |
| 2D Items | 11.42 | $(1.02)$ | $7-12$ |
| 3D Items | 10.96 | $(1.14)$ | $8-12$ |
| 4D items | 8.78 | $(2.11)$ | $2-12$ |
| Basic Set | 10.35 | $(1.50)$ | $5-12$ |
| DC Set | 11.17 | $(1.19)$ | $6-12$ |
| Load: Integration (n1 = 65) | 9.37 | $(1.98)$ | $3-12$ |
| Load: Coordination (n2 = 65) | 9.92 | $(1.78)$ | $4-12$ |
| Recall Cell 1 (Coordination, n2 only) | 10.78 | $(1.60)$ | $4-12$ |
| Recall Cell 2 (Coordination, n2 only) | 10.69 | $(1.98)$ | $0-12$ |
| APM | 13.35 | $(3.88)$ | $2-20$ |

variance $\left(\beta=.30, s r^{2}=.084, p=.001\right)$, whereas basic items did not significantly account for any additional systematic variance $\left(\beta=.14, s r^{2}=.018, p>.05\right)$. As hypothesized, DC did sustain the link with $G f$; and in fact, captured a larger proportion of variance in APM than basic items.

The final regression aimed to test the hypothesis that additional coordination and integration conditions could provide unique contributions to APM. The basic set was entered first, followed by load (regardless of type), then a load interaction variable distinguishing coordination from integration. Load items did account for a significant proportion of variance in APM performance, $\beta=.39, s r^{2}=$ $.14, p=.001$, over and above basic items, $\beta=.16, s r^{2}=.02$, $p>.05$. However, contrary to hypotheses, the regression lines were not different, $\beta=.10, s r^{2}=.01, p>.05$.

## Discussion

In Experiment 1, we flipped the typical $W M$ operationalisation, which uses recall as a primary task, to have processing as the primary task. Under these conditions, a storage-loaded version of the LST, relative to basic items, predicted a greater proportion of differences in $G f$, providing support for the notion that $W M$ does not have to be restricted to recall as an outcome, or processing as a distractor. The inability to distinguish integration from coordination was unexpected, though clashed with the results of the DC condition, which implicated pure integration alone as the strongest link between $W M$ and $G f$. It is possible the impact of the additional load conditions was confounded by the use of a primary task already highly loaded on integration processes. The burden of performing novel integration may have attenuated differences between the load conditions.

To address this limitation, Experiment 2 employed a different experimental task, the Arithmetic Chain Task (ACT; Oberauer et al., 2001). The ACT requires participants to solve a series of simple equations using mental arithmetic under additional load conditions, while mitigating the potentially high integration present in the LST by having a constant level of complexity. Furthermore, because the ACT is nonvisuospatial, it helps quell criticism that the modality overlap between the LST and APM was the core determinant of correlation. Although arithmetic is a form of integration
$(3+5=$ ? entails establishing the relation, sums-to( $3,5, ?)$; Halford et al., 1998), we argue that completing a chain of simple arithmetic provides a cognitively simpler instantiation of integration than the LST, thus allowing stronger differences to emerge between additional load conditions.

## Experiment 2

Oberauer et al. (2001) provided evidence for a distinction between coordination and integration in the ACT. They asked participants to complete a mental arithmetic task in which participants were shown an equation involving a number of digits, three of which were replaced by symbols (e.g., X, Y, and $Z$ ). In the control condition, participants were given a key showing the numerical values of $X Y Z$ for use in the equation. In the coordination condition, participants were briefly shown three additional numeric values associated with other symbols (A, B, and C). These variables were to be memorized and recalled later, though they were not relevant to the arithmetic. In the integration condition (dubbed 'access') however, $X Y Z$ was equated to $A B C$, necessitating both storage and integration (see Figure 2). The authors found that although the number of stored value mappings had little effect on performance in coordination; in the integration condition, higher levels of storage load produced declines in speed and accuracy. These diverging outcomes indicated the manipulations may have indeed tapped different functions.

In the current study, the ACT entails equations of six operations and seven addends. The format for control, coordination, and access from Oberauer et al. (2001) was used. We also introduced an additional condition, which modified the access condition to include fixed (e.g., $A B C=X Y Z$ ) as well as random (e.g., $A B C=Y Z X)$ mappings. Our complexity analysis (not reported here) suggests that random access imposes constraints on conceptual chunking, increasing the integration load, relative to access-fixed. In summary, the convenience of the serially ordered fixed mappings cannot be applied to random mappings, forcing participants to deconstruct and reconstruct the bindings holding the relation together - a critical source of demand in Oberauer et al.'s (2007) architecture of WM.

In addition to the ACT and APM, we employed the symmetry span as an additional criterion measure. We also aimed to replicate Experiment 1 by including the LST. If the LST-DC is indeed a measure of pure integration, it would provide a useful criterion measure.

Our primary hypothesis was that access and coordination aspects of the ACT should provide independent contributions to predicting APM variance. Further, we hypothesized that access-random should provide the strongest unique contribution, over-and-above other conditions, as it places the highest theoretical demand on a binding-based relational processing system of $W M$.

## Method

Participants and Procedure The participants were 60 firstyear students (44 females) at the University of Sydney who participated for course credit. The mean age was 19.22 (SD $=2.77$ ). Participants were tested in groups in 90 m sessions .

Measures The ACT required participants to solve arithmetic problems of six operations (additions/subtractions). Four blocks of problems (control, coordination, access-fixed, access-random) were generated such that all digits were between 1 and 7 , and final answers, between -9 and +9 . There were six items per block. Participants had practice with all conditions, then received the blocks in random order.

Control items were basic problems that entailed substituting variable-value mappings (e.g., $\mathrm{X}=2, \mathrm{Y}=1, \mathrm{Z}=4$ ) provided in the top half of the screen into equations where each operand was displayed one-at-a-time at a pace controlled by participants. After all 7 operands had been displayed, a textbox would appear prompting the participant for an answer. Feedback was then displayed.

Coordination items were identical to control items, with the exception that participants were given 6 s to memorize three variable-value mappings (e.g., $A=6, B=3, C=1$ ) to be recalled at the end of the trial.

Access-fixed items were similar to coordination items, except the $X Y Z$ variable-value mappings were directly linked to the $A B C$ mappings (e.g., $\mathrm{A}=6, \mathrm{~B}=3, \mathrm{C}=1$; and always, $\mathrm{X}=\mathrm{A}, \mathrm{Y}=\mathrm{B}, \mathrm{Z}=\mathrm{C})$. Again, participants were asked to reproduce the digits corresponding to $A B C$ after the equation had been solved. Thus, unlike the coordination condition, the $A B C$ mappings were required for the arithmetic. Accessrandom items were similar but the $X Y Z$ mappings were randomly linked to the $A B C$ mappings (e.g., $\mathrm{A}=6, \mathrm{~B}=3, \mathrm{C}=1$; and say, $\mathrm{X}=\mathrm{B}, \mathrm{Y}=\mathrm{C}, \mathrm{Z}=\mathrm{A}$ ).

Participants also completed the symmetry span, as in Kane et al. (2004), with set sizes of two to five (two of each). The
Phase 1: Memory

Figure 2. Example of Access condition of the Arithmetic Chain Task (adapted from Oberauer et al., 2001)
score analyzed was total number of recalled squares (0-28). The LST and APM were administered as in Experiment 1.

## Results

Difficulty Effects A repeated-measures ANOVA indicated differences in performance across conditions were significant ( $F_{3,180}=23.99$, mse $=1.51, p<.001$, partial $-\eta^{2}=.29$ ). Control performance ( $M=5.20, S D=1.01$ ) was not significantly different to coordination performance ( $M=5.00, S D=1.34$ ), $t_{59}=1.07, p=.29$. However, control performance was significantly higher than the access conditions on average (Access-fixed: $M=3.98, S D=1.75$; Access-random: $M=$ $3.60, S D=1.89$ ), $t_{59}=7.58, p<.001$. Although in the expected direction, the difference between fixed and random did not reach statistical significance, $t_{59}=1.60, p=.12$.

In summary, the ordering of performance was as expected. Recall was high for all conditions (coordination: 86.67\%, access-fixed: $92.59 \%$ and access-random, $90.37 \%$ ), meeting the criterion of the secondary task in CSPANs, though there was some evidence to suggest recall under conditions where the information was critical (access) is better than when it was irrelevant (coordination).

ACT Correlates The ACT correlated well with the APM, sharing $22 \%$ of variance ( $r=.47$ ). The total ACT-recall component correlated with the CSPAN $(r=.46)$, but was not related to either LST-DC or APM.

In efforts to understand the relationships among the data, step-wise analyses regressing each criterion measure (CSPAN, LST-DC, APM) on ACT were conducted. Results suggest different sets of unique predictors for each criterion in ways as might be expected. For CSPAN, the only ACT predictor accounting for significant variance was coordination recall. For both LST-DC and APM, control and access-random performance were unique predictors. In second models, the criterion measures not being predicted were added, but the results remained unchanged.

In order to fully explicate the ACT-Gf model, a hierarchical regression was conducted, with each condition predicting APM. Model 1, with just control items, predicted $15.3 \%$ of
variance in APM. Contrary to expectations, the coordination predictor did not account for additional unique variance in the second model $\left(\Delta R^{2}=.009, F_{l, 57}=.63, p=.431\right)$. Model 3 with access-fixed also failed to result in a significant change $\left(\Delta R^{2}=.032, \mathrm{~F}_{1,56}=2.19, p=.144\right)$, with control items and shared variance taking the majority of the contribution. However, model 4 with access-random added $6.4 \%$ of unique APM variance predicted - a significant contribution over-and-above all other variables, $\left(\Delta R^{2}=.064, \mathrm{~F}_{1,55}=4.77, p=\right.$ .03).

## Discussion

The findings for LST-DC and APM support the notion that integration is a key component of each of these tasks, drawing both on the control arithmetic (which is basic arithmetical integration) and access-random (which has the highest theoretical integration demands). CSPAN, which we have argued as capturing coordination, was related to recall in the coordination aspect of the ACT.

## General Discussion

The extant literature makes a distinction between coordination and integration functions of $W M$. We adopt a conceptualisation of coordination as the $W M$ function underlying dual-task requirements, where a storage load must be maintained despite ongoing, unrelated processing. This paradigm remains by far the most common used in investigations of the $W M-G f$ link (Ackerman et al., 2005). Process-oriented accounts of $W M$ instead focus on the capacity for integration: combining multiple representations into higher-order relational structures. Integration as a concept has been linked conceptually and empirically to $G f$ (Oberauer et al., 2008). The current work contributes to this research by investigating coordination and integration functions of $W M$ and their relationship to $G f$. A feature of our approach has been to focus on measures where the primary task is processing, rather than recall.

The LST provided mixed results on a distinction between coordination and integration. While additional load overall was incrementally predictive of $G f$, the load effect did not

depend on whether the recalled items were unrelated or related to the LST solution. However, evidence for integration was found in the DC condition, which exceeded expectations as a predictor of $G f$, improving performance while also increasing the association with APM. We replicated this in Experiment 2. This could be explained as a means of 'purifying' the LST into an assessment of raw integration, minimizing the impact of obfuscating storage demands associated with holding interim processing outcomes. DC may be a valuable tool for future use of processing tasks, in order to amplify the effect of integration.

We argued that one issue with the LST was the high integration load present in all manipulations, potentially swamping our additional load conditions by task-specific characteristics. This is especially plausible given the power of DC. The ACT was selected for Experiment 2 because those characteristics are less apparent. The ACT conditions were predictive of the criterion measures consistent with an account for a distinct coordination and integration. However, the coordination link to CSPAN only became apparent when using the recall portion of the ACT, indicating the relationship may have more to do with the outcome measure (i.e., recall) rather than a coordination function per se.

The results of the experiments support a compelling case for differentiating a specific role of integration in $G f$ over-and-above conceptualisations of $W M$ defined by CSPANs. The absence of storage in the LST-DC and other integrationbased tasks (Oberauer et al., 2008) contributes to the notion that storage maintenance is not a pre-requisite for $W M$ to be associated with $G f$, and supports process-oriented accounts of WM (Halford et al., 1998; Oberauer et al., 2007). Further, specific processing limits were alluded to in the results of access-random. That is, consistent with a relational binding approach (Oberauer et al., 2007), the random ordering forced participants to quickly and flexibly deconstruct and reconstruct the variable-value mappings from the way they were first presented into an order consistent with the way they were presented on the screen at the time of the equation. Because only this single condition could indicate binding as an ability, further research is needed to determine what processes contribute to the capacity for relational binding.

One limitation with the current results was that the DC variance could have represented a general task navigation ability (i.e., to apply the advantages of DC), as opposed to pure integration per se. It seems unlikely that such a strong unique effect (equal to $8.4 \%$ of variance in APM) could be attributed solely to DC (as opposed to any other condition), though there is no way to disprove such an explanation with the current data. Because participants could fill as many cells as they wished, we could not distinguish which cells were filled through trial-and-error and which were used as actual planning steps. This task navigation component could be explored using a variant of DC where participants are allowed only a limited number of cells to fill.

Another limitation was the LST and ACT both being integration-based tasks. While we have attempted to reconcile this by holding processing load constant in the

ACT , it is worth considering alternatives for future work. For one, it would be helpful to consider both a storage-based and a processing-based primary task, each with coordination and integration conditions. For instance, an integration version of the operation span could use numbers for the storage component, and these numbers could then be used in the processing component. While this does remove the ability to keep comparisons within a single task, it may at least provide some evidence of a coordination-integration dichotomy not restricted to processing-based tasks.

In conclusion, the current results offer mixed support for a strict coordination-integration functional dichotomy within $W M$. They do, however, provide evidence of a relational integration ability implicated within $G f$ across multiple task formats, with the storage-stripped DC set offering perhaps the strongest support. Further work is needed to determine the extent of integration across tasks; and to determine if coordination can be distinguished from mere recall.

#### Abstract

In this study, we wanted to investigate whether the processing of semantic information is easier when mapping names to pictures or is it the other way around. In order to test this hypothesis, we ran a behavioural and an ERP (Event Related Potential) study, with specific interest in the N400 component as an indicator of semantic processing. We compared three groups of participants who did a match/mismatch task with the only difference being that the labels would appear before, after or simultaneously with the pictures. Not surprisingly, the hardest condition was the one where the two information were presented simultaneously. The amplitude of the N400 was more prominent in the condition where labels were presented after the pictures in comparison to the condition where labels preceded picture presentation, suggesting that this second experimental situation led to smaller violation of expectation for our participants (word to picture condition) in comparison to mapping pictures to words.

Keywords: semantic processing; Event Related Potentials; N400; mental representations; word processing; picture processing

## Introduction

We are in constant interaction with novel and familiar objects on a daily basis. When learning about an object for the first time, we examine its visual characteristics and associate them with its name.

In this study, we wanted to investigate whether the processing of semantic information is easier when mapping names (as more abstract representations) to pictures (as more specific representations) or is it the other way around. Given that the most informative component which is well known to be sensitive to semantic processing/integration is the N 400 component it will be of our primary interest to test whether these mappings elicit differences in the N400 amplitude.

The discovery of the N400 component came in the now classical study of Kutas and Hillyard (1980) in which participants were presented with sentences (one word at a time), that ended with either congruent or
incongruent words. There were two types of incongruent endings: possible but improbable (She drinks tea with salt) or completely semantically unrelated to the previous context (She drinks tea with house). Incongruent words elicited a negative response at around 400 ms from the stimulus onset. Authors concluded that the N 400 is sensitive to context and semantic anomalies (Kutas \& Hillyard, 1980).

Since that study, different authors have reported finding the N400 in a variety of experimental tasks which required semantic processing such as match/mismatch task, semantic priming, word or picture recognition (Anderson \& Holcomb, 1995; Boutonnet, \& Lupyan, 2015; Ganis, Kutas, \& Sereno, 1996; Holcomb \& Anderson, 1993). In general, N400 is most prominent in the central and parietal regions of the scalp (Anderson \& Holcomb, 1995; Kutas \& Federmeier, 2011), but the topography changes depending on the experimental condition. For example, anterior regions are particularly active when processing pictures (Anderson \& Holcomb,1995). The latency of the component is usually in the time window of 200-600 ms from stimulus onset (Kutas \& Federmeier, 2011). The most interesting characteristic of the N 400 is its amplitude, given that it is most responsive to experimental manipulations, whereby a more negative amplitude is elicited by unexpected stimuli which are in turn harder to process (Kutas \& Federmeier, 2009).

## Semantic processing and the N400

Anderson and Holcomb used a semantic priming task in order to investigate the differences in processing of auditory and visually presented words (Anderson \& Holcomb, 1995). Word pairs (prim and target) were presented in the same modality (visual or auditory) using different stimulus onset asynchronies SOA- 0 ms , $200 \mathrm{~ms}, 800 \mathrm{~ms}$. N400 component was found in all of the experimental conditions, but lasted longer when word pairs were presented simultaneously (SOA-0 ms), suggesting that the processing of the two stimuli was
parallel.Apart from that, the highest error rates where in this experimental condition, supporting the hypothesis that it is harder to process two pieces of information at the same time.

Following a different line of research, Boutonnet and Lupyan (2015) where investigating whether visual processing of objects would be easier when they where primed with names or with nonverbal cues. In a match/mismatch task pictures of familiar animals and artifacts were preceded by their names or equally informative nonverbal cues (sound of dog barking preceding a picture of a dog). Participants were more succesful when they were cued with words, and the authors suggest that this is because words denote categories and are better at evoking mental representations which facilitates responding both to match and mismatch trials.

If in fact words evoke more general and abstract mental representations, it would be interesting to see in what way do pictures, that always represent a specific exemplar, can influence the processing of an object's name.

As previously mentioned, words can be treated as more abstract representations and refer to entire categories of objects, while a picture is always representing a single instance of an object and therefore evokes a more narrow and specific mental representation (Ković, Plunkett, \& Westermann, 2009; Ković, Plunkett, \& Westermann, 2010). Given that, to our knowledge, there are no studies directly comparing word to picture versus picture to word processing it remains unclear whether these processes differ, and if they do, which one is easier.

In order to investigate this, we constructed an experiment in which we manipulated the order of label presentation, thereby contrasting three experimental conditions: words preceding pictures, pictures preceding words, and words and pictures presented together. This allowed us to compare the processes of mapping abstract (word) to specific (pictures) representations and specific to abstract represenations by examining the amplitude of the N400 across conditions. Our hypothesis is that the hardest condition for our participants would be simultaneous presentation of words and pictures, given that they have to process two pieces of information at the same time (Anderson \& Holcomb, 1995). Furthermore, we expect that the easiest condition, which would elicit the smallest negative response, would be the pictures to words condition. Since names evoke broad mental representations (Boutonnet \& Lupyan, 2015), any picture shown after the label, no matter how typical of an exemplar it is, would most likely be somewhat different from our evoked mental representation which makes the task harder for the participant to respond. On the other hand, a picture can evoke only one name for a given object which makes the name easier to process when displayed after the picture.

## Method

## Participants

We tested sixty participants, twenty per experimental condition. Participants were psychology students at the University of Belgrade, all native Serbian speakers. They gave informed consent and received course credit for their participation. All participants reported normal or corrected-to-normal vision.

## Stimuli

The study consisted of 120 familiar, everyday objects from different categories such as: mammals, fruits, furniture, tools, clothes, etc. These objects were represented by pictures (original stimuli list taken from Kovic et al., 2009) and their coresponding labels. Labels were presented visually in order to control the duration of stimuli presentation, which wouldn't be possible in the case of auditory presentation. All stimuli were pretested and qualified as highly typical and highly familiar objects. We also conducted a naming task in which 8 participants were asked to name the objects presented in the pictures in order to ensure that there was only one appropriate name for a given picture. Hence, only pictures that were named in the same way by every participant, were included in the study.

## Experimental Design and Procedure

Participants completed 240 trials of a simple match/mismatch task. They were instructed to judge if the picture and the label represented the same object, and indicate their response by pressing one of two keys ( $C$ or $N$ ) on a keyboard (which were counterbalanced across participants). The number of match and mismatch trials was equal and the order of trials was randomized across participants. Depending on the experimental condition, participants were responding to pictures - when they were preceded by words (WP condition); words - when they were preceded by pictures (PW condition) or words and pictures when they were presented together (TO condition). The labels and pictures in the mismatch trials were from different categories and paired in a way to avoid phonological similarities and phonological onset competition (catcow); rhyme (dog-frog) as well as semantic association (cat-dog). Trials would start with a fixation cross, followed by a 700 ms presentation of word, picture, or word and picture together (depending on the experimental condition, with the difference being that in TO condition the stimuli would last until response, not only 700 ms ) after which they would see a picture or a word on which they had to respond to. The time sequence of a single trial for each experimental group is presented in Figure 1. In order to avoid preparatory movement potentials during the task a jitter of $\pm 200 \mathrm{~ms}$ for the fixation cross was introduced (Luck, 2005). According to Luck (2005) expecting a stimulus that requires a response can cause preparatory movement
potentials that are known to appear as contingent negative variations (CNV), a low frequency negative wave preceding an expected stimulus.

C Together Condition

Figure 1: Time sequence of individual trials for all three experimental conditions.

The experiment was conducted in a Faraday Cage. The participants were sitting in front of a computer, at approximately one meter distance from the screen. The stimuli were presented on a grey background at the center of the screen at eye level. Participants were instructed to avoid frequent blinking and reduce muscle movement as much as possible.

## ERP recordings

EEG signals were recorded continuously throughout the experiment. The signals were recorded from 15 electrodes placed at: F3, Fz, F4, C3, Cz, C4, P3, Pz, P4, PC5, PC6, T5, T6, O1 and O2 sites according to the international $10-20$ standard. Two electrodes were placed on the earlobes as a reference, and the ground electrode was positioned on the participant's forehead.

PSYLAB EEG8 biological amplifier in combination with PSYLAB SAM unit (Contact Precision Instruments, London, UK) were used for EEG measurements. Skin-electrode contact impedance was below $5 \mathrm{k} \Omega$ at the beginning of the trials. EEG signal amplification was 20 k and hardware band-pass filtering over the range $0.03-40 \mathrm{~Hz}$. Signals were sampled at 500 Hz using NI USB- 6212 (National Instruments, Austin TX) card for analog to digital signal conversion. For EEG signal acquisition and online display a custom software with graphical user interface developed in LabVIEW 2010 was used (National Instruments, Austin, TX, USA) (Savic,Maleševic, \& Popovic, 2013). For determining the exact moment of stimulus onset upon which we time-lock the ERPs a sensor for detecting changes in brightness was placed in the upper-left corner of the screen. The stimuli had a black square in the sensor area which was not visible to the participants. This allowed a precision of 1 ms for determining stimulus onset.

## ERP processing

Offline EEG processing was conducted using custom routines in MATLAB (version 2010a, The Mathworks, Natick, MA, U.S.A.). EEG signals from all channels were filtered using a zero-phase 4th order Butterworth bandpass filter with $0.1-25 \mathrm{~Hz}$ cut-off frequencies.
The high pass component of the filter removes near-DC drift and the low pass component filters out muscle artifacts and 50 Hz noise, along with related harmonics. Data were then segmented into epochs including 100 ms baseline prior to stimulus onset, 900 ms following stimulus onset. The baseline was corrected in all EEG channels by subtracting from each epoch the mean of a 100 ms interval prior to the stimuli onset. Epochs contaminated with ocular-movements and/or other artefacts were rejected from further analysis if absolute value of the signal from any of the channels exceeded a threshold manually determined for each subject within a range of $40-60 \mu \mathrm{~V}$ (mean value: $48 \pm 6.4 \mu \mathrm{~V}$ ). The individual event related potential was calculated for each electrode site in each of the three experimental conditions. In the case where an individual electrode contained substantial noise compared to the average signal for the participant, only that individual electrode was removed, resulting in a small number of exclusions. Only three participants (one in each experimental condition) were excluded from the study on the basis of poor EEG signal.

## Results

## Behavioral Data

Accuracy rates for all three experimental conditions were extremely high, on average participants were correct $97 \%$ percent of the time. Mixed ANOVA analysis showed no difference in accuracy across conditions, but revealed a significant effect of match $/$ mismatch $\left(\mathrm{F}(1,59)=133.33 ; \mathrm{p}<.01,{ }_{\mathrm{p}} \eta^{2}=0.72\right)$, with participants making more errors in the match (5\%) trials in comparison to mismatch trials (1\%). Regarding

RTs, we found a main effect of experimental condition $\left(\mathrm{F}(2,59)=478.86 ; \mathrm{p}<.01,{ }_{\mathrm{p}} \eta^{2}=0.95\right)$. Post hoc tests revealed that only the TO condition differed significantly from both WP and PW condition (See Figure 3.).

Figure 3. RTs for match and mismatch trials across three experimental conditions (WP-word to picture; PW-picture to word; TO-together condition)

## ERP Data

The model used for analysis consisted of 9 electrode sites: F3, Fz, F4, C3, Cz, C4, P3, Pz, P4, divided into three bands of coronal orientation (frontal-centralparietal), and three lateral regions (left-central-right). All analysis, including the determination of time windows of interest were done with difference waves. Namely, we substracted ERP wave forms of match trials from the ERP wave forms of mismatch trials in order to isolate the N400 component more accurately. For determining time windows of interest we adopted an exploratory approach to data analysis. Following the analysis of Kovic et al. (2010), mean amplitude measurements were extracted from the continuous EEG signal into 20 ms bins for each participant across all experimental conditions. Successive ANOVAs were conducted on each time bin. Windows of interest were defined if at least 3 consecutive 20 ms bins were significant ( $\mathrm{p}<.05$ ). After identification of windows, mean amplitudes across the window were computed for each experimental condition, and further analysis conducted. Two windows of interest ( $260 \mathrm{~ms}-440 \mathrm{~ms}$; $440 \mathrm{~ms}-680 \mathrm{~ms}$ ) were analysed with a $3 \times 3 \times 2$ repeated measures ANOVA with within-subjects factors of Frontality (Frontal, Central, Parietal) and Laterality (Left, Midline, Right), and between-subjects factor Time-condition (WP condition, PW condition). Given that the latency of the component of interest (namely N400) and pattern of responding was completely different between TO in comparison to WP and PW conditions, we decided to exclude the TO condition from the amplitude analysis.

Time window $260-440 \mathrm{~ms}$ We found that WP and PW condition differed in the N400 amplitude, given that there was a significant effect of Time-condition in the first time window $\left(\mathrm{F}(1,38)=6.01, \mathrm{p}<.01,{ }_{\mathrm{p}} \eta^{2}=0.14\right)$. PW condition elicited a more negative response than the WP condition (See Figure 4.) . Apart from that, we also
found a main effect of Laterality $\mathrm{F}(2,30)=79.24 ; \mathrm{p}<$ $.01,{ }_{\mathrm{p}} \eta^{2}=0.58$ ) and an interaction Laterality x Frontality $\left.\mathrm{F}(4,30)=7.86 ; \mathrm{p}<.01,{ }_{\mathrm{p}} \eta^{2}=0.18\right)$. The same effect reported here can be easily recognised in Figure 5. whereby the dark blue colour indicates the more prominent N400 effect across scalp distribution.

Figure 4. Difference waves showing the N400 and P600 effects across experimental conditions on the Cz electrode (WP-word to picture; PW-picture to word; TO-together condition)

## B Picture to Word Condition

C Word and Picture Together Condition

Figure 5. Heat maps showing time course of the distribution of the N400 and P600 effects across the scalp in all three experimental conditions. The dark blue color indicates the more negative amplitudes

Time window $440-680 \mathrm{~ms}$ A repeated measures ANOVA was conducted in order to analyze the difference of the P600 amplitude between the WP condition and PW condition. Analysis revealed a main effect of Time-condition $\mathrm{F}(1,38)=4.99 ; \mathrm{p}<.01,{ }_{\mathrm{p}} \eta^{2}=$ 0.12 ) with WP condition eliciting a more positive response (See Figure 4.). Similarly to the first, earlier time window, we found a main effect of Laterality
$\left(\mathrm{F}(2,30)=4.34 ; \mathrm{p}<.05,{ }_{\mathrm{p}} \eta^{2}=0.11\right)$ and a Laterality x Frontality interaction $\left(\mathrm{F}(4,30)=8.95 ; \mathrm{p}<.01,{ }_{\mathrm{p}} \eta^{2}=\right.$ 0.19 ). Figure 5. shows the distribution of activity through time and across scalpe. Orange colour indicates the more positive responses in amplitude.

## Discussion

In this study we tested if and how the order of stimuli presentation impacts semantic processing. In particular, we tested the hypothesis that the mapping from picture to name would be easier for processing in comparison to name-to-picture mapping given that there are many instances of pictures and thus mapping a single name to multiple potential objects seemed as a harder experimental condition in comparison to mapping from a particular picture to the name (which we pretested to select the most adequate for the given object).

The results we obtained demonstrate that the hardest condition for the semantic processing is the one in which the labels and pictures were presented at the same time. This finding was in accordance with our expectations because participants needed to process both information (word and picture) in parallel, which opens possibilities of interference as well as competitive processes making the task harder. Additionally, in the together condition, there was no priming in a strict sense as in the other two conditions, which prevented participants from forming any expectations which would help them with the task. It is noteworthy to say that in this study latency of ERP response in TO condition corresponds to a time window commonly associated with the P600 component. However, unlike the P600 component, here its polarity is negative. This is why we believe it is in fact a late N400 effect, delayed because of the difficulty of the task, which was also represented through longer RTs. All of this could account for the different morphology of the N400 in the TO condition.

Regarding the other two conditions, we observed a larger N400 amplitudes in PW condition in comparison to WP condition. Thus, in accordance with our expectations we found that picture to label mapping (PW) was easier for participants to process given that the N400 amplitude was more prominent in this condition in comparison to label to picture (WP) condition.

A more parsimonious way of interpreting this data would be in terms of violation of expectation reflected through the amplitude of the N400 component. This is consistent with a hypothesis that one can predict a word from a picture with more precision than the opposite (which leads to a larger violation of expectations).

The observed pattern of results in picture to word mapping would potentially be different in the case of less typical or atypical pictures. Violation of expectation in that case would certainly be higher than observed in the current study. Similarly, when mapping from word to picture, we would also expect greater violation of expectation then the one reported in this study.

Another interesting stream of research would be to contrast WP and PW mapping in the situation of novel object formation, that is - during the process of category formation. Here, we would have better control of the variability of the objects used in the study, given that with familiar objects the variability is much higher for the pictures (then for words).

Another component that turned out to be sensitive to semantic processing in this study, was the P600 component which in relevant literature is commonly related to syntactic processing (Kotz, Frisch, von Cramon \& Friederici, 2003; Osterhout \& Holcomb, 1992). However, there are a few studies which also reported P600 to be sensitive to semantic processing and interpreted as additional processing of meaning (Frisch, Schlesewsky, Saddy \& Alpermann, 2002; Martín-Loeches, Nigbur, Casado, Hohlfeld \& Sommer, 2006).

In our study, WP condition elicited a more positive P600 response in comparison to PW condition, which would suggest the information in this condition required additional processing in the later stages. However, given that there is an ongoing debate over the meaning of P600 in semantic processing, and since this component wasn't of main interest in this study, we would reserve from making firm claims when interpreting these results.

Practical implications of this research would be that in a classical priming experiments the best way to design the experiment would be to consistently map from pictures to words (that is, from more specific to more general representations), at least in the situation when typicality, familiarity and frequency of the selected pictures are high.

## Acknowledgments

We would like to express our gratitude to prof. Suzy Styles from Nanyang Techological University in Singapore for the valuable comments she made on the study, as well as to anonimous reviewers whose suggestions were incorporated in the final version of this paper.

This research was partially supported by the Ministry of Education, Science and Technological Development, Republic of Serbia, Belgrade, Project No. 179033 and Project No. 179006.

#### Abstract

Executive function is a fundamental component of the human cognitive architecture. Here, we investigate the relationship between executive function and scientific reasoning. Eighth graders completed measures of three executive functions (EFs): shifting, inhibiting, and updating. They also completed a measure of cognitive flexibility, the Wisconsin Card Sort Task (WCST), that has predicted scientific reasoning in prior studies. Scientific reasoning was measured by a standardized test of science achievement. A principal components analysis found that the three EFs were separable. Different EFs predicted different aspects of cognitive flexibility; notably, participants with poor shifting ability made more perseverative errors. Both EF and WCST predicted science achievement. Of note was the finding that better updating (i.e., working memory) was associated with higher science scores. These findings illuminate the role of EF in cognitive flexibility and scientific reasoning, and point the way to future studies of the effect of training EF on science achievement.

# Contrasts in reasoning about omissions 

Paul Bello, Christina Wasylyshyn, Gordon Briggs, Sangeet Khemlani \{paul.bello, christina.wasylyshyn, gordon.briggs.ctr, sangeet.khemlani\}@nrl.navy.mil<br>Naval Research Laboratory, Overlook Ave. S.W.<br>Washington, DC 20375 USA

#### Abstract

Omissions figure prominently in causal reasoning from diagnosis to ascriptions of negligence. One philosophical proposal posits that omissions are accompanied by a contrasting alternative that describes a case of orthodox (nonomissive) causation (Schaffer, 2005; Bernstein, 2014). A psychological hypothesis can be drawn from this contrast view of omissions: by default, humans should interpret omissive causations as representing at least two possibilities, i.e., a possibility representing the omission and a possibility representing a contrast. The theory of mental models supposes that reasoners construct only one possibility (the omission) by default, and that they consider separate alternative possibilities in sequential order. Two experiments test the contrast hypothesis against the model theory, and find evidence in favor of the model-theoretic account.

Keywords: omissive causation; mental models; reasoning; contrasts

## Introduction

A mechanical failure in a car to start causes a missed meeting. A friend's broken promise causes hurt feelings. The lack of rainfall causes drought. Each is a case of omissive causation, where an omission or lack of some event brings about some effect. Take the following oft-cited example:

> You come home after a business trip to find your rosebushes desiccated and ruined. You learn from your neighbor that your gardener did not show up to water the plants.

Omissive causes feature in both prediction and explanation. Intuition suggests that the death of the roses is explained by the failure of the gardener to show up. Similarly, we would expect that future failures of this kind would yield the same result. And omissions are often invoked in moral judgment. If you had signed a contract with the gardener and were especially litigious, you would have grounds to sue for damages. While we take for granted the fact that omissions are causes, omissions pose deep puzzles for theorists who wish to treat them in much the same way that "orthodox" (i.e., non-omissive) causes are treated.

It seems reasonable to think that orthodox causation concerns relations between events. But omissions are nonevents, and it is unclear how a non-event can be an argument to a causal relation. One idea is that omissions could be nothing at all (Clarke, 2014; Beebee, 2004), but this notion fails to explain why omissions seem to serve as sensible causal agents, as in, e.g., the lack of medicine caused sickness. If omissions were nothing, then they
couldn't be thought of as causes. Another proposal is that omissions denote a non-actualized possibility (Bernstein, 2014), such as that of the gardener showing up to water the bushes. Bernstein invokes the machinery of possible worlds to argue that omissions involve "counterpart relations" between actual omitted events and non-actualized contrast events at close-by possible worlds. A related idea in Schaffer (2005) is that omissions represent actual events, e.g., the event that occurred instead of the gardener showing up. The shared assumption from these latter two proposals about the nature of omissions is that they are definable in terms of contrasts between events (Schaffer, 2005), or between the omitted event and a non-actualized possibility (Bernstein, 2014).

Bernstein and Schaffer's accounts, while distinct, share the surface similarity of basing omissions on contrasts. In both cases, each theorist argues that an adequate metaphysics of omissions ought to not run afoul of human intuitions. In this spirit of consilience between intuition and metaphysical theorizing, it is worth exploring whether or not contrasts are present in mental representations of omissive causes and the inferences reasoners draw from them. The present paper explores if and how statements about omissions automatically refer to representations of contrasting events. Evidence from the psychology of counterfactual reasoning suggests that reasoners are in principle capable of maintaining two separate possibilities (Byrne, 2005), but whether they do so for reasoning about omissions remains unknown. If a strict interpretation of the contrast view is correct, reasoners should interpret omissive causation as referring to two representations by default.

In what follows, we review a psychological account of omissive-causal reasoning with mental models (Bello \& Khemlani, 2015). The theory predicts that reasoners tend to interpret omissive causation as referring to a single possibility: one in which the omitted event happens (e.g., the gardener fails to water the flowers), and the result follows (e.g., the flowers die). The theory posits that reasoners can potentially think about other possibilities including contrasts, e.g., the situation in which the gardener waters the flowers and they don't die, or the situation in which the gardener waters the flowers and they die for some other reason. But these alternative possibilities demand additional effort, and so by initially considering only one (non-contrasting) possibility, reasoners reduce the load on their working memories.

We describe two studies that test between the different hypotheses. The experiments support the model-based account in which reasoners do not represent contrasting possibilities by default, but instead consider alternatives
sequentially and in a systematic order. The paper concludes by discussing other puzzling aspects of omissive causation and plans for future research.

## The model theory

The mental model theory of reasoning - or "model theory" for short - posits that reasoners draw conclusions by building and scanning mental models, or iconic representations of possibilities (Johnson-Laird, 2006; Johnson-Laird \& Byrne, 1991, Goldvarg \& Johnson-Laird, 2001; Goodwin \& Johnson-Laird 2005). The model theory makes three central assumptions:

1. The principle of iconic possibilities. The contents of perception, memory, language, or imagination yield models, i.e., sets of discrete possibilities. Models are iconic, i.e., they are isomorphic to the structure of what they represent (Peirce, 19311958, Vol. 4), but they can also contain abstract tokens, such as a symbol denoting negation (Khemlani, Orenes, \& JohnsonLaird, 2012). And they can represent temporal sequences of events as discrete possibilities that unfold in time the way events do (Khemlani \& Johnson-Laird, 2013).
2. The principle of parsimony. Models require maintenance in working memory, and so inferences that demand more models are more difficult and take longer than those that demand fewer models. Hence, the theory posits two primary systems for reasoning: a fast system builds and scans models without the use of working memory, and so it posits that reasoners tend to reason with a single mental model in most scenarios. A slower system revises and rebuilds models, and it searches for alternative models consistent with the premises. It can correct the errors and biases that the fast system yields, but it is subject to the limitations of working memory.
3. The principle of truth. Reasoners initially build models that represent only what is true in a compound clause, and not what is false. They can flesh out the initial mental models to yield a set of fully-explicit models, i.e., those possibilities that denote both true, false, possible, and impossible scenarios. Fullyexplicit models form a complete representation of the possibilities to which a statement refers.

To illustrate these three principles, we now turn to summarizing the theory of omissive causation presented in (Bello \& Khemlani, 2015).

## A model-based account of omissive causation

According to the model theory, different sorts of causal verbs refer to different sets of mental models (Goldvarg \& Johnson-Laird, 2001; Khemlani, Barbey, \& Johnson-Laird, 2014). For instance, the statement, acid causes flowers to die, refers to three separate possibilities that constitute a fully-explicit model, which can be depicted in the following diagram:

$$
\begin{array}{rr}
\begin{array}{r}
\text { acid } \\
\neg \text { acid } \\
\neg \text { acid }
\end{array} \quad \neg \begin{array}{r}
\text { death } \\
\text { death }
\end{array} \\
\text { death }
\end{array}
$$

Each row of the diagram represents a different temporallyordered possibility that renders the statement true. Hence, the first row denotes the possibility in which acid is introduced and the flowers die; and the latter two rows denote possibilities in which acid isn't introduced and the flowers do not die (row 2) or die anyway (row 3). The model does not represent situations inconsistent with the statement (e.g., the situation in which acid is introduced and the flowers do not die, or any situation in which death occurs before acid is introduced). Moreover, maintaining three separate possibilities is difficult for reasoners, and the principle of parsimony implies that most reasoners only construct the first possibility, i.e., the mental model:
acid death

The mental model can be scanned and combined with other premises to yield inferences rapidly, but reasoners who rely on the mental model alone are prone to make reasoning errors on certain inferences. Moreover, each additional model in the set of fully-explicit models above demands working memory resources, and reasoners should be progressively less likely to consider them.

Omissive causation operates similarly to orthodox causation under the model theory, with the proviso that omissions imply that the antecedent events are negated (Bello \& Khemlani, 2015) and negations increase difficulty (Khemlani et al., 2012). For instance, the statement, the lack of water causes flowers to die, refers to the following mental model:

$$
\neg \text { water death }
$$

which can be fleshed out into the following fully-explicit models:

$$
\begin{array}{lr}
\neg \text { water } \\
\text { water } \\
\text { water }
\end{array} \quad \neg \begin{aligned}
& \text { death } \\
& \text { death }
\end{aligned}
$$

And so, just as in the case of orthodox causation, the model theory predicts that reasoners should often build only the mental model (i.e., the possibility in which there is a lack of water and the flowers die). Those who consider additional possibilities should construct the second possibility less often than the first, and the third possibility less often than the second.

## Models and contrasts

Do omissive causes entail contrasts? If so, then a central assumption of the model theory would be incorrect. That is, a default representation of contrasts would imply that statements such as the lack of water causes flowers to die should refer to the following two models:

$$
\begin{array}{cr}
\neg \text { water } \\
\text { water } & \quad \begin{array}{l}
\text { death } \\
\text { death }
\end{array}
\end{array}
$$

instead of just one mental model (see above). Reasoners do appear to consider the contrasting possibility often. In recent studies by Briggs and colleagues, participants evaluated
omissive causal relations (of a structure akin to: the lack of $A$ causes $B$ ) by assessing whether four separate scenarios (not- $A$ and $B, A$ and not- $B, A$ and $B$, and not- $A$ and not- $B$ ) were possible given the truth of the relation. Participants in one study, for instance, selected not- $A$ and $B$ at ceiling, and they selected $A$ and not- $B$ close to ceiling ( $98 \%$ and $83 \%$, respectively; see Briggs et al., under review, Experiment 3). The preponderance of $A$ and not- $B$ responses lends some tentative support to the idea that omissions are understood in terms of contrasts, as some metaphysicians have suggested. But, the data are also consistent with the view that reasoners select the contrasting possibility ( $A$ and not$B$ ) only after considering the mental model (not- $A$ and $B$ ) first. No studies directly test between the contrast view and the model theory, and so we carried out two experiments in which reasoners made inferences about omissive causation. Certain inferences should be less error-prone if reasoners represent contrasting possibilities, but Experiment 1 showed no such improvement. Experiment 2 showed that reasoners spontaneously generate contrasting possibilities less often and after - they represent possibilities corresponding to mental models. Both studies support the predictions of the model theory.

## Experiment 1

Experiment 1 tests reasoners' inferences about the pattern of reasoning known as modus tollens, which is an inference in sentential logic of the following form:

## If A then C .

Not C.
Therefore, not A.
The inference is valid because it is true in every case that the premises are true (Jeffrey, 1981, p. 1). But, reasoners have difficulty with modus tollens inferences: they tend to respond that nothing follows from the premises instead of inferring that not $A$ follows (Nickerson, 2015, p. 41 et seq.). A causal version of the inference is as follows:

## Overexposure to UV light causes snowblindness. A particular mountaineer doesn't have snowblindness. What follows?

A valid conclusion from these premises is that the mountaineer isn't overexposed to UV light. But, even in the causal domain, many reasoners have difficulty generating the valid conclusion, and they instead respond that nothing follows (Cummins, Lubart, Alksnis, \& Rist, 1991). The model theory explains why: if reasoners represent only a single mental model of overexposure to UV light causes snowblindness, e.g.,
UV-overexposure snowblindness
then that single possibility does not correspond to the possibility referred to in the second premise: a mountaineer doesn't have snowblindness. And so, reasoners respond that nothing follows. Only those reasoners who construct the fully explicit models of the causal relation:

$$
\begin{array}{rr} 
& \text { UV-overexposure } \\
\neg \text { UV-overexposure } & \neg \text { snowblindness } \\
\neg \text { snowblindness } \\
\neg \text { UV-overexposure } & \text { snowblindness }
\end{array}
$$

can make the valid deductive inference, because the second premise corresponds to the second possibility above.

The same prediction, mutatis mutandis, holds for omissive causal relations. Consider the following inference:

A lack of vitamin C causes scurvy.
A particular sailor doesn't have scurvy.
What follows?
If, as the model theory predicts, reasoners represent only a single mental model, e.g.,

$$
\neg \text { vitamin-C scurvy }
$$

then they should have difficulty drawing a valid conclusion from the premises. If, however, reasoners construct both the mental model and its contrasting possibility, e.g.,

$$
\begin{array}{rr}
\neg \text { vitamin-C } & \text { scurvy } \\
\text { vitamin-C } & \neg \text { scurvy }
\end{array}
$$

then they should be more likely to make the valid conclusion that the sailor doesn't have a vitamin $C$ deficiency. Hence, the contrastive view of omissive causation predicts that reasoners should respond more accurately on modus tollens inferences when they concern omissions than when they concern orthodox causation.

To test this prediction, participants in Experiment 1 wrote out their natural responses to short vignettes concerning omissive and orthodox causal reasoning arguments.

## Method

Participants. Thirty participants volunteered through the Amazon Mechanical Turk online platform (see Paolacci, Chandler, \& Ipeirotis, 2010, for a review). Fourteen participants reported no formal logic or advanced mathematical training and the remaining reported introductory to advanced training in logic. All participants were native English speakers.

Design, procedure, and materials. Participants carried out the experiment on a computer screen. The study was designed in psiTurk (Gureckis et al., 2015). After reading instructions, participants completed eight experimental problems. Half the problems concerned omissive causation by making use of the word "absence" to establish an omission; and the other half concerned orthodox causation by using the word "presence". Each problem comprised two premises. The first premise always established the presence or absence of a causal relation (e.g., $A$ causes $B$ ). For half of the problems, the second premise asserted that the event $(B)$ occurred (and therefore allowed participants to draw an inference known as affirming the consequent), and for the other half, the premise asserted that the event did not occur (not-B), and so participants could draw a modus tollens inference. Participants wrote out responses to the question "What, if anything, follows?" An example problem is as follows:

```
Suppose the following statements are true:
    1. The [presence/absence] of a particular part causes a
        machine to fail.
    2. On a particular day, the machine [did/didn't] fail.
What, if anything, follows?
```

The information for each problem was presented simultaneously, and participants were prevented from continuing to the next problem until they typed in at least one possibility. Participants were informed that they should write out that "nothing followed" if they thought there was not enough information in the premises to make any conclusion with certainty. The materials were drawn from four domains: biology, nature, socioeconomics, and mechanics. The presentation order of the content and problem type of the vignettes was randomized.

## Results and discussion

Two coders blind to the predictions of the study judged whether participants' natural responses were accurate or inaccurate; they agreed on $99 \%$ of trials (Cohen's $\kappa=.99$ ). Table 1 shows the percentage of accurate responses in Experiment 1 as a function of whether the inference concerned omissive or orthodox causation. Across the study as a whole, participants produced more accurate responses for orthodox causation than for omissive causation ( $47 \%$ vs. $32 \%$ correct; Wilcoxon test, $z=2.49, p=.01$, Cliff's $\delta=$ .15), which is the opposite of the pattern predicted by the contrast view. As in previous studies (e.g., Cummins et al., 1991), participants produced more accurate responses for modus tollens inferences than for affirming the consequent inferences ( $63 \%$ vs. $15 \%$ correct; Wilcoxon test, $z=6.65, p$ $<.0001$, Cliff's $\delta=.48$ ). The interaction between the type of causation and the type of inference was not reliable (Wilcoxon test, $z=.64, p=.52$, Cliff's $\delta=.03$ ).

Participants in Experiment 1 violated the prediction of the contrast view: they were less accurate for inferences concerning omissive causation than for those concerning orthodox causation. Indeed, their patterns of inference corroborate the model theory, which predicts that inferences about omissive causes should be slightly more difficult because reasoners represent negated possibilities.

|  | Type of causation |  |
| :--- | :---: | :---: |
| Inference | Orthodox <br> The presence <br> of $A \ldots$ | Omissive <br> The absence of <br> A... |
| Affirming the consequent: |  |  |
| A causes B. B. |  |  |
| What, if anything, follows? | $22 \%$ | $8 \%$ |
| Modus tollens: <br> A causes B. Not B. <br> What, if anything, follows? | $72 \%$ |  |

Table 1. Proportion of correct responses in Experiment 1 as a function of the type of inference and the type of causation.

## Experiment 2

Experiment 1 concerned inferences, and its results suggest that reasoners do not make use of contrasting possibilities in their modus tollens or affirming the consequent inferences. But, the data do not conclusively establish whether or not reasoners represent the contrast by default. After all, people might initially represent such possibilities but fail to consider them when drawing inferences. Hence, Experiment 2 tested reasoners' interpretations of omissive causation directly. It elicited natural responses to the different possibilities for orthodox and omissive cause and enabling conditions. Participants read a single short premise and were asked to list the possibilities that correspond to each premise. We analyzed the order in which participants constructed each possibility, as well as the first possibility they constructed. The contrast view predicts that reasoners should construct the possibilities that correspond to not-A and $B$ and $A$ and not- $B$ equally often when they interpret omissive causation. The model theory predicts that reasoners should construct the possibility that corresponds to not- $A$ and $B$ first, then (if at all) the possibility that corresponds to $A$ and not- $B$, and finally (if at all) the possibility that corresponds to $A$ and $B$. And the theory predicts an analogous trend in latencies: reasoners should build not- $A$ and $B$ faster than $A$ and not- $B$, and they should build $A$ and not- $B$ faster than $A$ and $B$.

## Method

Participants. Thirty-one participants volunteered through the Amazon Mechanical Turk online platform. Twenty-two participants reported no formal logic or advanced mathematical training and the remaining reported introductory to advanced training in logic. All were native English speakers.

Design, procedure, and materials. Participants completed two practice problems and eight experimental problems, and they acted as their own controls. Each problem presented one premise that consisted of two events and a causal verb. The experiment manipulated whether the first event concerned orthodox or omissive causation: half the problems used the word "presence" and the other half used the word "absence." The experiment also manipulated the relevant causal relation: half the problems concerned causation and half concerned enabling conditions, though for brevity we analyze only those problems concerning causation below. An example problem is as follows:

> Suppose the following statement is true: The [presence/absence] of a particular preservative [causes/enables] a substance to decay.
> What is possible given the above statement?

Participants were then asked to construct a list of possibilities using pre-populated drop-down menus. Figure 1 shows an example of the interface used in Experiment 2. Participants could choose any combination of the possibilities from the drop-down menus, they could change

Figure 1. The interface used to elicit responses in Experiment 2. Participants completed sentences using drop-down menus and added possibilities using a button marked " + ".
their answer choices at will, and they could add additional sentences if they thought the statement was true in a number of possibilities; but, the interface allowed the construction of at most four different sentences. The presentation order of the trials was randomized. The order in which the participants endorsed possibilities was recorded, as was the latency between when the premises appeared and when participants pushed a button to finish the trial.

## Results and discussion

Table 2 shows the percentage of trials on which participants constructed the four possible sentences as a function of whether the premise in the trial concerned an orthodox or an omissive causal relation. The table also shows, in parentheses, the percentages of trials on which a given sentence appeared first in the set of sentences constructed by the participants.

For omissive causation trials, participants constructed not$A$ and $B$ more often than $A$ and not- $B(85 \%$ vs. $69 \%$, respectively; Wilcoxon test, $z=2.88, p=.003$, Cliff's $\delta=$ .03 ), in violation of the contrast view. Instead, the data corroborate the trend predicted by the model theory; participants constructed not-A and $B$ most often ( $85 \%$ of trials), then $A$ and not- $B(69 \%)$, then $A \& B(47 \%)$, and rarely not- $A$ and not- $B$ (19\%). A nonparametric trend test revealed a significant trend in their responses (Page's trend test, $z=5.16, p<.0001$ ).

One way of understanding participants' performance is to examine only the first sentence in the set of sentences they constructed: doing so allows for a coarse analysis of their online preferences for possibilities. Participants constructed not- $A$ and $B$ as a first sentence more often than $A$ and not- $B$

| Type of <br> causation | The four sentences (in abbreviated form) |  |  |  |
| :--- | :---: | :---: | :---: | :---: |
|  | $A \& B$ | $A \& \neg B$ | $\neg A \& B$ | $\neg A \& \neg B$ |
| Orthodox | $100(100)$ | $6(0)$ | $31(0)$ | $74(0)$ |
| Omissive | $47(26)$ | $69(26)$ | $85(48)$ | $19(0)$ |

Table 2. Percentages of trials on which participants in Experiment 2 constructed four separate sentences for trials that concerned omissive and orthodox causal relations. ' $\neg$ ' denotes negation. In parentheses: percentages of trials on which a sentence appeared first in the set constructed by participants. (Not shown: data from trials that concerned enabling conditions.)
( $48 \%$ vs. $26 \%$, respectively; Wilcoxon test, $z=2.06, p=$ .04; Cliff's $\delta=.22$ ). And they constructed $A$ and not- $B$ and $A$ and $B$ equally as often ( $26 \%$ vs. $26 \%$ ). We recorded the latency between when the premises appeared to when participants made a response. While those latencies are inflated to include the amount of time they read the premises, they nevertheless revealed that participants were faster to construct not- $A$ and $B(26 \mathrm{~s})$ as a first sentence compared to $A$ and not-B (38 s); a test on their overall selections corroborated the trend predicted by the model theory (Jonckheere's trend test, $z=2.95, p=.001$ ).

Participants' responses to orthodox causal relations likewise corroborated the predictions of the model theory. Every participant responded $A$ and $B, 74 \%$ of participants responded not- $A$ and not- $B$, and $31 \%$ of participants responded not- $A$ and $B$ (Page's trend test, $z=3.54, p<$ .001). And, every participant constructed $A$ and $B$ first.

The results largely corroborate the predictions of the model theory. The significant trends in the proportions of constructing the different sentences suggest that reasoners consider possibilities sequentially.

## General discussion

Two experiments showed that when people interpret and reason about omissive causal relations, they do not represent contrasting alternatives by default. Reasoners can, in principle, hold two separate possibilities in mind - they seem to do precisely that when reasoning about counterfactual assertions (Byrne, 2005). But, as the present studies show, they tend to interpret omissive causes as referring to a single model of a negated cause and its associated effect (Experiment 1). When they are asked to list possibilities, they list the mental model earlier, more often, and faster than contrasting possibilities (Experiment 2). These results corroborate the model theory of omissive causation (Bello \& Khemlani, 2015; Briggs et al., under review), and no alternative theory of omissive causation, whether psychological (Wolff et al., 2010) or philosophical, presently account for the results from the two studies.

The model theory provides a specific ordering on what kinds of possibilities reasoners consider. It is a process theory that explains why some possibilities (the mental models) are considered by default and why others (the alternative models) demand additional cognitive resources to construct. And it provides some constraints on the contents of alternative properties, though the specific contents depend on the semantics of the particular verbs used to describe omissive-causal premises.

How are contrast events identified in the first place? Both Bernstein and Schaffer highlight this open question, and they suggest that its answer is critical for shoring up their respective theories. Philosophers who interpret omissive causation using possible worlds are faced with developing a theory that specifies how to pick through the infinitude of possible worlds to find those that contain the most relevant contrast event. Actual-event theorists like Schaffer shoulder the same explanatory burden. To illustrate, it is perfectly
reasonable to think that the Queen of England might have shown up to water the rosebushes. This would have prevented their death, after all. Does her failure to do so qualify her as an omissive cause of their dying? What explains why the gardener's failure to do so is a better candidate for the actual cause of their death?

Recent work shows norms and pragmatics help establish relevant contrasts when reasoning about omissions (see Henne, Pinillos, \& De Brigard, 2016). Analogously, the model theory posits that background knowledge of the meanings of words and their contexts can introduce relations and block the construction of certain possibilities in a process known as modulation (Johnson-Laird \& Byrne, 2002). For instance, reasoners often infer a temporal relation from the conjunction, Mary studied and she passed her test, such that she studied before she passed her test (Juhos et al., 2012). In the case of omissive causes, modulation may rely on knowledge of norms to introduce relations or contents for the different contrasting possibilities, and future work will investigate the processes by which norms bias the representation of omissive causes.

## Acknowledgments

This work was supported by grants from the Office of Naval Research to PB and SK. We are grateful to Knexus Research Corporation for their help in conducting the experiments, and we are especially grateful to Ruth Byrne, whose research on counterfactual inferences inspired the design of Experiment 1. Finally, we thank Monica Bucciarelli, Felipe de Brigard, Todd Gureckis, Paul Henne, Laura Hiatt, Phil Johnson-Laird, Greg Murphy, L.A. Paul, Bob Rehder, and Greg Trafton for their advice and comments.

#### Abstract

People often use spatial vocabulary to describe temporal relations, and this has increasingly motivated attempts to map spatial frames of reference (FoRs) onto time. How people assign FRONT to time and to temporal entities depends on cultural conventions, and is crucial for diagnosing which temporal FoR a person actually adopts. Here, we report findings from a survey with speakers of Norwegian that aimed at assessing the cultural conventions involved in FRONT assignment. Data on temporal movements of events, on the temporal order of events, and on explicit FRONT assignments to events, time units, and "time itself" suggest that participants use different principles for describing fixed relations (static time) versus moving events (dynamic time).

Keywords: space; time; space-time mapping; frames of reference; mental timeline.

## Introduction

When talking about time, people tend to do so with vocabulary and concepts borrowed from the domain of space. Yet, while research in the two domains and the acknowledgement of cross-domain transfers do have a venerable tradition (reviewed in Núñez \& Cooperrider, 2013), the challenge of mapping a taxonomy of spatial representations onto the domain of time has been taken up only recently, and respective attempts differ considerably in terms of theoretical conceptualization and subsequent interpretation of data. Based on a review of advances in this field, we outlined how such taxonomies may be transferred from space to time (Bender \& Beller, 2014), with a focus on accounts that deal with frames of reference (FoRs).
Taking Levinson's (2003) well-established taxonomy of spatial frames of reference as starting point, the $t$-FoR account (Bender et al., 2010, 2012; Rothe-Wulf et al., 2015) derives a set of temporal frames of reference ( t -FoRs) following general design principles as described below. Yet, while these design principles provide an abstract structure for distinct frames of reference, their concrete specification depends on cultural conventions involved in how people assign FRONT to temporal entities per se. Previous accounts drew on intuitions regarding such conventions for speakers of English and related languages (such as that FRONT of an event is considered to be at its beginning). Here, we report findings from a survey that empirically assessed such conventions.

## Spatial and Temporal Frames of Reference

A frame of reference (FoR) is a coordinate system required to localize a figure $F$ in reference to a ground $G$ from an observer's point of view $V$. Levinson's (2003) taxonomy distinguishes three basic types of spatial FoRs, absolute, intrinsic, and relative, as well as different variants of the latter. In line with the underlying design principles, these FoRs can be mapped from space onto time as follows (Bender \& Beller, 2014; and see Table 1):

The absolute FoR is anchored in a superordinate field outside F, G, and V. As space itself is the superordinate field in the spatial domain, so is time in the temporal domain. Assignment of orientation to the field follows cultural conventions and may recruit, for instance, cardinal points, mountain slopes, rivers, or the land-sea axis on small islands (in the case of space), and correspondingly the asymmetry inherent in the 'arrow of time' (in the case of time), which is (presumably) pointing towards the future.

The intrinsic FoR is anchored in the reference or ground entity G and can thus only be adopted if G is perceived as being oriented itself (this includes an observer if serving as ground). Assignment of orientation again follows cultural conventions and may recruit, for instance, moving directions of objects such as cars (in space) and the beginning versus end of events (in time).

Table 1: Frames of reference and forward movements (indicated by the tips of the arrows) according to the $t$-FoR account (for more details, see Bender \& Beller, 2014), based on assumed cultural conventions for assigning FRONT in English speakers.

The relative FoR, finally, is anchored in the viewpoint V of an observer (separate from G). V's position can be established both in space (as the observer's location) and in time (as the observer's subjective present). In order to still be able to localize F in reference to G , the coordinate system primarily anchored in V needs to be shifted into G. This can be done in several ways, two of which are relevant here: the reflection variant under which FRONT is assigned to a position or time between G and V , and the translation variant under which FRONT is assigned to a position or time beyond G. In either case, FRONT assignments are point-symmetrical to the present, but have diverging directions (reflection: towards V; translation: away from V).
Each of these FoRs hinges on cultural conventions: the absolute FoR on how orientation is assigned to the superordinate field (for variation, see Núñez \& Sweetser, 2006), the intrinsic FoR on how orientation is assigned to the ground entity, and the relative FoR on which variant is preferred for shifting the primary coordinate system. So far, assumptions on these conventions are based more on intuitions than on data, especially for the domain of time. In the following, we explicate these for three Germanic languages.

## Frames of Reference in Germanic Languages

Empirical research in the spatial domain on three Germanic languages-English, German, and Swedish, (e.g., Beller et al., 2015; Grabowski \& Weiß, 1996; Majid et al., 2004)indicates that speakers of these languages make use of all basic spatial FoRs for describing locations and movements in space, with a pronounced preference in small-scale space for the reflection variant of the relative FoR and, albeit to a lesser extent, the intrinsic FoR.
In the temporal domain, the metaphorical space-time mapping emerging in language suggests a set of conventions for FRONT assignment that appear similar across the three languages. With regard to time itself (as the superordinate field in the absolute FoR), FRONT seems to be assigned to the future, as reflected in the 'arrow of time' pointing towards the future or in expressions such as "the future ahead", and "olden days passed by". With regard to events (as the ground entities in the intrinsic FoR), FRONT seems to be assigned to that part of time pertinent to the beginning of events, as reflected in expressions such as "the quiet before the storm". When it comes to the subjective viewpoint V of an observer (as the central point in the relative FoR ), it might be ventured that none of its variants are frequent in Germanic languages, as the point-symmetric patterns arising from them have been observed only infrequently (with $2.5 \%$ or less in any of the languages under investigation; see Rothe-Wulf et al., 2015).
Based on these assumptions, an absolute FoR would be diagnosed when events "in front of" other events or "moved forward" from their previous position are localized as further in the future, while an intrinsic FoR would be diagnosed when they are localized as further in the past (Table 1). Interestingly, the latter pattern has been described as canonical for all three Germanic languages for describing
fixed relations such as "the quiet before the storm" (German: "die Ruhe vor dem Sturm", Swedish: "lugnet före stormen"), while patterns in the three languages differ fundamentally when it comes to movement: Moving a meeting "forward" results in a later date (futurewards movement) for the vast majority of Swedish speakers, in an earlier date (pastwards movement) for the vast majority of German speakers, and in dissent between these variants for English speakers (Rothe-Wulf et al., 2015; and see Boroditsky \& Ramscar, 2002; McGlone \& Harding, 1998).

Whether, however, these diverging patterns can be diagnosed as arising from an absolute or intrinsic FoR, respectively, depends on whether our assumptions regarding the cultural conventions for FRONT assignment are correct. Data on this question was collected in the current study for a fourth Germanic language, namely Norwegian, for which research on spatial FoRs revealed the same preferences for references in small scale space (Beller \& Bender, 2017) as in the other three Germanic languages.

## Study

The study aimed at assessing whether and how FRONT is assigned to time itself (relevant for the absolute FoR) and to temporal entities such as events (relevant for the intrinsic FoR). We also remained open to the possibility of pointsymmetric response patterns indicative of a relative FoR.

## Methods

Participants. 81 volunteers participated in the survey; three were excluded from further analyses because they indicated a language other than Norwegian as their mother tongue. The resulting sample therefore consisted of 78 participants ( 59 female; age $M=25.3$ years, $S D=7.6$, range 19-62, with 5 not indicating their age).

Materials. The tasks described in the following were part of a larger paper-and-pencil survey, provided in Norwegian (bokmål). Here, we focus only on those tasks that are relevant for the questions under scrutiny in this paper.

The Event-Moving Task consisted of four items, with an event to be moved forward (Norwegian: fram) or backward (bakover) in time. Two items used the time scale days:

- The concert scheduled for Thursday last week was moved $\{$ forward/backward $\}$ two days. On which day of the week did it actually take place?
- The meeting scheduled for Wednesday next week will be moved \{forward/backward\} two days. On which day of the week will it now take place?
The other two items used the time scale hours:
- The departure scheduled for 9 a.m. yesterday was moved \{backward/forward\} three hours. At what time did it actually take place?
- The power cut scheduled for 4 p.m. tomorrow will be moved \{backward/forward\} three hours. At what time will it take place now?
For each time scale, a past and a future event was included;
this is necessary to be able to distinguish linear from pointsymmetric t-FoRs (cf. Table 1) that participants might adopt (Bender et al., 2010). The original scheduling of the events and the moving span were chosen so as to remain within the respective time cycle (e.g., for weekdays between Monday and Saturday), and hence to prevent ambiguous responses.

The items were implemented in four arrangements, crossing between-subjects two orders of time scales with the two moving directions. The task started either with the time scale days (first meeting, then concert), followed by hours (first power cut, then departure), or vice versa, and either with "forward" as moving direction for the first two events, followed by "backward" for the other two, or vice versa.
The Order Task consisted of six items that asked for the order of events, that is, whether a target event (figure F) is "in front of" (Norwegian: foran) or "behind" (bak) a reference event G. Four items used a forced-choice format:

- Lunch is normally ...
$\square$ in front of / $\square$ behind $\ldots$.. breakfast.
- Good Friday is two days ...
$\square$ in front of / $\square$ behind ... Easter Sunday.
- New Year's Eve is one week ...
$\square$ in front of / $\square$ behind ... Christmas Eve.
- The Stone Age was ...
$\square$ in front of / $\square$ behind ... the Middle Ages.
Two further items used an open format:
- The exam is generally nine days
\{in front of/behind \} the $17^{\text {th }}$ of May.
So, at which date does it take place?
- This year, Peter's birthday is three months \{in front of/behind \} midsummer.
So, in which month is his birthday?
The items were implemented in four arrangements, crossing between-subjects two orders of items either with two orders of response options for the items in the forced-choice format ("in front of" as the first vs. the second option) or with the two phrasings for the items in the open format ("in front of" for the birthday item and "behind" for the exam item, or vice versa). One item order was determined randomly with the second order being the exact reversal ${ }^{1}$.

The Front Task consisted of eight items that asked for indicating whether or not a time segment has a front (Norwegian: forside) or back (bakside), and if so, in which direction FRONT or BACK is pointing. All items followed the same schema and had four response options, here exemplified for the item on time in general:
\{Front/Back\} of time in general ...
$\square$ is at the beginning of time.
$\square$ is at the end of time.
$\square$ Something like that does not exist.
$\square$ Something else, namely $\qquad$ —.

As the two last response options were the same for all items, we explicate only the item-specific options for the remain-

[^278]ing items. Three items referred to the units of time day, month and year:

- $\{$ Front/Back $\}$ of today ...
$\square$ was early in the morning / $\square$ will be late at night.
- \{Front/Back\} of August ...
$\square$ is the $1^{\text {st }}$ of August / $\square$ is the $31^{\text {st }}$ of August.
- $\{$ Front/Back $\}$ of the current year ...
$\square$ was in January / $\square$ will be in December.
Four other items referred to events:
- \{Front/Back $\}$ of a meeting ...
$\square$ is at the introduction $/ \square$ is at the summary.
- $\{$ Front/Back $\}$ of a dinner...
$\square$ is at the appetizer / $\square$ is at the dessert.
- $\{$ Front/Back $\}$ of Easter ...
$\square$ is on Maundy Thursday / $\square$ is on Easter Monday.
- $\{$ Front/Back $\}$ of your life ...
$\square$ is when you were born / $\square$ is when you will die.
The items were implemented in four arrangements, crossing between-subjects two phrasings (asking for all items either for "front of X ..." or "back of X ...") with two orders of items (one random order starting with time in general, and the exact reversal ${ }^{1}$ ).

Design and Procedure. Four versions of questionnaires were constructed. The various types of tasks were presented within-subject in a fixed order (i.e., event-moving task followed by order task followed by front task) in line with the increasingly explicit nature of the task (asking for the "front" of time highlights the topic of interest more strongly than asking for the date to which an event is moved). The four item arrangements of each task were randomly assigned to one of the four versions of questionnaires, and varied between-subjects as indicated in the Materials section. Participants were instructed to work on all tasks in the given order.

## Results

For each task, we first describe how FRONT assignments were coded and then report participants' preferences.

Event-Moving Task. In this task, participants had to move an event either forward or backward in time. The responses were coded as whether they indicated that FRONT of the moving direction pointed towards the future or towards the past. For the items with "forward"-phrasing, the coding is obvious: If, for example, Wednesday's meeting is moved "forward" to Monday, then the assignment of FRONT and the moving direction points pastwards. For items with "back-ward"-phrasing, coding is reversed: If Wednesday's meeting is moved "backward" to Monday, then the assignment of FRONT and the corresponding forward direction point futurewards.

Each single item was tested first for potential influences of the order of time scales (days first vs. hours first) and the requested moving direction (forward vs. backward) on the actually chosen direction (futurewards vs. pastwards). No

Table 2: FRONT assignments (\%) in the event-moving task.

|  | Single items |  |  |  |  |
| :--- | :---: | :---: | :---: | :---: | :---: |
| FRONT <br> pointing | Concert <br> $(N=77)$ | Meeting <br> $(N=77)$ | Departure <br> $(N=77)$ | Power cut <br> $(N=76)$ | $M$ |
| futurewards | 63.6 | 71.4 | 58.4 | 68.4 | 65.5 |
| pastwards | 36.4 | 28.6 | 41.6 | 31.6 | 34.5 |
| Future/past items of time scale |  |  |  |  |  |

significant effects were found (all $G^{2} \leq 5.88 ; d f=3$; $p \geq .118$ ). Across items, futurewards movements dominated ( $65.5 \%$ on average; Table 2, upper half).

Then, we determined for each of the two pairs of items with the same time scale the pattern of FRONT assignments that resulted from considering both the future and past event as pointing futurewards, pastwards, towards V (present), or away from V (cf. Table 1). We checked whether the distribution of the four patterns for the time scale days differed from the distribution for the time scale hours, which would be indicative of an influence of time scale on temporal movements. According to a marginal homogeneity test for paired tasks, this was not the case ( $s t d$. MH statistic $=.906$, $p=.365$ ), thus justifying an aggregation across the time scales. Overall, the two linear patterns prevailed by far (Table 2, lower half). The majority of participants ( $60.8 \%$ on average) made futurewards movements, about one third ( $30.1 \%$ ) made pastwards movements, while of the two point-symmetric patterns, only the one with moving directions away from V (present) was chosen (9.2\%).

Order Task. In this task, participants had to specify whether a target event is "in front of" or "behind" a reference event. The responses were coded as whether they indicated that FRONT of the reference event was assigned to the end of the event, and hence pointing towards the future, or to the beginning of the event, pointing towards the past. For instance, Good Friday is always earlier in the year than Easter Sunday. The response "Good Friday is in front of Easter Sunday" therefore implies that FRONT of Easter Sunday is assigned to its beginning and points pastwards. With lunch as target event in reference to breakfast, coding would be reversed: As lunch is the later event, the response "Lunch is in front of breakfast" implies that FRONT of breakfast is assigned to its end and points futurewards.

Each item was tested first for potential effects of two factors on the coded FRONT of the event: the order of items (for all 6 items) and either the order of response options (for the 4 items with forced-choice format) or the phrasing (for the 2 items with open format). For the forced-choice items, no
significant effects were found (all $G^{2} \leq 3.77 ; d f=1$; $p \geq .052$ ). With some variation between events, the majority of responses indicated that FRONT of an event was assigned to its beginning and pointed pastwards ( $83.6 \%$ on average; Table 3, upper half). For the items with open format, main effects of the phrasing were found $\left(G^{2} \geq 12.95 ; d f=1\right.$; $p<.001$ ). Responses indicating that FRONT pointed pastwards were more frequent when participants had to specify whether the target is "in front of" the reference event $(100 \%)$ than when they had to specify whether the target is "behind" the reference event ( $76.4 \%$ on average; Table 3, lower half) ${ }^{2}$.

Finally, we determined how consistently the two possible FRONT assignments were made across the whole set of items. To this end, we counted for each participant how often FRONT pointed futurewards and how often it pointed pastwards. FRONT assignments were highly consistent. Participants used the same type of assignment on 5.17 (86.1\%) of the 6 items. Overall, 65 participants $(83.3 \%)$ had a preference for a pastwards directed FRONT and four participants (5.1\%) for a futurewards directed FRONT; the remaining 9 participants (11.5\%) had no preference.

Taken together, the results from the order task support the idea that FRONT of a time segment is at its beginning and that it points towards the past, at least for most of the participants. While in this task FRONT assignments were assessed indirectly from the order of events, the next task explicitly asked participants to indicate the "front" or "back" of events, time units, and time in general.

Front Task. In this task, participants had to specify whether "front" (or "back" respectively) of a temporal entity is at its beginning, at its end, does not exist, or something else. FRONT assignments were coded in four categories, with FRONT pointing futurewards, or pointing pastwards, is nonexistent, or something else ("other"). For the items asking to indicate the "front" of an event, coding is again obvious:

Table 3: FRONT assignments (\%) in the order task.

|  | Items with forced-choice format |  |  |  |  |  |
| :--- | :---: | :---: | :---: | :---: | :---: | :---: |
| FRONT <br> pointing | Lunch <br> $(N=77)$ | Good Friday <br> $(N=78)$ | New Year <br> $(N=78)$ | Stone Age <br> $(N=78)$ | $M$ |  |
| futurewards | 14.3 | 16.7 | 9.0 | 25.6 | 16.4 |  |
| pastwards | 85.7 | 83.3 | 91.0 | 74.4 | 83.6 |  |
| Items with |  |  |  |  |  | open format |
| FRONT | Exam $(N=41,37)$ |  |  |  |  |  |
| pointing | In front of | Behind | In front of | Behind |  |  |
| futurewards | - | 21.6 | - | 25.7 | 11.6 |  |
| pastwards | 100.0 | 78.4 | 100.0 | 74.3 | 88.4 |  |

[^279]Choosing, for example, the beginning as the "front of the event" implies that FRONT points towards the past. For the items asking to indicate the event's "back", coding was reversed: Choosing the beginning as its "back" implies that Front is assigned to the end of the event and points towards the future. Therefore, the response "the back of a meeting is at the summary" implies that FRONT is assigned to the beginning of the meeting and hence points towards the past.

Each item was tested first for potential effects of the phrasing and the order of items on the coded FRONT. A main effect phrasing was found in all cases (all $G^{2}>8.03 ; d f=3$; $p<.046$ ), a main effect order of items in three cases (life, year, and time; $G^{2}>9.38 ; d f=3 ; p<.025$ ), and an interaction of the two factors in two cases (dinner and Easter; $\left.G^{2}>11.15 ; d f=3 ; p<.011\right)$.
A joint log-linear analysis of the four event items (meeting, dinner, Easter, and life) suggested that the model phrasing $\times$ order of items was the simplest model that fitted the data ( $G^{2}=39.69$; $d f=36 ; p=.309$ ), justifying the aggregation across these items. As in the order task, a pastwards directed FRONT occurred more frequently when participants had to specify the "front" of an event (as compared to the "back"), but this was the preferred response only when the task did not begin with the item on time in general (cf. Table 4). In the other cases, the majority of participants indicated that something like "front" does not exist. Among the two directions future- and pastwards, pastwards assignments clearly prevailed ( $87.2 \%$; 129 of 148 responses).

A joint log-linear analysis of the four time and units items (day, month, year, and time) suggested again that the model phrasing $\times$ order of items was the simplest model that fitted the data ( $G^{2} \geq 40.903$; $d f=36 ; p=.264$ ), justifying to aggregate the data across these items. The results were quite similar to those from the event items: The pastwards directed FRONT occurred more frequently when participants had to specify the "front" of an event (as compared to the "back"), but this was the preferred response only when the

Table 4: front assignments (\%) in the front task.

| Front (pointing) | Order of items |  |  |  |
| :---: | :---: | :---: | :---: | :---: |
|  | Time item first |  | Time item last |  |
|  | Phrasing |  | Phrasing |  |
|  | Front | Back | Front | Back |
|  | Event items (meeting, dinner, Easter, life) |  |  |  |
| futurewards | - | 7.4 | 2.5 | 15.2 |
| pastwards | 39.8 | 30.9 | 73.8 | 20.3 |
| Nonexistent | 51.8 | 50.0 | 13.8 | 53.2 |
| Other | 8.4 | 11.8 | 10.0 | 11.4 |
|  | Unit items and time (day, month, year, time) |  |  |  |
| futurewards | 2.4 | 13.6 | - | 20.0 |
| pastwards | 35.7 | 18.2 | 81.3 | 12.5 |
| Nonexistent | 53.6 | 51.5 | 18.7 | 65.5 |
| Other | 8.3 | 16.7 | - | 5.0 |

task did not begin with the item on time in general. In the other cases, a majority of participants indicated that something like "front" does not exist. Among the two directions future- and pastwards, pastwards assignments again prevailed ( $81.3 \%$; 117 of 144 responses). This pattern includes the item on time in general. Futurewards directed FRONT assignment, which was the prevailing pattern in the eventmovement task ( $65.5 \%$ ) (cf. Table 2), occurred rarely when asked explicitly, and almost only when "back" had to be indicated ( 6 of 37 responses $=16.2 \%$ ).

Finally, we determined how consistently different responses were given across the whole set of items. To this end, we counted for each participant how often FRONT pointed futurewards, how often it pointed pastwards, and how often it was declared as nonexistent. Responses were fairly consistent. Participants gave the same type of response on 6.37 ( $79.6 \%$ ) of the 8 items. 29 participants ( $37.2 \%$ ) had a preference for a pastwards directed FRONT, and four participants (5.1\%) for a futurewards directed FRONT; 31 participants ( $39.7 \%$ ) were consistent in declaring that something like "front" or "back" does not exist; the remaining 14 participants ( $17.9 \%$ ) had no preference.

Taken together, the front task yields three results: First, the high number of participants indicating that something like FRONT or BACK does not exist for temporal entities is eye catching. Second, if FRONT was assigned to an entity at all, then it was assigned to its beginning and pointed towards the past. Finally, this tendency was also found for the item representing time in general.

## Discussion

Summarizing the findings across the three tasks presented here, the results indicate a preference among speakers of Norwegian for a futurewards orientation when "moving forward" an event (about 60\%), but a pastwards orientation when localizing earlier events as "before" later events (about $80 \%$ ). The latter is largely in line with the explicit assignment of FRONT to the beginning (rather than end) of events and time units-in fact, even to time itself-but assignments also depended on the order of items to some extent. These findings are surprising in at least three ways.

First, assignment of FRONT to temporal entities does not seem to follow the same principles across tasks, even though they were aimed at tapping the same underlying concepts. This is not unexpected per se, as people may have more than one timeline (Miles et al., 2011; and see Bender \& Beller, 2014, for a review of respective data). Here, the static versus dynamic nature of the tasks seems to make the difference: While the pastwards orientation prevails for fixed relations (revolving around the order or orientation of events), the futurewards orientation takes over when movement is involved. A similar pattern was observed for spatial referencing, in a task where participants had to pick the "front" token (from a set of several tokens) and move it "forward" by a given number of fields. In this case, FRONT was assigned to the token and the movement in diverging ways: closer to Ego for the former, and away from Ego for
the latter (Bender et al., 2012). Since movement itself provides orientation, it may serve as a direct source for FRONT assignment and thereby even override possibly conflicting orientations of the entities involved (Talmy, 2000). Interestingly, however, in the cases discussed here, the direction of movement is not specified beforehand, but is a consequence of FRONT assignment. This suggests that FRONT assignments follow different a priori preferences, but where these preferences are grounded in remains an open question.

Second, in the front task, time itself is treated similar to the smaller units year, month, and day, which themselves are treated similar to events in time. This appears at odds with the observation that for speakers of most languages (and especially English and related languages), FRONT is typically pointing towards the future (evidence summarized in Bender \& Beller, 2014). However, we hesitate to interpret our current data as strong evidence to the contrary for three reasons: The high proportion of "does not exist" responses observed for all items alike hints at the possibility that the phrasings (i.e., forside and bakside) have been infelicitous. Even if one were willing to assign a FRONT or BACK to a virtual, one-dimensional notion as time, assigning a whole front or back side may seem undue. In addition, the response options "beginning of time" and "end of time" may have evoked a notion of time that resembles an (excessively long) event rather than the superordinate field the item was meant to refer to. And finally, since the time question was embedded in questions on events and smaller time units, set effects may have led to an overgeneralization of assignment patterns that are applied to events.
The third way in which our findings are surprising concerns cross-linguistic patterns. What we found for speakers of Norwegian is more similar to previous findings on English than on Swedish-despite the fact that Norwegian and Swedish are much more closely related, and actually mutually understandable. Besides sharing almost identical proportions of the reflective versus translational variant of the relative FoR in the spatial domain (Beller et al., 2015; Beller \& Bender, 2017), speakers of English and Norwegian also exhibit a mix of preferences in the event-moving task, whereas speakers of Swedish strongly prefer the futurewards direction (Rothe-Wulf et al., 2015). Only in terms of relative preferences of the futurewards over the pastwards direction is Norwegian closer to Swedish.
Two conclusions may be drawn from these patterns. Most importantly, they indicate that cultural conventions are indeed crucial for establishing concrete frames of reference, as they determine how FRONT is assigned to temporal entities such as events or to time itself, both for fixed relations and for movement. In order to be able to identify which temporal FoRs people actually adopt, these conventions need to be assessed independently on an empirical basis. Furthermore, while FRONT assignment and FoR selection obviously differ across languages, it is not the languages themselves that are decisive here, but rather the agreement among their speakers, as attested to by the greater similarity of the Norwegian pattern with the English than the Swedish pattern.

This, we propose, renders the observed pattern a matter of negotiation and consensus, and hence a cultural phenomenon.

## Acknowledgments

This work was funded by the Deutsche Forschungsgemeinschaft DFG through a grant for the project Spatial referencing across languages: Cultural preferences and cognitive implications to AB (Be 2451/13-1) and SB (Be 2178/7-1). For help with data collection, we thank Marleen Wilms.

#### Abstract

In many ecologically situated cognitive tasks, participants engage in self-selection of the particular stimuli they choose to evaluate or test themselves on. This contrasts with a traditional experimental approach in which an experimenter has complete control over the participant's experience. Considering these two situations jointly provides an opportunity to understand why participants opt in to some stimuli or tasks but not to others. We present here a Bayesian model of cognitive and metacognitive processes that uses latent contextual knowledge to model how learners use knowledge to make opt-in decisions. We leverage the model to describe how performance on selfselected stimuli relates to performance on true experimental tasks that deny learners the opportunity for self-selection. We illustrate the utility of the approach with an application to a general-knowledge answering task.

Keywords: metacognitive control; Bayesian cognitive model; wisdom of the crowd; opt-in; missing not at random

## Background

In traditional approaches to experimental psychology, an experimenter has unilateral control over which stimuli a participant experiences and the tasks that they complete. Yet in many real-world situations, such as providing ratings to videos on the Internet, the participant has some or even total control over the specific stimuli and tasks that they experience. The choice behavior underlying such self-selection is an important domain of study called metacognition (Nelson \& Narens, 1990), and the self-selection of activities or stimuli is specifically called metacognitive control (Fiechter, Benjamin, \& Unsworth, 2016; Finley, Tullis, \& Benjamin, 2010). Some work on monitoring and control processes in memory tasks focused on confidence judgments as an indicator of self-selection questions (Kelley \& Sahakyan, 2003; Koriat \& Goldsmith, 1996). It is unclear precisely how this self-selection is generated, however. To better understand metacognitive control behavior, a model is needed that accounts for performance on the task of interest as well as the choice behavior that leads participants to select only some stimuli for exposure, evaluation, or testing.

The major difficulty of such an endeavor is that participants select tasks according to their interests and expertise, and so
the data is missing in a nonrandom fashion (see Little \& Rubin, 2014, for a description of other missing data scenarios). Consequently, participants can only be compared and their performance fairly evaluated if a model is specified for the opt-in process. If a participant does not opt in to a particular question, then we simply do not see that participant's response to that question.

A starting point in explaining opt-in behavior is that participants have some meta-knowledge of what it is they already know, and use that knowledge effectively in service of ongoing learning. People provide higher assessments of their ability to answer inference questions in domains in which they have greater expertise (Bradley, 1981), and learners often choose to engage more effective study techniques for material that is more difficult for them (A. S. Benjamin \& Bird, 2006). Memory reports are also considerably more accurate when respondents have the option of withholding answers that they are unsure of or of titrating the grain size of their answers to their perceived accuracy (Goldsmith \& Koriat, 2007).

Self-regulated learning often has substantial benefits in educational contexts (Mezirow, 1981; Zimmerman, 1989; Boekaerts \& Minnaert, 1999; Paris \& Paris, 2001). Learners use meta-knowledge to allocate time, resources, and activities to an array of learning goals, and this application increases overall performance compared to learners who have their learning activities dictated by an instructor (Winne \& Hadwin, 1998; Finley et al., 2010).

The benefits of self-control extend beyond these constrained tasks, however. In causal reasoning experiments, participants can more quickly understand the causal structure of a network if they intervene in the learning process and design their own "experiments" (Steyvers, Tenenbaum, Wagenmakers, \& Blum, 2003; Sobel \& Kushnir, 2006; Lagnado \& Sloman, 2004). Human strategy selection can be explained in terms of rational metareasoning, wherein humans flexibly choose strategies in accordance with their environment (Lieder \& Griffiths, 2015; Lieder et al., 2014).

The core claim across each of these examples is that selfselection within a task aimed at measuring performance is
driven by metacognitive knowledge, which leads to a higher rate of success, expertise, or interest for the selected items. This process makes it difficult to evaluate the stimuli and the participants in an unbiased way. One test-taker may, for example, outperform another not because they have greater knowledge but rather because they make more a judicious selection of problems.

Figure 1: Outline of our modeling approach. Latent knowledge and design both explain the performance on the task. In the case of a subject-chosen design, latent knowledge also explains the design.

The aim of this project is to develop a cognitive model of the metacognitive aspect of item selection. In doing so, it also provides a framework to relate performance on selfselected materials with performance on an unconstrained set of items or stimuli. Here we apply this model to data collected from participants answering general knowledge questions, but the model is considerably more general: the same principles could apply in other metacognitive control tasks, such as study time allocation or selection of items for restudy. We are aware of one current model of metacognitive control, which takes as a given the state of the world, which then causes the observed behaviors (Fleming \& Daw, 2017). We take a different approach, which starts with the latent knowledge that the participant is coming to the experiment with and uses that in both the selection process behind opting-in and the observed responses to questions, as illustrated in Figure 1 . Performance on the task is explained by both the de-sign-that is, the particular experience of the participant in the task-and the latent knowledge of the participant. In the case of a participant who can opt in to certain questions but avoid others, the design is also partially informed by the latent knowledge. We are interested in estimating the latent knowledge of each participant and evaluating how it relates both to performance on the task and to opt-in behavior. In order to infer latent knowledge from the observed data, we apply Bayes' rule in the equation below, where $\theta$ is the latent knowledge, $c$ is the experimenter design, $d$ is the subject-chosen design, $x$ are the performance data from a true experimental design (where subjects respond to all or to a random subject of probes), and $y$ are the performance data from a subjectchosen design (in which subjects choose which probes to re-
spond to):

$$
\begin{equation*}
p(\theta \mid c, d, x, y) \propto p(x \mid \theta, c) p(y \mid \theta, d) p(d \mid \theta) p(\theta) \tag{1}
\end{equation*}
$$

In a traditional cognitive model, the important part of the model is the specification of $p(x \mid \theta, c)$ and $p(y \mid \theta, d)$, termed the likelihood functions. These functions directly explain the empirical effect of interest by relating latent knowledge to performance on the task given the experimental design. The novel part of the model relates to the specification of the metacognitive control process $p(d \mid \theta)$, which explains how the participant self-designs on the basis of their latent knowledge. If we would ignore this model component, we would likely, and incorrectly, conclude that participants who selfdesigned were more knowledgeable than participants subject to the experimenter's design because they outperformed their experimenter-designed counterparts. Such an error could be catastrophic if we were trying to compare across individuals or across tests. Because subjects are randomly assigned to conditions, it is highly unlikely that they differ widely. The process by which the participants who self-designed outperformed those who could not lies in the opportunity to selfdesign. Here we see the importance of jointly modeling the selection process and the task at hand in order to understand the interplay between latent knowledge, opt-in behavior, and performance.

Since this is a task in which many participants give judgments to many questions, we also expect to find that averaging across participants leads to higher accuracy-an effect termed the wisdom of the crowd (Surowiecki, 2004; Steyvers, Miller, Hemmer, \& Lee, 2009). Here we have the opportunity to evaluate whether the opportunity to opt in to a selfselected portion of the questions will enhance or attenuate such benefits associated with averaging. Certainly, many participants will gravitate towards the same questions when they can opt in, which would potentially decrease the benefits of averaging across a crowd by virtue of reducing input to the more difficult questions. However, based on what is known about metacognition, we expect that participants will opt in to questions for which they have relevant knowledge, which could lead to a more informed set of responses to average with the remaining crowd. Crowd behavior provides an additional benchmark against which we can evaluate the performance of the metacognitive model.

## Experiment

Stimuli The question set consisted of 100 general-knowledge binary choice questions. The questions were drawn from 12 topics: World Facts, World History, Sports, Earth Sciences, Physical Sciences, Life Sciences, Psychology, Space \& Universe, Math \& Logic, Climate Change, Physical Geography, and Vocabulary. The question set was created by collecting from multiple sources. Two example questions are shown in Table 1. Based on the empirically observed accuracy levels, the first is difficult and the second is easy.

Participants A total of 83 participants were recruited through Amazon Mechanical Turk (AMT). Each participant

Table 1: Example questions.

| Difficulty Example |  |
| :--- | :--- |
| Hard | The Sun and the planets in our Solar system all rotate in the same direction because: (a) they were all formed from <br> the same spinning nebular cloud, or (b) of the way the gravitational forces of the Sun and the planets interact <br> Greenhouse effect refers to: (a) gases in the atmosphere that trap heat, or (b) impact to the Earth's ozone layer |

was compensated $\$ 1$ for the 30 minutes the experiment was expected to take, and assigned to one condition.

Design Participants could view the survey description on AMT. If they selected the survey they were redirected to another website. They were first directed to a study information sheet which provided details of the survey and compensation. If they agreed to continue, they were instructed to answer some demographic questions. Participants were randomly assigned to either a random condition $(N=44)$ or a self-selection condition $(N=39)$, determining the subject's role in selecting which questions to answer. Participants were not aware of the existence of other conditions. Each participant saw the questions in 5 blocks of 20 questions each. In each block, they were instructed to rate the difficulty of each question and then, if they were assigned to the opt-in condition, instructed to choose 5 of those 20 questions to answer. The participants in the random assignment condition were randomly assigned 5 questions from that block to answer. After rating the difficulty of all 100 questions and answering 25 of them, participants were thanked for their time and given instructions on how to receive payment.

## Model

The model utilizes an IRT model to generate subjective latent knowledge (the belief of a participant that she can answer a question), which informs all aspects of participants' responses including the observed accuracy and difficulty ratings, as well as the metacognitive process of question selection. We describe participants as opting-in to questions for which they believe they have knowledge, answering with accuracy dependent on whether or not they believe they have knowledge, and giving lower difficulty ratings when they believe they have knowledge.

We use an IRT model to generate the subjective latent knowledge, $\delta_{i, j}$, for each participant $i$ (across both the optin and random condition) and question $j$,

$$
\begin{equation*}
\delta_{i, j} \sim{\operatorname{Bernoulli}\left(\operatorname{logit}^{-1}\left(\theta_{i}+\eta_{j}\right)\right), ~}_{\text {a }} \tag{2}
\end{equation*}
$$

where $\theta_{i}$ is the self-perceived skill of participant $i, \eta_{j}$ is the perceived familiarity of question $j$, and $\operatorname{logit}^{-1}(x)=\frac{e^{x}}{1+e^{x}}$. This latent knowledge is represented as a 0 or 1 , indicating whether or not that participant believes that she has knowledge for that question. We place a Normal prior on the selfperceived skill, $\theta_{i} \sim \operatorname{Normal}(0, \sigma)$, such that participants are expected to have the same skill (on average) for both the selfselection and random conditions.

For the self-selection condition, we assume that participants have a preference to select questions for which they believe they have knowledge. Let $c$ represent the observed question selections with $c_{i, j}=1$ if question $j$ was selected by participant $i$. For each participant and question block, we model question selection in the opt-in condition by a sampling process:

$$
\begin{equation*}
c_{i} \sim \operatorname{SampleWR}\left(\left(\delta_{i, 1}+\kappa, \ldots, \delta_{i, K}+\kappa\right), M\right) \tag{3}
\end{equation*}
$$

where $K$ is the total number of questions available for selection in each block ( $K=20$ in our experiment), $M$ is the number of questions that need to be selected ( $M=5$ in the experiment), SampleWR ( $\delta, M$ ) represents a sampling without replacement distribution where $M$ items are sampled with probability proportional to $\delta$, and $\kappa$ is a fixed parameter that controls the randomness in the selection process. Higher $\kappa$ values make it more likely that questions are selected for which the participant has no subjective knowledge. For participants in the random condition, we assume that the questions are randomly sampled by a process that is under control of the experimenter (where $M$ out of $K$ questions are randomly allocated).

Let $x_{i, j}$ represent the observed accuracy for participant $i$ on question $j$. We do not assume a fixed relationship between belief of knowledge and accuracy. For each question, we introduce guessing rate parameters $\rho_{j}$ and $\lambda_{j}$ that control the probability of correct responding if the participant does or does not have subjective knowledge about a question:

$$
\begin{equation*}
x_{i, j} \sim \operatorname{Bernoulli}\left(\delta_{i, j} \rho_{j}+\left(1-\delta_{i, j}\right) \lambda_{j}\right) \tag{4}
\end{equation*}
$$

For example, with $\rho=0.8$ and $\lambda=0.4$, the probability of a correct response is 0.8 if a participant has subjective knowledge, but 0.4 if the participant does not. The guessing parameters are given Beta priors, $\rho_{j} \sim \operatorname{Beta}(\alpha, \beta), \lambda_{j} \sim \operatorname{Beta}(\alpha, \beta)$ where $\alpha$ and $\beta$ are hyperparameters that control the variability in guessing rates across questions.

To model the difficulty ratings, we use an ordered logit model (Williams et al., 2006). We assume that subjective latent knowledge informs the perceived difficulty of questions. Questions for which the participant believes they have knowledge are perceived as easier. Let $\phi_{i, j}$ represent the perceived difficulty for participant $i$ on question $j$. We determine the perceived difficulty by:

$$
\begin{equation*}
\phi_{i, j}=-\delta_{i, j}-\eta_{j} \xi+\omega_{i}-\beta_{j}+\sigma_{i, j} \tag{5}
\end{equation*}
$$

where $\beta_{j}$ and $\omega_{i}$ capture participant and item level effects (e.g. some participants might find all items easy, some items
might be judged as easy) independent of subjective knowledge. In addition, we also allow the perceived familiarity of a question $\eta_{j}$ to affect the perceived difficulty weighted by a fixed scaling parameter $\xi$. Finally, $\sigma_{i, j}$ represent small perturbations centered around 0 to explain the random variability in difficulty ratings unrelated to any of the previous factors mentioned. These perceived difficulties feed into the ordered logit model to generate the difficulty ratings $r_{i, j}$,

$$
\begin{equation*}
r_{i, j} \sim \operatorname{OrderedLogit}\left(\phi_{i, j}, \tau_{i}\right) \tag{6}
\end{equation*}
$$

where $\tau_{i}$ is the set of criteria cutoffs for participant $i$.
We used JAGS to perform parameter inference. All parameters were inferred jointly from the opt-in and random condition. All model predictions were derived from posterior predictives where we simulate new participants from the distribution and assess how they self-select from a new set of questions.

## Results

We examine several empirical effects within the data and observe that the model captures the appropriate trend in most cases.

Item selection and latent knowledge. The model captures the expected relationship between opting-in behavior and knowledge (see Figure 2). Participants were more likely to select questions for which they had pre-existing knowledge. Each question was randomly assigned to at least four participants in the random assignment condition. However, in the opt-in condition, there were seven questions that no participant chose to answer. Question selection strongly corresponded with the inferred latent knowledge ( $\delta_{i, j}$ ) for the participant-question pair, with participants choosing questions for which they had latent knowledge. Across conditions, latent knowledge is distributed in a similar manner: most participants have knowledge for popular questions, few participants have knowledge for unpopular questions, and some participants are more knowledgeable than others. However, the model has substantially more certainty about the localization of this knowledge in the opt-in condition compared to the random condition because it can leverage the opt-in behavior. In Figure 2, this certainty is expressed as black or white squares, while uncertainty is represented in gray. We see the uncertainty about which participants have knowledge for which question as a "blurring" of the latent knowledge space.

Effect of opting-in on participant performance. Average performance across questions was higher in the self-selection condition ( $86.05 \%$ ) than in the random condition ( $67.27 \%$ ). We computed a Bayes Factor (BF) given a binomial distribution with a shared or different rate of correct responding and find a $\log _{10} \mathrm{BF}$ of 21.12 in favor of a higher rate of correct responding in the opt-in condition. This corresponds to decisive evidence that average accuracy is higher in the opt-in condition than the random assignment condition. This occurs even when taking into account the fact that people tend to opt

Figure 2: Latent knowledge is similar between conditions and corresponds to opting-in behavior. Plotted are the opt-in behaviors and average $\delta_{i, j}$ values across conditions, all sorted by the popularity of the question in the opt-in condition. White corresponds to questions that the participant opted in to or the inferred presence of knowledge.
in to easier questions. In order to perform this analysis, we took the product of the evidence that performance is higher in the opt-in condition than the random assignment condition for each question and find a $\log _{10} \mathrm{BF}$ of 9.02. So, even when comparing on an item-by-item basis, opting-in provides an advantage.

Effect of opt-in on model performance. For the model, the average accuracy for posterior predictive samples in the self-selection condition (mean $=79.03 \%$ ) is also significantly higher than in the random condition ( mean $=67.07 \%$ ), both across all questions ( $99.86 \%$ of samples) and even within questions ( $68.93 \%$ of sample-question pairs). We observe this benefit in accuracy despite the average inferred ability of individual subjects $\left(\theta_{i}\right)$ being equivalent across conditions: $\bar{\theta}_{i}=0.00, \mathrm{SD}=0.99$ in the opt-in condition versus $\bar{\theta}_{i}=-0.09, \mathrm{SD}=2.04$ in the random assignment condition. This means that the benefit to accuracy that the model predicts is due to downstream consequences of the metacognitive selection process and not an (inaccurate) inference that participants in one condition were more skillful than in the other.

Difficulty Ratings. Participants tended to give lower average difficulty ratings to questions that they opted in to ( $\log _{10}$ $\mathrm{BF}=91.89$ ) and higher average difficulty ratings to questions that they did not opt in to $\left(\log _{10} B F=64.09\right)$, relative to the random condition. The model captures, but understates, this trend (see Figure 3).

Wisdom of the crowd. The left panel of Figure 4 shows the relationship between crowd size and crowd accuracy for the two conditions in the experiment, as well as a hybrid condition in which the two groups are combined. The right side of the Figure shows that the model captures this effect qualitatively. Crowd responses were determined by taking the most

Figure 3: Distribution of difficulty ratings for participants and model for questions that were selected or not selected in the opt-in condition and the random condition. Lower ratings indicate lower perceived difficulty.
common response across the participants in the crowd. Since seven questions went unanswered in the opt-in condition, we had to consider how unanswered questions impacted crowd performance. To treat the self-selection condition maximally conservatively, we graded any question that went unanswered as incorrect for that crowd. Even with this penalty, the crowd composed of the participants from the self-selection condition (79\%) outperformed the crowd of subjects from the random condition (73\%).

We also considered the impact of crowd size on performance. To do this, we evaluated the average performance of crowds composed of random samples of participants from a condition and varied the number of participants drawn to form the sample. We plot average crowd performance as a function of the total number of judgments, where a judgment is a person's response to a question. The hybrid condition provides a means of improving upon both conditions. To create a hybrid crowd, we first sampled participants that answered the question from the opt-in condition. If a question had no responses, we added the answer from one participant in the random condition in order to guarantee that all questions received at least one answer. This hybrid crowd has high performance across all questions. The model captures the general trends in the data in that larger crowds result in higher crowd accuracy, opt-in crowds outperform random-assignment crowds, and the hybrid crowds perform well across all questions.

Additional simulations. Given our model, we investigated which circumstances would likely lead to changes in the relative performance of the self-selection and random conditions in terms of both average overall accuracy and crowd performance. We varied the heterogeneity of perceived question difficulty $\left(\eta_{j}\right)$ and latent ability $\left(\theta_{i}\right)$. We did this by simulating experiments in which we varied the underlying hyperparameter corresponding to the variability of $\theta_{i}$ and $\eta_{j}$ by factors of $0.25,1$, and 4 while keeping other parameters constant

Figure 4: Crowd performance when varying the number of participants (measured by the total number of judgments)
(see Figure 5). We find that increasing the heterogeneity of perceived question difficulty increases self-selection accuracy overall, but decreases it at the crowd level since participants tend to avoid answering the same difficult questions. Heterogeneity in question difficulty does not have an appreciable impact on performance in the random condition. In both conditions, higher heterogeneity of participant skill leads to higher crowd performance and gives resilience to heterogeneously difficult questions in the opt-in condition. However, it detracts from overall accuracy in the self-selection condition.

Figure 5: Simulated performance depending on variability of question difficulty $\left(\eta_{j}\right)$ and participant skill $\left(\theta_{i}\right)$.

## Conclusions

A comprehensive model of cognition must make allowance for the fact that cognitive behavior is driven by motivations. We choose what we attend to and attempt to encode, and what we attempt to remember. Metacognitive behavior is at the heart of most learning outside the laboratory, and a fair amount within it as well (A. Benjamin \& Ross, 2008). The joint modeling of metacognitive behavior-like self-selection
of items-along with cognitive performance has the potential to address a wider and more representative range of realworld learning and testing behaviors, and can serve as the basis for drawing comparisons across individuals or tests that would otherwise be hopelessly confounded. Additionally, the model could be extended to explain various incentives given to the participant, which would impact how latent knowledge interacts with the task to generate opt-in behaviors. The model presented here provides a starting point for such an enterprise. It leads to a relatively good description of performance across a variety of metrics. A single latent knowledge state for each participant-question pair permits an explicit representation of the metacognitive process that governs the relationship between opt-in, accuracy, and difficulty behaviors. The model is successful in describing the nonrandom missing nature of the data that we observed by relying on principled psychological theories about why someone might choose one question over another.

An additional lesson of the current research can be seen in the crowd data. Opting in is generally beneficial to crowd accuracy in both the observed data and our model. This result indicates that the metacognitive skill of the individuals in self-selection can be leveraged in order to create a smarter crowd. This effect is sufficiently robust that it appears to outweigh the cost associated with small crowd sizes for some questions or no volunteered responses at all for a small number of questions. Such a result is particularly important when considering the widespread availability of datasets in which responses are self-selected.

#### Abstract

We tested whether conceptual processing is modality-specific by tracking the time course of the Conceptual Modality Switch effect. Forty-six participants verified the relation between property words and concept words. The conceptual modality of consecutive trials was manipulated in order to produce an Auditory-to-visual switch condition, a Haptic-tovisual switch condition, and a Visual-to-visual, no-switch condition. Event-Related Potentials (ERPs) were time-locked to the onset of the first word (property) in the target trials so as to measure the effect online and to avoid a within-trial confound. A switch effect was found, characterized by more negative ERP amplitudes for modality switches than noswitches. It proved significant in four typical time windows from 160 to 750 milliseconds post word onset, with greater strength in posterior brain regions, and after 350 milliseconds. These results suggest that conceptual processing may be modality-specific in certain tasks, but also that the early stage of processing is relatively amodal.

Keywords: conceptual processing; time; modality switch; perceptual simulation; amodal; event-related potentials; ERP

## Introduction

Research in the cognitive sciences has extensively investigated whether conceptual processing is modalityspecific (Barsalou, 2016). In a commonly used paradigm known as the Conceptual Modality Switch (CMS), participants perform a property verification task in which they decide whether certain property words can reasonably describe certain concept words. For instance, Pecher, Zeelenberg, and Barsalou (2003) presented sentences such as Blenders can be loud. Covertly, the conceptual modality of consecutive trials was manipulated in order to produce specific switches. A sentence like Blenders can be loud, which is mainly related to the auditory modality, could either be followed by a sentence within the same modalitye.g., Leaves can be rustling-, or by a sentence in a different modality-e.g., Cranberries can be tart (gustatory). Pecher et al. found that when the modalities of consecutive trials did not match, participants took longer to respond. Such an effect suggested that perceptual features of concepts (operationalized in the modality shifts) are
accessed during conceptual processing. More recently, however, the CMS effect was reanalysed using a nonperceptual alternative, language statistics (i.e., how words co-occur in a language). Louwerse and Connell (2011) found that language statistics were able to approximately predict what modality a concept and property pair belonged to. Specifically, they could predict a visual/haptic modality, an olfactory/gustatory modality, and an auditory modality, but they could not predict the subtler differences between visual and haptic, and between olfactory and gustatory, which seemed to be reserved for perceptual simulations. Moreover, when a language statistics explanation and a perceptual explanation were compared against one another, faster response times (RTs) were best explained by language statistics, whereas slower RTs were best explained by perceptual simulations (for similar findings with switches in emotion, see Tillman, Hutchinson, Jordan, \& Louwerse, 2013). Louwerse and Hutchinson (2012) further replicated these findings in an Electroencephalography (EEG) experiment in which they showed that those cortical regions commonly associated with language processing are relatively more active in the beginning of processing, whereas those regions commonly associated with perceptual processing are relatively more active later on. These studies demonstrated that the time course of processing is important in the study of language statistics and perceptual simulation.

## Time Course of Effects in Word Processing

The time course of word processing may be relevant for an effect such as the CMS. Hauk (2016) zooms into the one second during which a word is processed, proposing the following timeline. A reader or listener starts to identify a word and to access part of its meaning within around 150 milliseconds (ms) from word onset. Building on that information, working memory processes emerge at around 170 ms post word onset, followed by response-related processes at around 250 ms . Mental imagery and episodic memory are the last-emerging processes, both around 400 ms post word onset. Once started, each of these processes extends further, gradually overlapping with each other. This
timeline suggests two important things about the earlier and the later stages of word processing. First, having an early emergence-e.g., at 250 ms -does not make an effect lexicosemantic per se because the meaning encoded could have gone through working memory before activating the actual system of interest, e.g., sensorimotor (Mahon \& Caramazza, 2008). Second, it suggests that effects emerging later face that same challenge and, in addition, the potential influence of response-related and forthcoming processes.

If even an effect measured online with high temporal resolution (EEG or Magnetoencephalography) may be subject to alternative causation, effects measured with lower temporal resolution (functional Magnetic Resonance Imaging) or off-line (RT) are arguably more challenged by this. With regard to the current topic specifically, sensory and motor effects may possibly be epiphenomenal to the representation of concepts online, independently of what is suggested by the measurements off-line or online lagged.

There is a technique especially apt for testing the causality of cognitive systems, namely, Transcranial Magnetic Stimulation (TMS). Willems et al. (2011) found that comprehension of hand-related verbs was improved as a consequence of stimulating the hand area of premotor cortex. It was particularly improved when the TMS was applied in the hemisphere controlling the dominant hand. More recently, Vukovic et al. found an impairment in the processing of action-related words, along with an improvement in the processing of abstract words, after TMS was applied over motor cortex, 200 ms after word onset. The latter finding suggests that the contribution of modalityspecific systems (in this case, motor ones) can emerge relatively early (see also Amsel, Urbach, \& Kutas, 2014; Van Dam, Brazil, Bekkering, \& Rueschemeyer, 2014).

In our view, two interlocked questions stand out in the current topic area. The causality question asks whether modality-specific effects reflect a functionally relevant simulation process or arise only after basic conceptual processing has been attained. The compatibility question asks whether different processing systems, amodal and modal, may compatibly operate in conceptual processing.

## Experiment

We addressed the causality and the compatibility questions by revisiting the CMS paradigm (see most recent previous study in Scerrati, Lugli, Nicoletti, \& Borghi, 2016).

## Tracking the Time Course of the CMS

We measured the CMS online by time-locking EventRelated brain Potentials (ERPs) to the onset of the first word in the target trials. We wanted to establish where exactly the effect-indexing access to perceptual informationemerged, how far it extended, and the relative strength over the time course. These measures would allow us to relatively assess how strongly the CMS may be influenced by response-related and other extra-semantic processes (see Hauk, 2016). Concerning the compatibility question, previous research would predict an increase in the CMS
effect over time because earlier processing is relatively amodal (Louwerse \& Hutchinson, 2012).

The three previous ERP studies on the CMS time-locked the measurement to property words placed last in the target trials (Hald, Marshall, Janssen, \& Garnham, 2011; Collins, Pecher, Zeelenberg, \& Coulson, 2011; Hald, Hocking, Vernon, Marshall, \& Garnham, 2013). A potential problem of those measurements is a lack of certainty on the emergence of the effect, because a switch might reasonably emerge already at the first content word in the target trial. Therefore, in our design we placed the property word first in the target trial, and time-locked ERPs to its onset. This had an important advantage, as it helped avoid a confound caused by the relation between the property and the concept in each target trial (see Hald et al., 2013). The possibility of those two confounds-the lagged measurement and the within-trial relationship-could explain why the CMS effect has sometimes failed to appear in RTs (Hald et al., 2011; 2013; Collins et al., 2011; Scerrati et al., 2016).

We did not have clear hypotheses on what we would find as the time course of the CMS because we were the first to time-lock ERPs to the first word. Nonetheless, the effects found in the three ERP studies cited above were generally characterized as N400-linked to semantic violation-, with more negative amplitudes for modality switches than noswitches. The earliest emerging effect appeared in Hald et al. (2011), in a time window from 270 to 370 ms .

## Different Switches and Processing Speeds

In order to further explore the compatibility question, we drew on Louwerse and Connell (2011). As reviewed in the Introduction, they found that quick processing was able to pick up most switch types but missed the subtler ones, for instance, between haptic and visual. By contrast, slow processing had the advantage of picking up even those subtler switches. Here we brought these findings to a group design. We distinguished a Quick group of participants and a Slow group of participants based on their average RT. Maintaining the CMS as a within-subjects factor, we predicted that the larger modality switches (e.g., auditory to visual) would be picked up equally by both groups, whereas the subtler switches (e.g., haptic to visual) would be picked up only-or more clearly-by the Slow group.

## Method

Accuracy Pretest The task was validated in a behavioural pretest ( $N=19$; Radboud U., Tilburg U.) revealing that all participants but one had an average response accuracy over $50 \%$, and the overall average was $63 \%$ ( $S D=48 \mathrm{pp}$.).

Participants Forty-nine participants-native speakers of Dutch with no relevant disorders-were recruited at the Max Planck Institute for Psycholinguistics. They were paid a small fee after participating. Participants were randomly assigned to one of three experimental groups: a Quick response group ( $n=22$ ), a Self-paced response group ( $n=$ 21), and a Null group who got the same experimental design
as the Self-paced group but no instructions on response speed ( $n=5$ ) (see Figure 1). One participant had to prematurely leave the experiment. Another participant had to be removed from the data due to too noisy ERPs (7 retained trials out of 108). Under visual inspection, all other participants' waveforms-preprocessed and averaged per CMS condition-approximately presented the typical peaks of word reading. Last, one participant, the only one with an accuracy below $50 \%$-i.e., $37 \%$-, was also removed from further analyses. Forty-six participants remained. Because
the Groups presented rather close, significantly equal RTs, we pooled them together and re-split them in two groups on the basis of each participant's average RT. The effects CMS and CMS by Group were equally significant with the old and new groups in both ERPs and RTs. New groups were: Quick ( $n=23$; mean RT $=568.40 \mathrm{~ms}, S D=104.83$; age 1931, mean $=23.3$; 19 females), and Slow ( $n=23$; mean RT $=$ $937.21 \mathrm{~ms}, S D=265.56$; age $18-25$, mean $=22.2 ; 18$ females). The different tests-stimulus norming, pretest, and main experiment - did not share any participants.

Figure 1: Schema illustrating materials, design, and procedure. Note that Groups were pooled and re-split (see Participants).

Materials and Design As in previous CMS studies, the stimuli consisted of pairs of property and concept words, but we had a small novelty in this combination. Whereas previous studies presented the concept and the property in declarative sentences (Pecher et al., 2003; Louwerse \& Connell, 2011; Hald et al., 2011), or with the concept followed by the property alone (Collins et al., 2011), the current experiment presented the property followed by the concept alone, e.g., Soundless Answer. In this design, as in most, the property word took the most relevant position for the measurement, because properties are generally more modality-specific than concepts (Lynott \& Connell, 2013).

The properties and concepts, all in Dutch, were partly based on Lynott and Connell's (2009, 2013) norms. We normed our items similarly too, by asking forty-two respondents to rate 0 to 5 the extent to which they experienced each property or concept with the senses of hearing, touch, and vision. Then we computed the dominant modality of each word (Bernabeu, Louwerse, \& Willems, in prep.). Next, we created 216 trials by joining properties and concepts within the same modalities. ${ }^{1}$ Half of the trials contained a fairly related property and concept, while the other half presented rather unrelated pairs. These

[^280]relationships served to engage participants in a semantic task, yet conveniently did not affect the ERP measurement because ERPs were measured before the concept word was presented in each trial (Figure 1). In spite of this, we wish to acknowledge that some trials came out rather unnaturalLukewarm Volume-or fuzzy-Solid Ideal-because they were created out of a fixed set of modality norms (Bernabeu et al., in prep.). In order to alleviate that problem, the instructions of the experiment stated that the accuracy feedback following every response was based on the answers of previous participants (in reality, it wasn't). Furthermore, the stimuli and the task were validated by the accuracy rates in the pretest and in the main experiment.

For the critical CMS manipulation, trials were covertly paired as context and target trials. This was done pseudorandomly within participants and CMS conditions by using the software Presentation ${ }^{\mathrm{TM}}$. Three conditions were created-Auditory-to-visual, Haptic-to-visual, and Visual-to-visual-, each with 36 context trials and 36 target trials. One auditory-to-visual switch for one participant was: Soundless Answer | Bumpy Wage (bold added to ERP-target word). For another participant, the latter target trial was instead preceded by the context trial Loud Welcome. The pseudo-randomization ensured that ERP-target words (properties) were matched across CMS conditions on the
essential criteria-word frequency and length (letters), and semantic class. Also, ERP-target words occurred only once.

Procedure The entire experiment was in Dutch. By means of written instructions, participants were asked to respond in each trial whether the first word, a property, could be used to describe the second word, a concept. Two buttons were used to respond. An example was provided based on the property 'grey' and the concept 'snow.' Snow is often white, but it can also be grey. By contrast, a property that would not match is 'pink.' Then, the instructions diverged for the different groups of participants: while the Quick group was asked to respond as quickly as possible in every trial, the Self-paced group was asked to respond self-paced, and the null group was altogether unconstrained (see design constraints for each group in Figure 1). Further, the instructions stated that feedback would be provided for each response, and that this was based on all preceding answers (although it was not), and therefore participants need not worry too much about mistakes. Last, they were asked to move or blink as little as possible, and do so only while the cross was on the screen. Twelve practice trials ensued, after which participants could ask questions. The experiment ran on Presentation ${ }^{\mathrm{TM}}$. The experiment proper lasted about 20 minutes, with a break in the middle. Taking into account EEG procedures, it lasted about 1 hour and 45 minutes.

ERP Recording and Preprocessing The EEG signal was recorded with BrainVision Recorder $1^{\mathrm{TM}}$, in differential mode, utilizing 65 active $\mathrm{Ag} / \mathrm{AgCI}$ electrodes. The ground electrode was positioned just above the nose, at the glabella. Three other electrodes were used to register eye movements, two placed at the outer canthi of each eye, and one placed below the left eye. The remaining 59 electrodes were mounted in a custom, equidistant ActiCap cap. Impedance was kept below $10 \mathrm{k} \Omega$ by applying electrolyte gel at the tip of each electrode. The signal was amplified through BrainAmp DC amplifiers with a bandpass filter of 0.016100 Hz , and an online sampling frequency of 500 Hz (i.e., every 2 ms ). Afterwards, the signal was preprocessed in BrainVision Analyzer $2^{\text {TM }}$, with the following steps: CMS condition segmentation, automatic ocular correction, 200 ms baseline correction, artefact rejection via semi-automatic segment selection. ${ }^{2}$ The proportion of segments (trials) retained from the 46 final participants was: $77.4 \%$ in the Visual-to-visual condition, $78.0 \%$ in the Haptic-to-visual condition, and $78.6 \%$ in the Auditory-to-visual condition.

[^281]ERP Analysis The ERPs, averaged per CMS condition, were downsampled to 125 Hz due to computational demands. Electrodes were divided into an anterior and a posterior area (also done in Hald et al., 2011). Albeit a superficial division, we found it sufficient for the research question. Time windows were selected as in Hald et al., except for the last window, which was extended up to 750 ms post word onset, instead of 700 ms , because the characteristic component of that latency tends to extend until then, as we confirmed by visual inspection of these results. Window 1 was meant to capture N1-P2 components, window 2 the pre-N400, window 3 the N 400 , and window 4 the LPC/P600. Analyses were performed in the software R.

## Results

All final participants responded correctly in over half of the trials. The average accuracy was $63 \%$ ( $S D=48 \mathrm{pp}$.), nearly identical in each participant Group and CMS condition. ${ }^{3}$

ERPs The ERP results revealed a CMS effect from time window 1 on, larger after 350 ms . It appeared with both switch conditions, and was characterized by a more negative amplitude for the switch conditions compared to the noswitch condition. In certain parts over the time course, the effect appeared in both anterior and posterior areas, and in both participant groups, but it was generally stronger in the posterior area and in the Slow group (Figure 2).

The ERPs per window were analyzed with Linear Mixed Effects models (lmer R package). Random intercepts and slopes, and fixed effects, were tested with the critical factors and interactions, as well as with potential confounds, e.g., handedness, sex, age. Each inclusion was tested in a stepwise fashion based on the significance of the Likelihood Ratio. The final models presented good fits, with $R^{2}$ ranging from .748 (time window 4) to 862 (time window 2). Table 1 sums up the results. First, the CMS effect in time window 1 was confirmed significant (see detailed waveforms in Figure 3). Such an early emergence is unprecedented in the CMS literature, and it may have been enabled by the timelocking of ERPs to the first word in target trials. In this time window, the only process not lexicosemantic is possibly working memory (Hauk, 2016), and therefore this early emergence lends support to the possibility that the CMS had a lexicosemantic basis (but see Mahon \& Caramazza, 2008).

Whereas in time window 1 ( $160-216 \mathrm{~ms}$ ), the CMS effect was circumscribed to an interaction with Brain Area (anterior/posterior), by time window $2(270-370 \mathrm{~ms})$ a main effect of CMS emerged. Finally, in window 3 ( $350-550 \mathrm{~ms}$ ) and window $4(500-750 \mathrm{~ms})$, the only critical effect was CMS. Window 3 presented the largest main effect of CMS. Planned ANOVA contrasts into CMS conditions, corrected for multiple comparisons, revealed that the no-switch condition differed significantly from the switch conditions.

[^282]

Figure 2: Data per Group and Area, with $95 \%$ Confidence Intervals every 2 ms , and time windows. Negative up.

Table 1: Effect of CMS and its interaction with Ant./Pos. brain Area and with Group. ${ }^{* * *} p<.001 ;{ }^{* *} p<.01 ;{ }^{*} p<.05$.

| Time window | Factors | Effect: $\chi^{2}$ |
| :--- | :--- | :--- |
| $1) 160-216 \mathrm{~ms}$ | CMS | 1.40 |
|  | CMS x Ant/Pos Area | $48.59^{* * *}$ |
|  | CMS x Ant/Pos Area x Group | $23.63^{* *}$ |
| $2)$ | CMS | $6.40^{*}$ |
|  | CMS x Ant/Pos Area | $10.89^{* *}$ |
|  | CMS x Ant/Pos Area x Group | $4.13^{* *}$ |
| 3) $350-550 \mathrm{~ms}$ | CMS | $9.47^{* *}$ |
| 4$) 500-750 \mathrm{~ms}$ | CMS | $7.58^{*}$ |

By contrast, the switch conditions hardly differed from each other-statistically equal in some sections of the data-, fitting the CMS effect. The fit of these follow-up ANOVAs was high in time windows 1 to 3 , and medium in window 4 .

Although the interaction of Group and CMS was only significant in time windows 1 and 2, the waveforms in windows 2 , 3 , and 4 presented a pattern that precisely fitted

Figure 3: Subset of electrodes from the Slow group at time window 1 (the Quick group presented a slightly smaller but also significant effect). Y-axis ranges from $-1 \mu \mathrm{~V}$ to $+4 \mu \mathrm{~V}$. Red labels signal the equivalents in the 10-20 montage.
our predictions based on Louwerse and Connell (2011). Whereas the Slow group picked up the switches across all modalities similarly, the Quick group picked up the Auditory-to-visual switch more clearly than the Haptic-tovisual switch, fitting with an amodal-modal compatibility.

RTs This design was tailored to measure ERPs. RTs were not reliable enough regarding the CMS because the last word in the target trials-critical for RTs-had not been matched across conditions on the essential criteria (see Materials section above). Nonetheless, we analysed RTs, statistically controlling for the confounds. No effects involving CMS were found, all $p \mathrm{~s}<.05$ (model $R^{2}=.552$ ).

## Discussion

CMS effects are a well-known, replicated demonstration of the relevance of modality-specific information for conceptual processing. In the current study, we tracked this effect online in order to ascertain at what stages perceptual information is processed, and in what degree (see Mahon \& Caramazza, 2008; Hauk, 2016). Time-locking ERPs to the onset of the first word in the target trials brought the added advantages of cancelling confounds within the target trial and measuring the effect at the onset, un-lagged. On the other hand, this design had the disadvantage of some unnatural stimuli. In spite of these novelties, though, our broad randomization of trials and the results found suggest that this experiment preserved the essence of the CMS paradigm. We found the CMS effect emerging at the start of lexicosemantic and working memory processing, then
increasing through the rest of word processing. The virtually immediate effect upon word recognition offers further support for the suggestion that sensory brain regions have a functional role in conceptual processing, at least in a fairly demanding semantic analysis as in the current task (see Louwerse \& Hutchinson, 2012). Solving the causality question, nonetheless, may require in the future more fundamental research on word processing, in addition to TMS-based work, in order to qualify the degree of semantic and post-semantic processing in an effect (see Hauk, 2016). The increase in the CMS effect over the time course converges with previous findings in suggesting that distributional processing-language statistics-may play a greater role earlier on (Louwerse \& Connell, 2011; Louwerse \& Hutchinson, 2012). This early-late distribution fits with Hauk's (2016) word processing timeline, where the early stage has a greater relative proportion of lexicosemantic processing, which would presumably support language statistics. Increasing evidence on the compatibility of amodal and modal/embodied processing invites further research. Concerning the CMS specifically, we still need to establish whether this effect can best be explained by language statistics or by perceptual simulations. The current work at least demonstrates that it emerges early and increases throughout word processing.

## Supplementary Material, Acknowledgments

All data, including the stimuli, set-up, raw files, and results in detail, are available through https://osf.io/97unm/

We received funding from the Neurobiology of Language department at Max Planck Institute for Psycholinguistics, from the Experimental Psychology Society, and from the Cognitive Science Society. We received valuable advice from Gwilym Lockwood, Johan Weustink, Monique Flecken, Ronald Fischer, Sean Roberts, Brain Products staff, and the reviewers. Also, thanks to the participants.

# Object Representation in Multiattribute Choice 

Sudeep Bhatia (bhatiasu@sas.upenn.edu)<br>University of Pennsylvania, Philadelphia, PA.

Neil Stewart (neil.stewart@warwick.ac.uk)<br>University of Warwick, Coventry, UK.

#### Abstract

We propose a theoretical framework for understanding how everyday choice objects are represented and how decisions involving these objects are made. Our framework combines insights regarding object and concept representation in semantic memory research with multiattribute choice rules proposed by scholars of decision making. We also outline computational techniques for using our framework to quantitatively predict naturalistic multiattribute choices. We test our approach in two-object and three-object forced choice experiments involving common books, movies, and foods. Despite using complex naturalistic stimuli, we find that our approach achieves high predictive accuracy rates, and is also able to provide a good account of decision time distributions.

Keywords: Multiattribute choice, Semantic memory, Naturalistic decision making, Judgment and decision making

## Introduction

Most choices that people make on a day-to-day basis, from the books they read to the foods they eat, involve trading off attributes, so as to select the object whose attributes are overall the most desirable (Keeney \& Raiffa, 1993). There is, however, a disconnect between the way in which multiattribute choices are currently studied, and the way in which these day-to-day choices are typically made. Most multiattribute choice experiments explicitly present choice objects and their attributes to participants in a matrix of numerical quantities (e.g. Figure 1a). Everyday decisions, in contrast, are not usually composed of objects with a small set of explicitly presented and quantified attributes. Rather the objects in these decisions are much richer and complex (e.g. Figure 1b). Decision makers do have knowledge about these objects and their attributes, but this knowledge is represented in the decision makers' minds after having been learnt through prior experience with the choice domain.

Figure $1 a$ and $b$. Stimuli presentation in standard multiattribute choice experiments (left) and in Study 1 (right).

The divergence between the stylized stimuli used in current research and the complex multiattribute choices made in real-world settings is problematic. Choice processes
and resulting behaviors depend greatly on the ways in which attributes and objects are presented (e.g. Kleinmuntz \& Schkade, 1993) suggesting that real-world decisions, which seldom involve actual attribute-by-object matrices, may be different to the types of decisions observed in current experimental work. More importantly, by using artificial designs in which the attributes of objects are directly presented to decision makers, existing theoretical work has largely ignored the role of object representation. Storing, retrieving, and processing attribute information about the objects in a given choice problem is a pivotal part of the decision process, and a complete account of choice requires an approach that is able to specify the mechanisms involved at this stage in the decision, well as the relationship between these mechanisms and the final outcomes of the decision (see Bhatia, 2013 for a discussion).

This paper provides a theoretical framework capable of addressing these issues. It relies on insights in semantic memory research which suggest that low-dimensional attribute spaces are used to represent objects and concepts. For example, multi-dimensional scaling (Shepard, 1962) passes similarity ratings through a matrix decomposition algorithm, resulting in the recovery of a small number of latent attributes that best describe the structure of similarity for a given domain. Likewise, distributional models of semantic memory typically learn low-dimensional word representations through natural language. Some approaches, like latent semantic analysis, use singular value decomposition to perform dimensionality reduction on word-context occurrence matrices (Landauer \& Dumais, 1997). Others use Bayesian statistics or convolution based associative memory, but also result in low-dimensional representations for words (see Jones et al., 2015).

We suggest that these insights extend to everyday multiattribute choice, so that decision makers can be seen as using the distribution of observable features across choice objects in the environment to uncover low-dimensional latent attributes for representing the objects. Furthermore, we propose that it is these latent attributes that are evaluated and aggregated during the decision process. For simplicity we suggest that the recovery of latent attributes can be approximated using singular value decomposition on the observable feature space (as in e.g. Landauer \& Dumais, 1997), and that the evaluation of the latent attributes can be approximated with a linear model with decision weights for each latent attribute (as in e.g. Keeney \& Raiffa, 1993).

We also propose computational techniques for uncovering the latent attribute representations of common choice
objects. Particularly, keywords, tags, and other natural language descriptors for choice objects on internet websites, can be considered suitable proxies for the observable features of these objects. For a sufficiently rich online dataset, it is possible to train semantic models and learn the latent attribute representations for the objects in a choice environment, and subsequently examine peoples' choices between these objects.

## Framework

Let us consider a choice domain with $N$ total objects. Each of these objects has a set of observable features, and can be written as a vector of these features. If there are $M$ total unique features in the environment, then each for object $i$ we have $\boldsymbol{x}_{i}=\left(x_{i 1}, x_{i 2}, \ldots x_{i M}\right)$, with $x_{i j}=1$ or $x_{i j}=0$ based on whether or not feature $j$ is present in object $i$. Singular value decomposition involves processing the matrix $\mathbf{X}=\left[\boldsymbol{x}_{1}, \boldsymbol{x}_{2}, \ldots \boldsymbol{x}_{N}\right]$ to obtain $L \ll M$ latent attributes, corresponding to the $L$ largest singular values of $\mathbf{X}$. Using these singular values, we can represent an object $i$ as $z_{i}=$ $\left(z_{i 1}, z_{i 2}, \ldots z_{i L}\right)$, with $z_{i j}$ corresponding to the association between the object and the $j^{\text {th }}$ latent attribute. Note that $M$ can be very large in many naturalistic choice domains, whereas $L$ is typically much smaller.

The use of latent attributes for representing objects implies that our approach retains the multiattribute structure assumed by theoretical decision making research. Thus we can take common multiattribute decision rules and apply them very easily to latent attributes. We use a simple linear rule, which specifies a decision weight for each attribute and aggregates weighted attributes into a measure of utility for an object (Keeney \& Raiffa, 1993). The object with the higher utility is the one that is most frequently chosen. In the context of the latent attribute structure outlined here, this involves specifying an $L$ dimensional vector of weights $\boldsymbol{w}=$ ( $w_{1}, w_{2}, \ldots w_{L}$ ), and multiplying the latent attributes for an object $i$ by these weights, so as to obtain the utility for the object $U_{i}=\boldsymbol{w} \cdot z_{i}$. In order to permit random noise in the choice process we embed our utilities in the logit choice rule (Luce, 1959). In a two-object choice this specifies the probability of choosing an object $i$ over another object $i^{\prime}$ as $\operatorname{Pr}[i$ chosen $\left.]=\mathrm{e}^{U i}\right) /\left(\mathrm{e}^{U i}+\mathrm{e}^{U i^{\prime}}\right)=\mathrm{e}^{w \cdot z i} /\left(\mathrm{e}^{w \cdot z i}+\mathrm{e}^{w \cdot z i}\right)$. For the general case with $N^{\prime}$ choice objects we have $\operatorname{Pr}[i$ chosen $]=$ $\mathrm{e}^{U i} /\left(\Sigma_{\mathrm{n}=1 \ldots N^{\prime}} \mathrm{e}^{U n}\right)$.

In order to test our approach and illustrate its applicability we first need to uncover the actual attribute representations that characterize common choice objects. In related domains, such representations are usually obtained by asking experimental participants to generate features that describe the meaning of a given word (e.g. McRae et al., 2005). However common choice domains are so vast (involving thousands of features for thousands of objects) that the experimental elicitation of these feature norms may not practical. Thus we suggest that user-generated keywords, tags, and other descriptors for common choice objects on online datasets can be seen capturing the observable features that best describe the various objects.

In this paper, we use three large online datasets: www.GoodReads.com, which contains user-generated bookshelves for thousands of books; www.IMDB.com, which contains user-generated keywords for thousands of popular movies; and www.AllRecipes.com which contains user-specified ingredients for thousands of dishes. We scrapped these websites in 2014, and for each website we attempted to obtain as much information (as many objects and associated features) as was technically feasible. We obtained a total of 372,186 unique shelves for 15,737 books for the www.GoodReads.com dataset, a total of 160,322 unique keywords for 44,971 movies for the www.IMDB.com dataset, and a total of 24,688 unique ingredients for 39,979 recipes for the www.AllRecipes.com dataset. Using these user-generated descriptors as our observable features, each of the $N$ objects in each of the three datasets can be written as an $M$-dimensional feature vector $\boldsymbol{x}_{i}=\left(x_{i l}, x_{i 2}, \ldots x_{i M}\right)$, with $x_{i j}=1$ if object $i$ (a book, a movie, or a food dish) has observable feature $j$ (a keyword, a shelf, or an ingredient). A singular value decomposition on $\mathbf{X}=\left[x_{1}, x_{2}, \ldots x_{N}\right]$ can be subsequently performed to obtain $L$ $\ll \mathrm{M}$ latent attributes for the datasets.

## Study 1

In Study 1 we tested whether our theoretical framework and the computational techniques for applying this framework, actually predict peoples' everyday multiattribute choices. This is the primary experiment in this paper: It involves incentivized choices in the laboratory with reaction time measures. In later studies we examine variants of this design using non-incentivized online samples.

Method. In this study, 73 participant made binary choices between pairs of popular books. Participants were recruited from a university subject pool, and performed the study in a behavioral laboratory on computer screens. Participants were also incentivized, and one of their chosen books was selected at random and given to them at the end of the study.

Unlike most existing multiattribute choice experiments, the choice objects were not presented alongside a set of quantifiable attributes (as in e.g. Figure 1a). Rather they were shown to participants using just the covers of the books and the accompanying titles (as in e.g. Figure 1b). Overall, each of the 73 participants made 220 choices involving 150 unique books. The books used in this study were obtained from 30 different popular genres on www.GoodReads.com.

Model Fitting. We fit participant choices using the latent attributes recovered from a singular value decomposition (SVD) on the www.GoodReads.com data. We allowed the number of underlying latent attributes, $L$, to vary across participants. For a given value of $L$, we used the $L$ latent attributes with the highest singular values from the SVD on the www.GoodReads.com dataset. In order to ensure sufficient degrees of freedom for estimating decision weights, we restricted $L$ to a maximum of $L=100$ (and a minimum of $L=2$ ). In essence this leads to a total of 99 unique models for each participant, corresponding to $L=2$,
$L=3, \ldots L=100$. with a separate set of best fitting participant-level attribute weights for each model. The values of the 150 books in our study on the two latent attributes with the largest singular values are shown in Figure 2. Figure 2 also shows the ten shelves with the largest absolute weights for these two latent attributes.

Attribute 1

Figure 2. The values of the 150 books in Study 1 on the two latent attributes with the largest singular values, alongside the ten shelves with the largest absolute weights for these two latent attributes.

In order to avoid overfitting, we used ten-fold crossvalidation to test predictive accuracy and find the best performing model (i.e. best performing value of $L$ ) for describing each participant's choices. For model training, we recovered the weighting vector $\boldsymbol{w}$ that provided the best fit to the training data, with the assumption of a linear choice rule embedded in a logistic link function. This vector (whose dimensionality depended on the dimensionality of the model (value of $L$ ) in consideration), was recovered using maximum likelihood estimation. For model testing we calculated the proportion of choices in the test data predicted accurately by the recovered $\boldsymbol{w}$ for each model. A choice is considered to be predicted accurately if the utility assigned to the chosen option by the model in consideration is higher than the utility assigned to its competitor. Ultimately, the value of $L$ and corresponding weight vector $\boldsymbol{w}$ with the highest accuracy on the test data was considered to be the overall best fitting model.

Results. The mean accuracy of our approach for predicting the test data is $83 \%(S D=0.08)$, significantly above a baseline accuracy of $50 \%$ ( $p<0.01$ ). Additionally, the average best fitting value of $L$ across our participants is 39.67 ( $S D=27.95$. Table 1 summarizes statistics regarding model accuracy.

Table 1. Summary of model fits. Mean", "Std. Dev." and "Median" indicate the distribution of best-fitting model accuracy rates on test data across participants. "Best Fit" describes the proportion of participants for which the model has the highest accuracy (these proportions sum to greater than one as models are sometimes tied) and "Significant" indicates the proportion of participants that outperform the baseline model with $p<0.05$.

One possibility is that our technique achieves its high accuracy rates by allowing flexible weights across a large number of dimensions. In order to control for this, we attempted the above model-fits with randomly generated attribute vectors. Particularly, for each participant and each object offered to the participant, we artificially created a 100 -dimensional vector with each dimension randomly and uniformly distributed in the range [0,1]. We then performed a 10 -fold cross validation procedure that examined the fits of linear models with flexible weights for $L$ dimensions of the random vectors. With this approach we found the mean accuracy to be $69 \%$ ( $S D=0.08$ ) Additionally, $84 \%$ of
participants achieved a higher accuracy rate using the recovered latent attributes from www.GoodReads.com, compared to the randomly generated vectors (and $8 \%$ of participants had equal accuracy with both approaches). A participant-level paired t-test indicates shows that this difference is significant ( $p<0.01$ ). Table 1 provides further statistics involving the random vectors approach.

Another alternative to our SVD-based attributes involves the use of the raw observable features for the books. Of course it is impossible to actually recover separate decision weights for each of these observable features. However, we can use well-known decision heuristics applied to these observable features. For example, using the lexicographic heuristic (Tversky, 1969) would involve considering only a single feature, and choosing the object that is the most desirable on this feature. Likewise, applying the tallying heuristic (Russo \& Dosher, 1983) would involve counting up the positive and negative features of each choice object, and choosing the object with highest number of positive features relative to negative features. We applied these two heuristics to participant-level choice using 10 -fold cross validation. For the lexicographic heuristic we used the training sample to determine which of the object's features has the highest absolute correlation with choice. We then used this single feature to predict the choices on our test sample. For the tallying heuristic, we used the training sample to determine whether each of the features were positively or negatively correlated with choice. If they were positively correlated with choice, they received a weight of +1 , and if they were negatively correlated with choice they received a weight of -1 . These weights were then applied to the observable features in the test data to predict choices according to the tallying heuristic.

We found that the lexicographic heuristic achieved a mean accuracy rate of exactly $50 \%(S D=0.03)$, indicating that it is not a suitable way of making multiattribute choices with such large features spaces. In contrast, the tallying heuristic achieved a mean accuracy rate of $72 \%(S D=0.09)$. When comparing these heuristics with our latent attribute approach, we found that all participants were better fit by our approach compared to the lexicographic heuristic, and that $78 \%$ of participants were better fit by our approach relative to the tallying heuristic (with another $16 \%$ tied). The differences in accuracy rates shown here are statistically significant when evaluated with a paired t-test ( $p<0.01$ for both heuristics). Table 1 provides further statistics involving the lexicographic and tallying heuristics.

How well do our model fits predict decision time? We can perform this test by embedding our best fitting utilities into a drift diffusion model (Ratcliff \& Rouder, 1978). Our utilities are a measure of the desirability of the objects and, within the drift diffusion framework, are likely to determine the drift rate. We can formalize this by allowing the mean drift rate in the drift diffusion model to be a linear function of the best fitting utility difference. Thus, for trial $a$ for participant $b$, we can write this mean drift rate as $v_{a b}=\beta_{0}+$ $\beta_{l} \cdot\left(U_{a b}{ }^{L}-U_{a b}{ }^{R}\right)$. Here $U_{a b}{ }^{L}$ is the predicted utility for the left
option in the trial for the participant, based on the best fitting model for the participant. Likewise, $U_{a b}{ }^{R}$ is the predicted utility for the right option. $\beta_{l}$ is a multiplier mapping this utility difference on to a drift rate, and $\beta_{0}$ is an intercept term capturing an absolute bias in drift for the left option. In this model, hitting the upper boundary leads to the left option being selected, whereas hitting the lower boundary leads to the right option being selected.

We fit this modified drift diffusion model permitting trial-to-trial variability in starting points and trial-to-trial variability drift rates. For this purpose, we adopted a hierarchical model fitting approach, as implemented by the HDDM toolbox (Wiecki et al., 2013). This approach recovers group mean parameters for the decision threshold, non-decision time, drift rates, trial-to-trial variability in starting points, trial-to-trial variability, and trial-to-trial variability drift rates, while also permitting individual differences in these parameters. Importantly this toolbox makes it easy to fit linear functions for drift rates as we wish to do in this paper. The best fitting group mean parameters from our specification, as recovered by the diffusion analysis, are presented in Table 2. Again $\beta_{l}$ represents the weight on utility difference in the drift term. As can be seen, the bulk of the distribution of this parameter lies above 0 , indicating that the best fitting utility difference has a strong positive relationship with mean drift in the model. Table 2 also displays the deviance information criterion (DIC) value for this fits.

|  | Mean | SD | Median |
| :--- | :---: | :---: | :---: |
| Full model |  |  |  |
| Boundary | 3.26 | 0.09 | 3.26 |
| Non decision time | 0.46 | 0.02 | 0.46 |
| $\beta_{0}$ | 0.01 | 0.01 | 0.01 |
| $\beta_{1}$ | 0.26 | 0.01 | 0.26 |
| DIC: $60,694.76$ |  |  |  |
|  |  |  |  |
| Restricted Model |  |  |  |
| Boundary | 3.08 | 0.08 | 3.08 |
| Non decision time | 0.48 | 0.03 | 0.48 |
| $\beta_{0}$ | 0.01 | 0.01 | 0.01 |
| DIC: $68,571.64$ |  |  |  |

Table 2. Summary of best fitting group mean parameters for the drift diffusion model fits in Study 1. Here $\beta_{1}$ represents the weight on utility difference in the drift term, in the full model. The restricted model sets this to O. DIC indicates the deviance information criterion value for the fits.

In a related analysis, we fitted a simplified version of this model in which $\beta_{I}=0$, and drift is independent of the predicted utility difference. As shown in Table 2, the fits for this model, measured through the deviance information criterion (DIC), are much lower than those for the extended model, suggesting that the utility differences specified by our approach do improve reaction time predictions in naturalistic multiattribute choice tasks.

## Studies 2-5

As a secondary demonstration we applied our approach to two other domains: food choice and movie choice. We conducted a series of online studies offering participants two-object and three-object choices between various food dishes and between various movies, and we predicted these choices using latent attributes obtained from user-generated ingredients on www.AllRecipes.com and user-generated keywords on www.IMDB.com.

Method. In Study 2, 90 participants recruited from Amazon Mechanical Turk made 200 binary choices between various food dishes. The food dishes were obtained from www.AllRecipes.com, and there were a total of 100 unique food dishes used in the study (which were the most popular dishes on www.AllRecipies.com). Choices in this study were presented on the screen using just the names of the dishes. Participants had to click on the names in order to indicate their choices. In Study 3, 88 participants recruited from Amazon Mechanical Turk made 200 three-object choices between various food dishes. The dishes used were the same as those in Study 2, and their presentation was identical to that in Study 2 (except that each screen offered three different choices, instead of two). Participants in both Studies 2 and 3 were compensated with money.

In Study 4, 75 participants recruited from an undergraduate student participant pool made 200 threeobject choices between different movies. There were a total of 100 unique movies used. These were the 100 most popular movies on www.IMDB.com (Internet Movie Data Base). The choices were presented on the computer screen using just the names of the movies and their IMDB movie posters. Participants had to click on the movie name or poster in order to indicate their choices. Participants were compensated with course credit. Study 5 was identical to Study 4, except that participants were recruited from Amazon Mechanical Turk. There were 223 total participants in this study, and they were compensated with a monetary payment.

Model Fitting. The model fitting in Study 2 was identical to Study 1, except that the latent attributes were recovered from a singular value decomposition on the www.AllRecipes.com data. Study 3 used a very similar model fitting technique, except that instead of a binary logit choice rule, there was a three-object (multinomial) logit choice rule. Studies 4 and 5 also used this choice rule, applied using latent attributes recovered from a singular value decomposition on the www.IMDB.com data.

Results. The accuracy rates from our analysis for the Studies 2-5 are displayed in Table 1. The mean accuracy for Study 2 is $78 \%(S D=0.10)$, the mean accuracy for Study 3 is $74 \% ~(S D=0.13)$, the mean accuracy for Study 4 is $79 \%(S D=0.14)$ and the mean accuracy for Study 5 is $80 \%(S D=0.12)$. All of these are significantly ( $p<0.01$ ) higher than the baseline accuracy of $50 \%$ (for Study 2) and $33 \%$ (for Studies 3-5).

We also found that the best fitting latent attribute models have a relatively low dimensionality, for most participants.

Overall, the average best fitting value of $L$ (i.e. number of dimensions) across our participants is $31.95(S D=28.55)$ for Study 2, $56.02(S D=27.18)$ for Study 3, $50.05(S D=$ 28.12) for Study 4, and $52.64(S D=25.93)$ for Study 5.

Table 1 also displays the results of a random vector model for these studies. Again it shows that the majority of participants are better described by our approach relative to the random vector approach. Finally, Table 1 shows the fits of the lexicographic and tallying heuristics. For Study 2, these fits are performed similarly to Study 1. However, Studies 3-5 involve three object choice. Thus the weights for the individual features necessary for fitting these heuristics cannot be obtained through a simple correlation analysis between the relative presence or absence of a feature and the choice in a trial. Instead we calculated, for each feature in each trial, Relative Presence $=C-0.5\left[U C_{1}\right.$ $\left.+U C_{2}\right]$. Here $C=1$ if the feature is present in the chosen option and 0 otherwise. Likewise, $U C_{I}=1$ if the feature is present in the first unchosen option and 0 otherwise, and $U C_{2}=1$ if the feature is present in the second unchosen option and 0 otherwise. For each feature, we summed Relative Presence over all the observations in the training data for the participant in consideration. This gave us a measure of the Total Relative Presence of the feature in the chosen options for the participant. For the lexicographic heuristic, we then selected the single feature with the highest absolute Total Relative Presence for the participant in the training data, and used this feature to predict the participant's choices in the test data. For the tallying heuristic we recoded the Total Relative Presence for a feature to generate a weight of +1 if Total Relative Presence was positive and -1 if it was negative. These binary weights were then used to predict the participant's choices according to the tallying heuristic. Using this approach, we again found that the lexicographic and tallying heuristics were out performed by the latent attribute approach, as shown in Table 1.

## Discussion

In this paper we have proposed that decision makers use low-dimensional latent attributes in order to make decisions in naturalistic multiattribute choice settings. We have obtained latent attribute representations for various everyday choice objects using user-generated object descriptors in large online datasets, and in five experiments, have predicted participant choices between these objects by fitting linear models with our latent attributes. Our fits reveal that our approach provides high accuracy rates, which significantly outperform accuracy rates obtained through other sophisticated methods (such as linear models with random attribute vectors, and lexicographic and tallying heuristics). The best fitting models in our analysis often have small or moderate number of dimensions. Additionally, these models are able to quantitatively predict decision times, when their estimated utilities are embedded within a drift diffusion process.

Our primary theoretical contribution involves the formal characterization of the processes involved in choosing between everyday choice objects. In doing so we extend insights from semantic memory research to the field of multiattribute decision making. The resulting framework attempts to describe all key aspects of the decision process, from the learning of object representations for common choice objects, to the use of these representations for evaluation and decision making. This is in contrast to most theories of multiattribute choice, which specify the mechanisms involved in aggregating decision attributes but seldom attempt to describe what these attributes actually are (see Bhatia, 2013 for a discussion).

Our results suggest that dimensionality reduction is not only at play in representing words, concepts, and various non-choice objects (as in e.g. Landauer \& Dumais, 1997; Shepard, 1962) but is also a critical feature of multiattribute choice object representation in preferential decision making. There are many reasons why this would be the case. Firstly, common multiattribute choice objects involve a large number of observable features, as well as systematic relationships between the features. Good decision making involves understanding these feature relationships, and using these relationships to make inferences about the objects. Even though the inferences in preferential choice are primarily evaluative, knowledge is used in a very similar manner as in categorization, language comprehension, object recognition, and other related tasks. Additionally, the use of latent attributes also offers a number of distinct advantages relative to the use of raw observable features. There are fewer latent attributes than there are observable features, and for this reason, latent attributes simplify the decision process. These attributes also reduce redundancy in object representation, and do so in the most efficient manner possible. In fact, our approach is not unlike principle components regression, which possesses a very similar set of statistical benefits (see Draper \& Smith, 1981).

That said, the approach presented in this paper is fairly simplistic: It involves a linear technique for dimensionality reduction combined with a linear multiattribute utility model. Both of these assumptions should be tested, it wouldn't be surprising if more sophisticated and more realistic approaches to building semantic representations ( Jones et al., 2015) and making choices (Oppenheimer \& Kelso, 2015) outperform the current approach. It may also be the case that the representations of choice objects depend not only on feature co-occurrence, but also on the reward structure of the domain in consideration. Individuals may, for example, learn object representations that best predict rewards, rather those that best predict feature occurrence. If this is the case then it would be necessary to train models of object representation alongside models of evaluation and choice (rather than training the former separately, as is done in this paper). This could be accomplished using neural networks with backpropagation from a preference (reward) layer to an object representation layer. Supervised topic
models may also facilitate the learning of such representations.

Despite the need to test more sophisticated representation and choice models, the success of our current approach nonetheless opens up a new avenue for studying naturalistic multiattribute choice. It can be applied to examine whether existing multiattribute choice effects also emerge in more realistic choice settings, where attribute information is not presented numerically (as in Figure 1a). It can also be used to extend the psychological analysis of multiattribute choice beyond the laboratory and predict real world choice data. Ultimately, by combining existing theories of semantic representation and multiattribute choice with rigorous analysis of large-scale data, this paper has proposed tools to capture the large number of important decisions made in the real-world, that are not currently within the scope of decision making research. This has the potential to significantly expand the theoretical, descriptive, and practical scope of this area of study.

# The Interactive Shaping of Social Learning in Transmission Chains 

Lucas M. Bietti (lucas@bietti.org), Adrian Bangerter (adrian.bangerter@unine.ch), Eric Mayor (eric.mayor@unine.ch)<br>Institute of Work and Organizational Psychology, University of Neuchâtel, Rue Emile-Argand 11, Neuchâtel, CH-2000, Switzerland

#### Abstract

This study investigated the social transmission of memories and skills collected from a collaborative cooking task (raviolimaking) and across transmission chains. The transmission over three generations of pairs of participants occurred under two conditions. In the interactive condition, transmissions over generations occurred in face-to-face conversations, whereas in the non-interactive condition, generations videorecorded their instructions to the next generations. We analyzed the effects of verbal and embodied features of informational transfer on task performance. Our results show that performances improved over generations regardless of interactivity. In the discussion we suggest that tools (like cooking utensils) may have operated as cultural affordances encapsulating and transmitting important cultural knowledge for the successful completion of the task.

Keywords: social transmission; embodied interaction; social learning; joint complex task; cultural affordances; cooking

## Social learning and the necessary ingredients

 for cumulative cultural evolutionSocial learning (e.g. Bandura, 1977) is learning by observing or interacting with another individual or a product. Social learning mechanisms enable individual improvements in the efficiency or productivity of cultural artefacts (e.g. Ramstead, Veissière, \& Kirmayer 2016) to accumulate from one generation to the next (e.g. Boyd \& Richerson, 1994; Tomasello et al., 1993;). Such mechanisms include teaching (Kline, 2015), imitation or emulation (reverse engineering) (Caldwell \& Millen, 2008). Teaching and imitation represent cases of high-fidelity transmission, allegedly allowing "complex behaviors to disseminate and be retained in populations until beneficial modifications occur" (Vale, Flynn \& Kendal, 2012, p. 223). Currently, however, it is unclear whether teaching is a necessary ingredient for cumulative culture to accrue (Zwirner \& Thornton, 2015). The aim of our study is to investigate how different variants of teaching (interactive vs. non-interactive) affect cumulative cultural transmission of skills in a
complex joint task (collaborative cooking) in a laboratory setting.

## Cultural transmission in the laboratory

Transmission chains are a method used to study cultural evolution in the laboratory. Bartlett's (1932) seminal serial reproduction design allowed studying how content changes when transmitted from individuals of one generation to the next. Although Bartlett's method is more focused on constructive remembering of information originally provided to the first generation of participants and not on the accumulation of such information, it has largely inspired modern laboratory research on cumulative cultural evolution (e.g., Caldwell, Atkinson, \& Renner, 2016; Mesoudi \& Whiten, 2008) or the evolution of language and other communication systems (e.g. Fay, Arbib, \& Garrod, 2013; Kirby, Cornish, \& Smith, 2008). However, the method in its standard form prescribes one-way transmission without receiver feedback and has thus been criticized for neglecting the interactive processes germane to conversational remembering (Edwards \& Middleton, 1987). Indeed, recent work has shown that giving participants the opportunity to freely interact during transmission improves transmission quality (Tan \& Fay, 2011).

## Cultural transmission of manual tasks

In a series of experimental studies using transmission chains, individuals built paper airplanes or towers made of spaghetti and modeling clay (Caldwell \& Millen, 2008). For the paper plane task, successive generations had access to different types of social information: (i) information about actions (new generations observed what previous generations did); (ii) information about results (new generations observed final products and their performance measured in flying distance); and (iii) information
generated through teaching (new and old generations interacted about the completed task). These three types of social information were designed to enable imitation (information about actions); emulation (information about results) and instructed learning (information generated through teaching). The results indicated that cumulative learning was found in all three conditions (imitation, emulation and teaching). Such findings seem to challenge widespread claims about the necessity of social transmission for cumulative cultural evolution (e.g. Boyd \& Richerson, 1994).

Building paper airplanes is arguably an artificial task likely to be confounded by prior experience. Zwirner and Thornton (2015) extended these findings using a more realistic basket construction task. They found that teaching increased the accumulation of improvements over generations, but that it was not necessary for them to occur, further supporting the hypothesis that imitation and teaching are not "fundamental prerequisites for cumulative culture" (Zwirner \& Thornton, 2015, p. 7).

## Cultural transmission and social interaction

A recent study examined the influence of social interaction in transmission chains (Tan \& Fay, 2011). In an interactive condition, chains of participants interacted freely with one another to transmit narrative information from one generation to the next. In a non-interactive condition, receivers of the information had to listen to audio-recordings of narrations produced by senders (previous generation) and then recorded their own accounts of what they had listened to, which were passed on to a new generation of receivers for the same procedure. Transmission was more accurate in the interactive condition than in the non-interactive condition, and was due to the effect of receivers' behavior, including backchannels or clarification questions. The authors suggested that the motivation or ability to interact during information transmission may contribute to the emergence of cumulative culture.

## Our experiment

In Tan and Fay (2011), it could be the case that benefits of the interactive transmission of information are related to the nature of the task (information transfer) rather than to general mechanisms of cultural transmission. Hence, it is unclear whether interactivity plays a role in transmitting manual skills. Our experiment thus investigated the interactive context in which the cultural transmission of manual skills occurs. That is, we studied whether the teaching behaviors of senders who have experience with a skill is affected by the presence or absence of receivers from a subsequent generation. The experiment consisted in the cultural transmission of memories and skills collected from a collaborative cooking task (ravioli-making) via transmission chains. Chains of three generations (G1-G2-G3) of pairs of participants made ravioli and transmitted their experience to a pair in the next generation. This occurred under two conditions (interactive condition vs. non-interactive condition). In the interactive condition, transmissions occurred in face-to-face conversations, whereas in the noninteractive condition they were video-recorded as instructions to the next generation. All transmissions were video-recorded in order to analyze both verbal and embodied features of information transfer (e.g., gestures that depict an action), which may be particularly important for the transmission of manual skills.
In line with Caldwell and Millen's (2008) studies using manual tasks, we expect that performance will improve over generations due to the accumulation of learned improvements. We further expect interactive transmissions to allow receivers of information to ask questions and request clarifications (Tan \& Fay, 2011), and thus, to stimulate senders to talk and gesture more. This in turn may lead to a better transmission of skills. As a result, we also expect interactive transmissions to lead to better performance than non-interactive transmissions. Finally, we expect longer transmissions from senders to lead to subsequent higher performance in receivers when compared to performances following shorter transmission.

Thus, the hypotheses we tested were:
H1) Performance improves over generations;
H2) During transmissions (G1-G2; G2-G3), senders gesture more (H2a) and speak more (H2b) in the interactive condition than in the noninteractive condition;
H3) Performance improves more in the interactive condition than in the non-interactive condition;
H4) Performance is predicted by the number of words and the duration of gestures in the preceding transmission session.

## Method

## Participants

Participants ( $n=246 ; 117$ men) were recruited from the student population of the University of Neuchâtel (Age $M=23.2$; $S D=4.07$ ). They were fluent speakers of French, and reported having limited previous cooking experience. They had previous practice of simple skills like combining and heating ingredients but did not master more complex skills (e.g. preparing pie from scratch). Participants received 25 CHF compensation each for half an hour of their time along with an incentive of 0.25 CHF in total for each produced ravioli of good quality. There were 41 chains ( 20 in the interactive condition and 21 in the noninteractive condition). Pairs of participants were randomly assigned to different conditions (interactive vs. non-interactive) and generations (G1-G3) in the chains.

## Task

The task consisted of two kinds of sessions, performance sessions and transmission sessions (Fig. 1). In performance sessions, participants from each generation prepared ravioli together in pairs. Their goal was to produce as many goodquality ravioli as possible in 10 minutes. Each pair had at their disposal a ball of 150 grams of dough; 200 grams of filling made of ricotta cheese, concentrated tomato paste and salt; a 24-hole ravioli mold with zigzag sealing for easy release; a pasta maker; a rolling pin; a cutting board; 2 pizza cutters; 2 knives; 4 teaspoons; 2 kitchen cloths and kitchen paper; 250 grams of flour; and a stopwatch. Immediately after the time was up, the ravioli were evaluated by the experimenter.

Transmission sessions occurred immediately after each performance session (except for the last one, see Fig. 1). Pairs who had just completed the task explained to next-generation pairs how to prepare the ravioli. These sessions were unstructured and did not have time constraints (they typically lasted 2-8 minutes).

Figure 1. Sequence of sessions in the experiment and groups involved in each session.

## Procedure

Participants signed consent forms upon their arrival. G1 pairs watched a 3 min 47 sec video tutorial that was recorded for the study (Fig. 1). It provided information about the steps to be followed to prepare ravioli in pairs. They then completed Performance session 1, followed by Transmission session 1 (together with G2 pairs). Then, G2 pairs completed Performance session 2. During this time, G1 pairs were paid, debriefed and allowed to leave. After having completed Performance session 2, G2 pairs participated in Transmission session 2 (together with G3 pairs). Then, G3 pairs completed Performance session 3. During this time, G2 pairs were paid, debriefed and allowed to leave. After performance session 3, G3 pairs were paid, debriefed and allowed to leave.

## Measures

All sessions were videotaped and transcribed. Information transmission (teaching) was measured by the total number of words uttered by senders as well as the total duration of their manual gestures (iconic and pointing gestures) in the transmissions. Performance was measured as the quantity of "good" ravioli each pair produced. The criteria that experimenters considered to count ravioli as good exemplars were that they should contain enough filling and they should be perfectly sealed.

## Results

Descriptive results appear in Tables 1 (performance) and 2 (transmission).

Table 1. Performance ( $M, S D$ ) by condition and generation

|  |  | Interactive |
| :--- | :--- | :--- |
| G1 | $8.70(10.70)$ | Non-interactive |
| G2 | $10.65(11.51)$ | $10.33(9.36)$ |
| G3 | $14.80(10.75)$ | $12.57(8.81)$ |

Table 2. Transmission variables ( $M, S D$ ) by condition and transmission

|  | Interactive | Non-interactive |  |  |
| ---: | :--- | :--- | :---: | :---: |
|  | Sender words |  |  |  |
| G1G2 | $872.45(290.22)$ | $545.14(222.655)$ |  |  |
| G2G3 | $924.15(447.53)$ |  |  | $480.19(196.16)$ |
|  | Sender gestures |  |  |  |
| G1G2 | $196.19(69.93)$ | $152.40(76.00)$ |  |  |
| G2G3 | $216.80(98.52)$ | $117.27(57.64)$ |  |  |
| Note. | G1G2: Transmission | session |  |  |
| Transmission session 2. |  |  |  |  |

We tested our hypotheses using random intercept mixed-model regression (in R 3.4, packages lme4 and lmerTest). We included chains as clustering variables.

## H1: Performance improves over generations.

To test H1, we included condition and the linear trend of generation as predictors of performance.

Performance improved marginally (linear trend: $B$ $=2.79, S E=1.41, t=1.98, p=0.051)$. Condition was not a significant predictor of performance ( $B$ $=-0.19, S E=2.13, t=-0.09, p=0.92$ ). Thus, H1 is marginally supported.

H2: During transmissions (G1-G2; G2-G3), senders gesture more (H2a) and speak more (H2b) in the interactive condition than in the non-interactive condition.
To test H2, we included condition as a predictor of sender's gestures (H2a) and words (H2b), controlling in each model for transmission session. The interactive condition was the reference category. H2a was supported ( $B=-$ 71.04, $S E=20.59, t=-3.48, p=0.001$ ). H2b was also supported $(B=-385.63, S E=81.16, t=-4.75$, $p<.001$ ). Transmission (reference category: first transmission) was not related to the dependent variables (for sender's gestures: $B=-7.94, S E$ $=12.90, t=-0.615, p=0.54$; for senders' words: $B=-8.05, S E=49.06 ; t=-0.16, p=0.87$ ). Overall, H2 is supported.

H3: Performance improves more in the interactive condition than in the noninteractive condition.
To test H3, we included the condition, the linear trend of generation and their interaction term as predictors of performance. The performance of groups in the interactive condition improved across generations (linear trend: $B=4.31, S E=$ $2.03, t=2.12, p=0.04)$. Groups in the noninteractive condition do not improve less than groups in the interactive condition, as shown by the non-significant condition $x$ linear trend of generation interaction ( $B=-2.97, S E=2.84, t=-$ $1.04, p=0.30$ ). Thus, H3 is not supported.
The marginal improvement in performance in the test of H1 is probably driven by the interactive condition, as the magnitude of the negative interaction term in the test of H 3 is close to the main effect.

H4: Performance is predicted by the number of words and the duration of gestures in the preceding transmission session.

To test H4, we simultaneously included the number of words uttered by senders and their gestures during the transmission preceding the task as predictors of performance (we did not predict the performance of G1), controlling for condition and generation. H4 was not supported (for senders' words: $B=0.01, S E=0.06, t=0.15$, $p=0.87$; for senders' gestures: $B=0.03, S E=$ $0.02, t=1.41, p=0.16$ ). Neither Condition ( $B=$ $1.43, S E=2.70, t=0.53, p=0.60$ ) nor Generation ( $B=3.44, S E=2.04, t=1.68, p=0.10$ ) were related to performance.

## Discussion

We investigated whether the interactive context in which cultural transmission occurred affected the transmission process and its outcomes. We observed that senders behaved differently depending on the presence or absence of listeners (longer transmissions in terms of talk and gesture). However, such differences did not affect the subsequent performance of the receivers (see Table 1). That is, performance improved over generations (albeit marginally) regardless of interactivity, further supporting previous findings (e.g. Caldwell \& Millen, 2008; Zwirner \& Thornton, 2015) and research on cumulative learning in humans (e.g. Boyd \& Richerson, 1994). However, in contrast to the manual tasks previously employed (e.g. paper airplanes, spaghetti towers, and baskets), our collaborative cooking task presented some particularities. Some materials that the participants had the possibility to use (e.g. ravioli mold; pasta maker and rolling pin) may have operated as cultural affordances (e.g. Ramstead, Veissière, \& Kirmayer 2016) already encapsulating relevant information for the successful completion of the task. Material culture, as transmitted by cooking utensils, has played a central role in the evolution of human cognition (Malafouris, 2013). Future studies on cultural transmission in the laboratory should begin to take into consideration the importance of such cultural affordances if they want to better understand the actual ecologies of teaching and learning.

Tan and Fay (2011) showed that "that interaction between senders an receivers promotes more accurate recall and transmission of cultural information" (p. 405). Our analyses did not deal with verbal protocols and the amount of information accurate recalled over generations. However, based on this previous evidence we expected to find more increased performance in the interactive condition compared to in the noninteractive condition. In other words, if more accurate information were produced in interactive chains (as previous evidence suggests), it could lead to an increase in performance over generations in the interactive condition. Against our expectations, in our study, this was not the case. We did not find an effect of the number of words and duration of gestures produced by senders on performance of receivers over transmission chains (see Table 2). Although, senders spoke and gestured more in the interactive condition than in the non-interactive condition (see Table 2), this did not affect receivers' performance. This result suggests that there is no clear correspondence between the quantity of information transmitted over generations and performance.
In our analyses we did not examine the content of the information transmitted over generations or how it was recalled during performance. A possible theme for further investigation related to our current results is whether better or worse performing generations transmit more useful information over chains. It may well be the case that worse performing generations communicate more useful information to next generations if they focus their accounts on the errors they committed during performance.
In contrast to Tan and Fay (2011), our findings showed that in complex joint tasks having the possibility of asking questions and requesting clarifications (interactive condition) did not bring benefits. This could be related to the nature of the task participants were asked to perform. Whereas in Tan and Fay (2011) participants simply relayed information received from previous generations, in our study participants had the opportunity to perform the task before transmitting information to the next generation. This involved access to the
tools provided as well as the opportunity to test different strategies and solve problems. Throughout human evolution, "the social environment, not just individual minds, has become increasingly organized to support the flow of information across the generations" (Sterelny, 2012, p. 27). Looking at the multiple ways in which interactive contexts, task specificity, and cultural affordances affect the transmission of everyday skills (e.g. cooking) is an important step towards better understanding the mechanisms of cultural transmission.

# Language Modality Affects Responses in Left IFG during Processing of Semantically Ambiguous Sentences 

Lena M. Blott<br>University College London<br>Jennifer M. Rodd<br>University College London<br>Jane E. Warren<br>University College London

#### Abstract

Ambiguity resolution requires high-level interpretation processes, at least some of which are subserved by the inferior frontal gyrus (IFG), a region that is susceptible to modulation by task demands. This fMRI study investigates the extent to which ambiguity-related activation in IFG is modulated by the specific cognitive-linguistic demands posed by the modality in which a sentence is presented. In the present study, ambiguous sentences and matched unambiguous sentences were presented in three conditions: listening, reading, and rapid serial visual presentation (RSVP). The RSVP modality elicited stronger ambiguity-related haemodynamic responses than the other two modalities, particularly in left anterior IFG. This indicates that the RSVP modality cannot be used as a simple substitute for natural reading without taking into account the additional processing resources it requires.

# Generalized Representation of Syntactic Structures

#### Abstract

Analysis of language provides important insights into the underlying psychological properties of individuals and groups. While the majority of language analysis work in psychology has focused on semantics, psychological information is encoded not just in what people say, but how they say it. In the current work, we propose Conversation Level Syntax Similarity Metric-Group Representations (CASSIM-GR). This tool builds generalized representations of syntactic structures of documents, thus allowing researchers to distinguish between people and groups based on syntactic differences. CASSIMGR builds off of Conversation Level Syntax Similarity Metric by applying spectral clustering to syntactic similarity matrices and calculating the center of each cluster of documents. This resulting cluster centroid then represents the syntactical structure of the group of documents. To examine the effectiveness of CASSIM-GR, we conduct three experiments across three unique corpora. In each experiment, we calculate the clustering accuracy and compare our proposed technique to a bag-of-words approach. Our results provide evidence for the effectiveness of CASSIM-GR and demonstrate that combining syntactic similarity and tf -idf semantic information improves the total accuracy of group classification.

Keywords: Syntax; Text Clustering; Syntactic Similarity; Text Classification; CASSIM.

## Introduction

Language lies at the heart of human communication, and analysis of language has been shown to be an essential lens for investigating and understanding many different psychological properties. Language analysis has provided insight into depression (Ramirez-Esparza, Chung, Kacewicz, \& Pennebaker, 2008), moral values (Graham, Haidt, \& Nosek, 2009; Dehghani et al., 2016), neuroticism and extraversion (Mehl, Robbins, \& Holleran, 2012), political orientations (Dehghani, Sagae, Sachdeva, \& Gratch, 2014), and cultural backgrounds (Maass, Karasawa, Politi, \& Suga, 2006; Dehghani, Bang, et al., 2013) among many others.

Most of these studies, however, focus on quantifying word choice or semantics. While semantics undoubtedly play an important role in capturing psychological properties, it is vital to also include analysis of syntax in this process. Prior research has shown that syntactic structures also capture individuals and group differences for various demographic and psychological factors such as educational or regional background (Bresnan \& Hay, 2008), gender (Vigliocco \& Franck,
1999), socio-economics (Jahr, 1992), and emotional states and personality (Gawda, 2010).

Recently, several tools have been developed for automated analysis of syntactic structures. For example, Lu's (Lu, 2010) system analyzes fourteen different measures including the ratio of verb phrases, number of dependent clauses, and Tunits to calculate documents' syntactic complexity. Similarly, TAALES relies on several features such as frequency, range, academic language, and psycholinguistic word information to measure lexical sophistication (Kyle \& Crossley, 2015). By comparison, Coh-Metrix is a tool which provides measurement for over 200 different facets of syntax (e.g. mean number of modifiers per noun phrase, mean number of high-level constituents per word, and the incidence of word classes that signal logical or analytical difficulty) (Graesser, McNamara, Louwerse, \& Cai, 2004).

While each of these tools provides different mechanisms for measuring various syntactic features, they all rely on previously identified features of interest. More recently, we introduced ConversAtion Level Syntax Similarity Metric (CASSIM) to incorporate constituency parse trees when calculating the syntactic similarity of documents (Boghrati, Hoover, Johnson, Garten, \& Dehghani, 2017). CASSIM compares groups of documents based on underlying syntactic differences between groups of documents.

There are some situations, however, where hypothesis testing about predefined features or groups may not be the only aim. Instead, researchers may wish to identify new groupings of documents and the features which tie them together. These group-level linguistic representations can lead to important, novel discoveries about how a group communicates. Clustering techniques are widely used for this type of analysis. There is an extensive literature studying various text clustering approaches and their applications (Song, Li, \& Park, 2009; Sasaki \& Shinnou, 2005; Lin, Jiang, \& Lee, 2014). This literature demonstrates that many linguistic features facilitate improvements in text clustering (T. Liu, Liu, Chen, \& Ma, 2003; L. Liu, Kang, Yu, \& Wang, 2005), some of which address the effect of synonymy, hypernymy, syntax, and part of speech tags on text clustering methods (Sedding \& Kazakov, 2004; Lewis \& Croft, 1989; Lewis, 1992; Zheng, Kang,

Figure 1: CASSIM-Group Representation Process.
\& Kim, 2009).
In the current paper, we introduce ConversAtion Level Syntax Similarity Metric-Group Representations (CASSIMGR), a tool that captures the generalized representation of syntactic structure used by individuals in a certain group. CASSIM-GR groups documents into separate clusters based on their syntactic similarity scores, and uses the centroid of a cluster as a generalized representation of the syntactic structures used in that cluster. These centroid syntax representation can then be used to understand within-group syntax similarities and between-group syntax variations. As we will show, these generalizations of syntactic structures can be useful when analyzing differences between documents written by different individuals or groups.

This paper is structured as follows: First, we describe our proposed approach, CASSIM-GR, in more detail. Next, we validate the approach with a corpus of syntactically similar documents. Then, we apply CASSIM-GR to two other corpora: documents marked as dogmatic and non-dogmatic (Fast \& Horvitz, 2016) and documents from conservative and liberal weblogs (Dehghani, Sagae, Sachdeva, \& Gratch, 2013) and evaluate the classification accuracy of CASSIM-GR compared to tf-idf approach and a combination of the two approaches. Finally, we discuss limitation and future directions of our work.

## CASSIM-GR

In this section we describe CASSIM-GR for clustering groups of documents with similar syntactic structures. CASSIM-GR includes four general steps: 1 . constructing the syntactic similarity matrix, 2 . applying spectral clustering, 3 . calculating the center of clusters, 4. classification. Figure 1 demonstrates the steps involved in CASSIM-GR to compute the generalized representation of syntactic structures.

First, we use CASSIM (Boghrati et al., 2017) to calculate the syntactic similarity between each pair of documents. CASSIM relies on edit distance difference of constituency parse trees. It first generates parse trees for the sentences in each document. Next, it calculates the edit distance between each two sentences' constituency parse trees and matches the most syntactically similar sentences using Hungarian algorithm. Finally, it provides a score between 0 and 1 where
higher numbers indicate higher similarity between two documents. Using the syntactic similarity scores measured by CASSIM, we build a syntactic similarity matrix. With $N$ documents in our corpus, the syntax similarity matrix is $A_{N \times N}$; where $A_{i, j}$ is the syntactic similarity of the two documents $i$ and $j$.

Next, spectral clustering (Shi \& Malik, 2000) is used to cluster documents into a pre-defined number of groups. It has been shown that spectral clustering often outperforms traditional clustering algorithms (Von Luxburg, 2007). The general idea behind spectral clustering is to apply $k$-means clustering on eigenvectors of Laplacian matrix of $A$. The syntactic similarity matrix $A$, which is constructed in the previous step, and the number of clusters are provided as inputs to the spectral clustering method.

Clustering documents leads us to an essential next step which is extracting general attributes or representation of clusters. One way to address this concern is to calculate a centroid for each cluster. Clusters' centers facilitate researchers to better understand and analyze the syntactic structures used by a group of people or under certain situations by only analyzing center documents and without going through hundreds of documents. Hence, the third step in CASSIM-GR is calculating a centroid for each cluster. We define a cluster's center as the document which has the highest syntactic similarity to other documents in its cluster. To identify a cluster's center, we calculate average syntactic similarity of each document to other documents in its cluster and return the document with the highest average similarity. Additionally, we may return the top $n$ documents with the highest average syntactic similarity to other documents in a cluster as representative samples of that cluster.

Finally, we use cross-validation to test the accuracy and representativeness of the clusters' centers. To cross-validate, our approach uses CASSIM to calculate the syntactic similarity of the left-out document to each centroid and assigns the document to a cluster with the highest similarity. This process is repeated $N$ times and an accuracy of classification is reported by the method. In the following sections, we evaluate CASSIM-GR by performing classification experiments on three different corpora.

## Experiments

We conducted three experiments to validate CASSIM-GR and to examine the representativeness of the cluster centroids. Additionally, we examined how well documents with similar syntactic structures cluster together and demonstrate the importance of syntactic similarity in classification. Further, we compare the accuracy of syntactic clustering to bag-of-words clustering. For this purpose, we use the tf-idf similarity matrix as input to spectral clustering. Lastly, we combined tf-idf and CASSIM-GR to see how including both sets of information affect the classification accuracy. Below, we discuss the three experiments in detail.

## Experiment One

Experiment one was conducted on a corpus of syntactically similar documents. The corpus was generated by Amazon Mechanical Turk participants and consists of four groups of documents; each has high within-group syntactic similarity and low between-group syntactic similarity.

We used CASSIM-GR along with tf-idf, to group documents into clusters. Further, we combined these two approaches and calculated the overall accuracy. We first introduce the dataset and then report the results.
Data 118 MTurk participants answered a set of four questions. In each question they were asked to generate sentences with similar grammar rules to the sentence prompts in the question. Each of the four prompts had a different syntactic structure. Later, two independent coders, coded whether a sentence generated by a participant was grammatically similar to its prompt. Sentences which were identified as dissimilar by both coders were excluded from the dataset. Finally, a total of 272 documents, 68 documents in each group, were collected. See Boghrati et al. (2017) for more details.

Since participants were asked to write sentences similar to four different sets of prompts, the corpus is therefore divided to four separate groups, each associated to a question and its responses. Documents which are in the same group are considered to have similar syntactic structures.

Analysis We performed leave-one-out cross-validation for both of the clustering techniques. Namely, we ran the analysis on all the documents except for document $i$. Next, we labeled the clusters with the name of the group to which most of the documents belong. Then, we calculated similarity of document $i$ to each cluster's center. Finally, document $i$ was assigned to the cluster with which it had the highest syntactic similarity. The classification was considered successful if the assigned cluster's label and the document's group were identical.

We used the following approach to combine tf-idf and CASSIM-GR: First, we used CASSIM-GR and tf-idf approach separately to cluster documents into $k$ clusters. Cluster $j, j \in[1, k]$ in tf-idf approach and cluster $j^{\prime}, j^{\prime} \in[1, k]$ in CASSIM-GR were labeled with the same name, that is, the majority of documents in cluster $j$ and the majority of docu-
ments in cluster $j \prime$ were from the same group (e.g. 'liberals'). We averaged the syntactic similarity of document $i$ to center of cluster $j$ and the syntactic similarity of document $i$ to center of cluster $j \prime$. We repeated this procedure $k$ times to measure the similarity of document $i$ to all $k$ clusters and assigned document $i$ to the cluster with highest similarity score. If the cluster's label and document $i$ 's label were the same, we would conclude that prediction was successful.

Results Our results demonstrate that CASSIM-GR is able to accurately cluster the corpus. Following the instructions discussed in above, we performed leave-one-out crossvalidation on 272 documents. In each step, 271 documents were clustered in four groups and later the left-out document was assigned to one of the four clusters based on its similarity to the center of clusters.

Following this mechanism, CASSIM-GR yielded 95\% accuracy while tf-idf approach was only $84.5 \%$ accurate. Running a chi-squared test demonstrates that CASSIM-GR results in significantly higher accuracy than tf-idf, $X^{2}(1)=$ $17.01, p<.001$. Since the dataset consists of groups of syntactically similar documents, it is not surprising that clustering based on syntactic structures surpasses the word-based approach and achieves a higher accuracy.

Next, we combined the two approaches and obtained an accuracy of $97.8 \%$. While this result is not significantly higher than CASSIM-GR accuracy, $X^{2}(1)=2.67, p=.10$, we may conclude that incorporating syntactic and semantic information together could potentially improve clustering accuracy.

## Experiment Two

In the second experiment, we used the Dogmatism Dataset collected by Fast and Horvitz (2016). This dataset includes comments from New York Times which are rated based on their level of dogmatism. As explained below, we first categorized the documents as dogmatic or non-dogmatic based on this ratings. Next, we followed the procedure which was explained in the first experiment and clustered the documents using CASSIM-GR and the tf-idf approach. In the following subsections, we first introduce the dataset and then report the results.

Data The Dogmatism Dataset includes comments from New York Times. Amazon Mechanical Turk participants were asked to rate the level of dogmatism of each of the collected comments on a 5-point Likert scale. More details on the dataset and the annotation process are available at Fast and Horvitz (2016).
Analysis Dogmatism is subjective, and consequently interannotator agreement is higher for comments in both extreme sides of the spectrum. In other words, human coders tend to agree more on posts rated as very high in dogmatism and posts rated as very low in dogmatism (Fast \& Horvitz, 2016). Following the method used by Fast and Horvitz (2016), to have a representative and balanced dataset, we selected the top 250 and the bottom 250 documents based on the dogma-

Table 1: Corpora Overview.

|  | Experiment One | Experiment Two | Experiment Three |
| :--- | :--- | :--- | :--- |
| Corpus | Syntactically Similar Sentences | Dogmatism in New York Times | Political Weblog Posts |
| Number of Groups | 4 | 2 | 2 |
| Number of Documents | 272 | 500 | 452 |

Table 2: Accuracy of approaches in three experiments.

|  | Experiment One | Experiment Two | Experiment Three |
| :--- | :--- | :--- | :--- |
| CASSIM-GR | $95 \%$ | $54.8 \%$ | $69.9 \%$ |
| TF-IDF Approach | $84.5 \%$ | $61 \%$ | $64.4 \%$ |
| Combined Approach | $97.8 \%$ | $66.6 \%$ | $71.9 \%$ |

Table 3: Comparison of approaches in three experiments.

|  | Experiment One | Experiment Two | Experiment Three |
| :--- | :--- | :--- | :--- |
| CASSIM-GR vs. TF-IDF Approach | $X^{2}(1)=17.01, p<.001$ | $X^{2}(1)=3.94, p<.05$ | $X^{2}(1)=3.13, p=.07$ |
| TF-IDF Approach vs. Combined Approach | $X^{2}(1)=29.61, p<.001$ | $X^{2}(1)=3.39, p=.06$ | $X^{2}(1)=5.89, p<.05$ |
| CASSIM-GR vs. Combined Approach | $X^{2}(1)=2.67, p=.10$ | $X^{2}(1)=14.59, p<.001$ | $X^{2}(1)=.43, p=.51$ |

tism rating. We labeled the top 250 posts as dogmatic and the bottom 250 as non-dogmatic, hence the final dataset contained 500 posts with 250 in each group.

Results Following the instruction in Experiment 1, we performed leave-one-out cross-validation; we ran the clustering algorithm with 499 documents and left document $i, i \in$ [ 1,500 ], out. Then, we predicted to which cluster document $i$ belonged. CASSIM-GR and tf-idf approach resulted in $55 \%$ and $61 \%$ accuracy respectively. Even though, the tf-idf approach outperformed our approach significantly, $X^{2}(1)=$ $3.94, p<.05$, combining these two approaches resulted in a higher accuracy of $66.6 \%$, which is a marginally significant improvement over the tf-idf accuracy, $X^{2}(1)=3.39, p=.06$.

This result provides evidence for the importance of syntactic structure similarity in clustering documents. It demonstrates that not only what different groups of people say, but also how they say what they say provide important information about the characteristics of the group. This is evident by the fact adding syntactic similarity to word-level similarity can improve the clustering accuracy.

## Experiment Three

In this experiment, we applied CASSIM-GR on a corpus of political discussions taken from a set of conservative and liberal weblogs, and focus on the discussion about the Ground Zero Mosque (Dehghani, Sagae, et al., 2013).

Data The top five popular conservative and liberal news blogs were selected according to www.blogs.com. Next, a dataset of these weblogs posts which contained word mosque
and were written in the time frame of the debate, were complied. For more details about the dataset and the data collection process please refer to Dehghani, Sagae, et al. (2013).

Analysis In this experiment, we randomly selected 250 posts from conservative weblogs posts and 250 posts from liberal weblogs posts, but due to encoding issues the final dataset included 226 posts from each group (total of 452 posts).
Results Similar to the previous experiments, we used the leave-one-out cross-validation procedure described above. Specifically, we trained the clustering algorithm on 451 documents and predicted to which cluster the left-out document belonged. This process was repeated 452 so that each document was tested once.

CASSIM-GR was able to successfully predict the correct cluster for a document with $70 \%$ accuracy, while tf-idf was $64.4 \%$ accurate. This difference is only marginally significant, $X^{2}(1)=3.134, p=.0767$. Next, we combined these two approaches as described in the Experiment section. The total accuracy was $72 \%$ which is significantly more accurate than tf-idf approach alone, $X^{2}(1)=5.8905, p=.0152$.

These results demonstrated that, in some cases, syntactic structures similarity may capture more crucial features needed for clustering compared to tf -idf approach. However, there are some features that only tf-idf approach can pick up. Thus, the combination of these two sets of features is needed for more accurate clustering.

## Discussion and Future Work

Across three studies, we presented and validated a new approach called CASSIM-GR. CASSIM-GR clusters documents into separate groups based on their syntactic similarity and calculates a generalized representation of group-level syntax usage by performing four general steps: First, it creates a syntactic structure similarity matrix of documents using CASSIM. Second, it uses spectral clustering to group the documents into a pre-defined number of clusters using the syntactic similarity matrix generated in the previous step. Next, the algorithm selects the document which has the highest syntactic similarity to the other documents within each cluster and identifies it as the centroid of that cluster. Finally, it can be used to classify unknown documents based on the document's syntactic similarity to the clusters' centers.

We applied CASSIM-GR to three unique corpora (Table 1) across three experiments to compare its accuracy to both a bag-of-words approach and a combined approach incorporating tf-idf semantic information and CASSIM-GR. As Table 2 demonstrates, tf-idf and CASSIM-GR varied in their relative strength for clustering accuracy across studies. The combined approach incorporating both syntactic (CASSIM-GR) and semantic (tf-idf) information resulted in the highest clustering accuracy across all three experiments. While not a significant improvement beyond both single approaches, the combination approach significantly outperformed tf-idf in two of the three experiments and CASSIM-GR in the second experiment. Therefore, we may conclude that word-level similarity and syntactic similarity capture different aspects of language, and consequently, combining the two features' similarities results in more accurate clusters.

Our results indicate that methods assessing syntactic similarity may more accurately cluster documents than methods which rely on semantics alone. While there may be situations in which groups use the same general words to discuss a topic, syntactic similarity differences could still allow researchers to distinguish between different subsets of individuals.

More importantly, CASSIM-GR gives researchers an opportunity to study syntactic differences between groups by analyzing the prototypical syntactic structures at the clusters' centers. The syntactic structures used by a cluster's center document is defined as a generalized representation of syntactic structures of the documents in that cluster. Assessing differences in these structures may help to capture underlying psychological differences between groups in the ways that they conceptualize a topic or how they communicate with each other.

A vital component of CASSIM-GR is measuring syntactic similarity among documents using CASSIM. As mentioned previously, CASSIM's general focus is on comparing constituency parse trees. Building on CASSIM, we intend to compare dependency parse trees among sentences and documents to add another syntactic similarity measurement to CASSIM. Unlike constituency parse trees which posit the connection between part of speech tags, dependency parse
trees reveals the relationship between the words in a sentence. By incorporating this feature into CASSIM, researchers may further use CASSIM-GR not only to generalize syntactic structure of a group of documents, but also their dependency structures. This extension will help researchers study human language in finer grained detail by looking at the relationship between words.

In summary, we introduced a new method for computing generalized representations of syntactic structures of documents, allowing researchers to distinguish between groups of documents based on syntactic differences. Further, In the three experiments, we demonstrated the benefits of including syntactic structure similarity scores in clustering documents. In each experiment, we repeated a clustering procedure, once using CASSIM-GR and once using tf-idf similarity matrix. Then, we calculated clustering accuracy of each approach using leave-one-out cross-validation mechanism. Finally, we combined the results of these two approaches and calculated the accuracy when both sets of features were present. Our results support our assumption and demonstrated that syntactic similarity scores capture different aspects of language compared to bag-of-words, and therefore help improve clustering accuracy.

# Context reduces coercion costs - Evidence from eyetracking during reading 

Oliver Bott (oliver.bott@uni-tuebingen.de)<br>Project Composition in Context (CiC), DFG Priority Program XPrag.de<br>SFB 833, Nauklerstraße 35, 72074 Tübingen, Germany

#### Abstract

This paper presents an eyetracking during reading experiment that investigated the role of supportive context on processing aspectual coercion. Coercion sentences in need of aspectual enrichment were embedded in discourse contexts providing the necessary information for successful interpretation. The findings of the reported experiment show that context information can be used immediately without disrupting reading of coercion sentences. The lack of coercion costs in supportive discourse contexts provides experimental evidence for the proposed Composition in Context Hypothesis and against theories that view semantic composition as largely encapsulated from context. Furthermore, the present experiment investigated the role of inter-individual differences in verbal working memory capacity on the immediate use of contextual information in computing coerced interpretations.

Keywords: Aspectual coercion; Discourse context; Semantic processing; Eyetracking during reading; Working memory capacity

## Introduction

A central assumption in semantics is that interpretation is governed by the principle of compositionality (see, e.g., Pelletier, 1994). The prinholds that the meaning of a complex expression is entirely determined by the meaning of its parts and their syntactic combination. However, linguistic expressions are at the same time highly context dependent, and the language interpretation system is therefore not only dependent on the parts of complex expressions in a bottom-up fashion, but also has to be open to top-down influences of the context of utterance. The present study investigates the interplay between sentential and contextual information during the online composition of the event interpretation. In particular, I tested whether contextual information is immediately used to resolve compositional conflicts during online interpretation.

Cases of coercion have prominently figured in studies on the time course of compositional interpretation, see e.g. Piñango and Deo (2016) for an overview of studies on complement coercion, and Bott (2010) and Paczynski, Jackendoff, and Kuperberg (2014) for aspectual coercion. (1) displays a compositional conflict calling for aspectual coercion.

## (1) \# Yesterday, Peter jogged in only thirty minutes.

When uttered out of the blue, sentence (1) is hardly interpretable. This is because an in-adverbial requires a telic event predicate of the accomplishment type (Vendler, 1957), but Peter jog- expresses an atelic activity. Under a coercion analysis Peter jog- has therefore to be shifted into an accomplishment, i.e. the event representation of the activity has to be enriched by adding a culminating event. The required operation can be summarized as follows:
(2) $\quad[$ in thirty minutes $[$ Peter jog-] $]] \rightsquigarrow_{\text {coerce }}[$ in thirty
$\quad$ minutes[ADD CULMINATION $[$ Peter jog- $]]]$

The inserted coercion operator ADD CULMINATION is a function that takes as input an activity and outputs an accomplishment (see, e.g., Dölling, 2014, for semantic representations of various coercion operators). The coercion operation solves the compositional problem. After the inclusion of the appropriate type shifting operator the resulting representation can be interpreted fully compositionally. Interestingly, the semantic problem in (1) seems to completely disappear once the sentence is embedded in an appropriate discourse context. Consider (1) in the context of (3).
(3) Half a year ago, Peter started to jog four kilometers $_{\text {culmination }}$ every day. When he began, he was quite slow but now he is really fast.

Based on the pragmatic literature (Recanati, 2010) two theoretical alternatives can be contrasted on how compositional interpretation might make use of contextual information. The Composition in Context ( CiC ) hypothesis predicts immediate availability of contextual information (e.g., Nieuwland \& van Berkum, 2006). Accordingly, the bounded path four kilometers from the preceding context should be immediately available when composing the adverbial with the rest of the target sentence in (1). Alternatively, however, compositional interpretation may operate in strictly locally in a bottom-up fashion (Cappelen \& Lepore, 2005). According to this view, which may be characterized as Encapsulated Composition $(E C)$ hypothesis, contextual information is only considered when the sentence information is not sufficient: Either to resolve compositional conflicts or to interpret context dependent expressions that are context dependent. In fact, in coercion theories it is standardly assumed that coercion operations are locally triggered by temporary semantic mismatch, i.e. many coercion analyses employ the EC hypothesis (cf. de Swart, 1998, p. 8).

According to the EC hypothesis the initial interpretation of (1) in the context of (3) should result in an aspectual mismatch that is only resolved in a second processing step. This should lead to measurable disruption during online interpretation. The CiC hypothesis, by contrast, predicts no processing costs of coercion sentences relative to non-coercing controls because the contextually given culmination can go right into the composed meaning.

Context effects on coercion have only been investigated in a small number of online studies so far. Traxler, McElree, Williams, and Pickering (2005) report a series of self-paced reading and eyetracking during reading experiments in which
they presented target sentences involving complement coercion (the student began the book: [begin[the book]] $\rightsquigarrow$ coerce [begin[to do something involving[the book]]]) and manipulated the preceding discourse context. Here is a sample item from Traxler et al. (2005, Exp. 3/4); c1/2 correspond to coercion vs. control contexts, $\mathrm{t} 1 / 2$ are coercion vs. control targets, critical regions underlined.
(4) c1) The student started a book in his dorm room.
c2) The student read a book in his dorm room.
t1) Before he started it, he checked his e-mail.
t2) Before he read it, he checked his e-mail.
Contextual facilitation was found in cases in which the context sentence either itself required complement coercion (c1), or explicitly introduced the relevant event (c2). In their Exp. 3 and 4, Traxler et al. (2005) observed coercion costs for c1 relative to c2. Crucially, however, the anaphor it in the coercion target t 1 was read as fast as in the control condition t 2 showing that the anaphor could be immediately linked to the relevant event in the discourse representation. This is prima facie evidence in favour of the CiC hypothesis. However, there is another explanation consistent with the EC hypothesis too. It is also possible that it was not interpreted as anaphoric to the book but rather as an event anaphor, which would make coercion unnecessary in the first place. The following example adopted from Asher (1993, p. 233) illustrates the difference between individual and event anaphora.

$$
\begin{equation*}
\text { If Timmy }{ }_{i} \text { hits }_{j} \text { John }_{k}, \mathrm{it}_{* i / j / * k} \text { will cause a fight. } \tag{5}
\end{equation*}
$$

As for aspectual coercion, Bott (2010, Exp. 3) reports a selfpaced reading experiment investigating whether German contexts such as (3) facilitate aspectual enrichment in German versions of (1). The findings provide preliminary evidence that supportive context can eliminate coercion costs observed for this type of sentences when presented out of context. After telic contexts such as (3) the reading times of coercion sentences did not differ from control targets allowing for plain compositional interpretation. However, this interpretation of the results is complicated by the fact that the comparison crucially involved a direct comparison between different adverbials (German in x time vs. for $x$ time).

Processing along the lines of the EC or the CiC hypothesis does not have to be an either or choice but could be subject to inter-individual differences. In particular, verbal working memory capacity may be an important constraining factor for being able to employ a highly context dependent processing strategy as put forward in the CiC hypothesis. Note that the CiC haypothesis presupposes full accessibility of all the relevant contextual information. Processing along the lines of the CiC hypothesis can therefore be expected to require more working memory capacity than the strictly local interpretation of the EC hypothesis. Existing research on sentential context effects has provided evidence that low-span readers make even less use of the immediate sentential context than highspan readers (van Petten, Weckerly, McIsaac, \& Kutas, 1997).

Thus, smooth aspectual enrichment in line with the CiC hypothesis may be especially expected for high-span readers, whereas low-span readers should be more likely to exhibit coercion costs. Inter-individual differences in working memory capacity have not been taken into account in coercion studies so far.

The present experiment studied contextual facilitation effects in aspectual coercion with four major modifications relative to prior research. First of all, the present study employed eyetracking during reading - an online method that provides us with a richer picture about the time course of interpretation than self-paced reading. Secondly, a larger set of experimental items was tested, and these materials were set up in such a way that the critical region was kept identical across conditions. Thirdly, the materials were more carefully pretested concerning their offline interpretation than the ones used in Bott (2010, Exp. 3). Finally, contextual facilitation effects were related to participants' verbal working memory capacity as measured by the reading-span task (Daneman \& Carpenter, 1980).

The experimental design of the present study included a coercion and a control condition as well as a mismatch condition. Two kinds of contexts were constructed. Both, telic contexts such as (3), and atelic contexts such as (6) introduced a repetitive event (contexts translated from German). The only difference is that the telic context (3) establishes a series of telic, bounded events (e.g., jog four kilometers) while the atelic context (6) introduces a series of atelic, unbounded activities instead. Both types of contexts put emphasis on the actual duration of the respective events at reference time now.
(6) Half a year ago, Peter started to jog every day. When he began, he had to stop after a short time but now he can run for quite a long time.

Target sentences were of two types manipulating the adverbial: telic sentences (7-a) including German in-adverbials, and atelic sentences (7-b) with German for-adverbials.
(7) a. Als es ihm vorhin gelang, in nur dreißig When he just managed in only thirty Minuten zu joggen,... minutes to jog...
'When he managed to jog in only $30 \mathrm{~min} . .$. '
b. Als es ihm vorhin gelang, ganze dreißig When he just managed for thirty Minuten zu joggen,... minutes to jog... 'When he managed to jog for $30 \mathrm{~min} . .$. '
c. ... war er sehr stolz auf sich.
... he was very proud of himself.
Discourse conditions were as follows. The coercion condition was constructed by combining telic contexts (3) with telic targets (7-a). The control condition combined atelic contexts (6) with atelic targets (7-b). For the aspectual mismatch condition atelic contexts (6) were paired with telic targets (7-a).

Figure 1: Mean judgments in Pretest 1 (left-hand side) and Pretest 2 (right-hand side). Error bars represent 95\% confidence intervals (by-participants analysis).

## Pretests

Two pretests were conducted. The first pretest was a sentence acceptability judgment experiment testing the telic (7-a) and the atelic (7-b) target sentences out of context. The second pretest was a discourse acceptability rating experiment that queried the felicity of the discourses in the coercion, the control, and the mismatch condition, respectively. The predictions are straightforward. Due to their need of coercion, telic target sentences should be less acceptable than atelic target sentences when encountered out of context. Supportive context should increase the acceptability of the coercion condition, though. After a telic context, a telic target should become as acceptable as the control condition. The mismatch condition should be judged as infelicitous.

## Pretest 1

Method 20 native German speakers (mean age: 26.9 years; 17 female) participated in the pretest for a payment of $€ 5$. Participants rated the acceptability of the telic and atelic target sentences on a scale from 1-7 from completely unacceptable to fully acceptable.

Target sentences were taken from the set of 24 items created for the eyetracking study. All were constructed following the scheme exemplified in (7). Pronouns were replaced by the proper names from the contexts (3)/(6). Two lists were constructed using a Latin square design and 100 filler sentences were added to each list. 60 of the fillers were infelicitous ('bad fillers') while the others were fully acceptable ('good fillers'). Ten participants were randomly assigned to each list.

Paricipants were tested individually in a quiet computer pool. Sentence materials were presented in randomized order in a single block which was preceded by a short practice of five trials. An experimental session took less than 30 minutes.

Results and discussion The mean judgments are shown in Figure 1. As predicted, acceptability of telic target sentences was judged significantly worse than atelic target sentences
$\left(t_{1}(19)=-5.4, p<.01 ; t_{2}(23)=-9.52, p<.01\right)$. The latter were judged even slightly better than the well-formed fillers (atelic targets: 5.90; well-formed fillers: 5.70) suggesting that the target sentences in the control condition are in fact fully acceptable. The telic target sentences received mean ratings of 4.24 and were thus well above the nonsensical fillers with a mean rating of 2.34 . Even though the telic target sentences were perceived as not fully acceptable when presented out of the blue, participants seemed to be aware of the fact that these sentences are in fact well-formed if embedded in an appropriate discourse context.

## Pretest 2

Method 30 new participants (mean age: 26.2 years; 16 female), all native speakers of German, took part in the pretest for a payment of $€ 5$. Participants rated the acceptability of the discourses in the coercion, the control, and the mismatch condition on a scale from $1-7$. In addition to the 24 experimental items 66 filler discourses were included ( 33 acceptable and 33 incoherent discourses). 20 of the incoherent filler discourses were globally incoherent, e.g. Lisa is very bad in maths. [...] . So, she wasn't surprised when she got an A., and 13 were locally incoherent, e.g. ...the jockey sat in his horse .... The items plus the fillers were distributed to three lists in a Latin square design. Ten participants were randomly assigned to each list. The procedure was the same as in the previous pretest
Results and discussion The mean judgments are also shown in Figure 1. As predicted, telic targets preceded by a telic context made the coercion condition fully acceptable. Paired t-tests revealed that the coercion condition did not differ reliably from the control condition $\left(t_{2}(29)=-1.65, p=\right.$ $.11 ; t_{1}(23)=-.76, p=.46$ ). Both, coercion (mean rating: 5.10) and control (mean rating: 5.27) received ratings in the range of the good fillers (mean rating: 5.82). As expected, the mismatch condition was judged similar to the incoherent fillers. Repeated measures ANOVAs revealed that mismatch was judged significantly worse than coercion and control $\left(F_{1}(2,58)=81.77, p<.01 ; F_{2}(2,46)=122,56, p<.01\right) .{ }^{1}$

Taken together, the results of the pretests show that the materials tested in the eyetracking study fully meet the assumptions stated in the introduction. The coercion targets are not fully interpretable on their own but require contextual support. Embedded in a telic context, however, the telic targets become fully acceptable. After atelic contexts, however, telic target sentences result in aspectually incoherent discourses.

## Eyetracking Experiment

The EC and the CiC hypotheses make fundamentally different predictions regarding the online processing of the three discourse conditions.

[^283]According to the EC hypothesis, the coercion operation is triggered by a temporary semantic mismatch during the intial interpretation of atelic activity verbs modified by inadverbials. Therefore, during first-pass reading the coercion condition should pattern with the mismatch condition and lead to processing difficulty relative to the control condition.

By contrast, the CiC hypothesis predicts smooth interpretation of the coercion condition. Coercion should therefore pattern with the control condition, and it should only be the mismatch condition that causes processing difficulty.

In order to assess effects of inter-individual differences in working memory capacity, between group analyses were conducted for high- versus medium- vs. low-span readers.

## Methods

Participants 48 new participants (mean age: 24.1 y., range $20-32$ y.; 40 female) all native speakers of German with normal or corrected-to-normal vision took part in the experiment for a payment of $€ 8$. Based on their performance in Daneman and Carpenter's (1980) reading span task they were divided into three groups. The first group consisted of 10 participants with a reading span of 3.0 , the median value in the sample. This group was included as MEDIUM SPAN readers in ANOVA analyses including the between factor READING SPAN. The group of LOW SPAN readers consisted of 19 participants with a mean reading span of 2.4 (range $2.0-2.5$ ). The group of HIGH SPAN readers consisted of 19 participants with a mean reading span of 3.7 (range $3.5-4.5$ ).
Materials The sentence materials were identical to those used in the pretest and the items were always presented on three lines. The first line contained the first context sentence, the second line the second context sentence, and the third line the target sentence. The target sentences were split up in ten regions of interest (ROIS):
(8) Als es ihm $\mid$ heute $\mid$ gelang, $\left.\right|_{a d v 1}$ in nur $\left.\right|_{a d v 2}$ dreißig $\left.\right|_{a d v 3}$ Minuten $\left.\right|_{\text {verb }}$ zu joggen, $\left.\right|_{\text {coda } 1}$ war er $\left.\right|_{\text {coda } 2}$ sehr stolz $\left.\right|_{\text {coda } 3}$ auf sich. $\mid$

The critical region was the verb RoI. Note that any aspectual mismatch only becomes evident at this ROI. For instance, als es ihm heute gelang, in nur dreißig Minuten vier Kilometer weit zu joggen, ... (when he managed today to jog four kilometers in only thirty minutes ...) would be fully acceptable even after an atelic context.

Apparatus and procedure Eye movements of the dominant eye were recorded with an SR Research Ltd. Eyelink 1000 eyetracker. The trial began with the presentation of a screen which served as calibration check and for drift correction with a yellow dot in the position where the centre of the first word would appear. If no fixation on the dot was registered within five seconds, recalibration was enforced. Otherwise, texts were presented. After reading, participants had to move their eyes to a yellow dot in the right bottom corner of the screen which triggered the presentation of the judgment
screen. Judgments had to be provided by pressing the left or the right button of a gamepad.

The experiment started with five discourses for practice, followed by the individually randomized presentation of the experimental trials in three blocks. A typical experimental session lasted less than 45 minutes. Immediately after the eyetracking experiment each participant was subjected to an experimenter-administered version of the reading span task (Friedman \& Miyake, 2004). Reading span was scored as follows. The highest stage for which at least two out of a total of three sequences could be correctly recalled determined a participant's basic reading span. If she was able to correctly recall one sequence from an even higher stage, a value of 0.5 was added to this basic value.
Eyetracking analysis Prior to all analyses the eyetracking data were preprocessed. Two trials with major track loss were exluded, and all fixations immediately preceding or following a blink were eliminated. All fixations shorter than 80 ms and further than 0.5 degrees from the last or next fixation as well as fixations longer than 800 ms were eliminated. Preprocessing affected $2.7 \%$ of all fixations.

The analyzed measures of first-pass reading included first fixation durations, first-pass times, and first-pass regression ratios, i.e. the proportions of regressions made during firstpass reading.Measures related to rereading included secondpass time and the proportions of regressions in.

## Results

The coercion condition was accepted $83.3 \%$ of all trials, control was accepted $86.9 \%$, but mismatch was rejected $66.5 \%$. Thus, discourses in the coercion and in the control condition were generally accepted while the aspectual mismatch condition was generally rejected. The analysis of judment RTs, corrected for outliers by eliminating all RTs more than 2.5 standard deviations above a participant's mean RT, revealed no significant differences between the three discourse conditions ( $F_{1 / 2}<1$ ).

Table 1 presents the descriptive statistics for the eyetracking measures related to first-pass parsing. The findings for the measures related to rereading are shown in Table 2.

First-pass reading Immediately when readers encountered the verb region, first fixation durations were longer in the mismatch condition than in the control condition $\left(t_{1}(47)=\right.$ $\left.2.29, p<.05 ; t_{2}(23)=2.12, p<.05\right)$. By contrast, verbs in the coercion condition were read equally fast as verbs in the control condition $\left(\left|t_{1 / 2}\right|<1\right)$. Before or after the critical verb ROI there were no significant differences in first fixation durations for any of the ROIs in the target sentences.

The analyses of first-pass times further corroborated this finding. At the verb ROI a clear mismatch effect was found $\left(t_{1}(47)=3.85, p<.01 ; t_{2}(23)=3.72, p<.05\right)$, but coercion did not differ from control $\left(\left|t_{1 / 2}\right|<1\right)$. The mismatch effect was again limited to the verb ROI, and discourse conditions did not differ reliably from each other at any target ROI.

Table 1: Mean first fixation durations (FFD), mean first-pass times (FPT), and mean first-pass regression ratios (FPRR) of the target sentences in the eyetracking experiment. Note: ROI a3 corresponds to the final adverbial region, verb to the critical verb region, and $c 1-c 3$ to the three sentence final ROIs.

|  |  | a3 | verb | c1 | c2 | c3 |
| :--- | :--- | :--- | :--- | :--- | :--- | :--- |
| FFD | contr. | 205 | 251 | 238 | 252 | 256 |
| (in ms) | coerc. | 210 | 247 | 247 | 247 | 264 |
|  | mism. | 213 | 266 | 240 | 243 | 257 |
| FPT | contr. | 217 | 311 | 290 | 333 | 403 |
| (in ms) | coerc. | 219 | 317 | 317 | 312 | 424 |
|  | mism. | 219 | 345 | 304 | 307 | 417 |
| FPRR | contr. | 14.6 | 18.5 | 6.4 | 25.4 | 45.8 |
| (in \%) | coerc. | 15.7 | 16.9 | 9.3 | 26.3 | 48.3 |
|  | mism. | 16.2 | 27.1 | 12.2 | 21.9 | 51.2 |

Mismatch not only slowed down reading speed during firstpass reading, it also gave rise to more regressions from the verb ROI. The analysis of first-pass regression ratios showed that readers launched more regressions from mismatching verbs than from verbs in the control condition $\left(t_{1}(47)=\right.$ $\left.2.23, p<.05 ; t_{2}(23)=3.08, p<.01\right)$. Again, coercion did not differ from control $\left(\left|t_{1 / 2}\right|<1\right)$.

Taken together, the findings from the three measures reflecting the first-pass reading of the critical verb ROI show that the initial interpretation of the coercion targets was as smooth as that of the control targets. Without a preceding telic context in the mismatch condition, however, first-pass reading was severely disrupted.
Rereading The analyses of the proportions of regressions in revealed that readers regressed back to the three adverbial RoIs in the mismatch condition. For all three RoIs reliable mismatch effects were observed (first ROI: $t_{1}(47)=2.52, p<$ . 05 ; $t_{2}(23)=2.82, p<.05$; second ROI: $t_{1}(47)=2.70, p<$ $.05 ; t_{2}(23)=2.84, p<.01$; third ROI: $t_{1}(47)=2.02, p<.05$; $\left.t_{2}(23)=2.16, p<.05\right)$. Also, on the verb ROI a mismatch effect was found that was marginally significant by subjects and significant by items $\left(t_{1}(47)=1.87, p=.07 ; t_{2}(23)=\right.$ $2.18, p<.05$ ). The coercion analyses showed that the adverbial ROIS did not receive more regressions in the coercion condition than in the control condition (all $\left|t_{1 / 2}\right|<1$ ). However, it turned out that readers regressed more often back into the verb ROI than they did in the control condition. This was reflected by a (by-items marginally) significant coercion effect $\left(t_{1}(47)=2.46, p<.05 ; t_{2}(23)=1.97, p=.06\right)$.

A similar pattern of effects was observed in the secondpass times too. The mismatch condition led to longer secondpass times than the control condition persisting from the adverbial ROIs (first ROI: $t_{1}(47)=2.83, p<.01 ; t_{2}(23)=$ $2.23, p<.05$; second ROI: $t_{1}(47)=2.40, p<.05 ; t_{2}(23)=$ $2.64, p<.05$; third ROI: $t_{1}(47)=1.70, p=.10 ; t_{2}(23)=$ $1.80, p=.08)$ to the verb ROI $\left(t_{1}(47)=4.71, p<.01\right.$;

Table 2: Mean second-pass times (SPT), and mean proportions of regressions in (RI) of the relevant ROIs of the target sentences.

|  |  | a1 | a2 | a3 | verb | c1 | c2 |
| :--- | :--- | :--- | :--- | :--- | :--- | :--- | :--- |
| SPT | contr. | 81 | 106 | 56 | 81 | 88 | 115 |
| (in ms) | coerc. | 85 | 104 | 59 | 143 | 115 | 132 |
|  | mism. | 129 | 160 | 89 | 167 | 87 | 108 |
| $R I$ | contr. | 35.7 | 22.8 | 19.7 | 4.6 | - | - |
| (in \%) | coerc. | 37.9 | 26.3 | 22.0 | 9.2 | - | - |
|  | mism. | 47.5 | 33.5 | 30.7 | 8.1 | - | - |

$\left.t_{2}(23)=3.90, p<.01\right)$. Also, a coercion effect was present, and, consistent with what was observed for the regressions in, this effect was limited to the verb ROI $\left(t_{1}(47)=3.25, p<.01\right.$; $\left.t_{2}(23)=2.46, p<.05\right)$.

Taken together, the analyses of late eyetracking measures besides substantial mismatch effects - show that participants were more likely to reread the verbs in the coercion condition than in the control condition.

Analyses contingent on reading span In order to investigate whether early and late effects were modulated by interindividual differences in working memory capacity ANOVAs with the within-factor DISCOURSE CONDITION and the between factor READING SPAN (three levels: HIGH SPAN vs. MEDIUM SPAN vs. LOW SPAN) were computed analyzing the first and second-pass times of the verb ROI. Table 3 presents the mean reading times of the verb ROI split up by groups.

The analysis of first-pass times only revealed a significant main effect of DISCOURSE CONDITION $\left(F_{1}(2,90)=\right.$ $4.61, p<.05$ ), i.e. the above reported mismatch effect. Neither the main effect of READING SPAN nor its interaction with DISCOURSE CONDITION reached significance (both $F_{1}<.05$ ). Thus, the three reading span groups did not differ with respect to their first-pass reading times of the verb.

The analysis of second-pass times also revealed no differences between the three groups. The main effect of DISCOURSE CONDITION was reliable $\left(F_{1}(2,90)=11.88, p<\right.$ .01), but neither the main effect of READING SPAN nor the interaction reached significance (both $F_{1}<1.3$ ).

To summarize, the three reading span groups had strikingly similar patterns of results. The three groups showed equally sized early effects of aspectual mismatch and late coercion effects that only started during rereading the sentence.

## Discussion

The present study investigated whether coercion sentences embedded in supportive discourse context lead to measurable processing costs during their initial interpretation. According to the EC hypothesis, the compositional system operates strictly bottom-up, and the coercion targets should therefore lead to temporary aspectual mismatch during the initial inter-

Table 3: Mean first- (FPT) and second-pass times (SPT) of the verb ROI split up by reading span groups.

pretation and subsequent context-driven repair. During firstpass reading target sentences in the coercion and the mismatch condition should exhibit qualitatively similar processing effects. The CiC hypothesis, by contrast, predicts smooth interpretation of the coercion targets if embedded in a supportive context because the culminating event from the context should be immediately available.

The findings of the present eyetracking experiment unambiguously provide evidence against the EC hypothesis. While aspectual mismatch led to substantial processing difficulty during first-pass reading, none of the three analyzed early eyetracking measures indicated any difficulty in the coercion condition. The processing of aspectual coercion involved a qualitatively different time course than aspectual mismatch.

Do the findings support the CiC hypothesis, then? Above, it was stated that supportive context should completely eliminate all coercion costs. The coercion effects observed during rereading of the coercion targets may therefore be taken as prima facie evidence against the CiC hypothesis. However, the exposition of this hypothesis in the introduction was grossly oversimplistic. On closer consideration, the hypothesis is fully consistent with overall higher processing demands in the coercion than in the control condition as long as difficulty only emerges after a smooth first composition step. Two potential sources of difficulty come to mind. Under the CiC hypothesis comprehenders still have to be able to exactly recall the culmination introduced two sentences before. Note that in order to make proper sense of the coercion target it is important to know the exact length of the path. Obviously, to jog a distance of three miles in half an hour is plausible but thirty miles is not. Therefore, successful coercion crucially depends on a precise representation of the context in all its particulars. Another potential source of difficulty may be attributed to the metalinguistic evaluation demanded from the participants: since the target sentences were exactly the same in the coercion and the mismatch condition, the metalinguistic evaluation may have been more difficult in the coercion than in the control condition.

Both explanations, the (un-)availability of the culminating event in working memory as well as difficulty during metalin-
guistic evaluation, would be consistent with the CiC hypothesis. The above reported analyses taking into account participants' working memory capacity suggest that the second explanation is more likely than the first.

## Acknowledgments

This research was funded by the DFG in the project Composition in Context of the Priority Program SPP 1727 XPrag.de. The author would like to thank Salome Mauthe and Maximilian Müller for conducting the experiments. The author would also like to thank four anonymous CogSci 2017 reviewers for their valuable comments on a first draft of this paper. The usual disclaimer applies.

#### Abstract

Most psychological theories attribute people's failure to achieve their goals exclusively to insufficient motivation or lack of skill. Here, we offer a complementary explanation that emphasizes the inherent complexity of the computational problems that arise from the structure of people's goal systems. Concretely, we hypothesize that people's capacity to achieve their goals can be predicted from combinatorial parameters of the structure of the network connecting their goals to the means available to pursue them. To test this hypothesis, we expressed the relationship between goals and means as a bipartite graph where edges between means and goals indicate which means can be used to achieve which goals. This allowed us to map two computational challenges that arise in goal achievement onto two classic NP-hard problems: Set Cover and Maximum Coverage. The connection between goal pursuit and NP-hard problems led us to predict that people should perform better with goal systems that are tree-like. Three behavioral experiments confirmed this prediction. Our results imply that network parameters that are instrumental to algorithm design could also be useful for understanding when and why people struggle in their goal pursuits.

Keywords: decision-making; goals; rational analysis; graph theory; computational complexity

## Introduction

The ability to set and achieve high-level goals, such as creating a CogSci paper, is a critical feature of human intelligence and a key challenge for artificial intelligence systems (Newell \& Simon, 1972). Critically, everyday problem solving requires people to juggle multiple goals in parallel (Atkinson \& Birch, 1970; Miller, Galanter, \& Pribram, 1960). Concretely, when people are given ten minutes to list their current pursuits they will report about 15 goals on average and each of those goals typically entails multiple subgoals at several levels of abstraction (Little \& Gee, 2007).

It is generally agreed that there are many situations in which people fail to act on their goals (Baumeister, Heatherton, \& Tice, 1994). The predominant explanations of such failures are lack of motivation, lack of planning (Gollwitzer, 1999), failure to delay gratification (Mischel, Shoda, \& Rodriguez, 1989), or the depletion of the capacity for selfcontrol (Muraven \& Slessareva, 2003). Here, we explore an alternative explanation for people's failure to achieve their
goals: the inherent complexity of the underlying computational problem.

The relationship between means and goals can be formalized in a bipartite graph whose vertices are divided into a set of means $M=\left\{m_{1}, \cdots, m_{k}\right\}$ and a set of goals $G=$ $\left\{g_{1}, \cdots, g_{l}\right\}$. In this graph, a mean $m$ is connected to a goal $g$ if and only if selecting $m$ will achieve the goal $g$. Such networks are called goal systems in the psychological literature (Kruglanski et al., 2002). For instance, the vertices at the top of the goal system illustrated in Figure 1 might correspond to your goals to become a prolific scientist $\left(g_{1}\right)$, be a wonderful partner $\left(g_{2}\right)$, become a great parent $\left(g_{3}\right)$, get physically fit $\left(g_{4}\right)$, and enjoy life to the fullest $\left(g_{5}\right)$.

Finding the best configuration of means for achieving a set of goals can involve considerable computational challenges. It has been suggested that findings from theoretical computer science can shed light on how people cope with hard computational problems (Van Rooij, 2008). For example, Van Rooij (2008) advocated applying the theory of fixed parameter tractability to study how people cope with hard computational problems. Yet, while previous research on problem solving has investigated which strategies people use to solve NP-hard problems (MacGregor \& Ormerod, 1996; MacGregor, Ormerod, \& Chronicle, 2000), this literature has focused on the Traveling Salesman problem and other problems that are structurally distinct from those that arise in goal pursuit. ${ }^{1}$ Here, we will fill this gap by analyzing goal achievement through the lens of computational complexity theory.

In theoretical computer science, it is well known that the performance of many combinatorial optimization algorithms critically depends on certain graph-theoretic properties of the networks they are applied to (Kleinberg \& Tardos, 2006). For instance, a well-documented phenomenon in algorithm design, artificial intelligence, and operational research is that NP-hard optimization problems often become easier on trees and tree-like graphs. Indeed, when restricted to trees, many

[^284]

Figure 1: Example of goal system: means appear at the bottom marked by $m_{1} \ldots m_{4}$. Goals appear on top marked by $g_{1} \ldots g_{5}$. A goal can be attained if at least one mean connected to it is chosen. The set $\left\{m_{1}, m_{3}\right\}$ is a minimal set of means covering all goals

NP-hard problems can be solved by efficient polynomial-time algorithms, such as divide-and-conquer methods and greedy algorithms. Here, we show that human performance on two goal management tasks is also well predicted by graph theoretic measures of the tree-likeness of the underlying goal system. Our results offer a fresh computational perspective on why people fail to achieve their goals. Our experimental results align well with theoretical knowledge from computer science and highlight that findings from computational complexity are relevant to cognitive psychology.

The plan for the paper is as follows. We start by formalizing two common challenges of goal achievement in terms of two classic NP-hard problems: Set Cover and Maximum Coverage. Next we derive our theoretical prediction by arguing that people's performance on these problems should increase with graph theoretic metrics of how tree-like the goal system is. We then test this prediction in three behavioral experiments and conclude with a summary of our findings and directions for future work.

## Formal analysis and predictions

Here we formalize, as well-defined NP-hard problems, two computational challenges that arise in means selection problems where one seeks to choose a set of means that are instrumental to the ends one is trying to achieve.

The first problem we consider is trying to achieve as many goals as possible with a fixed budget that limits the number of activities that one can perform. We formalize this challenge in terms of the Maximum Coverage problem (MC). In it, we are given a bipartite graph $H=(C, D, F)$ where $C, D$ are the sides of the bipartition, and $F$ is the set of edges connecting vertices in $C$ to vertices in $D$. We are also given a nonnegative integer $k \leq|C|$. We seek to find a set $C^{\prime} \subseteq C$, of cardinality at most $k$, maximizing the number of vertices in $D$ covered by vertices in $C^{\prime}$ (a vertex $b \in D$ is covered by a vertex $a \in C$ if $(a, b) \in F)$. As a goal system, the set $C$ corresponds to means, the set $D$ corresponds to goals, and $F$ represents to interconnections between goal and means. Observe that we assume that once a goal is covered by a single mean then it will be achieved. This assumption is made in order to simplify the experimental task, allowing for a simple and clean
description.
The second problem that we study is trying to achieve a given set of goals as efficiently as possible by selecting the minimal number of means that will accomplish all goals. We formalize this challenge in terms of the Set Cover problem (SC). In the Set Cover problem, we are given a bipartite graph $G=(A, B, E)$, where $A, B$ are the sides of the bipartition and $E$ is the set of edges connecting vertices in $A$ to vertices in $B$. As a goal system, the set $A$ corresponds to means, the set $B$ corresponds to goals, and the set $E$ corresponds to interconnections between goals and means. In the SC problem, our goal is to cover all vertices in $B$ by a set $A^{\prime} \subseteq A$ of minimal cardinality. Both MC and SC are NP-hard not only to solve exactly but also to approximate (Feige, 1998).

These two computational problems (MC and SC) capture essential aspects of means selection problems that have been studied in the psychological literature.

For example, it is generally agreed that people try to select means in order to maximize the number of attained goals (Kruglanski et al., 2002; Zhang, Fishbach, \& Kruglanski, 2007). Furthermore, representing goals as graphs and assuming interconnectedness between goals appear either explicitly or implicitly in several papers (Kruglanski et al., 2002; Thagard \& Millgram, 1995).

We shall use the following two performance measures in quantifying how well people do in MC and SC. Our first measure simply quantifies the ability to find the optimal solution. This is a binary measure that equals 1 if the person finds the optimal solution and 0 otherwise. Given an algorithm $A$ for MC or SC, the second measure, referred to as the solution quality, ranges between 0 (worst) and 1 (best). For the MC task, the solution quality is the number of goals achieved by $A$ divided by maximum number of goals that could be achieved with $k$ means. For the SC task, the solution quality is the minimum number of means that achieves all goals divided by the number of means selected by $A$. Solution quality (which is also referred to as the approximation ratio of $A$ ) is widely used in quantifying the quality of approximation algorithms for NP-hard problems (Vazirani, 2013).

The hardness of MC and SC gives a first indication for why people might find it difficult to juggle multiple goals at the same time. Yet, not every instance of these problems is equally difficult. Next, we introduce graph-theoretic measures that might be useful for distinguishing harder instances from easier ones.

## Features and predictions

A tree is a connected graph without cycles. Many NP-hard problems on graphs with small treewidth (Robertson \& Seymour, 1986, see below), allow exact or approximate algorithms which are significantly better than what is known to be achievable on worst-case instances.

The idea that tree-like graphs might be easier for people to deal with guided our search for features that quantify how similar a given network is to a tree. Four such features are presented below.

- Treewidth. Treewidth (tw) is a combinatorial parameter that is associated with a graph. ${ }^{2}$ Low treewidth implies that the nodes and edges of the network can be arranged in a way that resembles a tree (e.g., Kloks, 1994; Robertson \& Seymour, 1986). For a precise definition of treewidth see Kloks (1994).
- Combinatorial expansion. Given a graph $G=(V, E)$ and a nonempty subset $S \subseteq V$, let $\partial(S)$ be the set of edges crossing the cut $(S, V \backslash S)$ and let $N(S)$ be the set of all vertices in $V \backslash S$ having a neighbor in $S$. The vertex-expansion of $G$ is defined as $\min _{S \subseteq V, 0<|S| \leq|V| / 2} \frac{|N(S)|}{|S|}$. The edge-expansion of $G$ is $\min _{S \subseteq V, 0<|S| \leq|V| / 2} \frac{|\partial(S)|}{|S|}$. Trees of bounded degree have expansion $O(1 /|V|)$, hence large expansion suggests that the graph is dissimilar to a tree. We computed both vertex and edge expansion by solving an integer linear programs (ILPs) using IBM's CPLEX.
- Spectral expansion. The adjacency matrices of the graphs we consider are symmetric, hence have $n$ real eigenvalues $\lambda_{1} \geq \lambda_{2} \geq \ldots \geq \lambda_{n}$. The classical (discrete) Cheeger's inequality (e.g., Alon and Milman, 1985) implies that the larger $d-\lambda_{2}$ is, the larger the edge expansion of the graph. ${ }^{3}$

MC and SC instances with low treewidth $w$ are known to have exact algorithms that run in time $O\left(2^{w} n\right)$ (Alber \& Niedermeier, 2002), hence instances with low treewidth are likely to be easier to deal with algorithmically. Current algorithms that compute tree-decompositions are quite complicated, therefore it seems unlikely that people would use them to solve SC and MC problems. Nevertheless, treewidth might affect the performance of people's heuristics: the similarity between low treewidth graphs and trees might make the kinds of algorithms that people might use, such as greedy and divide-and-conquer methods, much more effective. Conversely, as worst-case instances of MC and SC are hard even to approximate, and as hard instances often have large treewidth and expansion (Clementi \& Trevisan, 1999), it is likely that it will be hard not only to solve exactly, but also to find approximate solutions for instances of large treewidth. Similar reasoning applies to our expansion measures. We therefore hypothesize that treewidth, vertex-expansion, edgeexpansion, and the spectral gap of $G$ are negatively correlated with the quality of people's solution to SC and MC problems and frequency with which they find an optimal solution.

## Additional predictors

A feedback vertex set (FVS) is a subset of vertices whose removal from a given graph results in a forest. The size of a minimal feedback vertex set is an alternative measure to the similarity of a graph to a tree. Hence we used this

[^285]feature as well. We calculated FVS using the implementation based on (Iwata, 2016; Wahlström, 2014) available at https://github.com/wata-orz/fvs.

Previous empirical hardness models have found additional features of graphs to be useful: the diameter, average eccentricity, and average path length (Leyton-Brown, Nudelman, \& Shoham, 2009). We thus included these features. The diameter of a graph is the longest distance between two vertices in the graph (where the distance, $\operatorname{dist}(u, v)$, is the number of edges in a shortest path connecting $u$ and $v$; all graphs considered are connected). The eccentricity $\varepsilon(v)$ of a vertex $v$ in an undirected graph $G=(V, E)$ is the maximal distance of a vertex in $V \backslash v$ from $v$. The average eccentricity (AvgEcc) is $\frac{1}{n} \sum_{v \in V} \varepsilon(v)$ ( $n$ is the number of vertices). The average path length (AvgPath) is $\frac{2}{n(n-1)} \sum \operatorname{dist}(u, v)$ where summation is taken over all pairs of distinct vertices.

## Behavioral experiments

To test how our predictors relate to human performance in MC and SC, we conducted three crowdsourced behavioral experiments. We used a between-subjects design where each participant was assigned randomly to one of twenty graphs with treewidths varying from 4 to 13 . In the first experiment, participants were asked to solve the SC problem, and in the second experiment participants were asked to solve the MC problem. In each case, the problem was graphically represented as a bipartite graph with 48 vertices. The 24 vertices at the bottom represent the available means (activities A-Z) and 24 vertices at the top represent the goals. Each edge from a means vertex to a goal vertex implies that completing that activity is sufficient to achieve the goal. In the SC task, participants were asked to select a minimal number of activities to achieve all of the goals. In the MC task, participants were asked to choose five activities that achieve as many goals as possible. The third and final experiment asked participants to solve a SC problem where goals are given semantic content and real values, and a different visual display is used to eliminate possible visualization effects. In each experiment we restricted our analyses to goal systems in which every goal and mean vertex had exactly 4 neighbors (i.e., each graph was 4-regular). This restriction meant that each graph required the same amount of memory to enable processing, ensuring that any difference between conditions cannot be explained by working memory limitations.

## Experiment 1: Human performance on Set Cover

Methods We recruited 655 participants on Amazon Mechanical Turk. Participants were paid $\$ 1.25$ and could earn a performance-dependent bonus of up to $\$ 2$. Each participant was randomly assigned to one of 20 conditions that differed only in the graph structure of the SC problem participants were asked to solve. After consenting to participate, participants read a cover story about a person trying to choose which set of activities (e.g., volunteer to improve the company's website and work out at the gym) they should perform in order to achieve all their goals (e.g., earn more money, improve

Figure 2: Interface and instructions for Experiment 1.
relationship with boss, get fit, etc.) with as few activities as possible because their time is limited. The story highlighted that some activities achieve multiple goals at the same time. Next, participants completed a simple practice trial involving only two means and two goals. Once they had solved this task successfully, participants proceeded to the Set-Cover problem they had been assigned to. When participants moused over an activity, this interface highlighted the goals it would achieve and the corresponding edges of the graph in green. Goals that had already been achieved and activities that had already been selected were highlighted by checkmarks, and the number of selected activities was shown at the bottom of the screen. Participants were asked to help a person achieve their 24 goals with as few activities as possible, and they were motivated by the prospect of earning a financial bonus of $\$ 2$ for achieving all goals as efficiently as possible. After submitting their solution, participants completed an exit questionnaire asking them for basic demographic information (age, gender, and primary language), and four 9-point Likert scales (anchors: "not at all", "somewhat", and "extremely") measuring the perceived difficulty of the task, motivation to achieve all goals, motivation to find the optimal solution, and their motivation to finish the task as quickly as possible. We excluded 30 participants ( $4.6 \%$ ) because their responses did not achieve all goals suggesting that they did not follow the instructions.

Results We found that treewidth alone explained $44.90 \%$ of the variance in the frequency with which people found the optimal solution across the 20 graphs $(F(1,18)=14.20, p=$ 0.0012 ): as we increased the treewidth of the graph the percentage of participants who discovered the optimal solution decreased significantly ( $\rho=-0.59, p=0.0058$ ) from more than $90 \%$ on the graph with treewidth 5 to only about $30 \%$ on the graph with treewidth 14 . We found that the aver-
age solution quality was negatively correlated with treewidth ( $\rho=-0.44, p=0.0525$ ) suggesting that our participants achieved fewer goals for goal systems with higher treewidth. Treewidth explained $17.59 \%$ of the variance in the median response time across problems $(F(1,18)=3.86, p=0.0650)$ : the median amount of time people took to solve the problems tended to increase with treewidth $(\rho=0.3426)$ but this effect was not statistically significant ( $p=0.1393$ ), and when we restricted this analysis to correct solutions the correlation was $\rho=0.3825$ ( $p=0.1297$ ). Perceived difficulty also tended to increase with treewidth ( $\rho=0.37$ ) but this correlation was not statistically significant ( $p=0.1062$ ). Our participants were highly motivated to find the optimal solution (average rating $7.91 \pm 0.06$ out of 9 ). Thus it appears unlikely that their motivation was a bottleneck to their performance. Furthermore, motivation appeared to be unaffected by treewidth ( $\rho=-0.23, p=0.34$ ). Thus the observed differences in performance appear to result from the inherent difficulties of the means selection problems posed by different goal systems.

Of the additional predictors evaluated, we found that graph diameter, average shortest path, and average graph eccentricity all were significantly positively correlated with the frequency of optimal solutions identified by our participants (graph diameter: $\rho=0.5691, p=0.0088$, avg. shortest path: $\rho=0.6516, p=0.0019$, avg. eccentricty: $\rho=0.6265, p=$ 0.0031 ). In addition, the spectral expansion (measured as $d-\lambda_{2}$ ) and the size of the graph vertex and edge expansions showed significant negative correlations with the frequency of optimal solutions (vertex expansion: $\rho=-0.5836, p=$ 0.0069 , edge expansion: $\rho=-0.4552, p=0.0437$, spectral expansion: $\rho=-0.6280, p=0.0030$ ). We also found that the average shortest path, average graph eccentricity, spectral expansion, and the size of the graph vertex expansions were significantly correlated with the average participant solution qualities (avg. shortest path: $\rho=0.4505, p=0.0462$, avg. eccentricity: $\rho=0.4316, p=0.0574$, spectral expansion: $\rho=$ $-0.4496, p=0.0467$, vertex expansion: $\rho=-0.4636, p=$ 0.0395 ). Finally, only the cardinality of the graph edge expansions exhibited a significant correlation with the median response times on the SC task ( $\rho=0.4538, p=0.0445$ ).

## Experiment 2: Human performance on Maximum Coverage

Methods Experiment 2 was identical to Experiment 1 except for the task: participants were now instructed to achieve as many goals as possible subject to the constraint that the person's limited time does not permit them to complete more than five activities. The 20 graphs and financial incentives were the same as in Experiment 1. The interface of Experiment 1 was modified to prevent participants from selecting more than five activities at a time. When a participant attempted to add a sixth activity they were told they would first have to remove one or more of the activities they had already selected. The cover story and survey were modified slightly to match the change in the task. We recruited 545 participants on Amazon Mechanical Turk. Participants were paid $\$ 1.25$
and could earn a bonus of up to $\$ 2$. The consent form specified that participants must not have participated in the previous version of this experiment. We excluded 23 participants $(4.2 \%)$ because they had selected fewer than five means.

Results The frequency with which people found the optimal solution decreased significantly with treewidth ( $\rho=$ $-0.4828, p=0.0311$ ). We found that treewidth alone explained $20.41 \%$ of the variance in the frequency with which people found the optimal solution across the 20 graphs $(F(1,18)=4.62, p=0.0455)$. We found that treewidth explained $25.25 \%$ of the variance in solution quality $(F(1,18)=6.08, p=0.0240)$ which significantly deteriorated as treewidth increased ( $\rho=-0.4972, p=0.0257$ ). The median amount of time people took to solve the problems did not increase significantly with treewidth ( $\rho=0.25, p=0.28$ ) and treewidth explained only $0.6 \%$ of our participants' median response times $(F(1,18)=0.10, p=0.76)$. When we restricted the analysis to the time taken by optimal solutions, the relationship was still not statistically significant ( $\rho=0.2994, p=0.1998 ; F(1,18)=0.10, p=0.76$ ). Finally, treewidth explained only $8.8 \%$ of the variance in the perceived problem difficulty across the 20 graphs $(F(1,18)=$ $1.74, p=0.20$ ), and the correlation between treewidth and perceived difficulty was not statistically significant ( $\rho=$ $0.26, p=0.26$ ). Our participants were highly motivated to find the optimal solution (average rating $8.11 \pm 0.06$ out of 9 ). Thus it appears unlikely that their motivation was a bottleneck to their performance. Furthermore, motivation appeared to be unaffected by treewidth $(\rho=-0.03, p=0.91)$. Thus the observed differences in performance appear to result from the inherent difficulties of the means selection problems posed by different goal systems.

In addition, we found that both the size of the graph edge expansion and the graph spectral expansion (measured again as $d-\lambda_{2}$ ) were significantly negatively correlated with the frequency of optimal solutions (edge expansion: $\rho=$ $-0.4802, p=0.0321$, spectral expansion: $\rho=-0.4782, p=$ 0.0330 ), while the average shortest path and average graph eccentricity showed a significant positive relationship (avg shortest path: $\rho=0.4912, p=0.0279$, avg. eccentricity: $\rho=0.4391, p=0.0528$ ). In contrast, only the size of the graph vertex and edge expansions showed a significant correlation with the average solution quality (vertex expansion: $\rho=-0.4431, p=0.0504$, edge expansion: $\rho=-0.4832, p=$ 0.0309 ), suggesting that in general graph treewidth and combinatorial expansions may be more robust predictors of human performance on the MC problem. None of the metrics surveyed were significantly correlated with median participant response times.

## Experiment 3: A more realistic Set-Cover task

While Experiments 1 and 2 capture some of the computational challenges of goal achievement, the tasks were relatively abstract. Experiment 3 addresses this limitation by as-
signing semantic labels to the 24 goals. These labels were common new-years resolutions such as "get in shape" and "earn more money". Similar semantic goals were used in previous research in goal-system theory (Zhang et al., 2007). We also used a different interface to avoid possible visualization effects that arise from graph drawings in the first two experiments.

Methods We recruited 600 participants on Amazon Mechanical Turk. Participants were paid $\$ 0.38$ for about 5 min of work plus a performance-dependent bonus of $\$ 0.50$ if they found an optimal solution. Each participant was randomly assigned to one of the twenty graph structures used in Experiments 1 and 2. For each graph, the order in which the means were listed and the order in which the goals were listed was randomized between participants. The participants' task was to achieve all goals with as few means as possible. The graphical interface of the task was changed to reduce visual clutter. Instead of drawing edges between mean and goals, the goals achieved by each mean were listed next to it (see Figure 3). The cover story was similar to the one used in Experiment 1 but the training trial used the new task interface shown in Figure 3. The consent form required that participants had not participated in any of our previous goal management experiments. All participants were included in the subsequent analyses.

Results On a scale from 1 to 9 participants rated their motivation to find a solution that achieves all goals with the minimal number of means as 7.38 , their motivation to finish the task as quickly as possible and move on as 4.35 , and the difficulty of the task as 5.67. We found that treewidth, the magnitude of the graph spectral expansion, cardinalities of the graph edge and vertex expansions, average eccentricity, average shortest path, and graph diameter were all significantly correlated with the frequency with which human participants identified the optimal solution (treewidth: $\rho=$ $-0.756, p=0.0001$; avg. eccentricity: $\rho=0.583, p=0.007$; avg. shortest path: $\rho=0.651, p=0.002$; graph diameter: $\rho=$ $0.525, p=0.017$; spectral expansion: $\rho:-0.708, p=0.0005$; edge expansion: $\rho=-0.7, p=0.0006$; vertex expansion: $\rho=-0.7303, p=0.0003$ ). Similarly, treewidth, the magnitude of the graph spectral expansion, cardinalities of the graph edge and vertex expansions, average eccentricity, and average shortest path were all significantly correlated with the average solution quality of human responses (treewidth: $\rho=-0.60, p=0.005 ;$ avg. eccentricity: $\rho=0.4872, p=$ 0.0293 ; avg. shortest path: $\rho=0.5243, p=0.0176$; spectral expansion: $\rho=-0.5308, p=0.0160$; edge expansion: $\rho=$ $-0.5670, p=0.0091$; vertex expansion: $\rho=-0.6047, p=$ 0.0047 ). None of the features were significantly correlated with median participant response times.

Figure 3: Graphical Interface of Experiment 3.

## Conclusions

We demonstrated that people's performance in Maximum Coverage and Set Cover can be reliably predicted from graph theoretic measures for the tree-likeness of the goal system, such as treewidth and expansion. Our data support the conclusion that tree-like goal systems are easier for people to handle. More generally, our results imply that parameters that are used in theoretical computer science to differentiate between hard and easy instances can be leveraged to predict human performance in NP-hard tasks.

One limitation of our experiments is that their complete, explicit representation of goals, means, and the connections between them is a simplifying idealization. In real life, people are often unaware of some of their goals and means, as well as some of the connections between goals and means. For example, maintaining goal systems of moderate size in working memory when solving means selection problems is likely to be nontrivial. Hence real-life representations of goals are likely to make means selection problems as those discussed here even more challenging to solve. Although such memory problems are not directly related to how treelike the goal system is, they are nevertheless consistent with our hypothesis that the cognitive difficulty of means selection is an important limiting factor for people's ability to achieve their goals.

In conclusion, our results suggest that even highly motivated people will likely fall short of achieving all their goals when they have to consider many goals and means in parallel. Our analyses provide a novel approach to predicting how likely people are to succeed in these settings, with implications for the design of goal systems that make it easier for people to meet their objectives.

# The Effects of Autonomy on Emotions and Learning in Game-Based Learning Environments 

Amanda E. Bradbury, Michelle Taub, \& Roger Azevedo<br>\{aebradbu@ncsu.edu, mtaub@ncsu.edu, razeved@ncsu.edu\}<br>North Carolina State University, Department of Psychology, 2310 Stinson Drive, 640 Poe Hall Raleigh, NC 27695 USA

#### Abstract

The current study examined the impact of agency on college students' emotions and learning during gameplay with CRYSTAL ISLAND, a game-based learning environment designed to foster microbiology learning. 96 undergraduate students ( $59 \%$ female) from a large North American university participated in the study. Participants were randomly assigned to one of three experimental conditions (i.e., full agency, partial agency, no agency), based on the level of control granted during gameplay, and were asked to uncover the source, identity, and best treatment for a mysterious illness. Results revealed participants in the partial agency condition achieved the highest (pre- to post-test) proportional learning gain (PLG), even when controlling for session duration. Additionally, there was a positive correlation between evidence scores of four emotions (anger, fear, confusion, and frustration) and PLG within the partial agency condition-meaning the higher the evidence of the above emotions, the higher the PLG. Further, a stepwise multiple regression showed anger as the sole predictor of PLG. Results from this study have important implications for understanding the role of autonomy and emotions during learning and problem solving with GBLEs designed to foster scientific thinking in STEM. The current study suggests that although GBLEs offer significant learning benefits, they also induce several emotions that can facilitate or inhibit learning gains, requiring further examination.

Keywords: human agency; emotions; learning; game-based learning environments; science

Autonomy is a critical determinant in human learning, problem solving, and performance (Bandura, 2001). Despite its importance in cognitive science, there is a paucity of research that experimentally manipulates autonomy and explores its impact on learning and emotions, in STEM gamebased learning environments (GBLEs). Various levels of autonomy likely affect learners' abilities to monitor and regulate their cognitive, affective, metacognitive, and motivational processes in dynamic, non-linear learning environments involving planning (e.g., coordinating multiple goals), learning activities (e.g., reading scientific texts), and scientific reasoning (e.g., collecting evidence and testing hypotheses) in different ways. Further, little is understood of how autonomy affects emotions in GBLEs, and in turn, how these emotions affect learning outcomes (Azevedo, Taub, Mudrick, Farnsworth, \& Martin, 2016; D’Mello \& Graesser, 2012). Our study focuses on the effects of autonomy on emotions and the impact of both on learning and problem solving within the GBLE, CRystal IsLand.

GBLEs offer powerful platforms to enhance student learning, problem solving, and performance. However, a majority of the research focuses on engagement and motivation and is often criticized for (1) a lack of theoretical framing, (2)
questionable operationalizations of key constructs (e.g., engagement, motivation), (3) overreliance on self-report measures, and (4) dubious empirical support, based on a lack of experimental rigor, methodological shortcomings, and inappropriate analytical techniques (see Mayer, 2014). Additionally, much of this research fails to assess learning gains, choosing to take an "everything but learning" approach, such as measuring engagement or motivation alone while ignoring educational outcomes (Mayer, 2014). Further, GBLEs have been criticized for overshadowing educational content with game elements that are superfluous and distracting to learning goals, drawing learner attention away from important educational content (Mayer \& Johnson, 2010). Interestingly, many of these distractors (e.g., game narratives, interesting characters) are the very elements thought to increase student motivation, engagement and positive emotions (Sabourin \& Lester, 2014). Further, research has indicted that while distractors may present opportunities for off-task behaviors, leading to decreased learning gains (Rowe, McQuiggan, Robison, \& Lester, 2009), off-task behaviors could in-fact be a strategy to alleviate frustration, allowing the student to reduce frustration and thereby increase learning gains (Sabourin, Rowe, Mott, \& Lester, 2014).

Students experience a diverse range of emotions when learning, which likely influence cognitive processes and academic performance (see Calvo, D'Mello, Gratch, \& Kappas, 2014). We address this issue by using online trace methods (e.g., facial expression detection software [FACET; Version 6.2], and logfiles), to assess the impact of autonomy on emotions and learning during gameplay (see Azevedo et al., 2016; Calvo et al., 2014), thereby increasing understanding of emotional monitoring and regulation in GBLEs (Rowe, Shores, Mott, \& Lester 2011). This research can inform the design of future intelligent, adaptive GBLEs that not only teach complex instructional material effectively but also train the skills necessary to successfully monitor and regulate emotions during learning, leading to improved learning outcomes.

## Theoretical Framework

D'Mello and Graesser's (2012) model of affective dynamics suggests certain emotional states arise as the result of an impasse during deep learning, creating cognitive disequilibrium. This model focuses on four learner-centered emotional states: flow/engagement, confusion, frustration and boredom. When learners reach a state of disequilibrium (e.g., during reading complex text), they are likely to experience confusion which if unresolved will likely transition to frustration, which if also left unresolved, will lead to boredom
and disengagement from the activity (e.g., reading, inspecting diagrams). This model posits that students systematically shift between learning-centered states during complex learning and that these shifts are predictive of learning, problem solving, and scientific reasoning. For instance, frustration is much more likely to transition to boredom than to engagement/flow, as learners have not yet transitioned to confusion, where through effortful reasoning and problem solving they can resolve an impasse and return to equilibrium. However, this model has some drawbacks. For instance, it ignores other emotional states such as the seven basic emotions (e.g., anger; Ekman, 1973), assuming that other basic emotions are unimportant to learning. Lastly, this model has not been used to examine autonomy and extended learning with GBLEs such as CRYSTAL ISLAND.

## Current Study

The goal of the current study was to examine the effects of autonomy on emotions and learning during gameplay with GBLEs such as CRYSTAL ISLAND. By experimentally manipulating autonomy, we could empirically observe how different levels of autonomy (e.g., agency conditions) affected learning gains as well as emotional states, and in turn, how these emotional states affected learning gains. Our research questions were as follows: 1) What are the effects of autonomy on proportional learning gains with CRYSTAL ISLAND, after controlling for session duration? 2) What are the effects of autonomy on learners' emotions throughout their interaction with Crystal IsLand? 3) Do evidence scores of emotional states predict PLG during gameplay with CRYSTAL ISLAND and are there differences in emotion evidence scores between high and low performers?

Our hypotheses were as follows. (H1): Participants in the partial agency condition will show significant PLG compared to the full agency and no agency conditions. (H2): The full agency condition will exhibit the highest evidence of positive emotions such as joy and the lowest evidence of negative emotions such as anger and frustration compared to the partial and no agency conditions. (H3): Higher evidence scores of negative emotions such as anger, confusion and frustration will lead to increased PLG in all conditions.

## Method

## Participants

96 undergraduate students ( $59 \%$ female) from a large North American university participated in the current study. Participants' ages ranged from 18 to $29(M=19.99, S D=1.79)$ and were randomly assigned to one of three experimental condition: full agency, partial agency or no agency (see Experimental Procedure). Additionally, they were compensated \$10/hour for participating.

## Materials

At the start of the experimental session, participants read and completed the informed consent, a demographics question-
naire and a series of self-report questionnaires. These questionnaires probed participants' emotions and motivation (e.g., Emotions and Values; Pekrun, Goetz, Frenzel, Barchfeld, \& Perry, 2011) as well as achievement goals (Elliot \& Murayama, 2008). Participants also completed a pretest ( $M=11.94, S D=2.79 ; 57 \%$ correct) and post-test ( $M=$ 13.92, $S D=2.86 ; 66 \%$ correct) on microbiology knowledge: a 21-item, four-choice multiple-choice test, with 12 factual and 9 procedural questions. Participants also completed the Perceived Interest Questionnaire (Schraw, Bruning, \& Svoboda, 1995), Intrinsic Motivation Inventory (Ryan, 1982), and Presence Questionnaire (Witmer \& Singer, 1998).

## Crystal ISLAND

CRyStal IsLand is a narrative-centered GBLE used to foster students' self-regulated learning, scientific reasoning, and problem-solving skills (Rowe et al., 2011). Participants experience the game in first person perspective, arriving on a tropical island where they discover a mysterious illness has infected the community. Taking a protagonist role, participants explore the island, seek clues by speaking to residents and patients, read content on microbiology and use lab equipment to scan for possible transmission sources, all to discover the source, identity, and best treatment for the infectious disease.

Buildings CRYSTAL ISLAND has five buildings, each embedded with a multitude of books, research papers, posters, food items, and non-player characters (NPCs). In the infirmary, participants interview sick patients and interact with the NPC, Kim the camp nurse, who provides the game narrative. Through this interaction, they gather pertinent information such as overall goals, background information, and clues pointing towards possible illness types and transmission sources. In the two living quarters (a dorm room and a microbiologist's home), participants converse with microbiology experts and another patient, and read books and posters on various microbiology topics. In the dining hall, participants meet Quentin the camp cook, who offers insight into what foods he had prepared and sick patients had eaten prior to the outbreak. Using information and clues gathered from these buildings, participants can infer which items are the likely transmission source and then test these hypotheses by scanning these food items in the laboratory.

Game Elements Participants complete concept matrices as they read about microbiology in books and research articles. For example, as they read about E. coli, they must fill in a diagram asking questions related to the reading (i.e., where E. coli is located, symptoms and common diagnostic tests). Additionally, by interacting with NPCs, participants receive valuable information (i.e., evidence), such as symptoms and food eaten. As participants collect evidence and begin making inferences, they can track and organize symptoms, test results, and make a final diagnosis via a diagnosis worksheet. This worksheet supports problem-solving processes by allowing participants to offload information as they interact with the game environment, later using this information to
make a final diagnosis, identify the transmission source, and propose a treatment plan. For instance, they may read about influenza then check the diagnosis worksheet to find the symptoms match the current epidemic. Additionally, participants generate hypotheses regarding which food items are the likely transmission source as well as the type of pathogen they might carry. These hypotheses are tested by collecting and scanning food items, and testing for a virus, bacterium, mutagen, or carcinogen. If a test comes back positive for a pathogenic substance, the participant can confirm the transmission source and add their finding to the diagnosis worksheet. Once participants correctly identify the illness type, transmission source, and treatment plan, the mystery is solved and the game concludes.

## Experimental Procedure

Conditions Participants were randomly assigned to one of three conditions (i.e., full agency, partial agency, no agency) prior to gameplay. These conditions varied in the level of autonomy assigned to each player, ranging from full autonomy (full agency), to some autonomy (partial agency), to no autonomy at all (no agency). In the full condition, participants were free to explore the game environment and its elements as much or as little as they wished, choosing what buildings to visit, what books to read, and with which NPCs to interact. Conversely, the partial condition contained strict game parameters with a pre-set order in which players visited buildings and a requirement that they interact with all game artifacts (e.g., read all books/posters, speak with all NPCs, etc.) before advancing to other buildings. In the no condition, participants did not play CRYSTAL ISLAND but instead watched a narrated video of an expert playing the game. This was an optimal instructional path designed to enhance learning without the opportunity to exercise autonomy as participants had no control over any aspect of the gameplay or content.

Experimental Procedure The experimental session lasted one to two and a half hours depending on condition ( $M=$ $89.64 \mathrm{~min}, S D=18.37 \mathrm{~min}$ ). Upon arrival, participants were greeted, directed to the workstation and asked to review and complete the informed consent. Next, they received an overview of the study, donned an electro dermal activity (EDA) bracelet (Empatica E4), and completed the microbiology pretest. Then, the SMI RED 250 eye tracker was calibrated using a 9-point calibration. Following successful calibration, a baseline for the facial recognition of emotion software (FACET) and EDA were established using Attention Tool (Version 6.2). Participants were then given instructions for the experimental session that included an overview of the game scenario covering their role as the protagonist, the importance of reading (i.e., books, articles, and posters), interacting with NPCs and scanning food items to solve the mystery. During gameplay, we collected logfiles, eye-tracking, facial expressions of emotions, and physiological data on all participants in the full and partial agency conditions only. Upon game conclusion, participants completed several self-
report measures and the microbiology post-test, after which they were debriefed, thanked, and paid for their time.

## Coding and Scoring

For the purposes of the current study, only logfiles and FACET data were used. Additionally, pre- and post-test scores (out of 21 possible points) of microbiology content knowledge were used to generate a PLG score (see below).

Logfiles Logfile data captured the sequence and timing of participants' movements and actions within the game (e.g., talking to NPCs, reading books). For this study, only session duration was analyzed. This variable was extracted from the trace data. Additionally, logfile data were only captured in the full and partial agency conditions as the no agency condition watched a video play-through ( 91 min ) of CRYSTAL IsLAND rather than play, thus not generating any log-file data.

Facial Expression Data Each experimental session included a video of the participant, which was later analyzed using FACET, facial expression recognition software included with Attention Tool. We used FACET (sampling rate of 30 Hz ) to analyze the following nine basic and learning-centered emotions: joy, anger, contempt, frustration, confusion, surprise, fear, sadness and disgust (see, Dente, Küster, Skora, \& Krumhuber, 2017, regarding the software's validity). Each emotion was given an evidence score automatically generated by FACET representing the likelihood of an expert human coder to similarly categorize the expression. This score was based on a logarithmic scale (base 10), meaning that a score of one indicated the likelihood of 10 human coders coding for that emotions while a score of two indicated the likelihood of 100 human coders coding for that emotion, and so forth. For the purposes of the current study, the mean evidence score for the entire session duration was used for each participant. The range of evidence scores for all emotions and across participants was 0 to 1.98 , excluding negative values. Negative scores indicated the emotion was not likely present, and since we were interested in emotions present, all negative values were replaced with zero.

Proportional Learning Gain (PLG) PLG scores were calculated from pre- and post-test ratios scores of microbiology content knowledge, using Witherspoon, Azevedo, and D'Mello's (2008) formula. For example, if a participant scored an 11 out of 21 on the pre-test and a 15 out of 21 on the post-test then their PLG score was .40 .

Median Split High versus low performers were determined through a median split of the PLG variable for the partial agency condition. The median for this condition was .40 (range: -0.17 to 0.70 ).

## Results

Research Question 1: What are the effects of autonomy on proportional learning gains with Crystal IsLAND, after controlling for session duration?
To investigate the effects of autonomy on PLG, we conducted an ANCOVA, using condition as the independent variable and session duration as a covariate, see Table 1 for mean session duration by condition. Results indicated a significant main effect for condition, $F(2,88)=3.35, p=.003, \eta_{p} 2=.13$. Post hoc LSD analyses indicated that the partial agency condition ( $M=.35, S D=.23$ ) showed significantly higher PLG than both the full ( $M=.18, S D=.27$ ) and no agency conditions ( $M=.11, S D=.28$ ); however, there was no difference between the full and no agency conditions.

Table 1. Mean session duration (min) by condition.

|  | Full Agency <br> $M(S D)$ | Partial Agency <br> $M(S D)$ | No Agency <br> $M(S D)$ |
| :--- | :---: | :---: | :---: |
| Session <br> Duration | $78.69(21.92)$ | $98.65(18.43)$ | $91.00(0)$ |

## Research Question 2: What are the effects of autonomy on learners' emotions throughout their interaction with CRYSTAL ISLAND?

A MANCOVA was conducted using mean evidence scores of the basic and learner-centered emotions as the nine dependent variables and condition as the one independent variable. No significant main effect was found by condition; Wilk's $\lambda=.78, F(16,164)=1.39, \eta_{\mathrm{p}}^{2}=.12$. Univariate results revealed that disgust, $F(2,89)=4.15, p=.02, \eta_{p} 2=.09$, anger, $F(2,89)=4.12, p=.02, \eta_{\mathrm{p}} 2=.02$, and joy $F(2,92)=$ $3.48, p=.04, \eta_{p} 2=.07$, showed statistically significant differences between conditions. No other emotions demonstrated significant differences. Post hoc LSD analyses indicated that those in the full agency condition exhibited higher levels of disgust ( $M=.22, S D=.34$ ) and anger $(M=.55, S D$ $=.62$ ) compared to those in the partial agency condition $(M$ $=.14, S D=.24 ; M=.37, S D=.49$, respectively). Additionally, those in the full agency condition exhibited higher levels of joy ( $M=.25, S D=.44$ ) compared to the partial agency condition ( $M=.06, S D=.13$; see Table 2).

Table 2. Mean emotion evidence scores by condition.

|  | $(.52)$ | $(.40)$ | $(.46)$ | $(.28)$ |  |

Note: $\mathrm{F}=$ full agency, $\mathrm{P}=$ no agency, $\mathrm{N}=$ no agency conditions

## Research Question 3: Do evidence scores of emotional states predict PLG during gameplay with CRYSTAL ISLAND and are there differences in emotion evidence scores between high and low performers?

To assess the relationship between emotions and PLG while playing CRYSTAL ISLAND, four correlation matrices were created: overall (all conditions; $n=92$ ), full agency ( $n=$ $30)$, partial agency $(n=32)$, and no agency $(n=30)$. The full and no agency conditions as well as all conditions combined showed no correlations between emotions and PLG; however, for the partial condition, four emotions were significantly positively correlated with PLG, anger, $r(30)=.39$, $p=.03$, fear, $r(30)=.36, p=.04$, confusion, $r(30)=.39, p=$ .03 , and frustration, $r(30)=.39$, meaning the higher the evidence of the above emotions, the higher the PLG.

To determine the predictive power of anger, fear, confusion, and frustration on PLG within the partial agency condition, a stepwise multiple regression analysis was conducted. Results indicated that anger ( $\beta=.39, p=.03, R^{2}=.15$ ) was the sole predictor of PLG, meaning that more evidence of anger predicted better PLG, accounting for $15 \%$ of the variability in PLG.

Given the regression results for the partial agency condition, we performed a median split on these participants' PLG to examine whether there were differences between high- and low-performers' experienced emotions. Result of an independent samples $t$-test revealed that high performers exhibited significantly more evidence of facially expressed frustration, $t(18)=-3.75, p<.002, d=-1.78$, anger, $t(19)=-3.47$, $p<.003, d=-1.58$, and confusion, $t(21)=-2.97, p<.007, d$ $=-1.29$, compared to low performers.

## Discussion

Results of the current study revealed that students achieved the highest PLG in the partial agency condition compared to the full and no agency conditions, even after controlling for sessions duration. These results support H1, demonstrating the positive impacts of seceding partial agency to improve learning outcomes in GBLEs. Previous research explains that while offering a high degree of user control allows learners
to regulate their own learning, constructing knowledge based on the representations they find useful, this responsibility can lead to disorientation and negative learning outcomes when learners are unsure which path to follow (Greene, Bolick, \& Robertson, 2010), suggesting there may be on optimal level of autonomy to improve learning outcomes in GBLE. Future research should empirically test different parametrization of autonomy on GBLEs to assess the optimal level of autonomy to foster learning across domains.

For research question two, participants in the full agency condition were more emotionally expressive than those in no and partial agency conditions. For instance, those in the full agency condition showed significantly higher evidence of joy than those in the partial and no agency conditions, as well as significantly higher evidence of anger and disgust compared to the no agency condition. These results run contrary to our original hypothesis (H2), expecting the full agency condition to experience the least negative emotions; however, the full agency condition did experience the highest evidence of joy, partially supporting H2. A plausible explanation could be that those in the full agency had a greater potential to express autonomy which led to more emotional expressivity throughout task performance (Azevedo et al., 2016). A next step involves a micro-level analysis mapping specific game events (e.g., reading books, testing evidence, etc.) with emotional expressivity (e.g., higher evidence scores) and emotional states.

As for research question three, no correlations between emotional states and PLG were found with 1) all conditions combined, 2) the full agency condition or 3) the no agency condition; however, this was not the case within the partial agency condition. The partial agency condition found significant positive correlations between PLG and evidence scores of facially expressed anger, fear, confusion and frustration, meaning the higher evidence of the above emotions, the higher a participant's PLG. After imputing the aforementioned emotions into a stepwise multiple regression conducted within the partial agency condition, anger was the sole predictor of PLG. Further, high performers in the partial agency condition exhibited significantly higher evidence of anger, frustration and confusion compared to low performers, demonstrating that negative emotions, typically thought as unconducive to learning (Sabourin \& Lester, 2014), can have positive effects on learning outcomes. Previous work has reach similar conclusions, finding confusion, if appropriately regulated and resolved, as beneficial to learning (D'Mello, Lehman, Pekrun,\& Graesser, 2014).

In the current study, fear, anger, frustration and confusion had a positive effect on PLG, but only when the participant seceded partial control of the learning environment (i.e., partial agency condition). One explanation for these results could be explained using the model of affective dynamics (D'Mello \& Graesser, 2012). For instance, participants are likely to experience confusion and frustration when learning difficult subject matter and will hence experience cognitive disequilibrium (D'Mello \& Graesser, 2012). Equilibrium (e.g., engagement/flow state) is regained
through effortful reasoning, problem solving and reflection; however, when left unresolved, learners can digress from confusion to frustration and eventually disengage from the learning activity (D'Mello et al., 2014).

In the current study, participants were asked to learn new information in order to solve complex problems: what disease was infecting the community, what was the transmission source, and how to best treat patients. However, each condition offered different paths to learn this information (via varying levels of autonomy) and in turn affected emotions and learning differently. For instance, in the no agency condition, participants might have felt frustrated at not being able to play the game and this frustration may have led to boredom and disengagement, explaining poor PLG. In the full agency condition, participants could reduce confusion and frustration by simply avoiding books, research articles, or interactions with aspects of the game they found unappealing; however, even though they would return to equilibrium through these actions, they would have missed valuable educational content, thus reducing PLG. Conversely, the partial agency condition was forced to interact with all elements of the game before leaving a room. This stipulation may have forced participants to work through the confusion and frustration they experienced because they could not progress with the not step of the game until required actions (e.g., finishing a conversion with the NPC, filling in a concept matrix correctly) were completed. Therefore, these participants were more likely to engage in the effortful reasoning and problem solving necessary for both deep learning and a return to equilibrium.

## Limitations

There were a number of limitations with the current study. First, the operationalization of autonomy in the partial and full agency condition as this was a first attempt to parameterize key assumptions of autonomy in a GBLE. Also, because we were looking at autonomy, there may have been other metacognitive processes (e.g., motivation) affecting learning gains that we did not control for or measure, we only used log-files, FACET, and learning outcomes data. Converging these data along with EDA and eye-tracking data would further elucidate the role of autonomy and emotions during learning. For instance, eye-tracking data could be used to examine what activity a participant was engaged in prior, during and after the onset of a certain emotion. Additionally, EDA data could be used to validate the presence and relevance of emotions. For instance, spikes in EDA data could be mapped onto emotion evidence scores to determine when spikes and high emotion evidence scores co-occur revealing the quality of appraisals mechanisms (Gross, 2015).

## Implications and Future Directions

These results have important implications for understanding the role of autonomy and emotions during learning and problem solving with GBLEs designed to foster scientific thinking in STEM. The current study suggests GBLEs induce several basic and learning-centered emotions depending on
the level of autonomy granted to a learner and that autonomy and emotions can either facilitate or inhibit learning. However, further empirical examination is required. Future research should design and test additional experimental manipulations that operationalize key assumptions of autonomy (Bandura, 2001). Further, our results revealed a need to extend models and theories of affect to include basic emotions when considering transitions between emotional states in learning environments (D'Mello \& Graesser, 2012) and would benefit by including Gross's process model of emotional regulation along with emotion regulation strategies (Gross, 2015).

Methodologically, converging the multimodal multichannel data will allow researchers to examine the impact of autonomy on emotions and their impact on learning, problem solving, and reasoning. For example, how do emotions fluctuate during different activities during learning with GBLEs? What is their specific behavioral signature in terms of onset/trigger event, intensity, duration, evidence of emotion regulation strategy, and so forth? How do these emotions related to specific GBLE activities (e.g., reading books and posters, interviewing patients, interpreting results, deriving hypotheses)? Such questions can be addressed by traditional statistics as well as data mining and machine learning techniques and lead to the design of intelligent GBLEs capable of detecting, tracking, modeling, and fostering adaptive, realtime scaffolding to learners, depending on their individual needs, thus ensuring optimal learning.

# A Computational Model of the Role of Attention in Subitizing and Enumeration 

Gordon Briggs (gordon.briggs.ctr@nrl.navy.mil) Will Bridewell (will.bridewell @ nrl.navy.mil) Paul F. Bello (paul.bello@nrl.navy.mil)<br>Naval Research Laboratory<br>Washington, DC 20375 USA

#### Abstract

Recent studies in the perception of numerosity have indicated that subitizing (the rapid and accurate enumeration of small quantities) requires attention. We present a novel computational model of enumeration in which attention unifies distinct processes of numerosity approximation, subitizing, and explicit counting. We demonstrate how this model accounts for both the reaction time results from the subitizing literature and the effects of attentional load on subitizing accuracy.

Keywords: attention; subitizing; enumeration; perception of numerosity; counting; inattentional blindness

## Introduction

The perception of numerosity is one of the core faculties underlying much of the human ability to represent, reason, and communicate about number (Dehaene, 2011), and the precision and accuracy of this "number sense" is highly dependent on the amount of attention devoted to it. Imagine that you are asked to report the size of a small crowd gathered around a performer in a public park. Glancing at the crowd might suffice to obtain a rough figure (e.g., about thirty), but obtaining an exact number with high confidence would require looking at individual people and counting them. Converging lines of evidence suggest that numerical cognition is supported by two types of representations of numerosity (Feigenson, Dehaene, \& Spelke, 2004). The first is an approximate representation that can be quickly perceived through estimation. The second is a precise representation, associated with linguistic representations of number (Gelman \& Butterworth, 2005) that are usually generated through a slower process of explicitly fixating on and counting individual objects.

Yet, a simple dual-system account of numerosity judgment is incomplete. Since the 19th century, scientists have observed that the enumeration of small quantities of objects (under five) was both rapid and accurate (Jevons, 1871). This phenomenon is called subitizing (Kaufman, Lord, Reese, \& Volkmann, 1949). Within the subitizing range, each additional object requires only $40-100 \mathrm{~ms}$ more time to enumerate on average, whereas in the post-subitizing range, each additional object requires $250-350 \mathrm{~ms}$ to enumerate (Trick \& Pylyshyn, 1994). Previous work has proposed that subitizing is the result of a parallel and pre-attentive process (Trick \& Pylyshyn, 1994; Mandler \& Shebo, 1982) that transitions into slower, serial counting.

In contrast with this account, recent studies provide a body of evidence demonstrating that attentional manipulations, such as attentional blink or increased attentional load, adversely affect subitizing performance (Railo, Koivisto,

Revonsuo, \& Hannula, 2008; Olivers \& Watson, 2008; Egeth, Leonard, \& Palomares, 2008; Vetter, Butterworth, \& Bahrami, 2008). Therefore, subitizing has an attentional component, and an account of the processes underlying subitizing must explain both (a) why subitizing is significantly more rapid than explicit counting and (b) why it requires attention.

We claim that numerosity judgments of all types are subject to constraints on attention and that attention flexibly integrates the results of multiple number-processing capacities. Both classical and newer results in the subitizing literature can be explained by combining a capacity-limited, objectbased view of attention with a capacity for approximation that operates independently of attention. In this paper, we present a computational model of enumeration in which attention unifies distinct processes of numerosity approximation, subitizing, and explicit counting. We begin by introducing a computational cognitive modeling system, ARCADIA (Bridewell \& Bello, 2016b), in which attention features centrally. We then proceed to present a computational account of enumeration, proposing a model of rapid, serial subitizing in which the numerosity of objects encoded in visual short-term memory can be quickly established. We then demonstrate how this model of subitizing accounts for both the reaction time and the effects of attentional load. Finally, we discuss the various processes involved in the perception of numerosity and the role of attention in enabling and integrating them.

## ARCADIA's Architectural Features

ARCADIA provides a system in which attention is the primary organizing mechanism for perception, cognition, and action. In this section, we provide a brief overview of the key concepts necessary to understand ARCADIA models and point to a more detailed introduction by Bridewell and Bello (2016b). Each ARCADIA model consists of a set of components, which carry out all the processing for the model, that can read from or write to accessible content, a temporary buffer where components share their output on each cycle. Whereas representations inside of individual components can take arbitrary form, every component is designed to read from and express its results in a common representation called the interlingua. This shared language pulls together data in different formats so that they can be exchanged among components.

ARCADIA operates in discrete, cognitive cycles, each corresponding to 25 ms intervals (Bridewell \& Bello, 2016a). During each cycle, an attentional strategy selects an element
out of accessible content to be the focus of attention. Some components can respond to the focus of attention, while others operate independently of the focus. In this way, ARCADIA has natural resources for distinguishing processes that require attention from those that do not.

## Model of Enumeration

In this section, we present an ARCADIA model of numerosity judgment that includes both estimation and counting processes. The core processes within this model are illustrated in Figure 1. We model counting such that differences in enumeration speed result from the attentional and temporal constraints necessitated by maintaining count information in different memory stores. The model proposes that a count of the first set of seen objects can be calculated from visual shortterm memory (vSTM) and represents the subitized count. After this, an explicit, symbolic representation of the current count is maintained that requires rehearsal via subvocalization (i.e., inner speech) supported by a phonological loop.

The connection between subvocalization and slow counting has been previously established (Dehaene, 2011), and evidence has shown that articulatory suppression adversely affects counting performance (Logie \& Baddeley, 1987). Likewise, vSTM capacity-limits have been proposed as an explanation of subitizing (Railo et al., 2008), and there is evidence that vSTM load affects subitizing performance (Cutini \& Bonato, 2012).

## Visual Processing

For the sake of brevity, our discussion of these components is abridged. A more detailed walkthrough of visual processing mechanisms in ARCADIA can be found in Bridewell and Bello (2016a).
Early Vision: At the first stage of visual processing, image segmentation produces a set of segments, corresponding to hypotheses about object locations that we call proto-objects (Rensink, O’Regan, \& Clark, 1997). [Step 1].
Fixation Generation: Highlighter components produce candidate fixations on either individual proto-objects or a group of proto-objects. When a candidate fixation on a single protoobject becomes the focus of attention, an object-binding process begins [Step 2a]. If a candidate fixation for a group of proto-objects becomes the focus of attention, an estimation process is triggered [Step 2b].
Object Binding and Storage (vSTM): When a candidate fixation containing a single proto-object is focused on, a (visual) feature-binding process occurs, creating an object representation containing size, shape, color, and location information. This object representation can in turn be focused on, which updates vSTM. The ARCADIA model of vSTM has a maximum capacity of four objects (Bridewell \& Bello, 2016b).
Task Knowledge (Visual Cues): Task knowledge includes object property information used as visual cues to identify and distinguish between different types of task-relevant objects. This includes size and shape information about objects
that should be enumerated and mask objects that represent the end of a trial.

## Enumeration Components

Various components are responsible for subitizing and subvocal counting, estimation, and then merging these results into a single numerosity report.
Subitized Numerosity: When vSTM is full, or a mask object is detected, or when there are no more uncounted objects, then the number of objects to be enumerated in vSTM is returned. Note, this may be based on a subset of the objects in vSTM. Evidence supports the notion that people are able to selectively enumerate objects in vSTM based on various object properties (Chesney \& Haladjian, 2011).
Lexical Count: For precise numerosity representations to be remembered, they first must be converted into a lexicalized form (e.g., "one," "four," "eight"). This happens when a subitized numerosity representation is focused on [Step 3]. When a lexicalized count representation already exists in working memory, and a new object is focused on, the next lexicalized number in the count sequence is returned [Step 5]. The presence of lexicalized number representations triggers subvocalization in the phonological loop.
Phonological Loop: The phonological loop is implemented with a component that generates a series of subvocalization actions over multiple cycles, ensuring that the number of sequential subvocalization actions corresponds to a model of subvocalization time. Currently, the number of ARCADIA cycles required to subvocalize a word is calculated based on the approximation from Huss and Byrne (2003): 150 ms per syllable and one syllable per three characters in a lexeme. For example, "seventeen" would have three estimated syllabes for a total subvocalization time of 450 ms .
Approximate Number System (ANS): The ANS responds when the focus is a fixation on a group of proto-objects, by producing a noisy number-sense representation [Step 4]. The result is a normal distribution with a mean of $n_{e}$ (the number of proto-objects in the group fixation region) and standard deviation of $w \cdot n_{e}$, where $w$ is the model's Weber fraction parameter (Halberda \& Feigenson, 2008).
Numerosity Reporter: The numerosity reporter is responsible for merging both the results from the ANS and the serial count into a single numerosity judgment. If time allows for an explicit count to be fully generated, the explicit count is recorded. Otherwise, an educated guess is made:

$$
\operatorname{Guess}\left(n_{c}, n_{e}, w\right)=n_{c}+\operatorname{sample}\left(\mathcal{N}\left(n_{e}-n_{c}, \sqrt{w \cdot\left(n_{e}-n_{c}\right)}\right)\right)
$$

where $n_{c}$ denotes the number of explicitly counted objects. This reflects the basic phenomenon that enumeration error decreases gradually in conjunction with the number of items able to be explicitly counted (e.g., Mandler \& Shebo, 1982; Railo et al., 2008). Whether this can be fully explained by approximation on uncounted fixation candidates or approximate mathematical operations on partial results (e.g., Gallistel \& Gelman, 2000) is a topic for further investigation.

Figure 1: Information flow within the ARCADIA model of enumeration. Red lines indicate information flow that requires focus of attention.

## Modeling Rapid vs. Slow Counting

In this section, we demonstrate the application of the ARCADIA numerosity perception model to a basic enumeration task (the enumeration of one to eight objects with no effective time limit). Our goals in examining this base case are to investigate and account for the origins of the bilinear reaction time curve found in the subitizing literature. To evaluate the model, we generated 40 videos, each containing a randomized, irregular pattern of one to eight (non-overlapping) circles. There were five videos for each number of circles, and the model was run 10 times for each video.

## Attentional Strategy

Attentional strategies in ARCADIA determine which element from accessible content becomes the focus of attention on a given cognitive cycle. The attentional strategy for the enumeration model embodies two constraints and prioritizes selection to jointly satisfy them. First, each task-relevant object must be counted. As such, after a new candidate proto-object is focused on, priority is given to processing that updates the count. Second, objects must not be counted more than once. Candidate proto-object fixations are ordered in a left-to-right manner, and the position of the last counted object is tracked.

## Results

Figure 2 provides a plot of the simulated reaction times from the ARCADIA model of counting ( 25 ms per cycle) with human subject results from Trick and colleagues (1996) . The simulated RTs from the model are consistent with human subjects from the 22 year-old group, $r^{2}=.990, p<.001$.

The model predicts that enumerating a single object requires at least 375 ms (or 15 ARCADIA cycles). The first seven cycles are needed to generate a lexicalized representation of numerosity for report. The first cycle is needed for
image processing to occur and fixation candidates to be generated [Step 1]. The first fixation candidate is focused on in the second cycle [Step 2a]. The third cycle is required for object binding, and the fourth cycle is required to encode the object representation into vSTM. The fifth cycle is required for the subitized numerosity process to determine that there are no more unvisited candidate fixations. Finally, the sixth and seventh cycles are required for the subitized numerosity process to produce an object count from vSTM [Step 3] and for this numerosity representation to be converted into lexicalized form. The remaining eight cycles are required for subvocalization and generation of the final numerosity report.

When vSTM is below capacity (not filled to its four item limit) only 50 additional milliseconds are required for each additional item to be enumerated, which is consistent with the $40-100 \mathrm{~ms}$ per additional item result from the subitizing literature (Trick \& Pylyshyn, 1994). During subvocalized counting each new enumerated object necessitates updating the last enumerated point in working memory (to keep track of which points were counted) and an explicit subvocalization of the updated count. This additional attentional requirement adds roughly $250-350 \mathrm{~ms}$ per item ( 75 ms for object binding and inhibition updating and $175-275 \mathrm{~ms}$ for subvocalization and number report). Simulated RTs from the ARCADIA model are more consistent with previous human studies that the Peterson and Simon (2000) ACT-R model of subitizing (SUBIT-R), which predicts enumerating one to two objects as taking roughly 200 ms and over 1000 ms for four objects.

## Modeling Enumeration: Attentional Effects

As a second test of the model, we replicate the results from Railo and colleagues (2008). In that study, the authors used a paradigm originally applied to study inattentional blindness (Rock, Linnett, Grant, \& Mack, 1992). Subjects had two
potential tasks: (1) report which line of a centrally located cross is longer and (2) report the number of dots clustered in a quadrant outside the central cross. Videos consisted of a series of trials in which the cross appeared, with a critical trial in which a peripheral dot cluster appeared for the first time (and subjects were unaware of the enumeration task).

There were three experimental conditions (for more detail see Bridewell and Bello, 2016a). First, the inattention condition consisted of the critical trial. Subjects were asked first to report the results from the length comparison task. After the third, critical trial, subjects were asked whether they noticed any dots and, if so, to report their quantity. Next, the dividedattention condition consisted of trials in which subjects were asked to perform both tasks. Finally, the full-attention condition consisted of trials in which subjects were told to ignore the length comparison task and focus only on enumeration. In the inattention condition, subjects who were not inattentionally blind to the dots ( $\sim 80 \%$ ) had enumeration accuracy close to $100 \%$ for up to two dots, after which accuracy dropped to under $25 \%$. In the divided attention condition, enumeration accuracy was at or near $100 \%$ for one and two dots, after which accuracy more gradually declined. In the full attention condition, enumeration accuracy was at or near $100 \%$ for up to three dots before beginning a decline. Because the attentional manipulation is the result of a dual task, additional components are necessary to allow the model to produce results for both, which we outline below.

## Model Configuration

We generated 36 videos to serve as stimuli for our simulation of the task environment with six videos for each number of peripheral dots. Each video consisted of a fixation cross presented for 1500 ms followed by a 200 ms stimulus interval with a centrally located cross and peripheral dot cluster. After the stimulus interval in each video, a mask was displayed for 500 ms . The model was run on each video 20 times.

Additional Components Bridewell and Bello (2016a) present a computational model of inattentional blindness applied to similar stimuli. The current stimuli use the same paradigm, and as such many of the components from that early model are reused. ${ }^{1}$

Attentional Strategies As in the previous enumeration model, ARCADIA follows a left-to-right prioritization of candidate fixations for enumeration. However, in the inattention and divided attention conditions, peripheral fixations are inhibited until a length comparison result is encoded in working memory (ensuring enumeration processing occurs after the primary task is complete). After this, in the divided attention condition, group fixations are given prece-

[^286]

Figure 2: Simulated RT for ARCADIA enumeration model compared with human data from Trick and colleagues (1996).
dence over individual fixations (until an ANS result is memorized), whereas in the inattention case, group fixations are not prioritized (reflecting lack of awareness of the dot clusters and the time limited enumeration task). In the full attention condition, peripheral inhibition is absent, length comparison task elements are not prioritized, and group fixations are prioritized over individual fixations.

## Results

Bridewell and Bello (2016a) analyzed focus traces generated by ARCADIA to demonstrate the precise effect attentional and temporal constraints had on the processing of inattentional blindness stimuli. In Figure 3, we present similar focus traces for each experimental condition in the dual task. Because the stimulus interval for the dual task was 200 ms , only eight ARCADIA cycles were available for completing both tasks. The primary (length comparison) task required four cycles to accomplish, leaving only four cycles for any enumeration or secondary processing. The amount of enumeration processing in these four cycles (or eight in the case of the full attention condition) influences how accurate the numerosity judgment could be.

In the inattention condition, after the primary task is accomplished, there is time to fixate on and encode two dots into vSTM. However, these fixations are incidental, and because the attentional strategy in the inattentional case does not prioritize focus on any group fixations, there are no resulting estimation results from the ANS. As such, there is no basis for an educated guess. If there were only one or two dots, then a correct numerosity judgment would be made. Otherwise, the system would generate an incorrect report. In constrast, the system generates an estimate when the attentional strategy is configured for the divided attention condition. However, there is time to generate and memorize the ANS estimate only and not to begin a serial estimation process. Therefore, accuracy begins to drop after one item, which corresponds to the increased noise associated with the ANS judgment (and subsequent guess inaccuracy). Finally, in the full attention condition, estimation can occur in the time that would have

Figure 3: Focus traces from ARCADIA model of Railo et al. (2008) dual-task in different attentional conditions.
otherwise been required for the primary task. This provides time for two dots to be fully encoded in vSTM and explicitly enumerated. As such, performance does not begin to significantly decline until there are four dots or higher. ${ }^{2}$

The resulting performance curve can be found in Figure 4. A Weber fraction $w$ of 0.13 was used, which is consistent with the range observed in normal adults (Halberda \& Feigenson, 2008). Fischer's exact tests showed that accuracy in the full attention condition was significantly higher than in the divided attention condition for dot numbers of two ( $p=.002$ ), three ( $p<.001$ ), four ( $p<.001$ ), five ( $p<.001$ ), and six ( $p<.001$ ). Qualitatively, this matches the previously described attentional effects from the human subjects, with exception of the two dot results. Railo and colleagues did not find significant differences in performance for three or five dots, but ascribed this to potential perceptual difficulties in their stimuli. Our model may underestimate accuracy for two dots in the absence of other sources of numerosity information (i.e., pattern recognition, which we discuss in the next section).

## Discussion

The boundary between the subitizing range and the postsubitizing range is commonly found to be four objects (Atkinson, Campbell, \& Francis, 1976). Trick and Pylyshyn (1994) proposed that the four-object subitizing range (and the rapid enumeration within this range) emerges out of the limited capacity of "pre-attentive" individuation mechanisms. This "pre-attentive" characterization of subitizing stands in contrast to the serial, attention-bound enumeration mechanisms of explicit counting. However, in light of studies showing attentional effects within the subitizing range (e.g., Railo et al., 2008), the pre-attentive characterization must be reevaluated.

The results from Railo and colleagues (2008) support two key points about the role of attention in enumeration. First, subitizing requires serial focus on individual objects. Other-

[^287]

Figure 4: Mean model accuracy in different attentional conditions.
wise, there would be no significant performance differences between the divided and full attention conditions. In other words, subitizing (at least for arbitrary, irregular patterns) is unusually rapid, serial counting. The results also support the notion that even enumeration processes like the ANS have an attentional dependence, as subject performance in the divided and full attention conditions declined more gradually than in the inattention condition. In the inattention case, subjects attended incidentally to one or two dots, but in the absence of an intention to enumerate, they likely did not engage in approximation. As such, performance did not gradually decline. Attention, therefore, is a necessary feature of any unified account of numerosity perception.

The contrast between parallel and serial processes in enumeration may better be characterized by a distinction between a weak and strong sense of attentional involvement (rather than "pre-attentive" vs. "attentive"). Enumeration, in general, requires an intention to report on the absolute or relative quantity of objects in a visual scene. Therefore, there is at least the need to attend to the results of a parallel mechanism of numerosity judgment (the weak sense). In contrast, precise enumeration via counting requires attentional focus on each individual object to be enumerated (the strong sense). ${ }^{3}$

Other Subitizing Processes Regular and common patterns of objects (e.g., such as patterns found on dice) enable rapid and accurate numerosity beyond four objects (Mandler \& Shebo, 1982), suggesting that pattern recognition may play a role in subitizing performance for certain spatial arrangements of objects. We view the reported model of subitizing as a complementary rather than competing account to pattern-recognition based ones (Peterson \& Simon, 2000). A pattern-recognition component could be subsumed into the ARCADIA model as an alternate (and attentionally prioritized) number sensor that responds to focus on groups of proto-objects. This addition would enable us to make and model the following prediction: regular patterns such as those

[^288]presented by Mandler and Shebo (1982) would show minimal performance differences between the divided-attention and full-attention conditions in the dual task from Railo and colleagues (as compared to the irregular patterns used in the original study and in this paper).

As such, we view the perception of numerosity as a potentially four-part phenomenon. Estimation provides a rapid, parallel, but imprecise source of numerosity information, whereas subvocal counting provides a serial, slow, but accurate enumeration procedure. Subitized counting and pattern recognition provide both a serial and parallel mechanism, respectively, to achieve rapid and accurate enumeration.

To summarize, we have presented a novel computational model of numerosity perception in which attention unifies processes of subitizing, subvocal counting, and estimation. Attention is the glue that enables and binds these separate numerosity faculties together. The limits of attention-bound processes such as object-binding and subvocalization determine how quickly subjects can report numerosity judgments. Likewise, serial attentional focus to individual objects and the need for explicit attention to estimation is necessary to account for the accuracy of enumeration in dual-task settings.

# Effects of transmission perturbation in the cultural evolution of language 

Thomas Brochhagen (t.s.brochhagen@uva.nl)<br>Institute for Logic, Language \& Computation, University of Amsterdam

Michael Franke (mchfranke@gmail.com)<br>Department of Linguistics, University of Tübingen

#### Abstract

Two factors seem to play a major role in the cultural evolution of language. On the one hand, there is functional pressure towards efficient transfer of information. On the other hand, languages have to be learned repeatedly and will therefore show traces of systematic stochastic disturbances of the transmission of linguistic knowledge. While a lot of attention has been paid to the effects of cognitive learning biases on the transmission of language, there is reason to expect that the class of possibly relevant transmission perturbations is much larger. This paper therefore explores some potential effects of transmission noise due to errors in the observation of states of the world. We look at three case studies on (i) vagueness, (ii) meaning deflation, and (iii) underspecified lexical meaning. These case studies suggest that transmission perturbations other than learning biases might help explain attested patterns in the cultural evolution of language and that perturbations due to perceptual noise may even produce effects very similar to learning biases.

Keywords: cognitive biases; iterated learning; language evolution

## Introduction

Language is shaped by its use and transmission across generations. Linguistic properties are therefore not necessarily solely due to functional pressure, such as the selection of more communicatively efficient behavior. They may also be effected by a pressure for learnability. In the extreme, an unlearnable language will not make it to the next generation. The effects that (iterated) learning has on language are often seen as stemming from a combination of general learning mechanisms and inductive cognitive biases (e.g. Griffiths \& Kalish 2007, Kirby et al. 2014, Tamariz \& Kirby 2016). Proposals of biases that shape language acquisition abound, e.g.; mutual exclusivity (Merriman \& Bowman 1989, Clark 2009), simplicity (Kirby et al. 2015), regularization (Hudson Kam \& Newport 2005), and generalization (Smith 2011). But forces other than learning biases may also systematically perturb the transmission of linguistic knowledge and thereby contribute to the shaping of language by cultural evolution (cf. Perfors \& Navarro 2014). In the following we focus on one particular source of transmission noise: agents' imperfect perception of the world. Our overall goal is to give a formalism with which to study the possible effects of such perturbations and to apply it to three case studies on (i) vagueness, (ii) meaning deflation, and (iii) underspecified lexical meaning.

## Iterated Bayesian learning

We model the transmission of linguistic knowledge as a process of iterated learning (Kirby et al. 2014, Tamariz \& Kirby 2016). More specifically, we focus on iterated Bayesian
learning, in which a language learner must infer unobservables, such as the lexical meaning of a word, from the observable behavior of a single teacher, who is a proficient language user (e.g. Griffiths \& Kalish 2007, Kirby et al. 2007). Concretely, the learner observes instances $\langle s, m\rangle$ of overt language use in context, where $s$ is a world state and $m$ is the message that the teacher used in state $s$. The learner's task is to infer which latent type $\tau$ (e.g., which set of lexical meanings or which grammar) may have produced a sequence of such observations. To do so, the learner considers the posterior probability of $\tau$ given a data sequence $d$ of $\langle s, m\rangle$ pairs:

$$
P(\tau \mid d) \propto P(\tau) P(d \mid \tau)
$$

where $P(\tau)$ is the learner's prior for type $\tau$ and $P(d \mid \tau)=$ $\prod_{\langle s, m\rangle \in d} P(m \mid s, \tau)$ is the likelihood of type $\tau$ producing the observed data $d$, with $P(m \mid s, \tau)$ the probability that a type $\tau$ produces message $m$ when in world state $s$. It is usually assumed that learners exposed to $d$ adopt type $\tau$ with probability $F(\tau \mid d) \propto P(\tau \mid d)^{\gamma}$, where $\gamma \geq 1$ regulates whether learners probability match $(\gamma=1)$ or tend towards choosing a maximum of the posterior distribution $(\gamma>1)$. If the set $D_{k}$ of data a learner may be exposed to is the set of all sequences with $k$ pairs $\langle s, m\rangle$, the probability that a learner acquires type $\tau_{i}$ when learning from a teacher of type $\tau_{j}$ is:

$$
P\left(\tau_{j} \rightarrow \tau_{i}\right) \propto \sum_{d \in D_{k}} P\left(d \mid \tau_{j}\right) F\left(\tau_{i} \mid d\right)
$$

If a population is a distribution over types, then iterated Bayesian learning predicts the most likely path of change in the population due to learning from finite observations.

The prior $P(\tau)$ can be understood as encoding learning biases. For example, learners may have an a priori preference for simpler languages over ones with a more complex grammar, or over ones with larger or more marked lexical or phonemic inventories (cf. Kirby et al. 2015). Crucially, even weak biases can magnify and have striking effects on an evolving linguistic system, especially if learning is fueled by only limited input (small $k$ ). Experimental and mathematical explorations of iterated learning have consequently suggested that the linguistic structure evinced by the outcome of this process reflects learners' inductive biases (Kirby et al. 2007; 2014).

## Iterated Bayesian learning with state-noise

Other stochastic factors beyond learning biases in $P(\tau)$ can influence the adoption of a linguistic type $\tau$ based on the observation of $\langle s, m\rangle$ sequences. One further potential source

Figure 1: State-noise during observation of language use.
of "transmission noise" are regular stochastic errors in the perception of world states (see Figure 1). Imperfect perception may lead teachers to produce utterances that deviate from their production behavior had they witnessed the state correctly. Similarly, learners may mistake utterances as applying to different states than the ones witnessed by the teacher who produced them. For instance, when learning the meaning of a vague adjective such as tall from utterances like "Jean is tall", agents may have diverging representations of how tall Jean actually is, even if she is in a shared perceptual environment. The main idea to be explored here is that regularities in misperceptions of states may have striking and possibly explanatory effects on language evolution.

We denote the probability that the teacher (learner) observes state $s_{t}\left(s_{l}\right)$ when the actual state is $s_{a}$ as $P_{N}\left(s_{t} \mid s_{a}\right)$ $\left(P_{N}\left(s_{l} \mid s_{a}\right)\right)$. The probability that $s_{a}$ is the actual state when the learner observes $s_{l}$ is therefore:

$$
P_{N}\left(s_{a} \mid s_{l}\right) \propto P\left(s_{a}\right) P_{N}\left(s_{l} \mid s_{a}\right) .
$$

Assuming a finite state space for convenience, the probability that the teacher observes $s_{t}$ when the learner observes $s_{l}$ is:

$$
P_{N}\left(s_{t} \mid s_{l}\right)=\sum_{s_{a}} P_{N}\left(s_{a} \mid s_{l}\right) P_{N}\left(s_{t} \mid s_{a}\right) .
$$

The probability that a teacher of type $\tau$ produces data that is perceived by the learner as a sequence $d_{l}$ of $\left\langle s_{l}, m\right\rangle$ pairs is:

$$
P_{N}\left(d_{l} \mid \tau\right)=\prod_{\left\langle s_{l}, m\right\rangle \in d_{l}} \sum_{s_{t}} P_{N}\left(s_{t} \mid s_{l}\right) P\left(m \mid s_{t}, \tau\right) .
$$

It is natural to assume that learners, even if they (in tendency) perform rational Bayesian inference of the likely teacher type $\tau$ based on observation $\left\langle s_{l}, m\right\rangle$, do not also reason about statenoise perturbations. In contrast to, e.g., noisy-channel models that have agents reason over potential message corruption caused by noise (e.g. Bergen \& Goodman 2015), our learners are not proficient language users that could leverage knowledge about the world and its linguistic codification to infer
likely state misperception. ${ }^{1}$ In this case the posterior probability of $\tau$ given the learner's perceived data sequence $d_{l}$ is as before: $P\left(\tau \mid d_{l}\right) \propto P(\tau) P\left(d_{l} \mid \tau\right)$. Still, state-noise affects the probability $P_{N}\left(\tau_{j} \rightarrow \tau_{i}\right)$ that the learner adopts $\tau_{i}$ given a teacher of type $\tau_{j}$, because it influences the probability of observing a sequence $d_{l}$ (with $F\left(\tau_{i} \mid d\right)$ as before):

$$
P_{N}\left(\tau_{j} \rightarrow \tau_{i}\right) \propto \sum_{d \in D_{k}} P_{N}\left(d_{l} \mid \tau_{j}\right) F\left(\tau_{i} \mid d\right)
$$

In sum, it may be that learner and/or teacher do not perceive the actual state as what it is. If they are not aware of this, they produce/learn as if what they observed was the actual state. In particular, the learner does not reason about noise when she tries to infer the teacher's type. She takes what she observes as the actual state that the teacher has seen as well, and infers which linguistic type (e.g. which set of lexical meanings or grammar) would have most likely generated the message to this state. This can lead to biases of inferring the "wrong" teacher type if noise makes some types err in a way that resembles the noiseless behavior of other types. That is, such environmental factors can, in principle, induce transmission perturbations that look as if there was a cognitive bias in favor of a particular type, simply because that type better explains the noise.

## Case studies

In what follows we present three case studies that show how iterated learning under noisy perception can lead to the emergence of linguistic phenomena. The studies are ordered from more to less obvious examples in which state-noise may be influential and explanatory: (i) vagueness, (ii) meaning deflation, and (iii) underspecification in the lexicon. No case study is meant to suggest that state-noise is the definite and only explanation of the phenomenon in question. Instead, our aim is to elucidate the role that transmission perturbations beyond inductive biases may play in shaping the cultural evolution of language. We therefore present minimal settings that isolate potential effects of state-noise in iterated learning.

## Vagueness

Many natural language expressions are notoriously vague and pose a challenge to logical analysis of meaning (e.g. Williamson 1994). Vagueness also challenges models of language evolution since functional pressure towards maximal information transfer should, under fairly general conditions, weed out vagueness (Lipman 2009). Many have therefore argued that vagueness is intrinsically useful for communication (e.g. van Deemter 2009, de Jaegher \& van Rooij 2011, Blume \& Board 2014). Others hold that vagueness arises naturally due to limits of perception, memory, or information processing (e.g. Franke et al. 2011, O’Connor 2014, Lassiter

[^289]\& Goodman 2015). We follow the latter line of exploration here, showing that vagueness can naturally arise under imperfect observability of states (see Franke \& Correia (to appear) for a different evolutionary dynamic based on the same idea).

Setup. We analyze the effects of noisy perception on the transmission of a simple language with 100 states, $s \in[0,99]$, and two messages, $m \in\left\{m_{1}, m_{2}\right\}$. The probability that agents perceive actual state $s_{a}$ as $s_{t} / s_{l}$ is given by a (discretized) normal distribution, truncated to [0;99], with $s_{a}$ as mean and standard deviation $\sigma$. Linguistic behavior is fixed by a type $\tau \in[0 ; 99]$ which is the threshold of applicability of $m_{1}$ : $P\left(m_{1} \mid s, \tau\right)=\delta_{s \geq \tau}=\left(1-P\left(m_{2} \mid s, \tau\right)\right)$. In words, if a speaker observes a state that is as large or larger than its type, then message $m_{1}$ is used (tall), otherwise $m_{2}$ (small).

Results. The effects of a single generational turnover under noisy transmission of a population that initially consisted exclusively of type $\tau=50$ is depicted in Figure 2. As learners try to infer this type from observed language use, even small $\sigma$ will lead to the emergence of vagueness in the sense that there is no longer a crisp and determinate cut-off point for message use in the population. Instead, borderline regions in which $m_{1}$ and $m_{2}$ are used almost interchangeably emerge. For larger $\sigma$, larger borderline regions ensue. The size of such regions further increases over generations with growth inversely related to $\gamma$ and $k$. As is to be expected, if $k$ is too small to discern even strikingly different types, then iterated learning under noisy perception leads to heterogeneous populations with (almost) no state being (almost) exclusively associated with $m_{1}$ or $m_{2}$.

Figure 2: Noisy iterated learning ( $\gamma=1, \sigma=0.4, k=20$ ).

Discussion. Transmission perturbations caused by noisy state perception reliably give rise to vague language use even if the initial population had a perfectly crisp and uniform convention. Clearly, this is a specific picture of vagueness. As
modeled here for simplicity, each speaker has a fixed and nonvague cut-off point $\tau$ in her lexicon. Still, the production behavior of a type- $\tau$ speaker in actual state $s_{a}$ is probabilistic and "vague", because of noisy perception:

$$
P_{N}\left(m \mid s_{a}, \tau\right)=\sum_{s_{t}} P\left(s_{t} \mid s_{a}\right) P\left(m \mid s_{t}, \tau\right) .
$$

An extension towards types as distributions over thresholds is straightforward but the main point would remain: systematic state-noise perturbs a population towards vagueness.

Of course, convergence on any particular population state will also depend on the functional (dis)advantages of particular patterns of language use. Functional pressure may therefore well be necessary for borderline regions to be kept in check, so to speak. Which factor or combination thereof plays a more central role for the emergence of vagueness is an empirical question we do not address here. Instead, we see these results as adding strength to the argument that one way in which vagueness may arise is as a byproduct of interactions between agents that may occasionally err in their perception of the environment. If state perception is systematically noisy and learners are not aware of this, some amount of vagueness may be the natural result.

## Deflation

Meaning deflation is a diachronic process by which a form's once restricted range of applicability broadens. Perhaps the most prominent example is Jespersen's cycle (Dahl 1979), the process by which emphatic negation, such as French ne ... pas, broadens over time and becomes a marker for standard negation. As argued by Bolinger (1981), certain word classes are particularly prone to slight and unnoticed reinterpretation. When retrieving their meaning from contextual cues, learners may consequently continuously spread their meaning out. For instance, Bolinger discusses how the indefinite quantifier several has progressively shifted from meaning a respectable number to broader a few in American English. We follow this line of reasoning and show how state confusability may lead to meaning deflation. Other formal models of deflationary processes in language change have rather stressed the role of conflicting interests between interlocutors (Ahern \& Clark 2014) or asymmetries in production frequencies during learning (Schaden 2012, Deo 2015).

Setup. The setup is the same as that of the previous case study, except that we now trace the change of a single message $m$, e.g., emphatic negation, without a fixed antonym being sent whenever $m$ does not apply. This is a crude way of modeling use of markers of emphasis or high relevance for which no corresponding "irrelevance marker" exists. Learners accordingly observe positive examples of use $\langle s, m\rangle$ but do not positively observe situations in which $m$ did not apply to a particular state. This causes asymmetry in the learning data because some types will reserve their message only for a small subset of the state space and otherwise remain silent.

Learners take the absence of observations into account but cannot know what it is that they did not observe. We assume that learners are aware of $k$ so that: ${ }^{2}$

$$
\begin{array}{r}
P\left(\tau \mid d_{l}\right) \propto \operatorname{Binom}\left(\text { successes }=k-\left|d_{l}\right|, \text { trials }=k,\right. \\
\text { succ.prob } \left.=\sum_{i=0}^{\tau-1} P(s=i)\right) \prod_{s \in d_{l}} P(m \mid s, \tau) .
\end{array}
$$

As before, the second factor corresponds to the likelihood of a type producing the perceived data. The first is the probability of a type not reporting $k-|d|$ events for a total of $k$ events. $P \in \Delta(S)$ is assumed to be uniform. In words, a long sequence of data consisting of mostly silence gives stronger evidence for the type producing it having a high threshold of applicability even if the few state-message pairs observed may be equally likely to be produced by types with lower thresholds.

Results. The development of an initially monomorphic population consisting only of $\tau=80$ is shown in Figure 3. Even little noise causes a message to gradually be applied to larger portions of the state space. The speed of meaning deflation is regulated by $\sigma, k$, and to lesser degree $\gamma$. In general, more state confusion due to higher $\sigma$, shorter sequences, or less posterior maximization will lead to more learners inferring lower types than present in the previous generation.

Figure 3: Noisy iterated learning $(\gamma=1, \sigma=0.4, k=30)$.

Discussion. In contrast to the previous case study, we now considered the effects of noisy perception under asymmetric data generation where overt linguistic evidence is not always produced, i.e., acquisition in a world in which not every state is equally likely to lead to an observable utterance. The outcome is nevertheless similar to the previous one: Noisy perception can cause transmission perturbations that gradually

[^290]relax formerly strict linguistic conventions. In contrast to the case of vagueness, if there are no relevant competing forms, e.g., small vs. tall, asymmetry in production and noise will iteratively increase the state space that a form carves out.

## Scalar expressions

Scalar expressions have been at the center of many studies on pragmatic inference. Examples include quantifiers such as some and most, adjectives such as cold and big, and numerals such as four and ten. Commonly, their use is taken to pragmatically convey an upper-bound which is not present in their lexical semantics (Horn 1972, Gazdar 1979). For instance, while "Bo ate some of the cookies" is semantically compatible with a state in which Bo ate all of them, this utterance is often taken to convey that Bo ate some but not all, as otherwise the speaker would have said all. A semantically weak meaning is thus pragmatically strengthened by interlocutors’ mutual reasoning about rational language use (Grice 1975).

Why does such pragmatic strengthening not lead to widespread lexicalization of upper-bounded meanings? To address this question, Brochhagen et al. (2016) explore an evolutionary model that combines functional pressure and iterated learning. This account assumes a prior that favors a lack of upper-bounds. Here, we demonstrate that state-noise can mimic the effects of such a cognitive learning bias.

Setup. The simplest possible model distinguishes two kinds of lexica and two behavioral strategies to use them, a pair of which constitutes a type. Both lexica specify the truthconditions of two messages in either of two states. Let us mnemonically label them $m_{\text {some }}, m_{\text {all }}, s_{\exists \neg \forall}$ and $s \forall$, where the former state is one in which natural language some but not all holds, and the latter one where all holds. In lexicon $L_{\text {bound }}$, which lexicalizes an upper-bound for some-like expressions, message $m_{\text {some }}$ is only true of $s_{\exists \neg \forall}$ and $m_{\text {all }}$ only of $s_{\forall}$. In the English-like lexicon $L_{\text {lack }}$, message $m_{\text {all }}$ is also only true of $s_{\forall}$, but the meaning of $m_{\text {some }}$ is underspecified and lexically holds in both states. Speakers follow one of two strategies of language use: literal or pragmatic. The former select a random true message, whereas the latter prefer to send the most informative messages from those that are true in the observed state (Grice 1975). This gives rise to probabilistic speaker behavior $P(m \mid s, \tau=\langle$ lexicon, use $\rangle)$ which approximates the following choice probabilities: ${ }^{3}$

| Literal | $\underline{L_{\text {bound }}}$ |  |  | $\underline{L_{\text {lack }}}$ |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  |  | $m_{\text {some }}$ | $m_{\text {all }}$ |  | $m_{\text {some }}$ | $m_{\text {all }}$ |
|  | $\begin{aligned} & s_{\forall} \\ & s_{\exists \neg \forall} \end{aligned}$ | $\left(\begin{array}{l}0 \\ 1\end{array}\right.$ | $\left.\begin{array}{l}1 \\ 0\end{array}\right)$ | $s_{\forall}$ $s_{\exists \rightarrow \forall}$ | $\left(\begin{array}{c}0.5 \\ 1\end{array}\right.$ | $\left.\begin{array}{c}0.5 \\ 0\end{array}\right)$ |
|  |  | $m_{\text {some }}$ | $m_{\text {all }}$ |  | $m_{\text {some }}$ | $m_{\text {all }}$ |
| Pragmatic | $\begin{aligned} & s_{\forall} \\ & s_{\exists \exists \forall} \end{aligned}$ | $\left(\begin{array}{l}0 \\ 1\end{array}\right.$ | $\left.\begin{array}{l}1 \\ 0\end{array}\right)$ | $s_{\forall}$ $s_{\exists \neg \forall}$ | $\left(\begin{array}{l}0 \\ 1\end{array}\right.$ | $\left.\begin{array}{l}1 \\ 0\end{array}\right)$, |

[^291]where $P(m \mid s, \tau)=M_{[s, m]}$ with $M$ being type $\tau$ 's choice matrix. As pragmatic users of $L_{\text {lack }}$ are (almost) indistinguishable from types with $L_{\text {bound }}$, the emergence of a predominance of $L_{\text {lack }}$ in a repeatedly learning population must come from transmission biases. A learning bias in favor of $L_{\text {lack }}$ in the learners' priors will select for it (Brochhagen et al. 2016), but here we assume no such cognitive bias. Rather we assume state-noise in the form of parameters $\varepsilon$ and $\delta$. The former is the probability of perceiving actual state $s_{\exists \neg \forall}$ as $s_{\forall}$, $P\left(s_{\forall} \mid s_{\exists \rightarrow \forall}\right)=\varepsilon$, and $P\left(s_{\exists \rightarrow \forall} \mid s_{\forall}\right)=\delta$. For instance, states may be perceived differently because different numbers of objects must be perceived (e.g., quantifiers and numerals) or they may be more or less hard to accurately retrieve from sensory information (e.g., adjectives).

Results. To quantify the effects of the dynamics we ran a fine-grained parameter sweep over $\varepsilon$ and $\delta$ with 50 independent simulations per parameter configuration. Each simulation started with a random initial population distribution over types and applied iterated learning with state-noise for 20 generations, after which no noteworthy change was registered. Mean proportions of resulting pragmatic users of $L_{\text {lack }}$ under different noise signatures are shown in Figure 4. These results suggest that when $\delta$ is small and $\varepsilon$ high, iterated noisy transmission can lead to populations consisting of almost exclusively English-like lexica with pragmatic language use. Similar results are obtained for larger $k$ or $\gamma$.

Figure 4: Mean proportion of pragmatic $L_{\text {lack }}$ users after 20 generations $(\gamma=1, k=5)$.

Discussion. The main goal of this case study was to show that noisy perception may mimic effects of learning biases. In the case of Brochhagen et al. the assumed bias was one for simplicity; learners had an a priori preference for not codifying upper-bounds lexically, which increased their propensity to infer pragmatic $L_{\text {lack }}$ over $L_{\text {bound }}$ even if the witnessed data
could not tease them apart. We assumed no such bias but nevertheless arrived at evolutionary outcomes that comparable to those predicted if the bias were present. However, this result strongly depends on the types involved. Whether a type thrives under a particular noise signature depends on the proportion of types confused with it during transmission. The addition or extraction of a single type may therefore lead to different results.

At present, it is unclear what role noisy perception should play in the selection of underspecified meaning. These results should therefore be taken as suggestive but not indicative of a relationship between the two. In the case of quantifiers, a possible way to explore this relation may lie in their connection to empirical work on the verification of quantified statements (see Szymanik 2016 for a recent overview). The idea being that some states are easier to verify, e.g., $s_{\forall}$, and therefore less confusable with other states than others, e.g., $s_{\exists \neg \forall}$.

## General discussion

We proposed a general model of iterated Bayesian learning that integrates systematic noise in agents' perception of world states, giving rise to stochastic perturbations that may influence and (potentially, partially) explain language change. We investigated the model's predictions in three case studies that show that iterated noisy transmission can lead to outcomes akin to those found in natural language. As stressed before, these results are not meant to suggest noisy perception to be the sole or main determinant of these phenomena. Instead, our aim was mainly conceptual and technical in nature.

Beyond technical aspects, we foregrounded two intertwined issues in the cultural evolution of language. First, the fact that noise signatures may mimic the effects of cognitive biases has consequences for the interpretation of outcomes of acquisition processes. Care must therefore be exercised in reading off the influence of possible learning biases from data obtained "in the wild" or the laboratory. Noisy perception instead offers a neutral model of cultural evolution that appeals to neither functional competition nor differential learnability among types (Reali \& Griffiths 2009). Second, and more importantly, these results can be seen as complementing and stressing the pivotal role of systematic transmission perturbations as explanatory and predictive devices of language change - independent of the perturbation's source. They thereby strengthen and widen the scope of research on iterated learning by bringing attention to forces beyond inductive biases (cf. Perfors \& Navarro 2014).

## Conclusion

Acquisition is a central force shaping linguistic structure. The consideration of the (imperfect) means by which such knowledge is transmitted is therefore crucial to our understanding of the cultural evolution of language. Here, we focused on one factor that may give rise to systematic stochastic perturbation in learning -agents' noisy perception of the worldand analyzed its effects in three case studies on (i) vagueness,
(ii) meaning deflation, and (iii) underspecified lexical meaning. Our results suggest that the class of relevant perturbation sources reaches beyond the well-studied effects of inductive learning biases. In particular, that some linguistic properties, such as (i), (ii) and more tentatively (iii), may emerge as a byproduct of constraints on agents' perception of the world.

#### Abstract

Color is a critical part of objects representation as well as critical cue for recognizing objects. However, it is less clear how people represent color in memory. The present study aimed at investigating this issue. We designed a procedure based on short-term sensory memory load procedure mixed with a color-priming paradigm. Participants learned three visual stimuli (either non-words - lexical load condition - or visual-shapes - visual-shape load condition). Then, they performed a color discrimination task on colored patch (e.g., a yellow patch). Each target was preceded by a color-related concept word either congruent (e.g., word "banana") or not (e.g., word "lettuce"). Finally, they performed a recognition task either on non-words or on visual-shapes depending on the memory load condition). We showed that color-priming effect was selectively disrupted in visual-shape load condition. We interpreted this finding as an evidence that automatic modal simulations occur during access to the meaning of color-related concept.

Keywords: Color knowledge, perceptual simulation, priming effect, visual memory

## Introduction

Color knowledge about object is an important part of conceptual representation. Indeed, color is often a critical cue for recognizing object (Tanaka \& Presnell, 1999) or natural scene (Oliva \& Schyns, 2000) in everyday life. Hansen, Olkkonen, Walter, and Gegenfurtner (2006) suggested that research about color should investigate how people represent color rather than how people perceive color because color of an environment is never stable over the time (i.e., dependent of the objects' illumination) and, as a consequence, dependent from color knowledge. The question is how do people represent color knowledge?

First, color knowledge could be considered as stored in an amodal format within conceptual representation of an object. In that view, meaning of an object is distributed across semantic features (see Masson, 1995) and relationships between concepts are explained in term of
overlapping between semantic features. As soon as two concepts share the same semantic color feature, one can prime the other. For instance, hearing the word "lips" could facilitate the detection of the picture of a strawberry (Huettig \& Altmann, 2011). However, several studies suggest that access to color knowledge depend on the nature of the stimuli (i.e., lexical vs. visual, see Nijboer, Zandvoort \& Haan, 2006). Indeed, because the word "banana" and "yellow" co-occurs frequently in everyday language, color knowledge could also be stored in a lexical format: a color label (see Landauer \& Dumais, 1997). In that case, as soon as two concepts share the same color label, one can prime the other. For instance, hearing the word "pea" could facilitate the detection of the picture of a green blouse (see Huettig \& Altamann, 2011) because both objects share the label "green". In the same vein, Roberson and Davidoff (2000) have showed a loss of the categorical perception (i.e., better discrimination across color categories than within the same color category) when participants had to simultaneous discriminate between colors and maintain words in memory. This effect was not observed when they had to follow a curved line with the eyes. Accordingly, it seems that lexical access interferes with categorical perception, while visual interference does not. This result suggests the implication of lexical units during access to color knowledge. Moreover Nijboer and collaborators (2006) demonstrated that color-priming effect (from objectword or object-picture to colored-patch) is dependent of the nature of the prime (either picture or word, see also Heurley, et al., 2013). This result suggests the existence of both a semantic-based and lexical-based representation of color. These two formats of color knowledge are not necessary incompatible and authors suggested a time-based access distinction for accounting existence of both level of representation (Heurley et al., 2013).

Alternatively, theories of embodied or grounded cognition (see Barsalou, 2008) assume that access to a representation is linked with perceptual sensory simulations. In other words, performing a conceptual task like verifying that a
"banana" is "yellow" is associated with the automatic simulation of a former visual experience associated with the banana (Pecher, Zeelenberg, \& Barsalou, 2003, 2004; Van Dantzig, Pecher, Zeelenberg, \& Barsalou, 2008; Vermeulen, Chang, Corneille, Pleyers, \& Mermillod, 2013; Vermeulen, Corneille, \& Niedenthal, 2008). Thus, access to the meaning of concept involves automatic perceptual simulation in several sensory modalities and, as a consequence, influences processing of stimuli presented in the same modality than the simulated one (see Brunel, Goldstone, Vallet, Riou, \& Versace, 2013; Brunel, Labeye, Lesourd, \& Versace, 2009; Brunel, Lesourd, Labeye, \& Versace, 2010; Vallet, Brunel, \& Versace, 2010; for a review see Versace, Labeye, Badard, \& Rose, 2009). In that case, color knowledge could be defined as perceptual or modal rather than semantic or lexical. Indeed, neuroimagery studies showed that either perceiving or conceiving color involves common neural substrates (Simmons et al., 2007). Moreover, Richter and Zwaan (2009) showed that processing color words (e.g., word "red") involves perceptual simulation of the color. They showed that participants were faster at discriminating between targets colored-square displayed in the same category color (e.g., light red vs. dark red) when the prime color word and the targets colored squares match on their color rather than mismatch. According to the authors, their results ruled out an explanation based on a lexical competition since the prime word and the target squares shared the same color label. Finally, Yee, Ahmed and Thompson-Schill (2012) found a contextual-based color priming effect using a semantic priming procedure. Indeed they found that color-priming effect is observed only when color was sensitized before the priming procedure. According to the authors, this result seemed to indicate that color knowledge is context dependent rather than stable over the time that is consistent with an embodied approach but not with a semantic approach (see also Connell, 2007; Connell \& Lynott, 2009 for a similar conclusion)

Given existence of empirical evidence for both approaches (embodied vs. semantic or lexical), this article aims at addressing the issue about the representational format of color knowledge in memory. In the present study, we designed a single paradigm in order to test simultaneously each assumption regarding the nature of color knowledge (i.e., perceptual/modal vs. lexical/amodal). To do so, we adapted the procedure of Vermeulen and coworkers (2008, see also Vermeulen, Chang, Mermillod, Pleyers \& Corneille, in press, Experiment 2). In their experiment, they combined a short-term memory task (i.e., memory load) with a property verification task. Consequently, they manipulated both the nature of the memory load (i.e., visual or auditory) and the nature of the property (i.e., visual or auditory) during the property
verification task. First, participants had to learn items visually or auditory displayed. Then they had to perform a property verification task like verifying that a banana could be yellow. After that, they had to recognize the previously learnt items from a new list displayed in the same modality. The main results of their study is that participants were significantly slower at verifying visual properties preceded by a visual-shape load than an auditory load and conversely for auditory properties. Authors concluded that sensory memory and conceptual memory share the same modal properties. In our procedure, we changed the nature of the items in the short-term memory task and replaced the property verification task by a color priming procedure (Heurley, et al., 2013). As a consequence, participants firstly maintained three stimuli in visual memory either meaningless lexical stimuli (i.e., non-words) or meaningless visual-shapes (i.e., Gaussian blobs) before performing a color discrimination task on colored patches. Each target colored patch (e.g., a yellow patch) was preceded by a word prime that could represent a color-related concept (e.g., the word "banana") or not (e.g., the word "lettuce"). Heurley and collaborators (2013, see also Nijboer et al., 2006) found that participant were faster at discriminating the color of the patch when prime was congruent rather than incongruent, attesting a color-priming effect from color-related concept primes to colored targets patches. Finally, participants completed a recognition task on the previously learnt elements.

Our procedure should let us to directly test different assumptions about the format of the color knowledge. First, if accessing to color knowledge from a color-related concept involves semantic amodal knowledge about color, we should find a significant interaction between Prime Type (yellow or green color related concept) and Color Target (yellow or green patches) irrespective the nature of the memory load. A given word activates its conceptual semantic representation in memory (see, Masson, 1995) which include diagnostic feature about the concept. Since this representation is activated at a semantic level, it should not interact with any of the item of the load conditions because each item for these conditions is meaningless. This result would be a direct replication of Heurley and coworkers (2013) Experiments. Then, if accessing color from a color-related concept involves lexical knowledge (such as verbal label), we should find an interaction between Prime Type and Color Target and the Nature of the Memory Load. In that case, the word prime activates the color representation at a lexical level and should interact specifically with the items of the lexical load condition. As a consequence, we might predict a diminution (or a lost) of color-priming effect consecutive to the lexical load condition while the color-priming effect should be observed

Figure 1: Trial overview for both training and test phase in the visual-shape load condition. Note: The colored patch is represented into grey scale but was displayed either in yellow or green during the experiment.
with the visual-shape load condition. Finally, if accessing color from a color-related concept involves visual simulation, we should observe the opposite pattern. In that case, processing the word automatically simulates former visual experiences associated with the concept and those simulations should interact with the items of the visualshape load condition. As a consequence, we might predict a diminution (or a lost) of color-priming effect consecutive to the visual-shape load condition while the color-priming effect should be observed with the lexical load condition.

## Experiment

Participant - Twenty-Four native French speakers (student from Université Paul-Valery, Montpellier, France) were recruited and received courses credits for their participation. All have a normal or corrected to the normal vision and none of them reported having atypical color perception (Daltonism or synesthesia)

Stimuli \& Material - We created 12 Gaussian blobs (6 for training and 6 for test) that were equilibrated in term of surface, number of angles and of peaks in both sides regarding a vertical symmetric axis. We created also 12 CVC-CVC non-words (6 for training and 6 for test) following Reinitz, Lammers, and Cochran (1992) methodology. These stimuli were used in the short-term memory task, respectively in the visual-shape load and lexical load conditions. For the priming phase, we used the same material than Heurley and co-workers (2013; see also Reilhac \& Jiménez, 2006). The 16 priming words (4 for training and 12 for test) depicted either animal or vegetable typically associated with the color green (e.g., lettuce) or yellow (e.g., banana). The target stimuli were yellow ( $\mathrm{R}=$ 255; $\mathrm{G}=255 ; \mathrm{B}=0)$ or green patches $(\mathrm{R}=34 ; \mathrm{G}=163$; B $=13$ ) according to the RGB color model. We also used a
mask that was a white screen with 17 lines of 60 black stars (i.e., *).

Procedure - After filling out a consent form, participants were tested individually in a computer room. Each trial started with a fixation-cross lasting on the screen during 500 ms followed by three successive visual stimuli (either non-words or visual-shapes depending on the memory load condition), each lasting 500 ms . Participants were informed that they have to learn these stimuli in order to perform a later recognition task. Then a prime word was prompted on the screen $(150 \mathrm{~ms})$ and was immediately replaced by a visual mask ( 100 ms ) itself replaced by a blank screen ( 100 ms ). A target colored patch followed and participants had to judge as quickly and accurately as possible its color. After 1500 ms blank screen, 3 stimuli (non-words or visualshapes) were successively displayed and participants have to judge for each stimuli if it corresponded or not to a previously learnt stimulus. We set the inter-trial interval at 1500 ms (see Figure 1). Participant indicated their responses by pressing different keyboard's keys for the color discrimination task and for the recognition task. The responses keys were counterbalanced between participants.

The experiment started with a training phase ( 16 trials) followed by a test phase composed by 48 trials randomly presented: 24 in the visual-shape-load and 24 in lexical-load condition. Each prime was seen followed by each target patch and for each load condition. For the short-term memory task, we have controlled that the number of "same" and "different" was identical for each position during test compared to the learning and for each conditions: visual-shape-load and lexical-load.

## Results

Table 1. Mean correct RT and correct response rates for each experimental condition. Note: Priming effect was calculated by subtracting incongruent experimental conditions (e.g., "yellow" prime / green target condition) to the congruent ones (e.g., "yellow" prime / yellow target condition). A negative value indicates facilitation (i.e., a gain toward the congruent condition) whereas a positive value indicates a cost.

|  |  | Lexical |  |  |  | Visual-shape |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  |  | "Yellow" Prime |  | "Green" Prime |  | "Yellow" Prime |  | "Green" Prime |  |
|  |  | RT (ms) | CR | RT(ms) | CR | RT(ms) | CR | RT (ms) | CR |
| Target Color | Yellow | 493 (21) | 0.965 (.018) | 531 (26) | 0.971 (.013) | 518 (28) | 0.978 (.012) | 525 (27) | 0.942 (.021) |
|  | Green | 529 (24) | 0.965 (.017) | 490 (28) | 0.976 (.013) | 517 (27) | 0.962 (.013) | 528 (29) | 0.957 (.018) |
|  | Priming effect | -36 |  | -42 |  | 1 |  | 2 |  |

Color Discrimination Task - The mean correct response latencies and mean percentages of correct responses were calculated across subjects for each experimental condition. Latencies below 250 ms and above $1,250 \mathrm{~ms}$ were removed (this cut-off resulted in the exclusion of $2.95 \%$ of the data, see Brunel et al., 2009). The participants performed the test color categorization task accurately (overall correct response rate of $96.45 \%$, see Table 1). Practice trials were removed from the analysis.

A repeated analysis of variance was performed with subjects as random variable, Nature of Memory Load (Lexical vs. Visual-shape), Prime Type (yellow-related concept vs. a green-related concept) and Target Color (Yellow vs. Green) as within-subjects variables.

Analysis revealed neither significant main effects of the Nature of Memory Load, $F(1,23)=1.79, p=.19, \eta_{\mathrm{p}}^{2}=.07$, Prime Type, $\mathrm{F}<1$, Target Color, $\mathrm{F}<1$ nor interaction between Nature of Memory Load and Prime Type, $\mathrm{F}<1$, and between Nature of memory Load and Target Color, F < 1. Analysis showed a significant interaction between Prime Type and Target Color, $F(1,23)=7.14, p<.05, \eta_{p}^{2}=.24$. However, the Nature of Memory Load modulates this interaction. Indeed analysis revealed a significant three way interaction between Nature of the Memory Load, Prime Type and Target Color, $F(1,23)=7.33, p<.05, \eta_{p}^{2}=.24$. This interaction is depicted in Figure 2.

Figure 2: Mean correct RT for each experimental condition. Error bar represents standard error.

As can be appreciated in Figure 2, the interaction between Prime Type and Target Color was observed in the lexical load condition, but not in the visual-shape load condition. Regarding the lexical load condition, participants were significantly faster at judging the green patch preceded by a congruent prime (i.e., a green-related concept like a lettuce) than an incongruent prime (i.e., a yellow-related concept like a banana), $\mathrm{F}(1,23)=7.60, \mathrm{p}<.05$. The reverse was observed for the yellow patch, $\mathrm{F}(1,23)=4.61, \mathrm{p}<.0 .5$.

Regarding the visual-shape load condition. The Prime Type did not modulate color discrimination. The difference between the primes was not significant for the yellow patch, $\mathrm{F}<1$, as well for the green patch, $\mathrm{F}<1$.

Recognition Task - A t-test conducted between the correct recognition rates of the different memory load conditions revealed that participants were significantly worst for the memory test in the visual-shape load condition ( $\mathrm{M}=.672$, $\mathrm{SE}=.021)$ than in lexical condition $(\mathrm{M}=.729, \mathrm{SE}=.015)$, $\mathrm{t}(23)=3.25, \mathrm{p}<.05$.

Correlation Analysis - We also tested the correlation between the memory test accuracy and the priming effect size (RT congruent - RT incongruent) ${ }^{1}$ for both condition of memory load and each participant. Indeed, Vermeulen and collaborators (2008) showed that memory performances were selectively influenced by the relation between the nature of the load (i.e., visual or auditory) and the nature of the to be verified property (i.e., visual or auditory). Accordingly, we might expect a negative correlation between the priming effect size and the memory performance in the visual-shape load condition. In other words, less the visual-shape load is efficient (attesting by a high recognition rate) the higher is the probability to observe a priming effect. Conversely, we should not observe any correlation for the lexical load condition.

[^292]We found a significant negative correlation (Spearman Correlation) between the priming effect size and the memory performance for the visual-shape load condition, $r(22)=-.46, p<.05$, but not for lexical load condition, $r(22)$ $=+.02$.

## Discussion

The aim of this study was to propose a procedure for disentangling between several conceptions about nature of color knowledge in memory. To do so, we combined a color-priming paradigm (Heurley, et al., 2013) with a shortterm memory load procedure (Vermeulen, et al., 2008). First, participants had to learn three visual elements (either non-words or shapes). Then, they had to perform a color discrimination task where each colored-target (e.g., yellow patch) was preceded by a congruent color-related word concept (e.g., "banana") or not (e.g., "lettuce"). Finally, they performed a recognition task on either non-words or visualshapes depending on the memory load condition. Our results seem to indicate that access to color knowledge involves perceptual simulation rather than lexical or semantic activation. Indeed, we found that color-priming effect (i.e., shorter RTs when the color of the patch was congruent with color-related concept word rather than incongruent) was incurred in the visual-shape load condition while it was observed in the lexical load condition. This should be due to a competition for same visual resources between the short-term storage of shapes in memory and the simulation of the color-related concepts (see Vermeulen, Corneille et al., 2008; Vermeulen, Chang et al., in press, for a similar conclusion). Moreover, the fact that we found a significant negative correlation between priming size effect and the accuracy in short-term memory task in the visualshape load condition (while the same correlation was not significant in the lexical load condition) is consistent with our interpretation. Moreover, this result is in accordance with Yee and co-workers' (2012) experiment. Indeed, they found a positive correlation between Stroop interference and color-priming gain only when the Stroop task was presented before the priming procedure. This result attested that colorpriming effect was modulated by the Stroop task. Taken together, these results indicate that access to color information related to object is not only contextually dependent but also sensory-based. Finally, our results bring direct evidence that access to an object concept using words involved automatic modal simulation (see also Vermeulen et al., in press). Indeed, this paper showed that words representing modal concept spontaneously involve perceptual simulations (without engaging participant in a property verification task) so that a perceptual load (in the same modality than the modal concept) selectively incurs memory for these words.

In conclusion, our study provides a strong argument in favor of the idea that access to conceptual knowledge is linked to the simulation of the sensory dimension captured within the concept (see Barsalou, 2008) so that experiencing
a concept in a given modality involves perceptual simulation in the same sensory modality and in the other related sensory (Brunel, Lesourd, et al., 2010) or motor modalities (Brouillet, Heurley, Martin, \& Brouillet, 2010).

# Recursion in Children's Comprehension and Formulation of Algorithms 

Monica Bucciarelli<br>Università di Torino, Italy<br>Robert Mackiewicz<br>University of Social Sciences and Humanities, Warsaw, Poland<br>Sangeet Khemlani<br>US Naval Research Laboratory, Washington, DC 20375 USA<br>Philip Johnson-Laird<br>Princeton University, Princeton, New Jersey, United States and New York University, New York, NY<br>10003, USA

#### Abstract

Recursive loops in informal algorithms are difficult to formulate, even for naïve adults (Khemlani et al., 2013). Children can formulate algorithms that do not require loops (Bucciarelli et al., 2016), and anecdotal evidence suggests that they can understand loops. As there were no previous studies, we examined how they made deductions of the consequences of loops, and how they abduced loops in creating informal algorithms in everyday language. We therefore tested fifth-grade children's ability carry out both these tasks in algorithms that rearrange the order of cars on a toy railway track with one siding. Experiment 1 showed that they could deduce rearrangements from algorithms containing loops, and Experiment 2 showed that they could formulate at least some algorithms that contained loops. These abilities are the likely precursors to the comprehension of recursion and to computer programming.

# Is Structural Priming in Children Facilitated by Interactions between Animacy and Syntax?

#### Abstract

Sentence production relies on the activation of both semantic information (e.g. noun animacy) and syntactic frames that specify an order for grammatical functions (e.g. subject before object; Levelt, Roelofs \& Meyers, 1999). However, it is unclear whether these semantic and syntactic processes interact (Gámez \& Vasilyeva, 2015), and if this changes developmentally. We thus examined the extent to which animacy-semantic role mappings in dative prime sentences and target scenes influenced choice of syntactic structure. 143 participants ( 47 three year olds, 48 five year olds and 48 adults) alternated with the experimenter in describing animations. Animacy mappings for themes and goals were either prototypical or non-prototypical and either matched or mismatched across the experimenter's prime scenes and participants' target elicitation scenes. Prime sentences were either double-object datives (e.g. the girl brought the monkey a ball) or prepositional datives (e.g. the girl brought the ball to the monkey). Participants' target sentences were coded for syntactic form. All age groups showed a main structural priming effect. For the youngest group, animacy-semantic role mappings facilitated prepositional dative priming. No animacy facilitation was found for the older groups. Our results demonstrate the changing influence of animacy cues on sentence production through interactions with syntactic structure over the course of development. The theoretical implications of our findings are discussed.

Keywords: structural priming; animacy; language production; semantics; syntax.

## Introduction

In order to communicate ideas, speakers must map concepts to syntactic structures. Where one idea can be expressed using multiple structures, speakers tend to use the most recently heard structure (Bock, 1986). For example, structural priming occurs where speakers are more likely to describe the transfer of a ball between a girl and a monkey using the double-object dative (DOD) sentence the girl brought the monkey a ball instead of the prepositional dative
(PD) structure the girl brought a ball to the monkey, following a DOD, rather than a PD prime. This occurs in children (Rowland, Chang, Ambridge, Pine \& Lieven, 2012) and adults (Bock, 1986).

In their residual activation theory, Pickering and Branigan (1998) argue that abstract representations of verbs, grammatical roles (e.g. direct object) and combinatorial notes are activated upon hearing a DOD sentence (i.e. NPNP). Structural priming occurs where speakers reuse the currently activated NP-NP node to produce another DOD construction rather than activating the alternative NPprepositional phrase ( PP ) node to produce a PD sentence.

The residual activation theory cannot, however, account for instances where structural priming is enhanced by animacy-syntax interactions. Gámez and Vasilyeva (2015) found that priming of passive sentences in children was greatest where primes and targets both contained animate patients and inanimate agents. For datives, animacy may interact with semantic role-grammatical function mappings (e.g. theme-direct object), before these mapped constituents are ordered, to determine syntactic structures (de Swart, Lamers \& Lestrade, 2008). Prototypical DOD sentences contain animate goals before animate themes, whereas prototypical PD sentences feature inanimate themes before animate goals (Bresnan, Cueni, Nikitina \& Baayen, 2007). Demuth, Machobane, Maloi and Odato (2005) found that children best understood double object applicatives in Sesotho where they contained human, rather than inanimate, benefactives before inanimate, as opposed to animate, themes. These studies suggest that structural and semantic information may be inseparable and represented at varying levels of granularity (Ambridge, Kidd, Rowland \& Theakston, 2015).

However, methodological problems with structural priming studies have made it unclear whether animacysyntax interactions could drive priming effects (Chang, Bock \& Goldberg, 2003). DOD sentences (e.g. the girl brought the monkey a ball) may prime participants to repeat the abstract syntactic frame and produce DOD targets. Alternatively, they may prime speakers to reuse the
animate-inanimate noun ordering, leading them to produce PD sentences where targets contain animate themes and inanimate goals (e.g. the boy brought the tiger to the zoo). Studies manipulating both prime and target animacy cues are needed to identify whether semantic processes influence structural priming (Goldwater, Tomlinson, Echols \& Love (2010).

Priming could be greater with semantically prototypical primes (e.g. Vasilyeva \& Waterfall, 2015). Alternatively, priming might be greater with non-prototypical primes because they are more salient, according to Chang, Dell and Bock's (2006) error-based learning theory. Error-based learning effects may decrease with age due to increased exposure to uncommon sentence types (Peter, Chang, Pine, Blything \& Rowland (2015). Priming is greater in children (Goldwater, et al., 2010) and adults (Cleland and Pickering, 2003) where primes and targets are semantically similar. Sensitivity to animacy and its effects on structural priming may also decrease with age (Corrigan, 1988).

Priming research may provide insight into how children extract representations of grammatical functions and animacy-semantic role mappings from caregiver speech to produce their own sentences (Bock, Dell, Chang \& Onishi, 2007; Pickering \& Ferreira, 2008). By investigating possible specification of semantic, and not just lexical, information in children's sentence representations, we can more accurately conclude whether or not representations are entirely abstract (Rowland \& Noble, 2010).

We assessed the extent to which structural priming in three year olds, five year olds and adults was influenced by interactions between animacy cues and syntax by manipulating prime structures (DOD/PD), prime animacysemantic role mappings (prototypical [AN goal \& IN theme]/non-prototypical [AN theme \& IN theme]), and prime-target match in animacy-semantic role mappings (match/mismatch).

Prior research implies relatively strong interactions between animacy and syntax and that these effects on sentence processing are greater in younger children than in older children and adults. Thus, we tested the following hypotheses: (i) structural priming effects will be greater where primes have prototypical animacy cues. Alternatively, error-based learning may entail greater priming with reversed cues, (ii) priming will be greater where primes and targets have matching animacy-semantic role mappings, (iii) the relative increase in priming where animacy-semantic role mappings are prototypical and matching across primes and target pairs will decrease with age.

## Method

## Design

We used a $3 \times 2 \times 2 \times 2$ mixed design. Age (3 years/5 years/adults) and prime structure (double-object dative [DOD]/prepositional dative [PD]) were between-subject
independent variables. Prime animacy-semantic role mappings (prototypical [AN goal \& IN theme]/ nonprototypical [AN theme \& IN goal] and prime-target match in animacy-semantic role mappings (match/mismatch) were within-subjects independent variables. The production of DOD target responses was our dependent variable.

## Participants

We tested 143 monolingual British English speakers; 47 three year olds ( 24 females), 48 five year olds ( 25 females), and 48 adults ( 35 females). One three year old was excluded for their failure to produce any dative sentences.

## Visual Stimuli

Sixty-eight 10 -second animations were created in Anime Studio Pro 10 and presented on a laptop using Microsoft PowerPoint. Forty-eight ( 24 for primes and 24 for targets) portrayed ditransitive events (e.g. a girl bringing a monkey a ball). Twenty depicted intransitive events featuring two characters simultaneously acting in the centre of the screen (e.g. a boy and girl jumping). Eight of these were used as practice scenes (four each for the experimenter and participant) and 12 were used as fillers (six each).

## Sentence Stimuli

Eighty- two sentences were created as descriptions for the 68 animations. These included:

- Practice Items (4): Intransitive sentences for the experimenter's turn in practice trials to introduce participants to the task.
- Fillers (6): Present-tense intransitive sentences for the experimenter's turn in filler trials to limit priming effects across prime-target pairs.
- Primes (48): Past tense dative sentences which included 24 DOD and 24 PD counterparts corresponding to the 24 prime scenes. Six different prime sentences were assigned to each of the four experimental conditions.
- Targets (24): Six different verbs were included in sentence initiations for target sentences (e.g. the boy brought). Primes and targets always contained the same verb and participants completed these sentence initiations to produce the full target sentence. See Table 1 for example prime sentences and target elicitation scenes.

## Procedure

The experimenter played the animations on a laptop, beginning with four practice-practice trials, followed by alternating prime-target and filler-filler trials. She described the first scene and produced the first sentence in each pair, producing all primes and participants described the second scene in each pair, including all targets. On target trials, the
experimenter produced initial sentence initiations (e.g. the girl brought...) to encourage participants' use of datives. Participants formed their own target structures as they finished the sentence (e.g. the monkey a ball or the ball to the monkey). Adult participants often produced entire target sentences including the initial subject and verb.

Table 1: Example prime sentences and target elicitation scenes for each condition

| Condition | DOD Prime | PD Prime | Target Elicitation Scene |
| :---: | :---: | :---: | :---: |
| Prototypical Prime (AN goal \& IN theme) / Matched Target | The girl brought the monkey a ball | The girl brought a ball to the monkey | Transfer of a flower from boy to a snail |
| Prototypical <br> Prime <br>  <br> IN theme) / <br> Mismatched <br> Target | The girl brought the bee a flower | The girl <br> brought a flower to the bee | Transfer of a monkey from a boy to a zoo |
| Non- <br> prototypical <br> Prime <br>  <br> IN goal) / <br> Matched <br> Target | The girl brought the zoo a tiger | The girl brought a tiger to the zoo | Transfer of a bee from a boy to a zoo |
| Non- <br> prototypical <br> Prime <br>  <br> IN goal) / <br> Mismatched <br> Target | The girl brought the garden a snail | The girl brought a snail to the garden | Transfer of a ball between a boy and a tiger |

## Coding

Target responses were coded for syntactic structure (doubleobject dative [DOD], prepositional dative [PD] and OTHER). Only DOD and PD target sentences were included in the analyses.

DOD: sentences with a goal - theme structure (e.g. the boy brought the tiger a ball).

PD: sentences with a theme - preposition - goal structure (e.g. the boy brought a tiger for the monkey). Both to and for were suitable prepositions.
OTHER: Such responses were excluded from the analyses and included:

1. Sentences without a DOD or PD structure (e.g. intransitive and/or incomplete sentences with only one noun such as the boy threw the whale, or locatives such as the boy threw the way into the sea).
2. Incomplete sentences with one object and a preposition but no second object (e.g. the boy threw the food to)
3. Sentences where nouns were assigned to the wrong semantic role (e.g. the boy brought the ball [goal] a tiger [theme], where the target scene actually showed the transfer of a ball [theme] between a boy and tiger [goal]. A misunderstanding of the target scene may influence target structures where animacy cues might interact with syntactic structures.
4. Sentences with incorrectly named nouns, indicating participant's misunderstanding of the event shown in the target scene (e.g. the boy brought the zoo/mouse a ball instead of the boy brought the tiger a ball).
The percentage of OTHER target responses was $38 \%$ in three year olds, $28 \%$ in five year olds and $27 \%$ in adults. This is to be expected because although our events involved three participants, it is perfectly acceptable to focus on only a subset of these in a linguistic description of the scenes.

## Results

The data were analysed using logistic mixed effects models in R, using the glmer function of the lme4 package (lme4 version 1.1-11: R Core Team 2012). Fixed effects for all final models included: age ( 3 years $=-1 ; 5$ years $=0$; adult $=$ 1), prime animacy-semantic role mappings (prototypical [AN theme -IN goal] $=1$; non-prototypical [IN theme AN goal] $=0$ ) and prime-target match in animacy-semantic role mappings (match $=1$; mismatch $=0$ ). All variables were centred to reduce multicollinearity (Neter, Wasserman \& Kuttner, 1985). Participant was always included as a random effect. Sentence item was excluded as a random effect and the analyses were separated by age since the model initially fitted to the full data set did not converge. For each individual age group, the Bonferroni method was used with a corrected alpha level of .025 for post-hoc analyses. The mean proportion of DOD target responses produced in each condition is shown in Figure 1.

## Age Three

The model initially contained only main effects of prime structure, prime animacy-semantic role mappings and prime-target match, but was significantly improved by adding a three-way interaction term and all the two-way interaction terms that are derived from it $(p=.03)$. We found a significant main effect of prime structure whereby
more DOD targets were produced following DOD ( $M=$ $0.27, S E=0.02$ ) as opposed to PD primes $(M=0.06, S E=$ 0.01 ) and a significant three-way interaction between prime structure, prime animacy-semantic role mappings and prime-target match.

To interpret the three-way interaction a model was fitted for each level of prime structure (DOD and PD). Analysis of DOD primes failed to reveal any significant effect for prime animacy-semantic role mappings, $\beta=0.20(S E=0.31), z=$ $0.65, p=.518$, prime-target match, $\beta=-0.12(S E=0.31), z$ $=-0.40, p=.688$, or the interaction between the variables, $\beta=0.61(S E=0.61), z=1.02, p=.31$. Analysis of PD primes, however, revealed a significant two-way interaction between prime animacy-semantic role mappings and primetarget match, $\beta=3.89$ ( $S E=1.39$ ), $z=2.81, p=.005$.

Two further models were run for PD primes, one for each level of animacy-semantic role mapping (prototypical [AN goal \& IN theme]/non-prototypical [AN theme \& IN goal]). Where PD primes featured non-prototypical animacysemantic role mappings, there was a marginally significant effect of prime-target match, $\beta=-2.33(S E=1.07), \mathrm{z}=-$ $2.19, \mathrm{p}=.029$. Fewer DOD responses were produced where targets contained matched (non-prototypical) animacysemantic role mappings ( $M=0.01, S E=0.03$ ) as opposed to mismatched (prototypical) animacy-semantic role mappings $(M=0.11, S E=0.03)$. However, where PD primes contained prototypical animacy-semantic role mappings there was no significant effect of prime-target match, $\beta=$ $1.47(S E=0.85), z=1.73, p=.08$.

## Age Five

The model originally featured only main effects but was significantly improved by adding two-way interaction terms between the variables $(p=.007)$. There was a significant main effect of prime structure whereby more DOD targets were produced following DOD ( $M=0.30, S E=0.02$ ) as opposed to PD primes $(M=0.02, S E=0.01)$ and a significant two-way interaction between prime animacysemantic role mapping and prime-target match $\beta=1.15$ (SE $=0.51), z=2.28, p=.002$.

To interpret the two-way interaction, a model was fitted for each level of prime animacy-semantic role mapping (prototypical [AN goal \& IN theme]/non-prototypical [AN theme \& IN goal]). For prototypical prime animacysemantic role mappings there was a significant effect of prime-target match, $\beta=0.83(S E=0.35), z=2.35, \mathrm{p}=.018$. DOD production was higher where targets featured matched (prototypical; $M=0.18, S E=0.02$ ) as opposed to mismatched (non-prototypical; $M=0.09, S E=0.02$ ) animacy-semantic role mappings. However, where primes contained non-prototypical animacy-semantic role mappings there was no effect of prime-target match, $\beta=-0.48$ ( $S E=$ $0.36), z=-1.35 p=.177$. There was no difference in the production of DOD targets where targets featured matched (non-prototypical; $M=0.14, S E=0.03$ ) as compared with
mismatched (prototypical; $(M=0.09, S E=0.03)$ animacysemantic role mappings.

Figure 1: The mean proportion of DOD responses following DOD and PD primes where primes contained either prototypical or non-prototypical animacy-semantic role mappings and these mappings were either matched or mismatched across primes and targets ( $S E$ in error bars).

## Adults

The model originally featured only main effects but was significantly improved by adding two-way interaction terms between the variables ( $p<.001$ ). We found a significant effect of prime structure with more DOD targets produced following DOD $(M=0.64, S E=0.02)$ than PD primes $(M=$ $0.07, S E=0.12$ ) and a significant two-way interaction between prime animacy-semantic role mapping and primetarget match.

To interpret the two-way interaction a model was fitted for each level of prime animacy-semantic role mapping (prototypical [AN goal \& IN theme]/non-prototypical [AN theme \& IN goal]). For primes with prototypical animacysematic role mappings we found a significant effect of prime-target match, $\beta=2.608(S E=0.51), z=5.09, p<$ .001. DOD production was higher where targets featured matched (prototypical; $M=0.43, S E=0.03$ ) as opposed to mismatched (non-prototypical; $(M=0.25, S E=0.03)$ animacy-semantic role mappings. Where primes contained non-prototypical animacy-semantic role mappings, there was also a significant effect of prime-target match $\beta=-1.33$ $(S E=0.43), z=-3.12, p<.001$. Fewer DOD responses were produced where targets contained matched (nonprototypical; $M=0.30, S E=0.03$ ) as opposed to mismatched (prototypical; $(M=0.40, S E=0.03)$ animacysemantic role mappings.

## Results Summary

All age groups showed an effect of structural priming, producing more DOD responses following DOD primes, as compared to PD primes. Three year olds also exhibited effects of animacy-semantic role mappings on the magnitude of structural priming, showing an increase in PD sentence priming effects where primes and targets contained matching non-prototypical mappings (AN theme \& IN goal) (although no effects were observed for DOD primes). Our hypothesis that priming would be greater with prime-target match was met, indicating that animacy mappings were represented to a relatively strong degree. However, priming increased with non-prototypical rather than prototypical primes providing support for error-based learning accounts. As expected, animacy effects decreased with age; they had no influence on structural priming in five year olds or adults. Nevertheless, animacy did influence DOD target production in five year olds and adults, independently of prime structure. They produced more DOD sentences where targets (and also primes in the case of five year olds) contained prototypical animacy-semantic role mappings (AN goal \& IN theme).

## Discussion

Our results support claims of structural priming effects in children (Rowland et al., 2012) and adults (Bock, 1986) and more importantly, they provide further clarification as to how structural priming works. Our results reveal that priming relies, first and foremost, on the repetition of abstract syntactic frames and not the repetition of animacy noun orders. This was previously unclear due to methodological issues with earlier research (Chang, Bock \& Goldberg, 2003). Non-prototypical (AN theme \& IN goal) DOD primes with an inanimate-animate noun order (e.g. the girl brought the zoo a monkey) were just as likely to yield DOD targets as prototypical (AN goal \& IN theme) DOD primes with an animate-inanimate noun order (e.g. the girl brought the monkey a ball). Mere repetition of animacy noun ordering would have resulted in more prototypical PD targets with an inanimate-animate noun order (e.g. the girl brought the flower to the snail) following non-prototypical DOD targets. All age groups showed a main structural priming effect, suggesting that children's linguistic representations do not need to specify animacy-semantic role mappings for priming to occur.

PD sentence priming was enhanced in three year olds where there was prime-target match in non-prototypical (AN theme \& IN goal) animacy-semantic role mappings. This is consistent with Gámez and Vasilyeva's (2015) finding that prime-target match increased priming in five and six year olds. Our results are thus at odds with Pickering and Branigan's (1998) residual activation theory as it cannot explain how semantic information could influence structural priming. We found that animacy-semantic role mappings were specified and represented to a relatively strong degree and could influence priming through error-based learning in
support of Chang, et al (2006). We suggest that error-based learning may have been less likely to occur following DOD primes as three year olds generally use fewer DOD than PD constructions (Rowland, et al., 2012). They might not have been sensitive enough to the typical animacy mappings in DOD sentences for surprisal priming effects to occur.

Five year olds and adults showed no evidence of increased priming where primes contained non-prototypical (AN theme \& IN goal), as opposed to prototypical (AN goal \& IN theme) animacy-semantic role mappings. This developmental decrease in error-based learning may be due to increased exposure to such lower frequency sentence types and is consistent with Rowland, et al., (2012) and Peter, et al.'s (2015) results. Our results also complement those of Corrigan (1988) who found animacy effects on children's sentence interpretations to decrease with age.

Nevertheless, five year olds and adults produced more DOD targets where targets (and also primes for five year olds) contained prototypical (AN goal \& IN theme) mappings, regardless of prime structure. This indicates a preference to use animate goals and inanimate themes in DOD as opposed to PD constructions. These data therefore support claims that animacy interacts with semantic rolegrammatical function mappings and can influence subsequent word order (Zorzi \& Vigliocco, 1999; Goldberg, 1995; Garrett, 1975). Animate goals tended to be realised as indirect objects more than as oblique objects and were often placed before inanimate theme-direct objects, resulting in DOD constructions (e.g. brought the monkey [animate goal] a ball [inanimate theme]).

Speakers' tendency to encode animate goals and inanimate themes in DOD constructions increased with age. Very small surprisal effects may have moderated five year olds' DOD production. Non-prototypical (AN theme \& IN goal) PD primes may have subtly increased PD sentence priming through error-based learning. Non-prototypical DOD primes may have sometimes primed participants to reuse noun animacy orders in prototypical PD constructions. E.g. the DOD prime the girl brought the zoo [inanimate] a monkey [animate] could have prompted the PD response the boy brought the ball [inanimate] to the tiger [animate]).

We should however, also seek to clarify whether animacy could influence word orders in sentence production independently of syntax and/or grammatical roles. Bock, Loebell and Morey (1992) provide evidence to suggest that this is possible. Following primes with animate subjects before inanimate objects, participants were more likely to produce targets with the same noun animacy order than an inanimate subject-animate object order. It did not matter whether subjects were agents or patients of active or passive sentences. Little research has been conducted to address this topic in adults and it is yet to be explored in children.

## Conclusion

In our study animacy-syntax interactions appeared to facilitate structural priming in young children but this effect was subject to a developmental decrease. The extent to
which animacy-semantic role mappings could influence speakers' choice of syntactic structure independent of structural priming, rather increased with age. Animacysyntax interactions can therefore influence sentence production. We consequently propose that theories of structural priming and sentence production in general should seek to consider the role of animacy-syntax interactions.

# Equiprobability principle or "no change" principle? Examining reasoning in the Monty Hall Dilemma using unequal probabilities 

Bruce D. Burns (bruce.burns@sydney.edu.au)<br>University of Sydney, School of Psychology, Brennan MacCallum Building (A18)<br>Camperdown, NSW 2006, Australia

#### Abstract

The Monty Hall Dilemma (MHD) is a well-known cognitive illusion. It is often claimed that one reason for the incorrect answers is that people apply the equiprobability principle: they assume that the probability of the two remaining options must be equal. An alternative explanation for assigning the same probabilities to options is that they had the same prior probabilities and people perceive no significant change. Standard MHD versions do not distinguish these possibilities, but a version with unequal prior probabilities could. Participants were given an unequal probabilities version of MHD and told that either the high or low probability option had been eliminated. This affected participants' choices and their posterior probabilities. Only $14 \%$ of participants' responses were consistent with applying the equiprobability principle, but $51 \%$ were consistent with a "no change" principle. Participants were sensitive to the implications of the prior probabilities but did not appear to use Bayesian updating.

Keywords: Monty Hall Dilemma, probabilistic reasoning, cognitive illusions, cognitive reflection

## Introduction

In the Monty Hall Dilemma (MHD) participants are presented with a scenario in which there are three doors, one of which conceals a prize. The participant initially chooses one and then some mechanism (a game show host in the original version) opens one of the other two doors to show that it does not conceal the prize. This mechanism never opens a door with the prize behind it, knows where the prize is, and it always operates. The participant is then offered the choice of staying with the original choice or switching to the other unopened door. Almost all participants say they would stay with their first choice and that the probability of winning is $50 \%$ (Granberg \& Brown, 1995), however the correct choice is to switch and the probability of winning is $2 / 3$. When Marilyn vos Savant published the MHD in her magazine column and gave its correct answer she reports having received thousands of letters with $92 \%$ of the general public disagreed with her, but so did $65 \%$ of letters with university addresses (vos Savant, 1997). As such the MHD has proved to be one of the best examples of a cognitive illusion (Piattelli-Palmarini, 1994) and it has been the subject of a number of research studies (see Krauss \& Wang, 2003; Tubau, Aguilar-Lleyda \& Johnson, 2015, for reviews).

## Factors driving the illusion

Tubau et al. (2015) point out that it has been observed in many empirical studies that when participants are given the MHD they display a strong tendency to see the two remaining
doors as equally likely to conceal the prize. Stibel, Dror, and Ben-Zeev (2009) found that even in the 100-door version of the MHD in which 98 doors were opened, participants still tended to say that the last two remaining doors had a $50 \%$ chance each of concealing the prize. Although Tubau et al. point out that a number of factors have been argued to contribute to the illusion in MHD, one factor that it has been argued is a strong factor is misapplication of the equiprobability principle (Falk, 1992; Johnson-Laird, Legrenzi, Girotto, Legrenzi, \& Caverni, 1999; Falk \& Lann, 2008). Once participants see the options as equally probable they then choose to "stay" due to either illusion of control (Granberg \& Dorr, 1998) or anticipation of regret (Gilovich, Medvec, \& Chen, 1995).
The equiprobability principle suggests that in the absence of any apparent reason to differentiate options, all options will be assigned the same probability (Johnson-Laird, et al, 1999). So if there are just two apparently identical options they must each have an equal $50 \%$ chances of being correct. The equiprobability principle has often been observed when people are faced with uncertain options. For example, Fischhoff, Parker, Bruine de Bruin, Palmgren, Dawes and Manski (2000) found that a large number (over 20\%) of US 16 year olds estimated a $50 \%$ chance of dying in the next year. Tversky and Kahneman (1974) report that when participants were presented with a party made up of people with one of two professions, but given a description of an individual that the representativeness heuristic could not allocate to one of the groups, they said the probability of him being in either group was $50 \%$ regardless of base-rate. Even when Burns and Wieth (2004) presented a variation of the MHD that induced $51 \%$ participants to see that it was better to switch, most still said the probability of wining was $50 \%$. Johnson-Laird et al. present ample evidence of the equiprobability principle being applied to a number of situations, but it appears to be particularly strong in the MHD. However the frequency of the $50 \%$ answer may not be as strong as evidence of application of equiprobability as has been assumed because there is more than one path to this answer.

Burns and Wieth (2004) suggested that a major barrier to correct reasoning about the MHD is that participants fail to understand the causal structure underlying it. Therefore they see the host's action in opening a door as having not having changed the underlying probabilities. Thus given that the two unopened doors had equal probabilities before any door was opened they may still have equal probabilities. Occasionally participants have report that each of the two doors now has a $33 \%$ chance of concealing the prize, making this reasoning
transparent, although mathematically incoherent. However participants may be applying this reasoning to conclude that the ratio of the two probabilities of the remaining doors has not changed, and thus the probability of winning after switching is $50 \%$. Thus participants could come to the same answer (i.e., that each door has the same $50 \%$ chance of concealing the prize) in two different ways: 1) by misapplying the equiprobability principle; 2 ) by assuming no change. With the standard version of the MHD it is difficult to distinguish which form of reasoning led to the $50 \%$ answer, but a modification used by Granberg (1999) could.

## MHD with unequal probabilities

Granberg (1999) tried to probe how people use conditional probabilities in the MHD by giving them an alternative version of the MHD with four doors and unequal probabilities. The Bayesian analysis shows that whether staying or switching has the highest probability of winning depends on which door is initially selected and which door is opened. The optimal strategy for this version is to first select the least likely alternative then switch away from it after a door is opened. Granberg gave participants 60 trials of either equal or unequal probability 4-door versions of the MHD. On the first trial only $11 \%$ switched in the equal-probability condition but even fewer ( $7 \%$ ) switched in the unequalprobability condition, despite there being a $75 \%$ chance of winning (on average) if switching in the later condition. Over 60 trials the switch rates improved in both conditions but at similar rates. Participants in unequal-probability condition increasingly utilized the optimal strategy, but still only used it on an average of about $30 \%$ of trials in their last block of 10. Granberg saw this as evidence that participants were satisficing (Simon, 1955).
Granberg (1999) did not ask participants about what they thought were the probabilities that they would win by switching, but by not doing so an opportunity was lost. Few participants would be expected to get these probabilities correct, given how poor participants are at getting the percentage correct in standard version of the MHD (Burns \& Wieth, 2004, found only $2 \%$ did so). However their incorrect answers could be windows into their reasoning. In the 3-door equal-probabilities version of the MHD the same percentage answer could result from either form of the erroneous reasoning identified above. If a participant was applying the equiprobability principle then they would say there is a $50 \%$, but they would answer the same if they thought that Monty had changed nothing (except for cutting down the options). However in an unequal-probabilities version applying the equiprobability principle would still yield a $50 \%$ chance of winning, but if they applied the "no change" principle then the probability of winning would be a function of the unequal probabilities. Thus an unequal probability version of the MHD can be used to probe to what extent are participants’ errors due to either of these principles.

## The current experiment

In the experiment presented here participants were given a three-door version of the MHD but told that the probability that Door A concealed the prize was $30 \%$, the probability that Door B did was $60 \%$ and the probability that Door C did was $10 \%$. (These probabilities were chosen because they yielded different correct answers to staying or switching depending on which door was opened, and because they allowed easy calculation of the percentages corresponding to reasoning I expected from participants.) They were then told that they had initially selected Door A (fixing the first choice eliminated the strategic considerations that were not the focus of this experiment), then that one of the other doors had been opened. Figure 1a shows diagrammatically the scenario for the condition in which Door B was the one unopened, and in Figure 1 b for when Door C was unopened.

Figure 1a: Diagrammatic depiction of the scenario presented to participants in the Door-B unopened condition.

Figure 1b: Diagrammatic depiction of the scenario presented to participants in the Door-C unopened condition.

Participants were then asked whether they would stay with their first choice or switch to the unopened door, and to express their probability of winning if they switched. They were also asked if they had ever seen a question like this before. There were two conditions: Door- $B$ in which participants were told that Door B was unopened; and Door$C$ in which participants were told that Door C was unopened.

Bayes' Theorem yields the correct answer to the problems in the two conditions. In the Door-B condition the optimal choice is to switch because there is a $80 \%$ chance of winning if they switch, but in the Door-C condition participants
should stay because they would have only a $40 \%$ chance of winning if they switched (these answers were confirmed by simulations assuming that if the prize was behind Door A then there was an equal chance of opening either Door B or C). If participants apply the equiprobability principle then they should indicate a $50 \%$ chance of winning by switching in both conditions. If they are applying the "no change" principle then in the Door-C conditions they may say $25 \%$ (.1/(.1+.3)) and in the Door-B conditions $67 \%$ (.6/(.6+.3)). However they may apply a cruder version of the "no change" principle and just repeat the prior probabilities of $10 \%$ for the Door-C condition or $60 \%$ for the Door-B condition.

Tubau et al. (2015) suggest that use of the equiprobability principle may be due to lack of cognitive reflection, so it may be possible to analyses reasoning about the MHD in terms of dual-system models (see Stanovich, 2011). Applying "no change" and repeating prior probabilities may be the least reflective response. However "no change" but updating the probabilities to maintain the same ratio may be the most reflective. Thus responses to the unequal probability MHD may also be used to probe how reflective was the thinking employed.

The goal of the experiment was to analyze the type of reasoning participants used in an unequal-probabilities version of the MHD and thus to investigate what factors are behind the cognitive illusion. An improved understanding of the MHD can improve understanding of how people reason about probabilities.

## Method

## Participants

A total of 373 participants completed the experiment as part of a class at the University of Sydney. Of these, 105 indicated that they had seen a similar question before, so they were excluded from this analysis. The remaining sample of 268 consisted of 160 women and 108 men.

## Materials and procedure

During a class, participants were presented with the task as part of a set of tasks completed on a computer. They were told to read the following questions carefully and answer all the questions. If there were any they did not know the answer to, then they were instructed to guess.
"Pretend you are on a game show, where you are allowed to choose one of three closed doors. Behind one door is a prize (a car), and behind each of the other doors is a goat. After you have chosen a door, the door remains closed for the time being. The game show host, Monty Hall, who knows what is behind the doors, now has to open one of the two unchosen doors and reveal a goat. After he shows you a goat, he asks you to decide whether you want to stay with your first choice or switch to the remaining unopened door."
"By watching the show many times you have calculated that there is a pattern to where the prize is initially placed. Door A has the prize $30 \%$ of the time, Door B has the prize $60 \%$ of the time and Door C has the prize only $10 \%$ of the
time." Participants were then instructed to pretend they had first chosen Door A and that Monty Hall then opens Door B (if in the Door-C condition, otherwise Door C) and reveals a goat. Now he asks you whether you want to stick with your first choice (Door A) or switch to the Door C (or Door B if in the Door-B condition). Participants were also shown Figure 1a or Figure 1b, which ever was relevant to their condition.

They were then asked "Would you choose to switch doors or stay with your original door (Door A)?" and "What do you think is the chance of winning the prize if you switch doors (to Door B) [Door C in Door-C condition]?

Participants also completed the Cognitive Reflection Task (CRT) of Frederick (2005) which consists of three problems that require participants to reflect on the answers rather than give the obvious ones. It is used to assess the extent to which participants are reasoning reflective and thus using System 2 rather than relying on System 1 (in terms of Stanovich, 2011).

## Results

## Choice

After eliminating participants who reported having seen the question before and two with missing responses, there were 115 in the Door-B condition and 151 in the Door-C condition. Table 1 shows the number of participants choosing to stay or to switch depending on which door was left unopened. There was a large effect of condition, $\chi^{2}(1)=$ 74.35, $p<.001$.

This result shows that participants were sensitive to the implication of the prior probabilities of the unopened door, with $86 \%$ correctly switching when the unopened door had a high prior probability and $66 \%$ correctly staying when the unopened door had a low prior probability. This result already argues that the equiprobability principle is not being commonly applied.

Table 1: Number of participants in each condition (Door-B in which the high probability door is left unopened and Door-C in which the low probability door is left unopened) deciding to stay or switch.

|  |  | Choice |  |
| :---: | :--- | :--- | :--- |
|  |  | Stay | Switch |
| Door-B <br> unopened | $(60 \%)$ | 16 | 99 |
| Door-C <br> unopened | $(10 \%)$ | 101 | 50 |
|  |  |  |  |

A slightly surprising aspect of Table 1 was how high the switch rate was for the Door-C condition, given that so few participants switch in standard versions of the MHD despite it being the correct response. This may be due to the initial choice of Door A being allocated to participants rather than
being a true choice, which could reduce both the illusion of control (Granberg \& Dorr, 1998) and the anticipation of regret (Gilovich et al, 1995) factors that have been seen as driving the excessive number of "stay" decision in the standard MHD. Consistent with this is that previous studies have found that eliminating participants' first choice increased switch rates substantially (Tubau \& Alonso, 2003).

The large effect of the prior probabilities is also surprising in light of the lack of an effect of unequal prior probabilities observed by Granberg (1999) on his first trial. Possibly this was because the differences in probabilities for Granberg's four doors were quite small: .1, $2, .3$ and .4. It is also possible that because Granberg's first trial was the first of 60 participants were using it to explore rather than thinking deeply about the right choice to make.

## Percent

Participants in the Door-B condition gave higher mean percentage ( $M=.61, S D=.16$ ) chances of winning by switching than did those in the Door-C condition ( $M=.41$, $S D=.21), t(264)=8.85, p<.001$. Consistent with the choice data, participants thought they had a better chance of winning by switching if the higher probability door was left unopened.

Table 2 shows the number of participants giving each percentage response depending of their condition and their choice. Very few participants gave the correct percentages, only $4 / 266$. That these four actually calculated the Bayesian posterior probabilities is thrown into doubt by the observation that two participants generated these responses even when they were incorrect for their condition. Critically, Table 2 reveals that relatively few participant gave the equiprobability response of $50 \%$ when asked how likely they were to win if they switched. In total only 37/266 (14\%) of participants did so. Equiprobable responses were no more likely in the Door-C than the Door-B condition, $\chi^{2}(1)=$ $0.475, p=.47$. As expected based on results from the standard MHD, equiprobability was associated with more "stay" decisions, $\chi^{2}(1)=5.76, p=.016$.

There was strong evidence that participants followed the principle that nothing had changed. A total of 93/266 (35\%) of participants gave responses consistent with them calculating the ratio of the prior probabilities of the opened and unopened door ( $66 \%$ when Door B was unopened; $25 \%$ when Door C was unopened). As expected, the $66 \%$ response was much more common from participants in the Door-B than the Door-C condition, $\chi^{2}(1)=18.9, p<.001$, and the reverse was true for $25 \%$ responses, $\chi^{2}(1)=19.2, p<.001$. There is also evidence of participants using a cruder version of the "no change" principle and simply giving the prior probabilities as the posterior probabilities ( $10 \%$ in Door C; $60 \%$ for Door B). A total of 50/266 (19\%) did this. Again as expected, the $60 \%$ response was much more common from participants in the Door-B than the Door-C condition, $\chi^{2}(1)$ $=31.4, p<.001$, and the reverse was true for $10 \%$ responses, $\chi^{2}(1)=20.1, p<.001$.

Although only generated by 9 participants, the most common percent response that is not apparently associated
with applying equiprobability or a "no change" principles was $70 \%$. This answer could be due to participants adding together the prior probabilities of the opened and unopened doors. Such addition is sometimes proposed as a way to explain the correct answer to the standard version of the MHD. The unequal probability version of the MHD illustrates why this is a poor way to explain the MHD, but it is interesting that a small number of participants appeared to reasoning using it. If we see the 6 participants responding $30 \%$ as some sort of inversion of the $70 \%$ reasoning, this leaves only 10 out of 266 other responses which cannot in some way be linked to the "sum", equiprobability, or "no change" approaches.

Table 2: Frequencies of different values of reported percent chances of winning if participant switched, split by whether the participants decided to stay or switch and their condition
(Door-B or Door-C not opened). Two categories cover ranges of responses rather than precise responses.

| Percent <br> chance <br> of win if <br> switch | Door C <br> $(.10)$ not <br> opened | Door B <br> $(.60)$ not <br> opened | Door C <br> $(.10)$ not <br> opened | Door B <br> $(.60)$ not <br> opened |
| :--- | :--- | :--- | :--- | :--- |
|  | 0 | 0 | 0 | 2 |
| $10 \%$ | 19 | 0 | 5 | 0 |
| $11-24 \%$ | 1 | 0 | 0 | 1 |
| $25 \%$ | 22 | 0 | 1 | 0 |
| $30 \%$ | 2 | 0 | 2 | 1 |
| $33 \%$ | 25 | 2 | 5 | 2 |
| $40 \%$ | 3 | 0 | 0 | 1 |
| $50 \%$ | 16 | 7 | 7 | 7 |
| $60 \%$ | 1 | 3 | 1 | 23 |
| $65-67 \%$ | 8 | 4 | 26 | 52 |
| $70 \%$ | 3 | 0 | 1 | 5 |
| $75 \%$ | 0 | 0 | 0 | 1 |
| $70 \%$ | 0 | 0 | 1 | 1 |
| $700 \%$ | 0 | 0 | 1 | 2 |
| Totals | 101 | 16 | 50 | 99 |

A surprising aspect of the data in Table 2 was that a high number of participants in the Door C condition who switched gave $66 \%$ as the percentage chance of winning. This is consist with their choice but given that the prior probability
of this door concealing the prize was $10 \%$ and its posterior probability was $40 \%$, it is hard to infer the reasoning behind this answer. It may just be due to participants who were confused about the problem. Alternatively it could be that participants who had an intuition to switch, but were unable to calculate a probability fell back to using a plausible sounding percentage for a problem proposing three entities. Consistent with this is the similar number of participants giving $33 \%$ as the answer, particularly when deciding to stay. Another possibility arises from the fact that two-thirds is the correct answer to the standard MHD, so it is possible that some participants who said that they have not seen a similar problem actually had seen the standard MHD and then repeated its solution.

## Cognitive Reflection Task (CRT)

Participants' responses to the CRT were scored by counting how many of the three problems they gave the correct answer to. Overall the participants did quite poorly given that the maximum score is 3.0 but their mean score was 0.55 ( $\mathrm{SD}=0.86$ ).

There appeared to be an association between CRT scores and how participants responded. Those who generated the equiprobability percent of $50 \%$ did not differ from other participants on CRT scores ( $M=0.43, S D=0.83, n=37$ verse $M=0.57, S D=0.86, n=229), t(264)=0.92, p=.36$. However participants repeating the prior probability, either $10 \%$ or 60\% depending on their condition, had lower CRT scores than other participants, $(M=0.30, S D=0.61, n=50$ verse $M=0.61, S D=0.89, n=216), t(264)=2.34, p=.020$. Furthermore participants maintaining the ratio of prior probabilities, either $25 \%$ or $66 \%$ depending on their condition, had higher CRT scores than other participants ( $M=0.72, S D=0.96, n=116$ verse $M=0.42, S D=0.74, n=150$ ), $t(264)=2.92, p=.004$. So it appears that participants' responses to the unequal probabilities MHD reflect not only what principles they applied, but also how reflective was their thinking.

## Discussion

The equiprobability principle has often been presented as a strong driver of the illusion behind the MHD, yet there has been no attempt to test this hypothesis beyond the observation that most participants when given standard versions of the MHD report that that they would have a $50 \%$ chance of winning if they switched. To the extent that participants use similar reasoning when faced with the equal and unequal probability versions of the MHD, the finding here that only $14 \%$ of participants gave equal probability answers throws into doubt that the equiprobability principle is a strong driver of this cognitive illusion. In a way, it is also a powerful demonstration of just how strong the equiprobability principle can be for some individuals, given that it appeared to be followed by some participants even when it not only led to the wrong answer but it had to be invoked out of thin-air (i.e., there are no mentions of $50 \%$ and percentages presented
are unequal). So this principle may explain the illusion of the MHD for some people, but they appear to be a small minority.

The experiment's findings represent strong evidence that what leads participants to think that each remaining door is equally probable after Monty has revealed one is that there has be no change to these doors, so they maintain their equal status. Overall $54 \%$ of participants gave percentages in which they repeated the prior probability or they maintained the ratio of the prior probabilities. This is consistent with Burns and Wieth's (2004) argument that the main obstacle to correctly seeing the need for conditional reasoning about the MHD is failure to recognize that Monty's actions change things beyond just removing an option. Burns and Wieth argued that the MHD is difficult because it has a causal structure that people have difficulty recognizing and thus they fail to see that Monty's actions have causal consequences. We demonstrated this effect by showing higher switch rates when the MHD was presented as a competition. The finding here using the unequal probability MHD show directly that a belief that there has been "no change" could be driving many people's failures to reason correctly about the MHD.

The current results show almost no evidence of Bayesian updating by participants. They are sensitive to prior probabilities but they do not appear to recognize the problem as one involving conditional probabilities. The more reflective thinkers (as measured by CRT scores) recognize that the posterior probabilities are different from the prior probabilities, so have updated their probabilities after a door was opened. However they have only accounted for the missing door, not taken into account the new conditional probabilities.

The unequal probabilities versions of the MHD have the potential to be useful tools for examining the reasoning people use in the MHD because they have the potential to reveal this reasoning through differential answers. Almost all participants gave percent responses which could be interpreted as revealing their underlying reasoning. Questions concerning both the MHD and probabilistic reasoning more generally might be fruitful explored using appropriate versions of the unequal probabilities MHD.

## Does this experiment really address the MHD?

Reviewers of this paper raised some interesting issues regarding whether any experiment using an unequalprobabilities MHD can tell us anything about how people reason in the common equal probabilities version of the MHD.

One claim was that the current experiment had nothing to do with the MHD because participants were told their initial choice and told what door was opened, whereas the common description of the MHD allows people to make their own first choice. However assigning to participants their first choice has been the case in most empirical studies of the MHD going back to the first published study by Granberg and Brown (1995). Doing so has not eliminated the strong bias to decide to stay, so it does not seem to be a critical factor.

The question was also raised as to whether assigning unequal prior probabilities to the doors in itself invalidates the experiment as an examination of reasoning in the MHD. However, that the probabilities have to be equal has not been presented as a critical aspect of the MHD. If it is, then why it is critical needs to be explained. The MHD is a conditional probability problem and Bayes' Law can be as effectively applied to the MHD with unequal probabilities as to a MHD with equal probabilities. From the point of view of conditional probability, it is the equal probabilities presentation that is a special case of a more general problem. The reasoning described as being behind the MHD does not seem to rely on the prior probabilities being equal, although it may simplify the calculations.

An interesting claim made was that the unequal probabilities MHD cannot possibly address the equiprobability principle because it does not have equal prior probabilities. As pointed out earlier the equiprobability principle applies when there is no apparent reason to differentiate the options, thus the presentation of unequal prior probabilities may prevent it from being applied. The probabilities of the unopened doors are also not equal in the equal probabilities version, but people often don't perceive that to be the case. However this interpretation of the principle makes it somewhat circular, that is, it becomes a statement that people judge probabilities to be equal when they don't perceive them as unequal. Such an interpretation limits the explanatory value of the equiprobability principle. (Johnson-Laird et al [1999] also use the equiprobability principle to generating mental models, so perhaps the principle is better seen as a step in reasoning than as a result.) The finding in the current experiment that some participants thought the doors to be equally likely despite the prior probabilities being unequal suggests that a stronger version of the equiporbability principle is used by some people.

# Discovering simple heuristics from mental simulation 

Frederick Callaway (fredcallaway@berkeley.edu)<br>Jessica B. Hamrick (jhamrick@berkeley.edu)<br>Thomas L. Griffiths (tom_griffiths@berkeley.edu)<br>Department of Psychology; University of California, Berkeley; Berkeley, CA, USA

#### Abstract

In the history of cognitive science, there have been two competing philosophies regarding how people reason about the world. In one, people rely on rich, generative models to make predictions about a wide range of scenarios; while in the other, people have a large "bag of tricks", idiosyncratic heuristics that tend to work well in practice. In this paper, we suggest that rather than being in opposition to one another, these two ideas complement each other. We argue that people's capacity for mental simulation may support their ability to learn new cuebased heuristics, and demonstrate this phenomenon in two experiments. However, our results also indicate that participants are far less likely to learn a heuristic when there is no logical or explicitly conveyed relationship between the cue and the relevant outcome. Furthermore, simulation-while a potentially useful tool-is no substitute for real world experience.

Keywords: mental simulation, heuristics, physical reasoning

## Introduction

The world is a complex place, yet people are able to navigate it effortlessly. How is the mind able to do so much? One answer is that the mind builds rich, generative models of the world (Tenenbaum, Kemp, Griffiths, \& Goodman, 2011), which it then uses to "mentally simulate" potential futures and make inferences about objects and scenes. Indeed, there is a vast literature on how mental simulation underlies our core reasoning and problem solving abilities, including spatial reasoning (Hegarty, 2004; Shepard \& Metzler, 1971), physical scene understanding (Battaglia, Hamrick, \& Tenenbaum, 2013; Smith \& Vul, 2013), counterfactual reasoning (Gerstenberg, Goodman, Lagnado, \& Tenenbaum, 2014), and language comprehension (Bergen, Lindsay, Matlock, \& Narayanan, 2007; Matlock, 2004). Yet, despite the power and flexibility of mental simulation, there is a cost associated with its use: running simulations and evaluating their results takes time and resources. An alternative is to rely instead on simple heuristics that usually point to a good answer (Gigerenzer \& Todd, 1999). But, where do such heuristics come from in the first place?

Previous research has explored the notion of "learning by thinking" (Lombrozo, in press), demonstrating that people have the ability to learn new knowledge or re-represent old knowledge through internal processes such as simulation. For example, Hamrick, Battaglia, Griffiths, and Tenenbaum (2016) showed how people can use their mental simulations to learn about unobservable properties of the world such as the mass of objects; Khemlani, Mackiewicz, Bucciarelli, and Johnson-Laird (2013) illustrated how mental simulations can give rise to algorithmic problem-solving procedures; and Schwartz and Black (1996) demonstrated that people can learn simple rules about a physical system on the basis
of mental simulation. Thus, it is clear that people can acquire new knowledge or heuristics from mental simulation; but, under what circumstances will they do so?

In this paper, we propose that generative models can bootstrap the discovery of heuristics for novel tasks, but that people's prior biases strongly influence how likely they are to discover such heuristics. We pose three key questions regarding this claim. First, to what extent are people able to learn new information from their mental simulations? Second, to what extent do people use this information to construct new heuristics? And third, is mental simulation as reliable as realworld experience in learning such heuristics?

To determine how people learn heuristics from mental simulation, we designed and ran two experiments adapted from Hamrick, Smith, Griffiths, and Vul (2015) in which participants predict whether or not a ball would go through a hole based on its initial trajectory (see Figure 1). Importantly, we also manipulated an environmental cue-the color of the box containing the ball-that perfectly predicted the correct response. In the first experiment, we primed participants with the knowledge that a simple rule existed (but did not tell them the rule itself); in the second, we primed them with either weak expectations or no expectations, and then allowed them to do the task and discover the rule independently. Our results show that people are capable of crystallizing new rules solely on the basis of their mental simulations, though they are significantly less likely to do so if they are not already entertaining the hypothesis that a rule exists. Moreover, we show that mental simulation, while an avenue for learning such rules, is no substitute for real world experience.

## Experiment 1: Learning about known cues

In our first experiment, we asked to what extent people are able to learn heuristics from mental simulation when they are aware such a heuristic might exist. The heuristic took the form of an associative cue (see Stimuli) that perfectly predicted the correct response and that did not require mental simulation.

## Methods

Participants We recruited 119 participants on Amazon's Mechanical Turk using the psiTurk experimental framework (Gureckis et al., 2015). Participants were paid $\$ 1.50$ for roughly 14 minutes of work. We excluded 9 participants who did not finish the experiment and 8 participants who answered incorrectly on more than one catch trial. This left a total of 102 participants in our analysis.

Figure 1: Example of a medium trial.

Design We used a $3 \times 3 \times 2$ mixed design. We manipulated two within-subject variables, CUE and DIFFICULTY. CUE could take on three values: honest (the cue perfectly predicts the correct response), neutral (the cue contains no information), and deceitful (the cue predicts the incorrect response). DIFFICULTY could take on three values as well: easy, medium, and hard (see Stimuli). We manipulated one between-subjects variable, FEEDBACK, which determined whether people were allowed to see the full path of the ball (and thus the correct answer) after making a judgment.

Stimuli The stimuli were animations of a ball moving at a $400 \mathrm{px} / \mathrm{s}$ in a box with dimensions $900 \times 650 \mathrm{px}$. As the ball moved, it traced a gray line to reduce uncertainty about its direction. The initial stimulus presentation consisted of the ball moving for 0.2 seconds, after which the ball would freeze, remaining on screen along with its trace. The feedback animation picked up where the initial stimulus presentation left off, and showed the ball bouncing some number of times and then either (1) passing through the hole (a hit); or (2) bouncing off the central wall (a miss). The properties of a stimulus depended on the trial's difficulty. Easy stimuli had one bounce, a path length of 560 px , and a hole size of 300 px . Medium stimuli had one or two bounces, a path length of 880 px , and a hole size of 200 px. Finally, hard stimuli had two bounces, a path length of 1280 px , and a hole size of 100 px . The color of the background could be blue, green, or yellow depending on both the correct response and the value of CUE for that trial. For each participant, the three colors were mapped to hit, miss, and neutral (this mapping was counterbalanced). Thus, on an honest trial, the background would take the hit color if the ball would go through the hole, and the miss color, otherwise. This mapping was reversed for deceitful trials. Finally, on a neutral trial, the background was always the neutral color.

Procedure Participants were first given instructions in which the task was described. We specifically informed participants that they would observe three people playing a game on three different courts: "Player B" was playing on a blue court, "Player G" was playing on a green court, and "Player Y" was playing on a yellow court. We additionally told par-

Figure 2: Trial structure. The experiment begins with a block of eight "instruction" trials, shown with feedback regardless of condition. No cue is present. This is followed by nine twelve-trial "standard" blocks of increasing difficulty. Fiftyfour unique stimuli are each shown twice (in separate blocks), once with an honest cue and once with a neutral cue. Feedback is displayed on all or no trials depending on condition. At the end of each standard block, all participants saw their accuracy from the preceding block and responded to the cue quiz (see text). The final, "critical" block contains fourteen trials, shown without feedback. Trials with deceitful cues are interspersed to minimize the chance of participants noticing the change in cue reliability.
ticipants that one of the players was playing a game in which they were trying to get the ball in the hole, one was playing a game in which they were trying to avoid the hole, and one was playing a game in which they didn't care whether or not it went in. This backstory was designed to increase participants' subjective prior probability of and attention to the hypothesis that the background color was predictive of the correct response. Crucially, however, the backstory only motivated the existence of such a predictive relationship; it does not indicate its direction.

On each trial, participants were shown the scene, including the initial position of the ball and the location of the hole. Participants pressed 'space' to begin the trial, after which an animation of the initial stimulus began. Participants were then asked, "will the ball go in the hole?", and were instructed to press ' $q$ ' if they thought it would and ' $p$ ' otherwise. Participants in the feedback condition then saw "Correct!" or "Incorrect" as well as an animation showing the full remaining trajectory of the ball.

The structure of the experiment is shown in Figure 2. The early trials were easy so that participants in the no feedback condition had the chance to learn the cue when their simulation-based judgments were more reliable. The later trials were hard so they would be discriminative of participants' strategies: participants using simulation should perform poorly, while participants using the cue should be insensitive to trial difficulty. To assess declarative knowledge of the cue, we asked participants three multiple choice questions (the cue quiz) after each standard block: "Which player

Figure 3: Accuracy on critical and standard trials in Experiment 1. Error bars in all figures denote $95 \%$ confidence intervals by bootstrapping. (a) Critical trials were displayed either with an honest cue or with a deceitful cue. Participants performed better when the cue is honest, suggesting that they were relying on the cue rather than using simulation. (b) On standard trials, participants tended to respond more accurately on honest-cue trials than on neutral-cue trials.
is trying to get the ball into the hole?","Which player is trying to avoid the hole?", and "How confident are you in your response to the previous two questions?".

The last (critical) block was designed to provide evidence that participants were using the cue, as those using the cue should answer incorrectly on trials with the deceitful cue. The stimuli used for the first four honest trials and the deceitful trials were counterbalanced, and we excluded all honest trials after the first deceitful trial from analysis.

## Results

All analyses were planned unless specifically stated otherwise, and all contrasts are adjusted for multiple comparisons. All data and analysis code can be viewed at https://osf.io/ut3xp/
Hypotheses Based on our experimental design, we hypothesized the following: (1) Participants in both the no feedback and feedback conditions will learn the cue, as determined by their responses to the cue quizzes and based on their responses on the critical trials. (2) Participants in both the no feedback and feedback conditions will use their knowledge of the cue to respond more accurately in the task. (3) Participants in the feedback condition will be more likely to learn and use the cue than participants in the no feedback condition.
Cue quizzes To gauge whether a participant had successfully learned the cue after seeing all standard trials, we restricted our analysis to the final cue quiz. We conducted three one-tailed proportion tests comparing the proportion of participants in each condition who answered both questions correctly on the quiz, with a chance probability of $\frac{1}{6}$. We found that $56 \%$ of participants in the no feedback condition $\left(\chi^{2}(1)=54.465, p<0.001\right)$ and $68 \%$ of participants in the feedback condition $\left(\chi^{2}(1)=91.204, p<0.001\right)$ correctly identified the cue. These results suggest that participants were able to use their simulations to learn about the cue, confirming our first hypothesis.
Critical trials According to our first hypothesis, we anticipated that participants who learned and used the cue strat-
egy would fail on the four critical trials in which the cue was misinformative. We constructed a logistic regression model over accuracy on critical trials with factors for FEEDBACK and CUE. The results suggest that people in both the feedback and no feedback conditions were more likely to answer incorrectly on deceitful trials than on honest trials (Figure 3). Specifically, we found a significant main effect of CUE, with participants responding more accurately on honest trials than on deceitful trials ( $\chi^{2}(1)=4.252, p<0.05$ ). We also found a significant main effect of FEEDBACK $\left(\chi^{2}(1)=17.124, p<\right.$ 0.001 ), as well as an interaction between FEEDBACK and CUE $\left(\chi^{2}(1)=40.019, p<0.001\right)$. In both feedback conditions people were more likely to answer incorrectly on deceitful trials than on honest trials, though this difference was only marginally significant in the no feedback condition (for feedback, $\mathrm{LLR}=-2.31 \pm 0.23, z=-9.85, p<0.001$; for no feedback, LLR $=-0.41 \pm 0.20, z=-2.06, p=0.08$; where LLR is the log likelihood ratio).

The weak effect of cue honesty for the no feedback condition could be due to either an inability to identify the cue, or an inability to use knowledge of the cue to make predictions. To test these explanations, we conducted a posthoc analysis identical to that above but restricting the data to those participants that passed the quiz. We found highly significant effects of $\operatorname{CUE}\left(\chi^{2}(1)=10.862, p<0.001\right)$, FEEDВАСК $\left(\chi^{2}(1)=30.657, p<0.001\right)\left(\chi^{2}(1)=17.124, p<\right.$ 0.001 ), and the interaction between FEEDBACK and CUE $\left(\chi^{2}(1)=59.828, p<0.001\right)$. Contrasts revealed a significant effect of honesty in both the feedback (LLR $=-4.33 \pm$ $0.40, z=-10.85, p<0.001$ ) and no feedback (LLR $=$ $-0.88 \pm 0.27, z=-3.26, p<0.01)$ conditions. These results suggest that participants in the no feedback condition who identified the cue were also able to use it to make predictions, but not as well as those in the feedback condition.

Standard trials We also looked at the accuracy across trials during the main part of the experiment. We constructed a logistic regression model over accuracy with factors for FEEDBACK, DIFFICULTY, and CUE. The results are

Figure 4: Example cue learners. Each subplot shows a different participant in the no feedback condition of Experiment 1 who was identified as learning the cue by our model. The blue lines indicate average accuracy on each block when using the honest cue, while the gray lines correspond to the neutral cue. The vertical red lines indicate the trial, $C$, when our model inferred they switched from using simulation to using the cue. The title of each subplot displays the log likelihood ratio of the change model to the no change model, as well as the trial when they changed strategies.
shown in Figure 3. We found a main effect of difficulty $\left(\chi^{2}(2)=122.679, p<0.001\right)$, as well as a three-way interaction between FEEDBACK, DIFFICULTY, and CUE $\left(\chi^{2}(2)=\right.$ 12.363, $p<0.01$ ).

We investigated differences in accuracy within feedback conditions and cue types and found that, overall, people were more accurate on honest trials when they had feedback than when they did not have feedback (LLR $=-0.51 \pm 0.07, z=$ $-7.40, p<0.001$ ). This supports our third hypothesis that real data is more reliable than simulated data. We did not detect a difference between feedback conditions on neutral trials, however, indicating that feedback did not affect people's accuracy when using simulation (LLR $=0.03 \pm 0.06, z=$ $0.50, p=1.00$ ). We also found that people were more accurate when the honest cue was present than when the neutral cue was present, both in the feedback condition (LLR $=$ $-0.83 \pm 0.07, z=-12.24, p<0.001)$ and the no feedback condition $(\operatorname{LLR}=-0.29 \pm 0.06, z=-4.57, p<0.001)$.

## Modeling individual differences in cue learning

While the group-level effects in the previous sections confirmed our first and third hypotheses, we wanted to additionally investigate the individual behavior of participants who learned the cue. To this effect, we constructed a simple Markov model that allowed us to identify who actually used the cue and who did not.

Model For each participant, we defined a Markov model with observed states $J_{t}$ representing the participants' judgment on trial $t$. For each strategy, we defined a probability of answering correctly. For the simulation probability, we
fit $p_{\text {sim }}^{(\text {easy })}, p_{\text {sim }}^{(\text {med })}$, and $p_{\text {sim }}^{(\text {hard })}$ empirically based on the participant's average accuracy on trials without the cue for each level of difficulty. For the cue probability, we set $p_{\text {cue }}=0.95$ to reflect a high probability of answering correctly, but not perfectly. Finally, we introduced a variable $C \in\{1, \ldots, T\}$ which indicated the "change point" at which participants switched from using simulation to using the cue heuristic.

The probability of a participant's judgment was then:

$$
p\left(J_{t}=1 \mid C\right)= \begin{cases}p_{\mathrm{sim}}^{\left(d_{t}\right)} & t \leq C \\ p_{\text {cue }} & t>C\end{cases}
$$

where $d_{t}$ is difficulty of trial $t$. So, the probability of all responses was $\max _{C} p\left(\mathbf{J}_{1: T} \mid C\right)=\max _{C} \prod_{t=1}^{T} p\left(J_{t} \mid C\right)$, which we will refer to as the change model. We fit $C$ in the change model to each participant separately.

We additionally computed the likelihood of participants' responses under a no change model, in which we computed $p\left(\mathbf{J}_{1: T} \mid C=\infty\right)=\prod_{t=1}^{T} p\left(J_{t} \mid C=\infty\right)$, where the infinite change point $C$ indicates that the participant used the simulation strategy throughout the whole experiment.

Results To determine whether an individual participant learned the cue, we computed the log-likelihood ratio (LLR) between the change model and the null hypothesis (the no change model), and tested whether $2 \cdot$ LLR was significantly greater than zero under the $\chi^{2}$ distribution, with a significance threshold of $p=0.001$. Using this analysis, we found that 29 participants in the feedback condition switched to a cue-based strategy while 8 participants in the no feedback condition switched. To ensure these numbers were more than we would expect due to random chance, we additionally performed proportion tests with a probability of chance at 0.001 (corresponding to the significance threshold above). Both proportions were significantly different from chance (for feedback, $\chi^{2}(1)=16204, p<0.001$; for no feedback, $\left.\chi^{2}(1)=1068, p<0.001\right)$. The difference in proportions was also significant $\left(\chi^{2}(2)=17272, p<0.001\right)$

Figure 4 shows the two participants in the nofeedback condition with the highest log-likelihood ratios, and illustrates the clear effect of the cue: on the honest trials, the participants have nearly perfect performance, while on the neutral trials, they are significantly worse.

We additionally looked at the overlap between those participants who correctly answered the cue quiz and those who were identified by our model. The results, shown in Table 1, indicate that those people who were identified by the model answered correctly on the quiz, but not necessarily the other way around. This suggests that, counter to our second hypothesis, not everybody who explicitly identifies the cue is able to apply that knowledge when performing the task.

## Experiment 2: Discovering new heuristics

Based on the results of Experiment 1, it is clear that some people are able to use mental simulation to learn a cue-based heuristic-as long as they know that such a cue exists. In

Table 1: Number of participants identified by the quiz and/or model as having learned the cue in Experiments 1 and 2. FB = "Feedback", No FB = "No Feedback".

|  | Condition | Neither | Quiz <br> Only | Model <br> Only | Both |
| :--- | :--- | :---: | :---: | :---: | :---: |
| 1 | No $F B(52)$ | 20 | 24 | 3 | 5 |
|  | $F B(50)$ | 15 | 6 | 1 | 28 |
| 2A | No $F B(48)$ | 38 | 10 | 0 | 0 |
|  | $F B(49)$ | 31 | 14 | 1 | 3 |
| 2B | No $F B(52)$ | 41 | 11 | 0 | 0 |
|  | $F B(49)$ | 38 | 9 | 0 | 2 |

Experiment 2, we asked whether participants could discover and learn the heuristic without being given this information explicitly. By making two small alterations to the backstory presented in Experiment 1, we modulated the degree to which participants would expect the cue. Experiment 2A did not inform participants that the colors were predictive; it only associated the cue (color) with players. We hypothesized that this would allow participants to frame hypotheses about cue predictiveness in terms of more familiar concepts: one player might be more talented or have a different goal. Additionally, describing the colors in the instructions might increase their salience. In Experiment 2B, we did not verbally draw attention to the cue, nor did we provide any semantic meaning for the cue. Thus we expected participants would be even less likely to learn the cue, perhaps because they would not even consider the hypothesis that the colors are predictive.

## Methods

Participants We recruited 224 participants on Amazon's Mechanical Turk using the psiTurk experimental framework (Gureckis et al., 2015). Participants were treated in accordance with UC Berkeley IRB standards and were paid $\$ 1.50$ for fourteen minutes of work. We excluded 15 participants who did not finish the experiment and 11 participants who answered incorrectly on more than one catch trial. This left a total of 198 participants in our analysis.

Design and Procedure The design and procedure were identical to Experiment 1, with the following exceptions. In Experiment 2A we told participants that there were three different players, corresponding to three different colors, but not that they were playing different games. In Experiment 2B we gave participants a minimal backstory that made no reference to players or colors. In both experiments we administered the cue quiz once, at the end of the experiment.

## Results

Experiment 2A We performed the same analyses as in Experiment 1, and found that $35 \%$ of people in the feedback condition were able to identify the cue in the quiz $\left(\chi^{2}(1)=10.204, p<0.001\right)$. Without feedback, $21 \%$ of par-
ticipants identified the cue, which was marginally significant $\left(\chi^{2}(1)=1.680, p=0.10\right)$. We did not find an affect of CUE in the critical trials $\left(\chi^{2}(1)=0.518, p=0.47\right)$, though there was a trend towards people being more accurate on honest trials. We found no significant effect of the cue on accuracy in standard trials either $\left(\chi^{2}(1)=0.160, p=0.69\right)$.

The Markov model identified 4 people in the feedback condition $\left(\chi^{2}(1)=243, p<0.001\right)$ and 0 in the no feedback condition as having adopted the cue strategy. Together, these results show that when people are primed with a cover story that makes the cue plausible, some of them will indeed learn the cue; however, the majority still will not.
Experiment 2B Whereas in Experiment 2A the cue was explained with a cover story about people playing a game, in Experiment 2B the cue was entirely unexplained. The results suggest that when the cue is unexplained, participants are unlikely to discover the informativeness of the cue. We again performed the same analyses as those in Experiment 1, and found that people were not significantly different from chance at identifying the cue in the survey, regardless of whether they saw feedback ( $21 \%$ of participants, $\chi^{2}(1)=0.800, p=0.19$ ) or not ( $22 \%$ of participants, $\chi^{2}(1)=0.465, p=0.25$ ). We also found no effect of CUE in the critical trials $\left(\chi^{2}(1)=\right.$ 1.626, $p=0.20$ ), though as in Experiment 2A there was a trend toward people being more accurate on the honest trials. Again, we found no significant effect of the cue on accuracy in standard trials $\left(\chi^{2}(1)=1.269, p=0.26\right)$.

The Markov model identified 2 people in the feedback condition $\left(\chi^{2}(1)=43, p<0.001\right)$ and 0 in the no feedback condition as having adopted the cue strategy. These results suggest that when people are not already entertaining the hypothesis that a heuristic might exist, it is unlikely that they will spontaneously realize it.
Comparing Experiments Summary results of the three experiments are shown in Table 1 and Figure 5. We consistently find more evidence for cue-learning when feedback is given. However, our results suggest that an unexplained cue that has no intuitive relationship with the outcome is quite difficult to learn, even when feedback is present.

## Conclusion

In this work, we asked three questions: (1) are people able to learn about auxiliary properties in the world through mental simulation; (2) do they use their knowledge to make more accurate predictions; and (3) is mental simulation as reliable as real-world experience? In Experiment 1, we showed that (1) people can indeed learn a correlated cue through the use of mental simulation; and (2) people can sometimes apply such knowledge as a heuristic prediction strategy. However, (3) both discovery and application of the cue was weaker when people had to learn from only simulated data. We speculate on two potential explanations for the advantage of external over simulated data. First, simulations are noisy; thus, simulated data may not accurately reflect the world. In this study,

Figure 5: Comparing quiz, accuracy, and model results across experiments. (a) Participants who correctly identified the cue during the cue quiz. The dashed line indicates chance performance. (b) The difference in accuracy on the honest trials versus the neutral trials. Positive values indicate that participants were more accurate on honest trials. (c) The proportion of participants identified as having learned the cue by the Markov model. There are no error bars due to the particulars of this analysis; all non-zero proportions are significantly different from chance.
the cue was perfectly predictive; however, if one predicted incorrectly on $25 \%$ of trials, the cue would only $75 \%$ predictive. Furthermore, if people are aware that their simulations are error-prone, they may place less faith in the simulated data and any patterns therein. Second, simulations are costly, and it is possible that increased attentional and working memory load may have decreased participants' ability to simultaneously perform the task and pick up on the cue.

In both experiments, there was considerable withincondition variance in cue learning and use. The alignment between accuracy on the quiz and the Markov model predictions (Table 1) suggests that this is partly due to individual differences. It appears that some participants learned and applied the cue, while others completely ignored the cue. This between-subject variance could be due to true individual differences: perhaps some people are better able to learn associative cues (in general or specifically from simulated data). Alternatively, these differences could be the result of a constant learning ability that is stochastic and only occasionally expressed. Similar to flashes of intuition that strike seemingly at random, identifying a pattern in simulated data may be a powerful but rare event in human cognition.

Together, our results suggest that mental simulation on its own is not sufficient for learning: prior expectations are hugely important. This result is consistent with the ideas behind the hypothesis of theory-based causal induction (Tenenbaum, Griffiths, \& Kemp, 2006), which posits that inductive reasoning requires highly structured and systematic systems of causal knowledge. While it was possible for participants in our experiments to learn a new piece of causal knowledge (a heuristic), it was very difficult for them to do so if the cue did not easily fit into an existing causal framework. Thus, we suggest that while mental simulation can be a powerful tool for re-representing knowledge, it does not operate in a vacuum, and must work in tandem with other cognitive processes to fully realize its potential.

# Fast and Easy: Approximating Uniform Information Density in Language Production 

Jesús Calvillo (jesusc@coli.uni-saarland.de)<br>Saarland University, Germany

#### Abstract

A model of sentence production is presented, which implements a strategy that produces sentences with more uniform surprisal profiles, as compared to other strategies, and in accordance to the Uniform Information Density Hypothesis (Jaeger, 2006; Levy \& Jaeger, 2007). The model operates at the algorithmic level combining information concerning word probabilities and sentence lengths, representing a first attempt to model UID as resulting from underlying factors during language production. The sentences produced by this model showed indeed the expected tendency, having more uniform surprisal profiles and lower average word surprisal, in comparison to other production strategies.

Keywords: information density; sentence production; rational analysis; connectionist; semantics

## Introduction

For a given semantics, humans are able to produce a large number of surface representations that express its meaning. However, some constructions are preferred over others, some sentences are easier to understand, while some others are more difficult, so people tend to avoid them.

Uniform Information Density Hypothesis (UID, Jaeger, 2010; Levy \& Jaeger, 2007) presents one way to rank sentences according to how uniform their surprisal profiles are; where a sentence is preferred if the surprisal of each of its words remains uniform. This is explained as a rational strategy of language production at the computational level of analysis, as such strategy maximizes the probability of successful communication in a bandwidth-limited noisy channel while maximizing information transmission. Alternatively, and without the assumption of a noisy channel, comprehension effort is also minimized utilizing a UID strategy (Levy \& Jaeger, 2007), provided that the effect of surprisal on comprehension effort is superlinear (Hale, 2001; Levy, 2008).

Empirical evidence supports this hypothesis (e.g., Aylett \& Turk, 2004; Bell et al., 2003), however, as far as one can tell, no modeling attempts explore this at the algorithmic or implementational levels. Here, a mechanistic account of sentence production is presented, which balances on the one hand speed of information transmission and on the other hand comprehension and production effort. The sentences produced by this strategy present more uniform surprisal profiles, compared to other strategies, and thus, represent a first approximation to UID.

In particular, the model assumes that speakers act under three different pressures: a first one, pushing speakers to be fast under time restrictions; a second one, related to production effort, pushing speakers to produce available content first (see Ferreira \& Dell, 2000); and a third one, related to comprehension effort, pushing speakers to avoid high information
density structures. Here I present a way to balance these pressures in order to obtain sentences with more uniform surprisal profiles, which could be later linked to a bandwidth-limited communication channel.

The language production model proposed here extends the one presented by Calvillo, Brouwer, and Crocker (2016), which produces sentences describing a given semantics by maximizing word probabilities. The semantic representations used are a variation of those defined by the Distributed Situation Space model (DSS, Frank, Koppen, Noordman, \& Vonk, 2003; Frank, Haselager, \& van Rooij, 2009). The rest of this section briefly presents the DSS model as well as the model described by Calvillo et al. (2016).

## Distributed Situation Space

The DSS model (Frank et al., 2003, 2009) defines a microworld in terms of a finite set of basic events (e.g., play(charlie,chess)) -the smallest meaning-discerning units of propositional meaning in that world. Basic events can be conjoined to form complex events (e.g., play(charlie, chess) $\wedge$ win(charlie)). However, the microworld poses both hard and probabilistic constraints on event co-occurrence; as a result, some complex events are very common, and some others impossible to happen.

A situation-state space is a large set of $m$ microworld observations defined in terms of $n$ basic events, yielding an $m \times n$ matrix (see Table 1). Each observation in this matrix is encoded by setting basic events that are the case in the given observation to 1 (True) and those that are not to 0 (False). This matrix is constructed by sampling $m$ observations such that no observation violates any hard world knowledge constraint, and such that the $m$ observations approximate the probabilistic nature of the microworld. The resulting matrix encodes then all knowledge about the microworld, where each column, also called situation vector, represents the meaning of each basic event in terms of the observations in which the basic event is true.

Frank et al. (2009) successfully used these DSS representations in a connectionist comprehension model. They defined a microworld consisting of 44 basic events centered around three people. Then they constructed a situation-state space by sampling 25,000 observations. As an example, in this space the situation vector for play(charlie, chess) would correspond to a column in the matrix, where each dimension corresponds to one observation, and its value would be 1 if Charlie is playing chess in that observation. Finally, they reduced the dimensionality of the resulting $25 k$-dimensional situation vectors to 150 dimensions using a competitive layer algorithm.

Table 1: Situation-state space.

|  |  |  |  | $\ldots$ | \# |
| :---: | :---: | :---: | :---: | :---: | :---: |
| observation $_{1}$ | 1 | 0 | 0 | $\ldots$ | 1 |
| observation $_{2}$ | 0 | 1 | 1 | $\ldots$ | 1 |
| observation $_{3}$ | 1 | 1 | 0 | $\ldots$ | 0 |
| ... | . | . | . | .. | . |
| observation $_{m}$ | 0 | 1 | 0 |  | 0 |

## DSS Language Production

DSS representations were also used by Calvillo et al. (2016) in a connectionist model of language production, showing that they are suitable for modeling production.

While Calvillo et al. (2016) used the same microworld as Frank et al. (2009), the DSS representations were modified in order to avoid the competitive layer dimensionality reduction. Instead, the original $25-\mathrm{k}$ dimensional situation vectors were converted to belief vectors. Each dimension of the latter is equal to the conditional probability of each basic event given the original 25 k -dimensional DSS representation that is associated to each sentence. ${ }^{1}$ The result is a 44-dimensional vector that avoids the loss of information associated to the competitive layer algorithm, and consequently renders a higher performance in a language production task.

The architecture of the model presented by Calvillo et al. (2016), represented by the dotted rectangle in Figure 1, implements an extension of a Simple Recurrent Network (Elman, 1990) with a 45 -unit input layer, a 120 -unit recurrent hidden (htan) layer, and a 43 unit (softmax) output layer. The input layer contains 44 units corresponding to the 44 basic events in the microworld, plus one binary unit indicating whether the model must output an active sentence (1), or a passive one (0). The output layer contains 43 units matching the number of available words in the vocabulary.

Time in the model is discrete. At each time step $t$, the recurrent hidden layer receives as input the DSS representation, its own activation at time step $t-1$ (zeros at $t=0$ ) and the identity of the word that was produced at time step $t-1$ (ze$\operatorname{ros}$ at $t=0$ ). Activation of the hidden layer is then propagated to the softmax output layer.

The activation of the output layer yields a probability distribution over the available words, where the word produced at time-step $t$ is defined as the one with highest probability (highest activation). Production stops after an end-ofsentence marker has been produced.

[^293]The identity of the word that was produced at time-step $t-1$ is forwarded to the hidden layer through monitoring units connecting the output layer to the hidden layer, where only the output unit of the word produced at time-step $t-1$ is activated (set to 1 ), while all other units are set to 0 .

Finally, the hidden and output layers also receive input from a bias unit with a constant activation of 1 .

## UID Model

The here proposed model architecture, shown in Figure 1, consists of two paths of processing: the first one (above, inside the dotted rectangle), computes word probabilities given the context, and is identical to the model of Calvillo et al. (2016); and the second one (below), receives the output of the former and computes derivation length estimations, i.e., how long a sentence can be if a particular word is produced. We call probabilities the layer containing the output of the first path, and der_lengths the layer containing the output of the second path.

The output of these two paths is then combined in a final layer (words) that receives unmodified copies of the activation of probabilities and der_lengths and whose activation is a combination of these two types of information. At this point the model produces the word with the highest activation in words, whose identity is then passed to the first hidden recurrent layer through monitoring units in order to process the next word production. Finally, production stops when an end-of-sentence marker is produced.

The rest of this section presents in more detail each of these parts, along with their justification.

Figure 1: UID Production Model.

## Semantic and Linguistic Information

The information content or surprisal of a sentence $s$ is defined as its negative $\log$ probability $-\log P(s)$. Moreover, sentences express events in the world, such that a sentence can be paired with one or more events, and vice versa. Therefore, we can decompose the probability of a sentence $s$ into:

$$
P(s)=\sum_{i} P\left(s \mid e_{i}\right) P\left(e_{i}\right)
$$

where $e_{i}$ is an event in the world that is paired with $s$.
From this, we can distinguish two kinds of information: $P\left(e_{i}\right)$, related to each event that can be paired with the sentence; and $P\left(s \mid e_{i}\right)$, related to the linguistic elements used in this particular sentence to express $e_{i}$.

We call the first one semantic surprisal, and the second one linguistic surprisal (cf. Frank \& Vigliocco, 2011). Semantic surprisal represents how unexpected the events conveyed by the sentence are. Linguistic surprisal can be seen as the information that the sentence conveys, given that the semantics is already known; thus, it is not information about the world, but about the sentence itself.

These two types of information cannot be easily disentangled because they are embedded in each sentence/event. Knowing the identity of an event gives information about the possible related sentences, and vice versa. Nonetheless, based on our definition, we can express total semantic surprisal of a sentence $s$ as:

$$
\operatorname{SemSurp}(s)=-\log \sum_{i} P\left(e_{i}\right)
$$

where $e_{i}$ is each event that can be expressed by $s$.
While one sentence can be paired with several events, normally when a speaker produces a sentence, he/she has one specific event in mind $e_{\alpha}$. Thus, while total semantic surprisal is as described above, the semantic information/surprisal that the speaker is trying to communicate is only:

$$
-\log P\left(e_{\alpha}\right)
$$

As a result, the relevant information associated with a specific sentence $s$ assuming that the speaker is trying to communicate the event $e_{\alpha}$ is given by:

$$
\begin{gathered}
\operatorname{Surp}_{e_{\alpha}}(s)=-\log P\left(s \mid e_{\alpha}\right) P\left(e_{\alpha}\right) \\
\quad=-\log P\left(s \mid e_{\alpha}\right)-\log P\left(e_{\alpha}\right)
\end{gathered}
$$

where the semantic information $-\log P\left(e_{\alpha}\right)$ remains constant across all different surface realizations that could convey it; in contrast to the linguistic information $-\log P\left(s \mid e_{\alpha}\right)$, which can vary widely depending on the specific syntactic structures or words that the speaker chooses.

## Being Easy to Produce

Surprisal Theory (Hale, 2001; Levy, 2008) states that the cognitive effort associated to the processing of a word is proportional to its surprisal. Evidence supporting this has been shown for comprehension (e.g., Hale, 2001; Levy, 2008), and production (e.g., Griffin \& Bock, 1998). Therefore, one can assume that a rational model of production would try to minimize effort for both interlocutors.

While comprehension effort is minimized following a UID strategy, production effort can be minimized by following an Availability Based Production strategy (ABP, Ferreira \& Dell, 2000), where items are produced as they are available.

In this respect, producing the most probable word, and therefore most available, at each time step minimizes (to some extent) production effort by locally minimizing linguistic surprisal:

$$
w_{t+1}=\underset{w}{\arg \min }-\log P\left(w \mid D S S, w_{0}, \ldots, w_{t}\right)
$$

where $w$ is a word in the vocabulary and DSS is the semantic representation related to $e_{\alpha}$. This is already implemented by the model described by Calvillo et al. (2016), where the word produced at each time step is the one with highest conditional probability given the semantics and the previously produced words. In our model these probabilities are obtained at the Probabilities layer in Figure 1.

## Being Fast

The information contained by a sentence results from the sum of the information contained by each of its words. Thus, knowing that the semantic surprisal related to $e_{\alpha}$ should sum up to $-\log P\left(e_{\alpha}\right)$, and that this information is distributed among the words in the sentence, we can calculate average word semantic information/surprisal with respect to $e_{\alpha}$ :

$$
E\left[\text { WordSemSurp }_{e_{\alpha}}\right]=\frac{-\log P\left(e_{\alpha}\right)}{n}
$$

where $n$ is the number of words in the sentence. Hence, if one wants to maximize average semantic information transmission of the desired event $e_{\alpha}$, it suffices to minimize $n$.

We hypothesize that in general speakers tend to maximize information transmission of the desired semantics $e_{\alpha}$ by minimizing $n$, and therefore by favoring shorter sentences.

The model presented minimizes sentence lengths by estimating at each time step a score that reflects the expected derivation length that would follow the production of a certain word. This is done by the second path shown in Figure 1, below. This path is constituted by a hidden recurrent layer followed by a softmax layer. The recurrent layer contains 30 sigmoid units and receives as input the DSS semantic representation, the output of probabilities, and its own activation at time step $t-1$ (zeros at $t=0)$. Activation of this layer is then propagated to a softmax layer (der_lengths) with dimensionality equal to the size of the vocabulary(43), and that calculates for each word a probability value $D L$, where values closer to 0 represent longer derivations and values closer to 1 represent shorter derivations, and where probability mass is distributed among all words that can be produced at the given time step. Finally, these layers receive also input from a bias unit with a constant activation of 1 .

A model that produces at each time step the word that maximizes this score would prefer words leading to shorter derivations, regardless of their information content:

$$
w_{t+1}=\underset{w}{\arg \max } D L\left(w \mid D S S, \text { probabilities }_{t+1}\right)
$$

## Being Easy to Comprehend

A model combining the previous two strategies would produce sentences with more uniform surprisal profiles, compared to a model that only applies one of them. However, these strategies do not take into account that world events with high surprisal represent higher comprehension effort.

Speakers know beforehand how unexpected the event they are trying to communicate is. Therefore, one can propose that they balance these two strategies according to this information. That is, when the speaker is trying to communicate an event $e_{\alpha}$ with low surprisal, the speaker would prefer to be faster; but, when the event represents high surprisal, the speaker would prefer sentences with lower linguistic surprisal and possibly longer. Thus, at each time step, the model would produce the word that maximizes the score:

$$
w_{t+1}=\underset{w}{\arg \max }\left\{\left(1-P\left(e_{\alpha}\right)\right) P(w \mid \ldots)+P\left(e_{\alpha}\right) D L(w \mid \ldots)\right\}
$$

This final model is expected to produce sentences with more uniform surprisal profiles, compared to strategies that only maximize one of these measures, or that do not take into account semantic surprisal.

In our model this is computed at the words layer (see Figure 1), which receives $P(w \mid \ldots)$ values from the probabilities layer and $D L(w \mid \ldots)$ scores from the der_lenghts layer. The value of $P\left(e_{\alpha}\right)$ is assumed to be known.

## Training and Evaluation

## Examples Set

We use the same examples set as Calvillo et al. (2016), which consist of a set of pairs $\left.\left\{\left(D S S_{1}, \varphi_{1}\right), \ldots,\left(D S S_{n}, \varphi_{n}\right)\right)\right\}$ where each $D S S_{i} \in[0,1]^{45}$ is formed by a DSS representation plus an extra bit that indicates whether the model must produce a a passive sentence (0) or an active one (1); and $\varphi_{i}$ is the set of all the sentences that encode the information contained in the corresponding $D S S_{i}$ and in the expected voice.

The sentences are those generated by the microlanguage defined by Frank et al. (2009) (see their Tables 5-8). This microlanguage consists of 40 words that can be combined into 13556 sentences according to its grammar. After adding determiners (a,the) and an end-of-sentence marker (.), there were 43 words, which were encoded at the output layer probabilities in the form of localist vectors. After ruling out sentences expressing situations that are not allowed by the microworld, there were a total of 8201 sentences related to 782 DSS representations.

This set was used because it pairs each semantic representation with several sentences, allowing to define different ranking functions. In future work a new set could be defined in order to assess more specific phenomena.

Derivation Length Scores. For each DSS representation, we know beforehand the sentences that can encode it according to the grammar. Furthermore, we know at each derivation point what words can be produced and how long the sentences would be if a particular word is produced. Using this
information, we compute a probability distribution over the vocabulary that reflects the length of the sentences that one can expect after producing a particular word.

Given a DSS representation and a derivation point, for each possible word production $w_{i}$, we get its minimum derivation length min_dl $\left(w_{i}\right)$, which is the length of the shortest sentence that can be produced if $w_{i}$ is produced. Afterwards we calculate a score $d l\left(w_{i}\right)$ :

$$
d l\left(w_{i}\right)=\max _{w}\left\{\min _{-} d l(w)\right\}-\min _{-} d l\left(w_{i}\right)+1
$$

which is equal to the difference between the greatest min_dl value among all the words that can be currently produced and the min_dl associated to each specific word $w_{i}$, plus 1. Finally, in order to have a proper distribution, we normalize by dividing by the sum over all the possible word continuations.

These scores are the values expected at the output layer of der_lengths. According to these, all possible word productions at a specific derivation point have some probability mass that is inversely proportional to the length of the shortest sentence that can be obtained by following that production.

Semantic Probability. For each DSS representation in the examples set, a semantic probability value $P\left(e_{\alpha}\right)$ was computed. Considering that the model is trained only on the pairs given in the examples set and that all sentences are presented an equal number of times during training, then the probability of a DSS representation is given by the number of sentences related to that representation divided by the total number of sentences in the examples set.

However, since $P\left(e_{\alpha}\right)$ is used to balance word probabilities and derivation lengths, less biased values are needed because as it is, $P\left(e_{\alpha}\right)$ is in general very low, and $1-P\left(e_{\alpha}\right)$ is very high. Therefore instead of normalizing by the total number of sentences, normalization is done with respect to the highest number of sentences that can be related to a DSS representation, which is 130 . Hence, for each DSS, its probability $P\left(e_{\alpha}\right)$, or henceforth $P(D S S)$, is given by the number of sentences paired with the representation, divided by 130.

## Training Procedure

Since the output layer receives unmodified copies from probabilities and der_lengths, the connections from the latter to the former are fixed one-to-one and do not need training. In other words, the $i^{\text {th }}$ unit of probabilities is only connected to the $i^{t h}$ unit of words with a connection weight fixed to 1 , and likewise for the connections between der_lenghts and words.

Prior to training, all weights on the projections between layers (with the exception of those mentioned in the last paragraph) were initialized with random values drawn from a normal distribution $\mathcal{N}(0,0.1)$. Weights on the bias projections were initially set to zero.

Training consists of setting the connection weights leading to the computation on the one hand of probabilities and on the other hand of der_lengths, corresponding to the two paths of processing. Accordingly, training is performed in
two phases, in both cases using cross-entropy backpropagation (Rumelhart, Hinton, \& Williams, 1986) with weight updates after each word in the sentence of each training item.
probabilities. The first phase corresponds to the training of the path leading to probabilities, which is performed as described by Calvillo et al. (2016), where the model is trained to predict the next word given the semantic representation and the previously produced words.

During this phase, the monitoring units were set at time $t$ to what the model was supposed to produce at time $t-1$ (zeros for $t=0$ ). This reflects the notion that during training the word contained in the training sentence at time-step $t-1$ should be the one informing the next time step, regardless of the previously produced (and possibly different) word. During production, the monitoring units are set to 1.0 for the word that was actually produced and 0.0 everywhere else.

This path was trained for a maximum of 200 epochs, each one consisting of a full presentation of the training set, which was randomized before each epoch. Note that each item of this set consisted of a $D S S_{i}$ paired with one of the possible sentence realizations describing the state of affairs represented in $D S S_{i}$. Hence, during each epoch, the model saw all the possible realizations of $D S S_{i}$. An initial learning rate of 0.124 was used, which was halved each time there was no improvement of performance during 15 epochs. No momentum was used. Training halted if the maximum number of epochs was reached or if there was no performance improvement over a 40-epoch interval.
der lengths. The second path can be trained after the training of the first one is completed. During this phase, the connection weights calculated during the first phase are fixed, so that only the second path weights are modified.

At each time step, the DSS is fed into the first path, which outputs a probability distribution over the vocabulary. This is fed into the second recurrence, as well as the DSS representation. Monitoring units are handled exactly as in the first training phase. The activation of the second recurrence is then propagated to der_lengths. Its output is compared to the derivation length values, as defined in the previous section, and finally the connection weights are updated.

Training of this path was performed for a maximum of 80 epochs, with the training items arranged in the same way as in the previous phase. An initial learning rate of 0.24 was used, which was halved each time there was no improvement of performance during 10 epochs. No momentum was used. Training halted if the maximum number of epochs was reached or if there was no performance improvement over a 20-epoch interval.

## Evaluation

The model presented defines a production strategy as an interaction between production goals. Thus, in order to assess the model, its productions were compared to those obtained by using the following alternative strategies, where at each
time step the model produces the word with:

- Min Linguistic Surprisal
- Min Derivation Length
- Max Word Probability +/* Derivation Length Score
- Complete Model

For each DSS representation in the examples set that was related to more than one sentence (968), the model generated a sentence according to each production strategy.

In order to measure surprisal, a language model was trained implementing a Simple Recurrent Network (Elman, 1990). This model was trained on the whole set of sentences for 200 epochs with a learning rate of 0.24 which was halved each time there was no improvement in performance. Using this language model, surprisal values were calculated for each one of the words of the produced sentences.

Uniformity of information density was measured in terms of standard deviation of word surprisal, assuming that complete uniformity would produce a standard deviation of 0 .

## Results and Discussion

The results can be seen in Table 2, where the columns denote respectively: production strategy, production accuracy (Acc) as defined by Calvillo et al. (2016) and denoting how precise the sentences convey the given semantics, average sentence length (AvDL), average word surprisal (AvS), and standard deviation of surprisal (Std).

Table 2: Results of each production strategy.

|  | Acc | AvDL | AvS | Std |
| :---: | :---: | :---: | :---: | :---: |
| Min LS | 99.67 | 9.01 | 1.0 | 0.89 |
| Min DL | 99.86 | 7.55 | 1.20 | 0.97 |
| Max P(+/*) DL | 99.82 | 7.77 | 1.16 | 0.95 |
| Max 3P-2DL | 98.23 | 10.15 | 0.89 | 0.84 |
| SemSurp | 97.67 | 10.17 | 0.89 | 0.83 |

As expected, minimizing linguistic surprisal (Min LS) led to lower surprisal values compared to minimizing derivation lengths (Min DL). Combining these two strategies by a sum or product led to results almost identical to each other, and very close to Min DL, suggesting that derivation length scores were mostly dominating production.

Given that linguistic surprisal and derivation lengths are different in nature, one can expect a more complex relation between them in order for the resulting score to be helpful. Consequently, grid search was performed in order to find linear factors that would minimize the standard deviation of surprisal. The resulting model corresponds to the fourth row in Table 2, where the model produces at each time step the word that maximizes:

$$
3 P\left(w \mid D S S, w 0, . ., w_{n}\right)-2 D L(w \mid D S S, \text { probabilities })
$$

where one can see that minimizing linguistic surprisal is favored, while minimizing derivation lengths is penalized. As a result the sentences produced are longer than only minimizing linguistic surprisal. However, uniformity of information density is higher than with the previous models and additionally average surprisal is lowest.

The final row in Table 2 presents the results of the model that incorporates semantic probabilities. For this case grid search was also used, which led to a model that at each time step produces the word that maximizes:

$$
(3.5-P(D S S)) P(w \mid \ldots)+(P(D S S)-2.5) D L(w \mid \ldots)
$$

which is very similar to the previous model, but with some influence from semantic probabilities. While the performance of this model is very similar to the previous one, its sentences present slightly higher uniformity of information density; and the influence of semantic surprisal is in the expected direction, where semantics with high surprisal produce longer sentences and vice versa.

The small difference between the last two strategies could be caused by the nature of the language model, which receives no semantic information during training, which means that rather than being a joint model of semantics and sentences, it only considers word sequences. Furthermore, the production model here proposed uses semantic surprisal at a sentence level, while speakers can be sensitive to this information incrementally at a word level. These issues will be addressed in future work.

In general the model outlined here shows: first, that as expected, shorter sentences are more dense in terms of information content. Second, that longer sentences present information in a more uniform way. Third, that sentences with more uniform information densities present in average lower word surprisal, therefore minimizing comprehension effort. And finally and most importantly, that sentences with higher uniformity of information density can be produced by balancing sentence lengths and word probabilities. In future work, this can help to address uniformity for a given channel capacity.

## Conclusion

This article presents a model of language production that takes into account word probabilities and sentence lengths in order to produce sentences with uniform surprisal profiles, and in order to model the Uniform Information Density Hypothesis. The sentences produced by this model were compared to those produced using other strategies, showing that the proposed model produces sentences with more uniform surprisal profiles and lower average word surprisal. This model represents a first attempt to model the Uniform Information Density Hypothesis at the algorithmic level, where uniformity arises by balancing word probabilities and sentence lengths in a mechanistic way.

# Learning to Learn Visual Object Categories by Integrating Deep Learning with Hierarchical Bayes 

Andres Campero (campero@mit.edu)<br>Andrew Francl (francl@mit.edu)<br>Joshua B. Tenenbaum (jbt@mit.edu)<br>Department of Brain and Cognitive Sciences<br>Massachusetts Institute of Technology, MA 02139 USA

#### Abstract

Humans are capable of generalizing and learning new concepts after very little experience. They have the ability to create semantic structures from concepts they acquire, they can learn appropriate inductive biases that are later used as priors for different tasks, and they can learn novel categories from very few examples. While recent advances in neural networks and other machine learning methods are beginning to approach humanlevel capabilities in several tasks, building computational models that replicate these abilities has proven difficult. We propose a model that combines powerful features extracted from a deep neural network with a semantic structure inferred using probabilistic Hierarchical Bayes. We test and demonstrate the capabilities of our model in three different tasks: learning a new concept from a single example of a novel category, learning new categories from few examples of different categories, and learning the semantic tree from an unlabeled set of novel objects.

Keywords: hierarchical bayes; one-shot learning; inductive bias; neural networks; unsupervised learning

## Introduction

Recent advances in neural networks and other machine learning methods have led to computer vision object-recognition systems that are beginning to approach human-level performance. Trained on thousands of object categories, with thousands of labeled examples for each, deep convolutional networks can tell if a new image contains a familiar category almost as well as human adults can in a brief glance. Yet, even young children have abilities to learn and generalize that go beyond what current machine vision systems can do. Here we focus on three such abilities:
(1) By age 3, children can learn new object categories from just a single example. Furthermore, children generalize in different ways as appropriate for different kinds of categories: labels for artifacts with functionally relevant shapes are preferentially generalized according to those shapes, while labels for non solid substances or arbitrarily shaped objects are more likely to be generalized according to material properties.
(2) Children can learn to learn appropriate inductive biases, such as the shape and material biases described above, from experience with just a few examples each of a small number of categories that exemplify these biases in a consistent way. The shape-bias training studies of Smith and colleagues are the best known examples (Smith, Jones, Landau, GershkoffStowe, \& Samuelson, 2002).
(3) Children can, in a completely unsupervised way, sort novel objects into categories and supercategories in a meaningful way, and then use these hierarchical category structures
as strong constraints to learn and generalize names for objects from just one or a few examples.

Previous attempts to capture these abilities in computational models have had some success, but not with models that are "image-computable" on the same stimuli that people see. These earlier models have used either adult similarity judgments (Xu \& Tenenbaum, 2007) or highly simplified, idealized feature representations (Kemp, Perfors, \& Tenenbaum, 2007) to build their category hierarchies. Here we show that a computational framework can come close to capturing abilities (1-3) by combining two powerful representation-learning techniques: deep learning for feature construction and Hierarchical Bayes for unsupervised taxonomy construction.

We build on work by Salakhutdinov, Tenenbaum, and Torralba (2012) who build a Hierarchical Bayesian model that "learns to learn" by incorporating information from past experience into a prior when inferring statistical properties of a novel category. In particular, when presented with a few image examples of a new category, the model infers a supercategory and uses the higher-order knowledge abstracted from previous categories to identify the relevant features and allow generalization (Figure 1).

Figure 1: Learning a similarity metric for a new category. The goal is to identify the correct supercategory and estimate an appropriate similarity metric.

That work was extended by the same authors, who harnessed a two layer Deep-Boltzmann Machine to generate low level feature representations of the images while learning a prior using a hierarchical Dirichlet process. (Salakhutdinov,

Tenenbaum, \& Torralba, 2013). Their experimental data showed that using this prior in combination with more powerful features gave them a distinct advantage over other methods of classification. This progression of work suggests that building a model that combines complex feature spaces with a hierarchical semantic structure may lead to further increases in performance.

Building on this line of work, we contribute a model that combines the two components: powerful image representations extracted from Deep Neural Networks (DNNs) and a Hierarchical semantic structure that works as a Bayesian prior. We show how the combination of these two components can "learn to learn" in ways that resemble some aspects of child cognition. Additionally, we explore how this model's performance is affected as we vary different aspects of the model architecture and the structure of the training data.

Other approaches to combine probabilistic graphical models and DNNs have recently been proposed that focus on building unsupervised clustering algorithms (Dilokthanakul et al., 2016; Johnson et al. 2016). Instead, the focus of our model is to capture certain aspects of human cognition. This leads to some notable differences. First, representations in our model are a fixed set of visual relevant features instead of being learned for the inference task at hand. In addition, our model's generative component is limited to a hierarchical structure that aims to recover the semantic relations between concepts in a useful and meaningful way while other models are fully generative but tend to have graphs with simpler semantic structures. We therefore propose a relatively simple model that is not intended for general unsupervised learning but that instead focuses on traits of human object and category learning.

More specifically, we test our model's capacity to capture the previously discussed human abilities (1-3) in an image recognition framework. First, we evaluate the ability of our model to learn novel categories from only one or a few examples. To address this we allow the model to construct a semantic structure from labeled examples in a data set and then judge the model's performance on a one-shot learning task. Second, we assess the models capability to construct inductive biases in low data environments. We test this ability by repeating the first task but limiting the training data available to the model when it constructs the semantic tree. Finally, in a third task, we test the model's ability to learn a hierarchical semantic structure of novel objects in a completely unsupervised manner. Results suggest that this approach may be suitable for modeling certain aspects of cognition.

## Model and Learning to Learn

Our model combines two Machine Learning approaches that have recently been successful at a range of differing tasks. On one hand, powerful deep networks construct feature spaces that enable rapid and accurate classification. On the other, Hierarchical Bayesian Models have proven successful in creating taxonomies of the different concepts learned from pre-
vious experience. These taxonomies can then be used as a prior to identify the relevant features for learning a new category from one or a few examples based on the distribution of other similar categories. We create various versions of our model to compare combinations of feature spaces extracted from different architectures with variants of the Hierarchical Bayesian component.

Learning begins by constructing a 2-level tree of categories and supercategories that best explains the training observations under a Bayesian framework. The model learns structure in the observations by first generating useful general features from a DNN and then developing hierarchical priors that allow previous similar experiences to bias the learning of new concepts and categories. The priors are constructed by inferring the means and variances that define the most relevant dimensions from the DNN feature representations for each category and supercategory (Figure 1).

## Deep Network Features

We use features extracted from DNNs pretrained for object classification on ImageNet. We obtain a representation from each image by passing it through a network and extracting the response from the penultimate layer consisting of 4096 realvalued dimensions. In the regular deep network classification scheme, this response is then passed through a linear weighting and a generalized logistic regression layer. This layer maps this representation onto probabilities for each class in the specific classification task for which the network was trained.

We compare the performance of the different versions of our model on features extracted from two different DNN architectures: Alexnet (Krizhevsky, Sutskever, \& Hinton, 2012), which was the first implemented Deep Learning Model that significantly improved object classification on images; and VGG-16 (Simonyan \& Zisserman, 2014), a more recent architecture with 16 layers that achieves above $90 \%$ top 5 classification performance on ImageNet.

## Generative Semantic Organization

After obtaining a useful general image representation from the DNN, the Hierarchical Bayesian Model's parameters are inferred by approximating the posterior via Markov Chain Monte Carlo methods in the following way.

Consider a two-level hierarchy where $N$ observed inputs are partitioned into $C$ basic-level categories, these categories are in turn partitioned into $K$ supercategories. In this hierarchy of observations, categories, and supercategories, the higher levels determine a prior over the distribution of the lower levels. In particular, the distribution over observations (feature vector representations of images in our case) of each of the different basic level categories are assumed to be multivariate Gaussian with a category specific mean $M_{c}$ and with precision terms $\tau_{c}^{d}$ that are assumed to be independent across the $D$ dimensions of the feature space. These precision terms constitute a similarity metric by determining the relative importance of each of the features. In turn, we place a conjugate

Normal-Gamma prior over $\left\{M_{c}, \tau_{c}\right\}$, this prior is determined by the supercategory specific level-2 parameters $M_{k}, \tau_{k}, \alpha_{k}$, where $M_{k}$ and $\tau_{k}$ constitute the expected values of the lower level parameters and $\alpha_{k}$ controls the variability of $\tau_{c}$ around its mean. Finally, for the conjugate priors over the level-2 parameters, we respectively assume Normal, Exponential and Inverse-Gamma distributions that are further shaped by parameters $\alpha_{0}$ and $\gamma_{0}$. The full generative model is given in Figure 2 (Salakhutdinov et al., 2012).

Figure 2: Hierarchical Model
Given a set of observations, the model iteratively performs Bayesian inference by alternating between sampling the parameters and inferring the category assignments. When learning the distributions at each step of the iteration, the supercategory membership is fixed and the parameters are sampled from posteriors that are analytically computed using the conjugate priors ${ }^{1}$. The supercategory membership for each category is learned in a similar way by fixing the currrent parameters and the rest of the hierarchical structure. Every category can be assigned to any of the existing supercategories or to a newly created one. The posterior probability of belonging to a supercategory is computed as a combination the likelihood that the parameters of the category come from the parameters of the supercategory and a Chinese Restaurant Process (CRP) prior (Griffiths \& Tenenbaum, 2004). This nonparametric prior is a distribution over a partition on integers in which the $n^{\text {th }}$ number is assigned to set $k$ with probability:

[^294]\[

P\left(z_{n}=k \mid z_{1}, z_{2} ···, z_{n-1}\right)= $$
\begin{cases}\frac{n^{k}}{n-1+\gamma} & \text { if } n^{k}>0 \\ \frac{\gamma}{n-1+\gamma} & \text { if } \mathrm{k} \text { is new }\end{cases}
$$
\]

Where $n^{k}$ is the number of previous integers assigned to set $k$ and $\gamma$ is a concentration parameter sampled from a $\operatorname{Gamma}(1,1)$ distribution.

In an unsupervised setting where the categories of the observations are also unknown, the model utilizes a similar strategy to assign observations to categories as is used when assigning categories to supercategories. The model iterates through the observations and assigns each either to an existing or to a newly created category based on the prior and likelihood. By utilizing the CRP prior, the model can create an unbounded number of categories and supercategories. This entire process constitutes a Gibbs sampling procedure where both the tree structure and all of the parameters are simultaneously learned.

## Tests and Results

We test the model in scenarios that attempt to capture aspects of human cognition related to learning from limited data. First we measure the model's ability to generalize previous knowledge to learn novel categories from only a few examples. Next, we assess the model on this task when the training data for all of the categories is also limited to only a few examples. Finally, we exploit the model's full hierarchy in a completely unsupervised setting by exploring how the model recovers the underlying semantic structure.

## One-Shot Learning on MSR

In the first task, we test the model's ability to learn new categories form one or a few examples. First, we select a category that will be held-out for testing. Labeled observations for all other basic-level categories are provided for training. The model learns the semantic structure of the training set by clustering the basic categories into supercategories and inferring the relevant parameters at all levels of the Bayesian Hierarchy. The challenge is then to generalize the learned structure to the held-out category from only one or a few examples.

To do this, the model first infers the best supercategory from one or a few examples of the withheld category by

Table 2: Performance results using the area under the ROC curve (AUROC) on the MSR dataset with limited training data.

marginalizing over the category level parameters. Next, the model uses the supercategory priors and training examples to estimate the category similarity metric and mean for each dimension in the feature space.

We evaluate different versions of our model on the MSR Cambridge dataset (Kohli et al., 2005), which consists of 24 categories with varying numbers of images in each category. In total this dataset contains roughly 800 images. Figure 3 shows a typical partition over all the categories discovered by the full model. To quantify the models accuracy, a testset with unlabeled data from all categories is classified.

We repeatedly trained the model withholding one of the categories at a time and then inferred the withheld category parameters and supercategory membership using one or a few images. Next, we calculated the posterior probability for each testset image belonging to each category and variated a threshold to classify images as belonging to the heldout category or to any of the other categories. This created true and false positive rates for each point along our threshold which traced out a Receiver Operating Characteristic curve (ROC) for classifying objects from the withheld vs. all the other categories. The reported results are calculated by averaging the Area Under the ROC curve (AUROC) for the model trained with each of the 24 categories withheld (Table 1).

Performance is compared for each combination of an Inference Model and a Network Architecture. HB-Full is the full version of the model described above. One Supercategory places all the categories in the same single supercategory. NearestN classifies new points with the label of the nearest neighbor of its feature vector in euclidean distance. Texture of Textures (T of T)* replaces our DNN features with the set of responses from a three layer convolutional neural network that uses precomputed weights that resemble Gabor filters ${ }^{2}$. Finally, the Oracle is the same than our full model, but uses the true empirical mean and variances from the whole population (including testset). Table 1 shows the results for the two different feature spaces used.

[^295]

Figure 3: MSR semantic tree discovered by the Full Model
The results show that the model performs best when using the full hierarchy in combination with the feature space extracted from VGG. HB-Full considerably outperforms alternatives under both feature spaces, particularly for trials with one example from the withheld dataset. As more examples become available, the performance difference decreases reflecting the importance of the prior when little data is available. The importance of the learned features is highlighted when comparing with the T of $\mathrm{T}^{*}$ feature space where performance is considerably lower. It is interesting to note that the VGG representation improves most over Alexnet when in combination with NearestN, but the effect is mitigated when the hierarchy is used.

## Limited training data regimes

In a second task, we test the capability of our model to extract inductive biases from experience with just a few examples. To evaluative this capability, our full model was limited to only $1,4,10$ or 18 examples of each category used for training. The number of examples from the withheld category was varied separately. Table 2 shows the average AUROC for the same "one vs. all" metric used in the previous task ${ }^{3}$. For comparison, the full model performance from the previous table is included and labeled as "All examples" ${ }^{4}$.

We can see that the largest jump in performance happens when moving from 1 to 4 training examples. This likely reflects the fact that a single example provides information about the mean of the category but not about the variance or similarity metric, which has to be inferred completely from

[^296]the prior. However, 4 examples provide adequate information about the variance to allow the model to appropriately infer the parameters for new categories. As the number of training examples continues to increase, there are no further gains in performance. This is consistent with literature showing that children need at least two examples to learn inductive biases in certain contexts (Smith et al., 2002).

## Unsupervised Learning on Gazoobian Objects

Humans and children can sort new objects into categories and supercategories in a semantically meaningful way. While our model is also able to of recover meaningful structure from labeled examples (Figure 3), real situations often demand learning where labels are completely absent. Schmidt (2009) explores this human capability with a dataset composed of 45 novel objects that were generated using a modeling software to simulate a specific taxonomic structure. The dataset consists of three supercategories supposed to be alien equivalents of plants, tools and snails from the planet "Gazoob". The objects in each supercategory are further organized into a structure that can be approximated by basic-level categories (gray box in Figure 4).

Our model has the ability to infer both categories and supercategories in an unsupervised manner from observations. Schmidt (2009) shows that a model based on agglomerative clustering that uses adult similarity judgments is able to recover the taxonomic tree (Figure 4). Here our model is tested with the harder task of recovering the taxonomic tree directly from the same images that people saw. The model accomplishes this task in a fully unsupervised manner using a single image of each object.

This "image-computable" model is able, although with some mistakes, to recover the three supercategories and most of the basic-level category structure (Figure 5). Other unsupervised clustering algorithms were also able to capture some of the semantic structure, but the hierarchy between categories and supercategories was not evident.

## Discussion

One can think of the task of concept learning as consisting of two elements. The first involves obtaining relevant features to represent the objects and categories commonly observed in the world. The second involves constructing a semantic hierarchical structure with links between categories that humans can use to navigate and perform tasks. While recent results demonstrate the capabilities of DNNs to classify categories provided a large number of training examples, they struggle to perform tasks that require understanding the semantic relationships between classes. The ability of Hierarchical Bayesian Models to build these semantic structures can further help with understanding and classifying new categories.

We demonstrate how these two approaches can complement one another by combining them in a computational model. We tested the model's abilities tasks designed to approximate human capabilities that are currently difficult for computer vision systems such as concept generalization,
learning inductive biases, and constructing semantic structures. We show results for three tasks involving limited data availability. The model is able to learn relevant semantic structures from just a few examples of novel objects and effectively transfer appropriate similarity metrics from learned categories in the form of a prior. In all tasks, the computational framework comes close to capturing human abilities that other, more complex, machine vision systems struggle to reproduce.

#### Abstract

Recent studies demonstrate a puzzling decline in relational reasoning during development. Specifically, 3-year-olds fail in a relational match-to-sample (RMTS) task, while younger children (18-30 months) succeed (Walker, Bridgers, \& Gopnik, 2016). Hoyos, Shao, and Gentner (2016) propose that older children fail because of a bias toward individual object properties induced by "avid noun learning." If this is the case, children learning a language with a stronger emphasis on verbs, like Mandarin Chinese, may show an attenuated decline in relational reasoning. We first test this possibility by reproducing the causal RMTS task in China, and find that Mandarin-speaking 3 -year-olds outperform their Englishspeaking peers in the U.S. In a second experiment, we show that Mandarin speakers exhibit a corresponding bias toward relational solutions while English speakers prefer objectbased solutions in an ambiguous context. We discuss possible mechanisms through which language and culture may promote (or hinder) the early development of relational reasoning.

Keywords: cognitive development, causal learning, relational reasoning, overhypotheses, language, culture.

## The puzzling decline of relational reasoning

Relational reasoning is often cited as a defining feature of human cognition (e.g., Gentner, 2003), and a source of the differences between the abilities of humans and other primates (Penn, Holyoak, \& Povinelli, 2008). The ability to recognize relational similarities appears surprisingly early in human development: 7- and 9-month-old infants distinguish the abstract relations "same" and "different," looking longer at novel pairs of objects that differ from a habituated relation (Ferry, Hespos, \& Gentner, 2015; Tyrrell, Stauffer, \& Snowman, 1991).

Toddlers (18-30 months) can also employ these concepts to infer abstract causal properties in a relational match-tosample task (Walker \& Gopnik, 2014). In this task, children observe as four pairs of blocks are placed on a toy that plays music when "activated." Two of the pairs contain identical blocks ("same") and the other two pairs contain mismatched blocks ("different"). For toddlers in the same condition, the toy activates and plays music only when the "same" pairs are placed on top, while those in the different condition observe the opposite pattern. When shown novel pairs of "same" or "different" blocks and asked to choose which pair
would activate the toy, toddlers succeed in picking the pair that is relationally consistent with their training.

However, this early success in relational reasoning is quickly followed by a puzzling decline: 3-year-olds (36-48 months) fail to select the relational solution in precisely the same task (Walker, Bridgers, \& Gopnik, 2016). Similar difficulties have also been observed in a variety of relational reasoning tasks (e.g., Christie \& Gentner, 2007; 2010; 2014; Gentner, 1988; 2010; Hoyos, Shao, \& Gentner, 2016). By 4 years of age (52-60 months), children once again succeed in a standard RMTS task (Christie \& Gentner, 2014), but continue to neglect relational similarities in other contexts even at 5-6 years of age (e.g., Gentner, 1988). This pattern of early success, decline, and reemergence suggests that the development of relational reasoning may follow a U-shaped trajectory, rather than a continuous process of gradual improvement, as previously suggested (e.g., Gentner \& Medina, 1998). What causes this curious dip in children's relational reasoning?

One possibility is that preschoolers retain an early competence to reason about relations, but that this competence is overshadowed by a failure to attend to relational structure. In particular, Walker et al. (2016) suggest that 3 -year-olds neglect relational information as a result of a learned bias to attend to individual object kinds and their properties. This claim is consistent with a large literature demonstrating that preschool-aged children attend to objects and attributes, and proposals that children must overcome an "entity-based view" in order to effectively process relations (Christie \& Gentner, 2010; also, e.g., Christie \& Gentner, 2007; 2014; Gentner, 1988; Gentner \& Rattermann, 1991; Hall \& Waxman, 1993).

Several proposals link this well-documented object bias to language development, which has been shown to both foster and impair relational reasoning (e.g., Christie \& Gentner, 2014; Hoyos, Shao, \& Gentner, 2016). These seemingly incongruous findings have led some to regard the contradictory effects of language on relational thinking as a developmental paradox (Hoyos, Shao, \& Gentner, 2016).

## Noun learning and relational development

In a recent paper, Hoyos, Shao, and Gentner (2016) suggest that the decline of relational reasoning may stem from an object bias induced by language learning. They reason that
"avid noun-learning" in early childhood likely leads to a "captivation with objects," which in turn helps children to learn additional nouns. In support of this view, they provide evidence that an experimentally induced noun bias interferes with relational reasoning. In this experiment, they replicate a previously published finding (Christie \& Gentner, 2014) that 4-year-olds succeed on a standard RMTS task in a baseline condition, but show that priming nouns in a picture-labeling activity significantly reduces subsequent RMTS performance. On its own, this outcome suggests that language learning-and an emphasis on nouns in particular-may negatively impact relational reasoning in toddlers.

However, earlier work by Christie and Gentner (2014) leads to the opposite conclusion, that linguistic conceptsand nouns in particular-facilitate relational reasoning in the standard RMTS task. They find that providing children with a novel noun ("truffet") for pairs of objects improves toddlers' subsequent RMTS performance. Here, and elsewhere, the authors argue that young children do not initially have access to a hypothesis space that is "sufficient to allow for the range of possible semantic categories" but instead form hypotheses about relational meanings by comparing co-labeled items to identify common structure (Christie \& Gentner, 2010).

Taken together, this account and the conflicting findings create an apparent paradox, in which a linguistic emphasis on nouns orients young learners away from relations, but language simultaneously provides the necessary scaffolding for relational learning by highlighting relational structure. In this way, language learning appears to solve the very problem it creates. Accordingly, this account implies that language learning may be interpreted as a double-edged sword, drawing attention to objects at the expense of relations, but in doing so, ultimately helping children to construct novel relational categories.

## Language as a driver of children's hypotheses

The current research further explores the hypothesis that language learning influences the types of concepts and categories that young children entertain. Under the paradox account presented above, language learning helps children develop new relational categories to further populate their hypothesis space. An alternative possibility is that children have access to both relational and object-based hypotheses throughout development, but that the probabilities assigned to each type of hypothesis change as a result of prior knowledge and past experience, including language learning. This account draws on probabilistic models of cognitive development in which children are seen as Bayesian learners (e.g., Gopnik \& Wellman, 2012), who weight the likelihood of a given hypothesis (the probability of the data given the hypothesis) by its prior probability (the general probability of the hypothesis, before any data are observed). Consequently, if a hypothesis has high prior probability, it will require stronger data to overturn it. This reasoning may also be applied to entire categories of
hypotheses in the form of an overhypothesis, a general principle by which the learner assigns higher prior probability to particular types of hypotheses (Kemp, Perfors, \& Tenenbaum, 2007). From this perspective, the "noun explosion" in early language learning could motivate an object bias-and temporary dip in relational reasoningin the form of an overhypothesis that privileges object-based hypotheses over relational ones (for a discussion of language-induced overhypotheses and their relevance beyond language, see Colunga \& Smith, 2005). By this account, language acts as one of many possible influences that affect a learner's hypothesis space, not by providing for new hypotheses (as the paradox view suggests), but by adjusting children's existing prior expectations.

Despite this distinction, both of these accounts leave room for an important role of language in driving children's relational reasoning, and both predict that a noun focus in word learning would (at least initially) bias children toward object properties and away from relations.

Previous demonstrations (e.g., Christie \& Gentner, 2010; Hoyos, Shao, \& Gentner, 2016) have tested this hypothesis indirectly, showing that immediate exposure to nouns modulates success on RMTS tasks, presumably by directing the learner's attention toward or away from relational information. However, these findings (which may reflect simple priming effects) do not necessarily demonstrate a relationship between noun focus in word learning and RMTS performance, as the experimental groups all involve English speakers, without any systematic between-group differences in degree of noun focus.

Conveniently, not all word learning follows the same trajectory. In particular, the "noun explosion" that has been documented in English-language learners is not universal across languages. In Korean, for instance, there is evidence for a comparable "verb spurt" (Choi \& Gopnik, 1995). Similarly, several studies have found that children learning Mandarin Chinese produce more verbs than nouns in their spontaneous speech (both types and tokens), in contrast with English speakers of the same age, who produce a greater proportion of nouns than verbs (Tardif, 1996; Tardif, Shatz, \& Naigles, 1997).

If an emphasis on noun learning (relative to other parts of speech) indeed drives the dip in relational reasoning by fostering an object bias, then children learning a more verbcentric language should show an attenuated or reversed bias. While nouns may direct focus to object properties by relying on these in picking out meanings, verbs often signal relational meanings across multiple entities, and might serve to redirect attention accordingly.

The difference in noun focus between English and Mandarin Chinese therefore presents two natural conditions in word learning, which we exploit as a test of the proposal that properties emphasized in word learning induce a bias in reasoning more generally.

## Experiment 1: Causal relational reasoning in Mandarin-speaking children

To test for a relationship between noun focus in word learning and relational reasoning, we first reproduced Walker et al.'s (2016) causal RMTS task (see Figure 1) with Mandarin-speaking children (36-48 months) in China.

## Methods

Participants. A total of 64 Mandarin-speaking 36-48-month-olds ( $M=42.1$ months; 28 female) took part in Experiment 1. This sample size was chosen based on previously published studies using the same paradigm. Participants were pseudo-randomly assigned to either the same or different condition. Five additional participants were excluded due to experimenter error or failure to complete the study. All participants were native speakers of Mandarin Chinese, and were recruited and tested at preschools in China.

Materials and procedure. The materials and procedure replicated those used in Experiment 1 of Walker et al. (2016), with the exception that instructions were given in Mandarin Chinese. The original English instructions (described here in English) were independently translated and backtranslated to ensure accuracy.

Children were tested individually, seated at a table across from the experimenter. The causal RMTS task began after a brief warmup to familiarize the child with the experimenter. During the task, the experimenter placed matching and mismatched pairs of painted wooden blocks on top of a box which appeared to play music in response to certain blocks. In reality, the experimenter activated a wireless doorbell inside the box by surreptitiously pushing a button.

The experimenter began by placing an opaque cardboard box on the table, saying "This is my toy! Sometimes it plays music when I put blocks on top and other times it does not. Should we try some and see how it works?" The experimenter then produced two blocks, said "Let's try!" and put both blocks on top of the toy simultaneously. The toy played music and the experimenter said "Music! My toy played music!" The experimenter picked up the blocks and set them back on the toy, which again played music, saying "Music! These ones made my toy play music!" She then repeated this procedure with a new pair of blocks in the opposite relation. The new pair did not make the toy play music, and the experimenter responded to the first try with "No music! Do you hear anything? I don't hear anything," and after the second try, said "No music. These ones did not make my toy play music." This pattern was repeated with two additional pairs of blocks. The experimenter always began with a causal pair (identical blocks in the same condition and blocks of differing colors and shapes in the different condition), and alternated inert, causal, inert, using novel blocks in each new pair, and randomizing the specific blocks between participants.

Figure 1: Schematic illustration of training and test trials in Experiment 1. Reprinted from Walker et al. (2016).

After the four training trials, the experimenter said "Now that you've seen how my toy works, I need your help finding the things that will make it play music. I have two choices for you." The experimenter presented the child with two new pairs made of novel blocks, one "same" pair and one "different." Each pair was supported by a tray, which the experimenter held up as she said "I have these...and I have these. Only one of these trays has things that will make my toy play music. Can you point to the tray that has the things that will make it play?" They trays were placed on either side of the toy, just out of reach of the child, with the side of the correct pair and order of presentation counterbalanced between participants. The experimenter recorded the child's first point or reach, and scored the answer as correct if the child chose the test pair (same or different) that corresponded to her training.

## Results and discussion

Mandarin-speaking preschoolers selected the test pair that was consistent with their training in both same ( $69 \%$; onetailed binomial $p=.025$ ) and different ( $72 \%$; one-tailed binomial $p=.010$ ) conditions (see Figure 2). ${ }^{1}$

[^297]

Figure 2: Proportion of correct relational matches selected by English- and Mandarin-speaking toddlers. English speaker data is reproduced from Experiment 1 of Walker et al. (2016). Error bars indicate $95 \%$ confidence intervals.

As predicted, Mandarin-speaking preschoolers succeed in the RMTS task at an age at which their English-speaking counterparts fail (English speakers in the Walker et al. study performed at chance in both same (46\%) and different ( $43 \%$ ) conditions). ${ }^{2}$ Although this outcome is consistent with an account in which verb-focused word learning biases children toward relational solutions, it is also possible that Mandarin speakers succeed at the task for more general reasons (attention, etc.), without having a relational bias.

We can discriminate these two possibilities by examining bias in an ambiguous task, with both relational and object matches available, and no definitive correct answer. If Mandarin-speaking toddlers succeeded in Experiment 1 because of a general aptitude for test-taking, and not a specific bias toward relations, then they should respond at chance in a modified RMTS with no correct answer. Additionally, if an object bias is responsible for the poor performance of English speakers (and not just random responding), then we should observe systematic preferences for object matches when there is no conflicting evidence for relations. In Experiment 2, we assess these possibilities.

## Experiment 2: Comparing relational and object focus across cultures

Experiment 2 tests for baseline differences in bias toward relational or object-based hypotheses across Mandarin and English speakers. To do this, we created an ambiguous paradigm, in which it is unclear whether a particular object or the relationship between objects is causal. Specifically,

[^298]we presented children with a "different is causal" condition, in which the same object appears in each of the causal pairs (see Figure 3). In this case, it is perfectly reasonable to infer that either the individual object (i.e., the blue square) or the relation (i.e., different) produced the effect. We pit these options against each other by presenting the same objects in the test pairs. The individual objects come together to create a "same" pair-which is correct with respect to the object hypothesis, but incorrect with respect to the relational hypothesis, and the other objects associated with the effect come together to create a "different" pair-which is correct with respect to the relational hypothesis and incorrect with respect to the individual object hypothesis.

If a focus on verbs in early language learning induces a bias toward relational hypotheses, we should observe a tendency toward relational solutions in Mandarin-speaking toddlers, and a converse bias toward objects in nounfocused English-speaking toddlers.

## Methods

Participants. A total of 112 3-year-olds participated in Experiment 2, 56 native Mandarin speakers ( $M=41.4$ months; 28 female) and 56 native English speakers ( $M=$ 41.4 months; 21 female). An additional 11 children were tested but excluded as a result of experimenter error or failure to complete the study. Mandarin-speaking children were recruited and tested at preschools in China, and English speakers at preschools and museums in the U.S. In all settings, children were tested individually with the experimenter in a private room.
Materials and procedure. Materials were identical to those in Experiment 1, and the procedure closely resembled that of the "different" condition, but with several modifications to create an ambiguous causal structure (see Figure 3).

Test Trial
Figure 3: Schematic illustration of ambiguous training and test trials in Experiment 2, in which the evidence was consistent with both object and relational solutions.

First, one of the blocks (represented by the blue square in Figure 3) appears in both different pairs. This reoccurring block provides the object-based hypothesis (i.e., the blue
square is causal). Second, the test trial included two pairs composed of blocks that were previously observed in the "different" training pairs. Finally, due to the constraints of the study design, it was not possible to present an ambiguous same condition. As a result, Experiment 2 only included the different condition. As in the previous study, the experimenter asked the child to choose the pair that would activate the machine. The child's first point or reach was scored as consistent with either an object selection or a relational selection.

## Results and discussion

Given an ambiguous choice between object and relational matches, English-speaking preschoolers selected the object match ( $64 \%$; two-tailed binomial $p=.044$ ) and Mandarinspeaking preschoolers chose the relational match ( $66 \%$; two-tailed binomial $p=.022$; see Figure 4).

Figure 4: Proportion of object and relational matches selected by English- and Mandarin-speaking toddlers in Experiment 2. Error bars indicate $95 \%$ confidence intervals.

## General discussion

In two experiments, we find that Mandarin-speaking children tend to privilege relations whereas Englishspeaking children tend to privilege individual objects, often missing the abstract relation.

In Experiment 1, we evaluated whether the noun focus in English word learning can account for the dip in relational reasoning observed in English-speaking preschoolers. To do so, we examined relational reasoning in Mandarin-speaking preschoolers, whose early language learning is more focused on verbs. Consistent with the noun-focus account, we found that Mandarin-speaking preschoolers substantially outperform their English-speaking peers in identifying shared relational structure in the RMTS.

In Experiment 2, we tested for the key factor predicted to mediate the relationship between language and RMTS performance. This study explored whether English- and Mandarin-speaking preschoolers exhibit differing biases toward relational and object-based solutions. Indeed, we found that in an ambiguous context with no correct answer, Mandarin speakers tend to favor solutions consistent with
relational hypotheses and English speakers show a contrasting object bias.

It is important to note that while English-speaking preschoolers have often exhibited poor performance in relational tasks of the same format, their consistent selection of object-based matches in this experiment is not trivial. Choosing the object match may indeed present a more challenging cognitive task. In order to select the object match at test, children must track and remember the relevant object (the blue square) throughout the training trials, which (perhaps counterintuitively) increases the cognitive load compared with learning the abstract relation, which does not require tracking of any particular objects. Accordingly, this outcome demonstrates a surprising competence on the part of English-speaking preschoolers, which may also be attributable to their noun-centric language learning.

Taken together, these findings inform potential sources of bias in early learning and the development of relational reasoning. In particular, they rule out the possibility that language learning in general produces an object bias. Instead, we show that preschoolers of the same age in different linguistic and cultural contexts may have varying degrees of relational and object focus, and that these differences correlate with robust population-level differences in relational reasoning.

Our findings stand in contrast to the suggestion that language plays a paradoxical role in relational development, by both hindering relational reasoning and facilitating it (Hoyos et al., 2016). Although this may be true in nounfocused languages, like English, it does not appear to be a general feature of language learning.

Furthermore, we suggest that language may well act to hinder and facilitate relational reasoning, without the need to view this phenomenon as a paradox. Instead, it is possible that the object bias and the associated dip in relational reasoning observed in English speakers result from general learning processes with no exceptional role for language. Instead, the structures and features of language may be interpreted as some of many sources of input informing the types of concepts that are privileged during early learning.

Of course, several questions remain regarding the source of the population differences observed here. For example, it is certainly possible that cultural factors (other than language) play a role in facilitating a relational focus in Mandarin speakers. Indeed, there are well-documented differences between collectivist and individualist cultures, which may similarly result in an emphasis on relationships between entities or on characteristics of individual entity kinds (e.g., Chiu, 1972; Choi, Nisbett, \& Norenzayan, 1999; Nisbett, Peng, Choi, \& Norenzayan, 2001; Oyserman \& Lee, 2008; Peng \& Knowles, 2003). Our ongoing research is aimed at further pulling these hypotheses apart.

That said, regardless of whether language, culture, or some combination of the two is ultimately responsible for these effects, the current findings demonstrate that preschoolers have the capacity to infer relational properties, providing additional evidence that the object bias is learned after early competence in relational reasoning is achieved
(Walker et al., 2016). More broadly, we have established population-level differences in relational focus that occur naturally across cultures early in development and predict the developmental trajectory of relational reasoning.

## Acknowledgments

We thank Gail Heyman, Kang Lee, Jing Zhang, Caitlyn Lanigan, and Amy Zou for invaluable assistance with data collection. This work was supported by the Ammodo KNAW Award and the NSF Graduate Research Fellowship Program under grant DGE 1106400 to AC.

# Grammar-Based and Lexicon-Based Techniques to Extract Personality Traits from Text 

Maira B. Carvalho (m.brandaocarvalho@uvt.nl)<br>Tilburg Center for Cognition and Communication<br>Tilburg University<br>Tilburg, The Netherlands<br>Max M. Louwerse (mlouwerse@uvt.nl)<br>Tilburg Center for Cognition and Communication<br>Tilburg University<br>Tilburg, The Netherlands

#### Abstract

Language provides an important source of information to predict human personality. However, most studies that have predicted personality traits using computational linguistic methods have focused on lexicon-based information. We investigate to what extent the performance of lexicon-based and grammarbased methods compare when predicting personality traits. We analyzed a corpus of student essays and their personality traits using two lexicon-based approaches, one top-down (Linguistic Inquiry and Word Count (LIWC)), one bottom-up (topic models) and one grammar-driven approach (Biber model), as well as combinations of these models. Results showed that the performance of the models and their combinations demonstrated similar performance, showing that lexicon-based topdown models and bottom-up models do not differ, and neither do lexicon-based models and grammar-based models. Moreover, combination of models did not improve performance. These findings suggest that predicting personality traits from text remains difficult, but that the performance from lexiconbased and grammar-based models are on par.

## Introduction

In our daily interactions, we guide our behavior towards other people using information that is collected throughout these interactions, but also using knowledge about the world and social groups (Rich, 1979). These judgments are oftentimes made unconsciously.

Models of users' behavior, thinking and feeling typically rely on the personality traits that can be identified (McCrae \& John, 1992). Trait theory is an approach to the study of human personality in which it is believed that humans exhibit habitual patterns of behavior, thought and emotion. It is presumed that there is a relatively small number of dimensions that can be used to describe personality (O’Connor, 2002). Independent analyses have consistently yielded five broad dimensions, called the Big Five (or Five Factor Model): openness to experience, conscientiousness, extraversion, agreeableness and neuroticism (McCrae \& John, 1992).

Personality traits are generally identified on the basis of data collected from the users who fill out standardized questionnaires. However, such an approach has certain drawbacks. Firstly, it can be costly for the researcher and timeconsuming for the user (Gauch, Speretta, Chandramouli, \& Micarelli, 2007). Secondly, people are not reliable sources
of information about themselves: there is evidence to suggest that self-descriptions are heavily influenced by the social groups in which a person finds himself (McGuire \& PadawerSinger, 1976), and dissimulation can be a problem in selfreports (Wright, 2014).

Automatic inference of personality offers the advantages of being less intrusive and possibly more environmentally valid. Indeed, a range of studies have investigated the extent to which personality traits can be predicted from user behavior. The lion's share of these studies use linguistic data as sources of information, both language and speech (Beukeboom, Tanis, \& Vermeulen, 2012; Gawda, 2009; Mairesse, Walker, Mehl, \& Moore, 2007; Mehl, Robbins, \& Holleran, 2012; Oberlander \& Gill, 2006; Oberlander \& Nowson, 2006). Linguistic data has also shown to indirectly shed light on personality. For instance, linguistic cues have shown to be linked to deception (Louwerse, Lin, Drescher, \& Semin, 2010), and to different registers of communication (Louwerse, McCarthy, McNamara, \& Graesser, 2004). Furthermore, a person's emotional state is reflected in language use (Tausczik \& Pennebaker, 2009), not only by explicit lexical content but also by implicit semantic associations (Recchia \& Louwerse, 2014).

In considering the cognitive science literature that aims to extract behavioral information from linguistic data, two approaches can be distinguished. On the one hand, studies use lexical cues to extract information from text, for example emotional expression (Kahn, Tobin, Massey, \& Anderson, 2007), deception (Newman, Pennebaker, Berry, \& Richards, 2003), political orientation (Dehghani, Sagae, Sachdeva, \& Gratch, 2013), moral foundations (Graham, Haidt, \& Nosek, 2009), romantic relationship outcomes (Ireland et al., 2011), among others. On the other hand, extracting behavioral information from explicit lexical information can be problematic. First, in controlled experimental settings it is easy for participants to carefully monitor their semantic content. For instance, in deception studies participants might avoid using specific words. Second, sparsity issues may emerge if algorithms detect specific word use.

An alternative approach lies in using grammar-based cues. By performing a manual analysis of seven syntax markers, Gawda (2009) identified an increased use of certain features
in emotional narratives written by individuals with antisocial personality disorder. Current computational linguistic tools are able to extract many grammar-based linguistic features automatically and efficiently, and it is reasonable to assume that such features could also carry information about personality. Biber (1988) conducted a study on linguistic variation across speech and writing, and computed the frequency of 67 linguistic features (e.g. frequency of auxiliary verbs, pronouns, main verbs, adjectives); he was able to identify different writing genres using naturally occurring word patterns. Graesser, McNamara, Louwerse, and Cai (2004) proposed the tool Coh-Metrix, which allows the user to analyze texts on discourse, cohesion, and world knowledge. The Suite of Linguistic Analysis Tools (SALAT) calculates scores for aspects such as syntactic complexity (Kyle, 2016) and cohesion (Crossley, Kyle, \& McNamara, 2015). These tools open up a range of possibilities for the investigation of the relationships between personality and language use.

In conclusion, two approaches can be identified in extracting personality traits from language use: a lexicon-driven approach and a grammar-driven approach. As pointed above, the majority of cognitive science literature has focused on the lexicon-based approach. The question is to what extent the findings from a grammar-driven approach are comparable with the lexicon-driven approach that currently dominates the literature. We address this question in the current work.

## Extracting personality traits from text

Most studies on extracting personality from text focused on identifying words, collocations and general linguistic features that occur in texts produced by one group of people versus another group, aiming to uncover which features are informative when trying to differentiate the groups. Early attempts relied on word counting and predefined dictionaries that sort words in categories (Tausczik \& Pennebaker, 2009). This approach, albeit basic, has been used in many studies that show links between word usage and certain psychological processes and personalities, e.g. Beukeboom et al. (2012), and Mehl et al. (2012). Other researchers used bottom-up approaches to associate linguistic features with personality types. Oberlander and Gill (2006) collected large corpora of text labeled with the personality of the author and performed stratified corpus comparisons. Interesting findings included the fact that people who scored high in extraversion used more inclusive expressions and connectives, while those with low score were more tentative and used adjectives less frequently. The authors also noted that people with high neuroticism scores had preference for multiple punctuation.

Another approach is to treat the problem as a supervised classification task, employing machine learning techniques to identify the personality of the author of a given text. Oberlander and Nowson (2006) investigated a corpus of weblog posts from 71 participants, who completed a personality questionnaire online as part of the study. The authors used Support Vector Machine (SVM) classifiers and feature sets consist-
ing of n-grams extracted from the text and selected according to different levels of restriction. The same approach was later applied to a larger sample of bloggers (Iacobelli, Gill, Nowson, \& Oberlander, 2011). Argamon, Dhawle, Koppel, and Pennebaker (2005) used SVMs and four sets of lexical features to differentiate high and low extraversion and neuroticism, using a corpus of around 2400 student essays and personality assessments, collected by Pennebaker and King (1999). Mairesse et al. (2007) also worked on the same corpus, employing a series of classification and regression techniques and features from both the Linguistic Inquiry and Word Count (LIWC) and the Medical Research Council (MRC) Psycholinguistic Database. Their results confirmed previous findings and reveal new correlations between linguistic markers and personality, such as use of swear words and use of pronouns. As for the accuracy of automatic classification, the authors reported accuracies that are, according to their evaluation, significantly above chance; however, it is not clear whether these values are high enough to be useful in real applications (Mairesse et al., 2007).

Following the work by Mairesse et al. (2007), the task of automatic identification of personality from text gained a lot of attention from the research community, mostly due to the Workshop on Computational Personality Recognition (Celli, Pianesi, Stillwell, \& Kosinski, 2013). As part of a shared task, the organizers made available two datasets of text labeled with the personality traits of the authors - including the Essay Corpus by Pennebaker and King (1999). As a result, many researchers tackled the problem with different learning algorithms (e.g. Naive Bayes, SVM, kNN, ensemble methods, logistical regression) and using different features such as n-grams, LIWC, MRC, lexical nuances, part-of-speech tags, emotional values from the AFINN database, word intensity scale, sentiment analysis and word associations to emotions (Celli et al., 2013).

Although the results from these attempts are encouraging, it had been noted that top-down approaches based on lexical resources seem to perform better than bottom-up approaches based only on words or n-grams (Celli et al., 2013). Nevertheless, there are benefits in employing approaches that do not rely on pre-defined vocabularies, for example allowing exploration of topics not previously considered, easier application in different genres and languages, and saving the effort of creating the word lists (Schwartz et al., 2013).

Schwartz et al. (2013) used a large dataset of Facebook posts (over 15.4 million Facebook messages collected from 75 thousand volunteers) to perform an open-vocabulary analysis of correlations between personality types and vocabulary use. The goal of the work was to discover unexpected relationships that would not necessarily be evident from using pre-defined word categories. Although the focus of the work was mainly to explore and gain insights on the data, the authors also used the approach to predict personality from text, with results that are comparable to previous literature. Liu, Wang, and Jiang (2016) also attempted to predict personality
from text while avoiding to rely on predefined vocabularies. The authors proposed a model that expands latent Dirichlet allocation (LDA) to include the assumption that topic distribution depends not only on the characteristics of the corpus itself, but also on the five personality traits of writers. However, the topics identified by their model seem to be affected disproportionally by individuals with less common personality combinations, and for this reason the model must be trained with a massive, representative corpus for which the personality of the writers is known. Since obtaining such corpora is difficult, the applicability of their approach seems to be limited.

In this paper, we investigate how we can predict user personality from written text by using features that do not rely on closed-vocabularies, and compare the results to the state of the art. In the next section, we describe our approach.

## Procedure

## Dataset

We use the Essay Corpus (Pennebaker \& King, 1999), which consists of 2468 essays, written by introductory psychology students of the University of Texas as part of their course assignments. The students also completed the Five Factor Inventory personality questionnaire (John, Donahue, \& Kentle, 1991), so that all essays could be marked with five personality scores for each Big-5 trait (Openness to Experience, Conscientiousness, Extraversion, Agreableness, Neuroticism). In addition to the scores, the corpus contains binary values for each trait (high/low), which were obtained using a median split over the scores. The class distribution of the binary values is shown in Table 1.

Table 1: Class distribution in dataset.

|  | OPN | CON | EXT | AGR | NEU |
| :--- | :--- | :--- | :--- | :--- | :--- |
| Low | 1196 | 1214 | 1191 | 1158 | 1235 |
|  | $(48.46 \%)$ | $(49.19 \%)$ | $(48.26 \%)$ | $(46.92 \%)$ | $(50.04 \%)$ |
| High | 1272 | 1254 | 1277 | 1310 | 1233 |
|  | $(51.54 \%)$ | $(50.81 \%)$ | $(51.74 \%)$ | $(53.08 \%)$ | $(49.96 \%)$ |

## Features

We employed four groups of feature sets, which were chosen to investigate to what extent the performance of lexiconbased and grammar-based computational linguistic methods are comparable.

For the lexicon-based features, we used two main approaches: top-down (LIWC and MRC) and bottom-up (topic modeling with latent Dirichlet allocation (LDA)). For the grammar-based features, we selected the original Biber features (Biber, 1988).

## Lexicon-based, top-down

1) A total of 80 LIWC features were extracted using the LIWC2007 software, which outputs relative frequencies of
words found in each pre-defined category, and a few structural features such as word count and words per sentence.
2) The 14 MRC features refer to word length, number of syllables or phonemes, and values for frequency of use, imageability, concreteness, meaning, age of acquisition, among others. The MRC features were calculated by averaging the scores of the essay words found in the database (as opposed to averaging over total word count).

Lexicon-based, bottom-up For topic modeling, we preprocessed the corpus by lemmatizing the words using NLTK's WordNet lemmatizer, and removing non-English words (i.e. words that were not found in Wordnet). Given the relatively small size of the corpus, we did not filter out words based on frequency. Then, we trained three LDA models with different number of topics ( 30,65 and 100). Each document in the dataset was converted to a vector that represents the proportion in which each topic appears in the document. To train the model, we used the library Gensim, with 10 passes and default hyperparameters.

To illustrate the topics found in the corpus, these are the ten most relevant words for each of the three most frequently appearing topics extracted by the 30 -topic LDA model: "think, go, get, really, like, write, minute, time, wonder, need"; "go, get, really, time, friend, home, want, much, like, miss"; and "life, people, thing, know, think, time, one, make, feel, way".
Grammar-based, top-down For this study, we use the 67 features selected by Biber (1988) to reflect the linguistic structure of the text. These features primarily operate at the word level, such as parts-of-speech, and fall into categories such as tense and aspect markers, adverbials, pronouns, questions, nominal forms, passives, subordination features, prepositional phrases, coordinations and negations, and so on. These features were extracted from the text using software developed in-house.

Combinations In addition to considering these models separately, we investigated the model combinations in order to determine their complementary value.

## Classifiers

We trained five Support Vector Machine (SVM) classifiers with linear kernel, one for each personality trait. SVMs were chosen due to previous reports of them performing better on this task than other algorithms (Mairesse et al., 2007), and linear kernels were employed to retain interpretability of the model. For the implementation, we used the machine learning library Scikit-learn, which in turn uses an implementation based on Libsvm. The classifiers were trained without parameter tuning (i.e. penalty parameter $\mathrm{C}=1.0$ ).

## Results

Reservations have been expressed by the scientific community on the application of null-hypothesis statistical testing for comparison of machine learning algorithms for many rea-

Table 2: Average accuracy, precision and recall for each classifier, with $95 \%$ confidence interval.

sons, not the least of which the fact that any difference between two algorithms, no matter how small, can be shown to be statistically significant, provided that enough data are used (Japkowicz \& Shah, 2011). For this reason, instead of traditional hypothesis testing, we chose to adopt error-estimation techniques to obtain relatively robust estimates of the performance of the algorithms, which in turn allows us to compare the results considering their practical differences.

Table 2 shows the performance scores of the classifiers trained using the eight different sets of features discussed earlier. We focus our discussion around accuracy (Acc), but we also report precision $(\mathrm{P})$ and recall $(\mathrm{R})$ to give a better overall indication of the performance of the classifiers ${ }^{1}$. The performance of a simple majority classifier (i.e. it always predicts the class with the highest number of instances) is used as baseline. We report the estimated mean of the scores, calculated by running $10 \times 10$-fold cross-validation, using all 100 individual scores to estimate the mean and variance, and using 10 degrees of freedom to calculate the $95 \%$ confidence interval, as suggested by Bouckaert (2003).

As can be seen in Table 2, the performance scores of the classifiers vary for different traits, with the best accuracies ranging from approximately $56 \%$ for Agreeableness and Conscientiousness to $62 \%$ for Openness to experience (accuracies are highlighted in the table, and the highest accuracy scores for each trait are marked in bold). Nevertheless, we can make some general observations on the overall performance of the different sets of features, which we list below.

Confirming previous findings, top-down lexicon-based ap-

[^299]proaches generally provide the best accuracies. The top-down approach proposed in the literature, which uses MRC features in addition to LIWC, does provide a small added value for classifying Extraversion and Openness to experience. Conversely, for the other three traits, MRC features do not seem to provide any real improvement.

We note that bottom-up lexicon-based approaches can offer comparable accuracies to top-down approaches, with performance being basically equivalent among top-down and bottom-up over all traits but Neuroticism. Furthermore, the number of topics matters, as accuracy degrades with 100 topics (when the features are likely to become more sparse).

We can observe that a grammar-based approach on its own seems to give a slightly worse accuracy than lexicon-based approaches for three of the five traits: around $2 \%$ less accurate for Neuroticism and Extraversion, and 4\% less accurate for Openness to experience. Nevertheless, for the other two traits (Conscientiousness and Agreeableness), the accuracies are basically the same.

Finally, combining grammar and lexicon approaches does not lead to significant improvements in accuracy. In fact, it even seems to degrade the results of the top-down lexiconbased approach slightly.

In summary, Table 2 shows that lexicon-based top-down features and bottom-up features do not seem to differ in a practical way, and while grammar-based features seem to have slightly worse accuracies than lexicon-based features, the difference can be considered too small to be of practical significance. Furthermore, the accuracies of our proposed sets of features are on par with the results obtained by previous studies.

## General Discussion

The differences in performance between the different algorithms are very small. Using different feature sets yields similar results, and combining different features does not improve the performance in any meaningful way.

One possible reason could be a floor effect, in which the questionnaire used to assess personality traits in this corpus would not be able to distinguish reliably between subjects at the lower end of the scale. This is unlikely, since the test used in this corpus is a standardized questionnaire that has been validated and used in numerous studies (John et al., 1991).

It is also possible that the use of self-assessments of personality makes this task particularly difficult due to the potential unreliability of self-reports, as discussed in the introduction. Future investigation could incorporate personality assessments made by human observers, to evaluate to which extent self-assessment and observed scores differ, and whether the algorithms could match the performance of human judges. Furthermore, replicating the study with other corpora could also indicate whether different text types could be more suitable for detecting certain personality traits.

In this study, we used a relatively limited set of non-topdown features, namely the features proposed by Biber (1988) and topic modeling. Future work could investigate whether applying other grammar-based and bottom-up lexicon-based features (e.g. cohesion, syntactic complexity, n-grams, skip grams, Word2Vec, semantic similarities) would result in better performances. In addition, we could try to improve the models by using non-linear kernels, performing parameter tuning, and employing ensemble machine learning methods for combining different sets of features.

However, the difficulty of identifying personality traits from text could signal a more fundamental issue. Mischel and Shoda (1995) have argued that individual differences in social behaviors are actually variable across different situations (situationism), and not completely stable as it is proposed by trait theory. As such, if personality scales and textual analyses tap into different social situations, tasks that use questionnaire scores as gold standard will not be able to achieve acceptable performance. Further research is needed to investigate this hypothesis, and whether other stable patterns of behavior could be used as gold standard for automatic personality inferences.

The current study has used the most common personality traits classification, the Big Five, and the most commonly used corpus to identify personality traits, the Essay Corpus, in order to compare the difference between top-down and bottom-up lexicon-based and grammar-based computational linguistic techniques. Our findings show that no differences were obtained between lexicon-based and grammar-based or between top-down and bottom-up approaches, nor complementary advantages for combinations of models, despite the fact that all methods were on par with the performance previously reported.

## Acknowledgments

We would like to thank James W. Pennebaker for providing us access to the original personality scores of the Essay Corpus.

# Decomposability and Frequency in the Hindi/Urdu Number System 

Chundra Aroor Cathcart (chundra.cathcart@ling.lu.se)<br>Department of Linguistics and Phonetics Lund University

#### Abstract

Hindi/Urdu (HU) numbers 10-99 are highly irregular, unlike the transparent systems of most languages. I investigate the morphological decomposability of HU numbers using a series of computational models. While these models classify most forms accurately, problems are encountered in high-frequency forms of low cardinality, suggesting that some HU numbers are more transparent (i.e., morphologically decomposable) than others. These results are compatible with a dual-route access model proposed for the processing of numeral forms.

Keywords: numerals; computational modeling; Bayesian learning; Hindi/Urdu; phonology; morphology

## Introduction

Hindi/Urdu (HU, officially considered separate languages but differing in little other than orthography and high-register vocabulary) and most other modern Indic languages are unusual in that the numbers through 99 are highly opaque and irregular, undoubtedly posing difficulties in production and processing for language users. This phenomenon is understudied, and raises interesting questions regarding the design principles of cross-linguistic number systems, as well as the processing of complex morphological forms by language users.

In this paper, I investigate the mechanisms by which HU users extract structure and meaning from HU number terms. I address this issue using a series of unsupervised computational models designed to approximate HU users' processing of the numerals $10-99$. While it is generally agreed that number terms are acquired as individual lexical items, there is good reason to hypothesize that many numbers above a certain threshold of frequency are not accessed as individual lexemes during processing, but rather via their component parts, in line with a dual-route model of lexical storage and access (cf. Baayen, 1993). I expect that despite the irregularity of the HU number system, users can find regular patterns in various cues to numerical identity in the input, particularly in lowfrequency numbers, thus facilitating easier comprehension.

My methodology investigates the extent to which HU numbers can be morphologically decomposed. Brysbaert (2005) tentatively proposes a dual-route access model for English numeral storage, hypothesizing that frequent, opaque items like twelve are accessed directly, while morphologically transparent numbers of lower frequency (e.g., eighty-nine) are processed through decomposition. In line with this view, I predict that less frequent HU numbers can be segmented and labeled more accurately by a computational model, indicating greater morphological transparency.

I find that a model using $n$-grams as phonological features successfully assigns most HU numeral forms to the proper TENS/DIGITS cohort, but that, rather unsurprisingly, some highly opaque forms are misclassified. Major errors occur
among numbers of lower magnitude. Since these forms are highly frequent, this state of affairs is compatible with a dualroute account of processing. I find that in general, the model faces difficulties in capturing relationships between simplex (i.e., monomorphemic) forms (e.g., /วssi/ '80') and their complex counterparts (e.g., /corasi/ '84'), where a more sophisticated model of phonology might succeed. These results provide an important baseline for future investigations into mental representations of HU numerals.

## Background

The full list of numerals (taken from Comrie, n.d.) is given in Table 1. When encountering a datum like /bəjalis/ ' 42 ', listeners must infer the value of the TENS and DIGITS place with the aid of cues in the input, and must be able to contend with highly noisy allomorphy: $\operatorname{TENS}\{40\}$ and DIGITs $\{2\}$ have multiple surface realizations. In some cases, this allomorphy is suppletive (i.e., variants bear no phonological resemblance to each other). Listeners may possess the knowledge that HU is head-final, and that higher-order numerical information generally occurs closer to the root (Hurford, 1987), i.e., to the right. For some numerals, it seems plausible that high frequency facilitates access; for instance, $\mathrm{HU} /$ sola/ ' 16 ' is quite unlike other numerals with the feature digits $\{6\}$, all of which are $/ \mathrm{c}^{\mathrm{h}} /$-initial. This is a diachronic artifact; /sola/ faithfully continues Sanskrit sodaśa-, while other forms with DIGITS $\{6\}$ contain reflexes of an unattested dialectal variant *ks(v)aṭ- of attested Sanskrit saṣ- '6' (Turner, 1962-1966). It is also the only member of the teens which shows $/ 1 /$ in its allomorph of /das/ 'ten'. All the same, it may be used frequently enough that this twofold suppletion does not pose problems to speakers and listeners.

A major attempt to explore synchronic regularities among HU numbers is that of Bright (1969), who concludes that despite a lack of economy, implicit rules governing the system are available to language users. Berger (1992) outlines the complex historical development of HU numbers; sporadic phonological reduction, analogy, and language contact, among other phenomena, have resulted in a highly irregular and opaque system compared to the relatively transparent numbers of Sanskrit, HU's ancestor. These works aside, many aspects of the HU numeral system remain untreated.

## Representational issues

## Abstract representation of $\mathbf{H U}$ numerals

Above, I adopt the canonical abstract numerical representation found in much of the literature, where each surface form comprises two underlying factors corresponding to the TENS and DIGITS place. I make the assumption that DIGITs $\{0\}$

Table 1: HU numbers 1-99; rows represent the tens place, columns the digits place

|  | 0 | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9 |

does not map to any overt phonological information. Additionally, for forms such as /vntalis/, there is a mismatch between the abstract representation TENS $\{3\}$ DIGITS $\{9\}$ and the phonological form, since the morpheme representing the tens place closely resembles /calis/ ' 40 ', not /tis/ ' 30 '; this suggests an intermediate calculation TENS $\{4\}$ DIGITS $\{-1\}$. I assume that the representation Digits $\{-1\}$ is an integral part of HU numerical computation and is reflected explicitly in the morphology.

## Surface representation of $\mathbf{H U}$ numerals

Brysbaert hesitates to draw a categorical distinction between transparent and opaque English numerals, citing semitransparent forms like thirteen. Along these lines, I seek to situate HU numerals along a cline between mild and extreme opacity. I quantify a number's transparency or decomposability via the performance of a computational model designed to segment and label HU numbers, both in terms of (1) accuracy of the labeling and (2) low posterior uncertainty.

At the outset, I lack a principled means of separating suppletive and non-suppletive allomorphy found in the system. Numbers 11-18 exhibit three allomorphs for TENS $\{1\}$, /-də/, $/-\mathrm{rr} /$ and /-lə/, all from the diachronic source -daśa-, though synchronic $/ \mathrm{d} / \sim / \mathrm{r} / \sim / \mathrm{l} /$ alternations are not well known in HU. Numbers 49-58 show multiple bases for TENS $\{5\}$, all descended from Sanskrit pañcāśat- '50' but formally very dissimilar. I make no a priori assumptions about the status of suppletive allomorphy in the morphological system, and allow the model to simply group together forms according to the configuration it infers. I do, however, treat digits $\{-1\}$ as a separate morpheme, given its systematic occurrence. Nonparametric models (which assume an unbounded number of underlying morphological labels) may alleviate some of the problems that result from forcing suppletive allomorphs to be classified together, which I set aside for future work.

A model of HU numerical processing should characterize the morphological structure of the data encountered. HU numbers are highly fusional, exhibiting the effects of millennia of phonological and morphological change. As Bright reports, no economical set of rules helps to derive the surface representations from their morphological bases. There is often unpredictable allomorphy between simplex and complex forms of a given decade: for instance, /s/ alternates with /h/
in complex forms of /səttrr/ '70' < Sanskrit saptatí', but not in complex forms of $/ \mathrm{sat}^{\mathrm{h}} /$ ' 60 ' < Sanskrit sasți-; however, the latter decade's complex forms contain a reduced vowel $/ \partial /$, alternating with $/ \mathrm{a} /$. The short vowel and geminate consonant found in /assi/ ' 80 ' alternate with a long vowel and singleton consonant in derived /-asi/, but the short vowel found in /nəve/ does not appear in derived forms.

Despite these challenges, listeners should be able to form a probability distribution over possible morphemes contained in a complex input datum. HU's highly fusional phonology notwithstanding, listeners should be able to approximate the location of morpheme boundaries. This question is a key part of this paper's computational inference, and should be of broad interest to phonological theory, as it has the potential to incorporate a number of strategies for morphological boundary detection. The models introduced in this paper draw morpheme boundaries on the basis of what is most likely under the current parameters of the model, and are dependent on distributional information found in other numerals. This task is easier than that of many types of unsupervised segmentation in that at most one boundary must be located per input datum; however, the model must contend with a wider distribution of allomorphs which must be unified. This model does not use external distributional information for the purpose of segmentation (as do Harris, 1955; Saffran et al., 1996).

A question relevant to this paper concerns the types of morphological segmentation that should be permitted. Crosslinguistically, a morphological segmentation of the type [b][əjalis] might be permissible, but non-inflectional morphemes in HU tend to consist minimally of a unit with prosodic weight. As such, I restrict the proposal distribution for segmentations of HU numbers to exclude morpheme boundaries following the first and penultimate segments; this additionally speeds up inference and ensures that short forms like /bis/ ' 20 ' will be treated as monomorphemic.

## Phonological features

The methodology developed in this paper must capture allomorphy in the HU numeral system, inferring that different surface strings such as /-jalis/ and /calis/ correspond to the same underlying morpheme, TENS $\{4\}$. I cluster allomorphs together on the basis of phonological features using essentially the same likelihood formula used in unsuper-
vised Naïve Bayes/Dirichlet-Multinomial classifiers, popular in bag-of-words models of document classification. This is a model of convenience which I find fairly effective, though it is admittedly crude; it is insensitive to positional information and alternations, and does not strongly penalize the absence of potentially crucial morpheme-level information.

The model described in this paper lends itself to the use of different types of phonological features, and provides opportunities to investigate model performance under features with differing degrees of abstraction. In this paper, I limit myself to domain-general string-based features, namely $n$ grams. In many contexts, I expect segmental bigrams to fare well in assigning cohort membership. However, there are some cases where I fear that bigrams may fail to capture alternations caused by (among other things) deletion or insertion, as between the base /nəve/ ' 90 ' and /-nve/, found in complex forms. A unigram model will be sensitive to the co-occurrence of $/ \mathrm{n} /$ and $/ \mathrm{v} /$, whereas a representation consisting solely of bigrams will not (on the use of separate autosegmental tiers for consonants and vowels, see Goldsmith \& Riggle, 2012). I attempt to circumvent this problem with a phonological representation that uses both unigrams and bigrams (though this technically violates the independence assumption of Naïve Bayes). This allows the model to capture some similarities between paradigmatically related forms that would otherwise be lost in a strict bigram model.

## Model

Here, I introduce the core model employed in this paper, designed to approximate a HU speaker's recognition of numbers 10-99 (I assume that 1-9 are primitives). When encountering a numerical form, the listener must determine whether it is simplex or complex. If simplex, the value of the TENS place must be inferred; if complex, the DIGITS place must be as well. The model assumes that a complex form is generated by independent draws from two mixtures, a DIGITS mixture (the labels of which correspond to the values $\{-1,1, \ldots, 9\}$ ) and a TENS mixture (the labels of which correspond to the values $\{1, \ldots, 9\}$ ). Because HU morphology is generally concatenative, I make the simplifying assumption that phonological elements generated by a given mixture are adjacent to one another - i.e., that a morpheme boundary can be located somewhere in a complex form, however approximately. I make the assumption that the lefthand morpheme is generated by the digits mixture and the righthand morpheme is generated by the tens mixture; this convention essentially incorporates Hurford's insight that higher numerical elements occur closer to the root, which in turn can be interpreted as prior knowledge of a morphosyntactic headedness parameter. This system of numerical classification is schematized in Figure 1 .

## Inference

This paper's basic model of numeral classification assigns each form to one or two mixtures, given a $10 \times F$ matrix $\Omega^{D}$ and a $9 \times F$ (where $F$ is the number of feature types in

Figure 1: Schema of a proposed morphological segmentation, tens classification, and digits classification for form /bajalis/
the input) matrix $\Omega^{T}$ (specifying a prior over feature distributions associated with each label of the digits and TENS place, respectively), as well as a word-level vector $\mu$ representing a prior over morpheme boundary locations. I initialize these matrices with symmetric concentration parameters $\alpha^{T} \alpha^{D}, \alpha^{\mu}$, set to . 1 in order to encourage sparseness, such that unshared features from unrelated labels are not clumped together. The generative model draws probability simplices $\phi_{j}^{D} \sim \operatorname{Dirichlet}\left(\omega_{j}^{D}\right), \phi_{i}^{T} \sim \operatorname{Dirichlet}\left(\omega_{i}^{T}\right)$ representing the feature distributions associated with levels $j$ and $i$ of the DIGITS and TENS place, and assumes that for every word $w$,
$\varsigma \sim \operatorname{Dirichlet}(\mu)$ (a simplex of morpheme boundary probabilities is drawn, including the probability $p(m=\emptyset)$, i.e., the probability that there is no morpheme boundary)
$m \sim$ Categorical $(\varsigma)$ (a morpheme boundary is drawn from $\varsigma$ ) If $m=\emptyset$,
$z_{j}^{D}=0$
for each feature $f \in w$

$$
f \sim \operatorname{Categorical}\left(\phi_{i}^{T}\right), i \in\{1, \ldots, 9\}
$$

If $m \neq \emptyset$,
For each feature $f \in w_{1, \ldots, m}$ (through index $m$ )

$$
f \sim \operatorname{Categorical}\left(\phi_{j}^{D}\right), j \in\{-1,1, \ldots, 9\}
$$

For each feature $f \in w_{m+1, \ldots,|w|}$ (from index $m+1$ through the end of the word)

$$
f \sim \text { Categorical }\left(\phi_{i}^{T}\right), i \in\{1, \ldots, 9\}
$$

I marginalize out the parameters $\varsigma, \phi_{i}^{T}, \phi_{j}^{D}$ to obtain collapsed Dirichlet-Categorical updates for $p(m \mid \mu), p\left(z^{T} \mid \Omega^{T}\right), p\left(z^{D} \mid \Omega^{D}\right)$. For a given word, this yields the following conditional probability if $m=\emptyset$ (adopted from Yin \& Wang, 2014):

$$
\begin{align*}
P\left(m=\emptyset, z_{i}^{T}, z^{D}=\right. & \left.0 \mid z_{-i}^{T}, z_{-0}^{D}, \Omega^{T}, \Omega^{D}, \mu\right) \propto \\
& \frac{\prod_{f \in w} \prod_{n=1}^{c(f) w} c(f)_{z_{j}^{-w}}^{-w}+\alpha^{T}+n-1}{\prod_{k=1}^{w \mid c} c(\cdot)_{z_{j}^{T}}^{-w}+F \alpha^{T}+k-1} \tag{1}
\end{align*}
$$

If $m \neq \emptyset$ :

$$
\begin{array}{r}
P\left(m, z_{i}^{T}, z_{j}^{D} \mid z_{-i}^{T}, z_{-j}^{D}, \Omega^{T}, \Omega^{D}, \mu\right) \propto \\
\frac{\prod_{f \in \lambda_{m}^{\prime}}^{m} \prod_{n=1}^{c(f)} \lambda_{\lambda_{m}^{\prime}} c(f)_{z_{j}^{D}}^{-w}+\alpha^{D}+n-1}{\prod_{k=1}^{m} c(\cdot)_{z_{j}^{D}}^{-w}+F \alpha^{D}+k-1} \cdot \frac{\prod_{f \in \lambda_{m}^{r}} \prod_{n=1}^{c(f) \lambda_{m}^{r}} c(f)_{z_{i}^{T}}^{-w}+\alpha^{T}+n-1}{\prod_{k=1}^{|w|-m} c(\cdot)_{z_{i}^{T}}^{-w}+F \alpha^{T}+k-1} \tag{2}
\end{array}
$$

Above, $c(f)_{z_{i}^{T}}^{-w}$ denotes the number of instances of $f$ currently associated with label $z_{i}^{T}$, and $c(\cdot)_{z_{i}^{T}}^{-w}$ the number of instances of any item currently associated with label $z_{i}^{T}$ (both terms exclude any instances contributed by $w$ ); $c(f)_{\sigma}$ signifies the number of instances of $f$ in element $\sigma$. For simplicity, I write $\lambda_{m}^{l}$ for $w_{1, \ldots, m}$ and $\lambda_{m}^{r}$ for $w_{m+1, \ldots,|w|}$. Once new values of $m, z_{i}^{T}, z_{j}^{D}$ are chosen for word $w$, counts for the features in $\lambda_{m}^{l}$ (if $m \neq \emptyset$ ) and $\lambda_{m}^{r}$ can be allocated to $z_{j}^{D}$ and $z_{i}^{T}$, respectively.

## Priors on morphological segmentation

For this paper's most basic inference procedures, the prior over morpheme boundaries is symmetric, with equal probability allocated to all possible segmentations of word $w$. In certain inference regimes, I employ one of two priors on segmentation incorporating the principle of Minimum Description Length, popular in unsupervised morphological segmentation (Goldsmith, 2001; Creutz \& Lagus, 2007); these priors favor the insertion of morpheme boundaries which minimize the length of the code that generates the data. There are a number of ways to interpret this principle. Most intuitively, the "code" can be construed as the list of morph types, or alternatively, the sum of the lengths of morph types. Hence, an MDL or exponential prior on morphological segmentations disfavors analyses that add to the list, or the sum of (string) lengths of types in the list.

The first prior (MDL1), designed to keep the list of analyzed morphs short, assigns probability to a morphological segmentation for word $w$ proportional to the inverse of the number of morph types as currently analyzed, including the proposed segmentation for $w$; under the second approach (MDL2), the prior probability is inversely proportional to the sum of lengths of current morph types. I have employed these priors due to the importance of MDL in the literature on unsupervised segmentation, but remain somewhat skeptical as to whether HU numeral morphology can be rendered compact in the same manner as the morphology traditionally analyzed with MDL priors (e.g., of English, Finnish, Turkish, etc.), given the noisy allomorphy seen.

## Priors on cluster membership

Readers may note that the above formulae depart from traditional Dirichlet-Multinomial mixture models in that the Chinese Restaurant Process prior (a rich-get-richer scheme) over cluster membership is excluded. This prior, which makes it more likely for an item to be assigned to a cluster that already has many data points, seems inappropriate for this paper's model, which iterates over one token of each number, and should learn classes of roughly equal size. In one sampling regime, I place an exponential prior on TENS and DIGITS label membership, inversely proportional to the number of items currently assigned to the label in question (plus a concentration parameter). The intention here is to introduce a pressure toward clusters of uniform size.

## Inference procedure

Inference is carried out via Markov chain Monte Carlo. I run different versions of the model on three chains for 10000 iterations, discarding the first half of samples as burn-in. Each chain is initialized by randomly segmenting and assigning each item to a TENS and DIGITS label. Parameters are updated via Gibbs Sampling; for each number in 10-99, a morphological segmentation $m$, a TENS label $z^{T}$ and if relevant, a DIGITs label $z^{D}$ are drawn conditional on the labels currently assigned to all other data points (see eqq. 1-2). I use a simulated annealing procedure, raising each vector of update probabilities to the power of a constant $\frac{1}{\gamma}$, with $\gamma$ decreasing from 10 to 1 over the course of the burn-in. Code can be found at github.com/chundrac/HUnumerals.

I carry out an inference procedure using only bigrams as a phonological feature representation $(2 \mathrm{~g})$; this is followed by a regime using unigrams and bigrams $(1+2 \mathrm{~g})$. I modify the $1+2 \mathrm{~g}$ procedure to incorporate an MDL prior sensitive to the length of the current list of morph types (MDL1), followed by an MDL prior sensitive to the sum of their lengths (MDL2). I attempted to see how the MDL1 prior (which showed better performance) affected the bigram model. Additionally, I ran a simulation which augmented the $1+2 \mathrm{~g} /$ MDL1 model with a prior over component membership designed to keep clusters uniform (denoted by U). ${ }^{1}$

## Results

I use the overall F-measure (Fung et al., 2003) and the Vmeasure (Rosenberg \& Hirschberg, 2007), two evaluation metrics designed to quantify the similarity between two classifications, in order to monitor convergence and measure overall accuracy (convergence was also assessed via chain log-likelihoods). I compute pairwise F- and V-measures between the maximum a posteriori (MAP) configuration of each chain to assess the degree to which chains return the same classification, interpreting values greater than .9 as a token of convergence between two chains. I evaluate each chain's accuracy by computing the F- and V-measures between the chain's MAP configuration and the true classification of the numbers. These values are found in Table 2. In general, MDL priors do not appear to improve inference for bigrams, and do not significantly improve inference for $1+2$ grams.

Table 3 displays the MAP configuration for the top chain (2) in the regime with highest overall accuracy $(1+2 \mathrm{~g} / \mathrm{MDL} 1 / \mathrm{U})$. To measure the ACCURACY with which this regime decomposes individual numbers, I calculate the F-scores for each number's MAP TENS and DIGITS classifications with respect to its true TENS and DIGITS classifications, averaging these values. The resulting values are then averaged across chains. I calculate POSTERIOR UNCERTAINTY

[^300]by averaging the entropy of the posterior sample (comprising blocked draws of $m, z^{T}, z^{D}$ ) for each chain.

I extract numeral frequencies from the EMILLE Hindi Webnews corpus (Baker et al., 2002). For each number, accuracy and posterior uncertainty are plotted according to frequency in Figure 2, along with correlation coefficients and $p$-values. Both correlations are significant (albeit noisy), providing support for the idea that the HU numbers can be processed via a dual-route model. As seen in the lefthand plot, the majority of HU numbers occupy a quasi-Pareto frontier, indicating an efficient trade-off between decomposability and frequency. Several numbers in the teens (seen in the upper righthand corner of the plot) are both highly frequent and decomposable. These outliers in no way contradict the dualroute model, since a form's decomposability does not preclude the possibility that it is stored whole. However, a handful of numbers are found beneath the frontier (near the lower lefthand corner), meaning that they are both relatively infrequent and difficult to parse. These items can be viewed as vulnerable points in the grammar of HU numbers, and may be prone to "leakage" or analogical restructuring.

Table 2: F-/V-measures for different inference regimes

## Discussion

The models presented in this paper show that although HU numerals 10-99 are morphologically irregular, a large number can be classified according to their component parts. However, quite a few forms are difficult to decompose, most of them of low magnitude and high frequency. In general, the models handled some types of allomorphy well, and others

Figure 2: Log frequency as a predictor of model accuracy ( $\rho=-.55, p<.001$ ) and post. uncertainty $(\rho=.38, p<.001)$
poorly. Forms containing the TENS $\{5\}$ allomorphs /-pən/ $\sim$ /-vən/ are grouped together, due to their agreement in two out of three segments. Surprisingly, /solə/ '16' was recognized as a member of the teens, despite the unique allomorph /-la/; however, the model failed to properly classify it according to its digits place. Other forms with highly suppletive allomorphy (e.g., /vncas/ '49') were misclassified. Additionally, many simplex forms were not analyzed as monomorphemic, unless only a monomorphemic analysis was permitted under the proposal distribution.

As stated above, my results show that the HU numeral system's design is largely compatible with a dual-route model of access. In general, high-frequency items were more difficult for a computational model to decompose, indicating greater opacity. (Berger shows that many of these numbers were historically subject to erosion and evidently resistant to analogical changes that would otherwise make them more transparent and perceptually distinct.) At the same time, there are exceptions to this generalization: certain high-frequency items in the teens showed high accuracy, though this does not rule out the possibility that they are stored whole. Additionally, some problematic items are more opaque than would be expected, given their low frequency. It is likely that such vulnerable forms cause problems in planning and production.

The EMILLE Spoken Hindi corpus contains intriguing numeral variants (e.g., /it ${ }^{\mathrm{h}}$ janve/ ' 91 ' by speaker ehinsp041, /sintrjanve/ '97' by ehinsp035, /vnanve/ ' 89 ' by ehinsp044), though the data are too sparse to serve as the basis of a rigorous quantitative study. Many numbers are missing in the corpus; furthermore, the variation observed may stem from sources other than production difficulty, including transcriber error, multilingualism (with another Indic language; for example, speaker ehinsp017 utters the form /bavis/ '22', standard in Marathi but not HU), and stylistic factors. Studies of variability in the production of HU numerals - either in experimental contexts or naturalistic speech - will serve as a valuable research direction, particularly with an eye to whether vulnerable forms (i.e., sub-
optimal forms with higher opacity than expected relative to frequency) are subject to greater instability.

## Conclusion

In this paper, I have employed a simple and somewhat crude model of allomorphy, inspired in part by bag-of-words models used in document classification and intended to serve as a baseline for future work. A goal of this study was to test the limits of a simple mixture model in a HU numerical recognition task. A more sophisticated model of phonological processes may relate potential allomorphs to each other in terms of edits, as has been done in some MDL approaches (Virpioja et al., 2010). However, while such models can contend with or recover relatively regular allomorphy, no model has been designed, to my knowledge, to capture the highly noisy allomorphy found in the HU numeral system.

A true test of any computational model's value is in how well it agrees with human performance. A future direction for this work will involve carrying out experimental research to see how HU speakers process and produce numerical forms. It will serve us well to see how model inaccuracy fares as a predictor of greater response latency in psycholinguistic tasks. A joint approach which considers limitations in both experimental performance and computational simulation will help us identify weak points in this and other complex morphological systems that can potentially (though not obligatorily) undergo analogical change.

I have shown that frequency may facilitate the processing of more opaque HU numbers, but the question remains as to why most Indic number systems are on average more irregular than exact number systems found in other languages. Sociocultural factors may be partially responsible, ${ }^{2}$ and their role in shaping cross-lingustic number systems should be taken into account along with that of functional need (cf. Xu \& Regier, 2014).

## Acknowledgements

I am grateful to Stephan Meylan, Terry Regier, and three anonymous reviewers for helpful comments. All errors and infelicities are my own responsibility.

# Is the relative distribution of verbs and nouns modulated by socio-cultural influences? Evidence from bilingual infants and toddlers in Malaysia. 

Jun Ho Chai<br>The University of Nottingham Malaysia Campus<br>Hui Min Low<br>University Sains Malaysia<br>Tze Peng Wong<br>The University of Nottingham Malaysia Campus<br>Julien Mayor<br>University of Oslo, Oslo, Norway

#### Abstract

Early vocabularies in most languages tend to contain more nouns than verbs. Yet, the strength of this noun bias has been observed to vary across languages and cultures. Two main hypotheses have aimed at explaining such variations; either that the relative importance of nouns vs. verbs is language- specific, or that socio-cultural influences shape early vocabulary structures. The present study compares the relative distribution of verbs and nouns, in English, between two groups of bilingual infants and toddlers; Malay-English and Mandarin- English. We found that early English lexicons of Mandarin- English bilinguals contained more verbs than in the English lexicon of Malay-English bilinguals, in both comprehension and production. We discuss the potential role of socio-cultural influences on the vocabulary structure in young users of a language.

# Exploring the relations between oral language and reading instruction in a computational model of reading

#### Abstract

To become a proficient reader, children have to learn mappings between print, sound and meaning. There is debate over whether reading instruction should focus on the relations between print and sound, as in phonics, or on the relationship between print and meaning, as in sight word reading. In a study where participants learned a novel artificial orthography, Taylor, Davis and Rastle (2017) compared print to sound focused or print to meaning focused reading training, demonstrating that sound training was superior for learning to read. However, a benefit from sound focused training is likely dependent on prior acquisition of effective sound to meaning relations of words. To explore this issue, we developed a connectionist model of reading. We exposed the model to a sound or a meaning focused training, but varied the model's pre-acquired oral language skills. The simulation results showed that proficiency in oral language is a determinant of the advantage of print to sound focused reading training, suggesting that reading training should address both oral language skills and print to sound mappings.

Keywords: reading instruction; oral language; reading development; computational modelling; word learning.

## Introduction

Learning to read requires mastery of a set of complex skills involving encoding phonology ( P ), semantics ( S ), and learning to map orthographic (O) forms onto those representations of sound and meaning. Even for alphabetic orthographies, where a letter, or set of letters, corresponds approximately regularly to a phoneme in the word, learning to read is effortful and frequently fraught with difficulties (Seidenberg, 2017). Effective early reading instruction is therefore critical to help children become proficient readers. There has been a vigorous debate over whether reading instruction should focus on the relations between print and sound or on the relationship between print and meaning. The former is typically characterized by phonics-style training, where the phonemes associated with particular letters or letter clusters are trained intensively, enabling children to decode letter-by-letter. The latter is often referred to as meaning-focused or whole-word language instruction, where the meaning and pronunciation of the whole word is provided to the child during training.

Proponents of the phonics method argue that reading instruction should focus on learning spelling-to-sound mappings because exploiting the systematicity of alphabetic writing systems ought to be substantially easier than acquiring more arbitrary spelling-to-meaning mappings, where the arbitrariness of the sign is dominant and learning can only be accomplished word by word, without the benefit of generalising from one learned word to the next. Evidence for the strong predictive relation between phonological decoding skills and reading acquisition (see, e.g., Rayner et al., 2001, for a review) demonstrates that phonological skills are key to reading success.

Alternatively, researchers who advocate the meaningfocused method (see, e.g., Davis, 2013, for a review) argue that the primary goal of reading is to access the meanings of words and so this ought to be the priority of reading training approaches. Although spelling-to-meaning mappings are hard to learn, they may still be acquired early in reading development (Nation, 2009; Taylor et al., 2015). For example, Nation and Cocksey (2009) demonstrated that 7-year-old children could access semantic categories of words from orthography very quickly without evidence that the phonological form of the words mediated responses.

## Effectiveness of sound-focused and meaningfocused reading instruction

According to the Simple View of reading (Gough \& Tunmer, 1986), reading comprehension is the product of phonological decoding and oral vocabulary. During reading training, learners acquire mappings from print to sound, and access meaning based on their knowledge of sound-tomeaning mappings acquired pre-literacy. There is some evidence that both print to sound mapping skills (as indexed by pseudoword reading tasks) as well as sound to meaning mapping skills (as reflected in oral vocabulary tasks) are predictors of silent reading comprehension performance (e.g., Curtis, 1980; Nation \& Snowling, 2004; Ouellette \& Beers, 2010; Ricketts, Nation, \& Bishop, 2007). However, the Simple View of reading does not consider an alternative, which involves the role of accessing meaning directly from print (Taylor et al., 2015).

Within the connectionist view of reading (Seidenberg \& McClelland, 1989; Harm \& Seidenberg, 2004; Plaut et al.
1996), learning to acquire the meaning of written forms of words could be via developing direct orthographic to semantic mappings. Alternatively, acquisition could be indirect, through the learner developing orthographic to phonological mappings, which then map, via oral language knowledge, onto semantic representations. Computational modelling investigations have established that there is division of labour along these direct and indirect pathways from orthography to semantics over development (Harm \& Seidenberg, 2004; Plaut et al. 1996). However, comparisons between reading training that focuses on developing the direct orthographic-to-semantic, versus the indirect orthographic-to-phonological, pathways have not as yet been undertaken.

One exception to this is a recent study by Taylor, Davis and Rastle (2017). In a laboratory study using adults, Taylor et al. compared reading acquisition when training was biased toward orthography-to-semantics (OS) mappings versus orthography-to-phonology (OP) mappings. They trained literate adult participants to read two sets of 24 novel words which were written in two different unfamiliar alphabetic orthographies (in each orthography, one character related to one phoneme) - see Figure 1. Each novel word was assigned a familiar concrete noun meaning (e.g., /ged/ referred to camel, and $/ \mathrm{k} \varepsilon \mathrm{s} /$ referred to parsnip), and the mappings between novel words and their referents were counterbalanced across participants).

## NSM X XN

Figure 1. $/ \mathrm{g} \varepsilon \mathrm{d} /$ and $/ \mathrm{k} \varepsilon \mathrm{s} /$ in the artificial orthography from Taylor et al. (2017).

Prior to reading training, participants were exposed to the mappings between phonology and semantics for the novel words. Then, participants learned orthographic-tophonological and orthographic-to-semantic mappings for both orthographies. For one orthography, participants received OP focused training, which involved three times as many orthographic-to-phonological training trials as orthographic-to-semantic training trials, whereas for the other orthography they received OS focused training, which involved three times as many orthographic-to-semantic as orthographic-to-phonological training trials. The results demonstrated that OP focused training led to better accuracy and speed in reading aloud, and it also had a transferable benefit to reading comprehension. By contrast, OS focused training resulted in faster but not more accurate reading comprehension, and showed no transferable benefit for the reading aloud task.

Taylor et al. (2017) demonstrated that both reading aloud and reading comprehension accuracy could be promoted by focusing on OP mappings during reading training. However, unlike children learning to read for the first time, participants were acquiring an orthography which very likely piggy-backs on the reading system that the participants already have. Thus, an outstanding question is the extent to which prior language skills, particularly
between phonology and semantics, are critical to the OP versus OS focused reading training differences.
Furthermore, a key aspect of Taylor et al.'s (2017) study design was that participants were pre-trained on mappings between phonological and semantic forms for the novel words. This previously tuned phonology-semantics system is crucial to allow the transference of knowledge from training on OP mappings to access meaning from print, since this requires using not only the OP but also the PS routes within the reading system.

According to the connectionist view of reading, then, phonics instruction will be most successful if the participant has acquired an effective level of oral language knowledge. Thus, in relating the laboratory-based studies of reading acquisition to the child's task of learning to read, the relative contribution of training from OP and OS on reading acquisition needs to be considered alongside the contribution of pre-literate oral language skills.

## Computational models of reading

Computational models of reading have converged on an architecture involving two different pathways that are active during reading - a subword orthographic to phonological pathway and an orthographic whole word pathway, which may map onto a whole-word phonological representation and/or a semantic representation of the word (Coltheart et al. 2001; Plaut et al. 1996). There are also mappings between phonological and semantic representations, meaning that words can be comprehended both by direct OS mappings, and also indirectly via OP then PS mappings. In the connectionist tradition, the relative contribution for generating phonology or semantics via different reading pathways is flexible, and can be determined by properties of individual words, such as high-frequency words more likely to be read via direct OS mappings, or due to properties of the orthographic system itself, such as ideographic writing systems more likely to utilize the direct OS mappings than alphabetic writing systems (Chang, Welbourne \& Lee, 2016; Harm \& Seidenberg, 2004; Plaut et al. 1996).

In this study, we implemented the two reading schemes tested in Taylor et al.'s (2017) study, in order to determine whether the connectionist triangle model of reading is able to replicate the behavioural effects of an OP focused versus an OS focused training regime. Furthermore, we examined whether the advantage for the OP focused training demonstrated in Taylor et al.'s (2017) study was present even for the model with poor oral language skills, or only when well-established mappings between phonological and semantic representations were in place. Tracking the relative benefit of OP and OS focused training according to preliterate oral language skills enables greater clarity on how different reading training schemes may benefit readers with varying language abilities.

Following Harm and Seidenberg (2004), we developed a fully implemented connectionist model of learning to read, that mapped between representations of orthography, phonology, and semantics of words. The model was
pretrained to different degrees of proficiency in mapping between phonological and semantic representations of words, to simulate pre-literate oral language skills. We tested three different quantities of pre-training to reflect a model with moderate, medium, and high levels of oral language skills, in terms of the overall fidelity of phonological and semantic representations within the model, and the proportion of words in the language for which the model was able to generate the correct semantic and phonological representations. We then compared the effects of two reading training regimes with different focuses of reading instruction - orthography to phonology (OP) focused model or orthography to semantics (OS) focused model. Prior to learning to read, both models received three different amounts of pretraining (i.e. 500, 1000, or 2000 epochs) on mappings between semantics and phonology. The OP focused model then received three times as much training on the OP mappings, while the OS focused model received three times as much training on the OS mappings. We evaluated the model's performance under these different training regimes using tasks of reading aloud and reading comprehension.

Figure 2. The architecture of the developmental model of reading.

## Method

## Network Architecture

The architecture of the model is shown in Figure 2, which was the same as the developmental model of reading implemented in Monaghan, Chang, Welbourne, and Brysbaert et al. (2017) and Chang, Monaghan, and Welbourne (2016). The model consisted of three key processing layers representing orthographic, phonological and semantic representations respectively, and four hidden layers that learned to map between the processing layers. An attractor layer, which contained 50 hidden units, was connected to and from the phonological layers. Similarly, there was a set of 50 hidden units for the semantic layer. The use of attractors was to help the model to develop stable phonological and semantic representations of words. The semantic layer was connected to the phonological layer through a set of 300 hidden units, and the phonological layer was connected back to the semantic layer through another
set of 300 hidden units. The orthographic layer was connected to both the phonological and semantic layers through different sets of 500 hidden units.

## Training Corpus: Artificial Words

The training corpus comprised 24 artificial words, taken from the materials in Taylor et al. (2017). For the phonological forms, all items were monosyllabic consonant-vowel-consonant pseudowords. All items were constructed from 12 consonants (/m/, /t/, /g/, /b/, /k/, /d/, /n/, /s/, /z/, /v/, $/ \mathrm{p} /$, and, $/ \mathrm{f} /$ ) and four vowel phonemes ( $/ \varepsilon /, / \mathrm{I} /, / \rho /$, and, $/ \Lambda /$ ). For phonology, each word was represented in the $3^{\text {rd }}, 4^{\text {th }}$ and $5^{\text {th }}$ slots of a set of eight phoneme slots, with each slot consisting of 25 phonological features. Each word was thus positioned with its vowel at the fourth phoneme slot. The first three slots were for onset consonants, and the last four slots were for coda consonants, but because all words in the set had one onset and one coda consonant, only one of these slots was used during training (so for the word "tep" its phonology was represented as ${ }_{-} \mathrm{t} \varepsilon \mathrm{p} \ldots_{-}$, where indicates an empty slot). For orthographic forms, the correspondence between letters and phonemes was transparent (i.e., there was a one-to-one correspondence). For orthography, each word was represented across a layer containing 14 letter slots with each slot comprising 26 units, each of which could represent a distinct letter, so an alphabet up to 26 letters could be represented. Words were positioned with their vowel aligned on the fifth slot. Consonants preceding the vowel were positioned in slots right before the vowel and consonants following the vowel were positioned starting from the seventh slot. This representation was in alignment with Chang et al. (2016), which enabled words up to 14 letters to be represented. However, because all words were three letters in length, with one onset and one coda consonant, words occupied only the $4^{\text {th }}, 5^{\text {th }}$, and $7^{\text {th }}$ slots (so for the word "tep" its
 Note that we use here Roman alphabet as a short hand to reflect the alphabet used in the laboratory-based study. There is nothing particular in the representations used in the model regarding the particular alphabet used, only that the model is able to distinguish the letters from one another from the outset, but does not know the properties of the letters in other respects in advance of commencing training.
For semantics, a set of familiar objects consisting of six fruits and vegetables, six vehicles, six animals, and six tools were randomly assigned to the 24 artificial words. The semantic representation for each word was derived from Wordnet (Miller, 1990), following Harm and Seidenberg (2004). Each semantic representation was composed of 2446 semantic features. The presence of semantic features was encoded as 1 and the absence of semantic features was encoded as 0 in the respective slot.

## Training Procedure

The model was trained on the 24 artificial words. All the training parameters were exactly the same as those used in
our previous modelling work (Chang et al., 2016). The training process had two phases: pretraining and reading training. For the pretraining, the model learned to map from phonological to semantic (PS) representations in an oral vocabulary task and from semantic to phonological (SP) representations in a meaning naming task (e.g. picture naming). To investigate how oral language skills affected literacy development, three different amounts of pretraining were used $-500,1000$, or 2000 learning trials. For the oral vocabulary (PS) task, the phonological representation of the word was clamped at the phonological layer for eight time steps, and the model generated a semantic representation at the semantic layer. The difference between the actual and the target semantic representation was then calculated, and the weights on connections between all the layers were adjusted according to gradient descent backpropagation through time in order to reduce the error. The training rate was 0.1 . Similarly, for the meaning naming task (SP), the semantic representation was clamped at the semantic layer for eight time steps, and the model was required to produce a phonological representation. In pretraining, the model additionally learned to develop a stable phonological attractor (PP), and a stable semantic attractor (SS), by presenting the phonological or the semantic representation for two time steps, then allowing the model to cycle activation for a further six time steps to reproduce the initial representation. During pretraining, these four tasks (PS, SP, PP, and SS) were interleaved, with $40 \%$ of trials for the oral vocabulary task, $40 \%$ of trials for the meaning naming task, $10 \%$ of trials for the phonological attractor and $10 \%$ for the semantic attractor. For each trial, a word was randomly selected.

After pretraining, the weights on connections between the semantics and the phonology layers were frozen. The model was then trained to learn to read with different focuses of reading instruction, in two separate simulations as either the OP focused or OS focused model. For the OP focused model, there were three OP trials for every OS trial, and for the OS focused model the reverse was true. For an OP trial, the model's error at the phonological layer at the final time step was computed and then backpropagation with gradient descent adjusted the weights to reduce this error. For an OS trial, error was propagated from the semantic representation. Each model was trained for 1000 reading trials. For each reading learning trial, a word was randomly selected and presented at the orthographic layer for 12 time steps. Five versions of each model were trained with different random initial weights and different random samplings from the words.

## Testing Procedure

For testing the model's phonological output, we determined the number of words for which all phonemes were correctly produced. The closest phoneme representation from the set of all phonemes in the language was derived from the model's actual production and this was then compared against the target phoneme. If the actual and
target phonemes were the same, then the model was judged to have spoken the word correctly. For testing the model's semantic output, the activation of units at the semantic layer was recorded. Accuracy was measured by computing the Euclidean distance between the model's actual semantic representation and the semantic representation of each word in the training corpus. If the smallest distance was for the target representation then the model was judged to be correct. We examined how the different training focuses affected reading performance at various stages during training.

## Results

## Network Performance

For the pretraining tasks, the model that was trained with 500,1000 , and 2000 presentations achieved $74 \%, 89.6 \%$, and $100 \%$ accuracy on the meaning naming (PS) task and $41.7 \%, 80.2 \%$ and $97.9 \%$ accuracy on the oral vocabulary (PS) task, respectively. This pattern of results is in line with performance of the model when trained with a substantially larger vocabulary (Monaghan et al., 2017). The three training schedules thus reflect different levels of pre-literate oral language skills, from poorer through to near-perfect vocabulary knowledge.

Figure 3 shows the average performance of the OP and OS focused models with the different amounts of pretraining at different stages of reading training. We analysed the model's performance by using generalized linear mixed effects models with accuracies in reading aloud or reading comprehension as the dependent variable, depending on the task. Item and simulation (simulations one to five) were included as random factors, and training focus (OP or OS), reading time (epoch 100 to 1000 ) and pretraining $(500,1000$, or 2000) were included as fixed factors.

Overall, the model performed better on the tasks for which it had undergone intensive training. For reading aloud, the OP focused model performed better than the OS focused model. Adding training focus as a fixed factor resulted in a significant improvement in model fit compared to a model with random effects of item and simulation and with fixed effects of reading time and pretraining, $\chi(1)=398.86, p$ $<.001$. For reading comprehension, the OS focused model performed better than the OP focused models, as again indexed by the fact that adding training focus improved model fit, $\chi(1)=314.25, p<.001$.

However, the effect of pretraining had an asymmetric effect on the reading aloud and reading comprehension tasks, according to whether the model had been trained with OP or OS focus. For reading aloud, the effect of different levels of pretraining, reflecting oral language skills, had a null effect on performance for both the OP and the OS focused models. Adding pretraining as a fixed factor did not result in a significant improvement in model fit compared to a model with random effects of item and simulation and with fixed effects of reading time and training focus, $p>.05$. Note that the trajectories of the lines for the OS focused model for 500
and for 2000 pretraining trials are very close together, as they are for the OP focused model. In contrast for reading comprehension, the effect of pretraining had a substantial effect on the OP training focused model - adding pretraining as a fixed factor improved model fit compared to a model with random effects of item and simulation and with fixed effects of reading time and training focus, $\chi(2)=34.42$, $p$ $<.001$. Specifically, after substantial pretraining (2000 pretraining trials, producing close to $100 \%$ in oral vocabulary and meaning naming tasks), the performance of the OP focused model began to converge with that of the OS focused model. The beneficial effect of the OP training focus is strongest for the model with advanced oral skills prior to literacy onset. This observation was confirmed by the fact that adding the interaction between pretraining and training focus as a fixed factor improved model fit compared to the model containing random and fixed effects, $\chi(2)=$ 9.86, $p<.001$. Looking at each level of pretraining, the difference between the OP focused model and the OS focused model was the smallest for 2000 pretraining trials, $\beta$ $=1.47$, followed by 1000 pretraining trials, $\beta=1.81$, and then 500 pretraining trials, $\beta=2.01$.

These results for the skilled oral language model are in tune with the behavioural results from Taylor et al. (2017). Figure 3 (right) shows the performance of the participants trained with the OP versus OS focus languages on each day taken from Taylor et al.'s figures 3 and 4. Similar to the behavioural data, the performance of the OP and OS focused models converged after substantial training and this is likely due to the fact that the training sample was relatively small.

Figure 3. The performance of the OP and OS focused models with different amounts of pretraining over the time course of the reading training (Left). The performance of the participants trained with the OP and OS focus languages on each day from Taylor et al. (2017, right). The error bars indicate $\pm$ SEM.

## Discussion

We developed a fully implemented connectionist model of
reading that mapped between orthography, phonology, and semantics and explored the influence of oral language on the effectiveness of different types of reading instruction. The laboratory study on which this work was based indicated that focusing on learning mappings between print and sound also transferred to promote mapping between print and meaning, whereas focusing on learning print to meaning mappings resulted in deficiencies in learning print to sound and had little advantage for mapping from print to meaning. The consequences of this, if they extend to children's learning, are that, given limited instructional time, learning should focus on phonics, rather than on meaning-based strategies for reading acquisition.

Our model replicated these effects: a model which focused on print to meaning (i.e., OS training focused model) had deficiencies in learning to map from print to sound, whereas a model which focused on print to sound (i.e., OP training focused model) was better at learning reading aloud tasks, and converged in performance for reading comprehension tasks with the OS training focused model which had three times as much experience of comprehension trials during training.
However, importantly this convergence was dependent upon the model's preliteracy training. Only when the model had high accuracy in its mappings between phonology and semantics was it able to transfer performance from OP training trials to perform well on reading comprehension. This pattern of performance from the OP training focused model with high oral language skills was similar to the behavioural data reported in Taylor et al. (2017). Our computational results demonstrate that the advantage of OP focused training only pertains in cases where good oral language skills are present. This is because the transfer from OP training trials to OS task performance requires effective mappings from phonology to semantics. If these are not present then the effective learning of OP mappings in the model stops just there - any high fidelity representation of phonology cannot then accurately activate the target semantic representation. OP training, then, is only advantageous for reading comprehension when the learner has good oral language knowledge, consistent with the view that addresses the role of oral language in reading (Gough \& Tunmer, 1986; Harm \& Seidenberg, 2004; Plaut et al. 1996).
The results are thus far compatible with empirical evidence of the benefit of both print to sound decoding skills and oral language skills on reading ability (e.g. Curtis, 1980; Nation \& Snowling, 2004; Ouellette \& Beers, 2010; Ricketts, Nation, \& Bishop, 2007), which relate to the two segments of the indirect route from orthography to semantics via phonology. Further investigation of the model's performance will enable us to determine whether this is the way in which the model functions to solve the mapping tasks. We suggest that, for reading aloud, the direct OP pathway is likely to be most effective for performing the task regardless of the training focus, because the systematic mappings are easier to learn compared to the indirect OSP pathway which requires two arbitrary mappings. Thus, more
training of the direct OP pathway is likely to be beneficial. In contrast, for reading comprehension, the indirect OPS pathway may again be more effectively used, because it exploits a regular OP mapping and a previously learned arbitrary PS mapping, whereas the direct OS pathway is arbitrary and needs to be acquired. We might then expect the indirect pathway to have a substantial contribution to reading comprehension performance for both OP and OS focused training, in the context of highly accurate PS mappings.

Previous studies have showed that the division of labour between the phonological and semantic pathways in connectionist models of reading could be shaped by word properties or orthographic systems (Chang, Welbourne \& Lee, 2016; Harm \& Seidenberg, 2004; Plaut et al. 1996). In this work we show that reading instruction and prior oral language skill also seem to alter the division of labour. This is likely due to the broadly systematic versus arbitrary nature of OP versus OS mappings in English.

In summary, our simulation results have demonstrated that oral language skills mediate the effectiveness of reading instruction in early literacy development. In particular, the beneficial effects of print to sound instruction for reading comprehension depend on high levels of oral vocabulary knowledge. Thus, in line with the Simple View of reading, our modelling work suggests that teaching children about spelling-to-sound mappings needs to be accompanied by substantial training on oral vocabulary, in order to promote reading comprehension. Interventions based on promoting print to sound skills should also ensure effective oral language skills, in order to exploit the benefit of enhancing the regularities available in OP mappings in alphabetic writing systems.

# Evaluating vector-space models of analogy 

Dawn Chen (sdawnchen@gmail.com)<br>Joshua C. Peterson (peterson.c.joshua@gmail.com)<br>Thomas L. Griffiths (tom_griffiths@berkeley.edu)<br>Department of Psychology, University of California, Berkeley, CA 94720 USA

#### Abstract

Vector-space representations provide geometric tools for reasoning about the similarity of a set of objects and their relationships. Recent machine learning methods for deriving vectorspace embeddings of words (e.g., word2vec) have achieved considerable success in natural language processing. These vector spaces have also been shown to exhibit a surprising capacity to capture verbal analogies, with similar results for natural images, giving new life to a classic model of analogies as parallelograms that was first proposed by cognitive scientists. We evaluate the parallelogram model of analogy as applied to modern word embeddings, providing a detailed analysis of the extent to which this approach captures human relational similarity judgments in a large benchmark dataset. We find that that some semantic relationships are better captured than others. We then provide evidence for deeper limitations of the parallelogram model based on the intrinsic geometric constraints of vector spaces, paralleling classic results for first-order similarity.

Keywords: analogy; word2vec; GloVe; vector space models

## Introduction

Recognizing that two situations have similar patterns of relationships, even though they may be superficially dissimilar, is essential for intelligence. This ability allows a reasoner to transfer knowledge from familiar situations to unfamiliar but analogous situations, enabling analogy to become a powerful teaching tool in math, science, and other fields (Richland \& Simms, 2015). Computational modeling of analogy has primarily focused on comparing structured representations that contain labeled relationships between entities (Gentner \& Forbus, 2011). However, the questions of where these relations come from and how to determine that the relationship between one pair of entities is the same as that between another pair are an unsolved mystery in such models. Some models, such as DORA (Doumas, Hummel, \& Sandhofer, 2008) and BART (Lu, Chen, \& Holyoak, 2012), try to learn relations from examples, but have only demonstrated success on comparative relations such as larger.

Another possibility is that the representations of entities themselves contain the information necessary to infer relationships between entities and that relations do not need to be learned separately. An instantiation of this hypothesis is the parallelogram model of analogy (see Figure 1), first proposed by Rumelhart and Abrahamson (1973) over 40 years ago. In this model, entities are represented as points in a Euclidean space and relations between entities are represented as their difference vectors. Even though two pairs of points may be far apart in the space (i.e., they are featurally dissimilar), they are considered relationally similar as long as their difference vectors are similar. Although Rumelhart and Abrahamson found that this simple model worked well for a small
domain of animal words with vectors obtained using multidimensional scaling, little progress was made on the parallelogram model after the initial proposal, with the exception of a handful of reasonably successful applications (see Ehresman \& Wessel, 1978).

However, in the past few years, the parallelogram model was reincarnated in the machine learning literature through popular word embedding methods such as word2vec (Mikolov, Sutskever, Chen, Corrado, \& Dean, 2013) and GloVe (Pennington, Socher, \& Manning, 2014). These word representations enable verbal analogy problems such as king : queen :: man : ? to be solved through simple vector arithmetic, i.e., $v_{\text {queen }}-v_{\text {king }}+v_{\text {man }}$ results in a vector very close (in terms of cosine distance) to $v_{\text {woman }}$. Word embeddings like word2vec and GloVe have also been used successfully in a variety of other natural language processing tasks, suggesting that these representations may indeed contain enough information for relations to be inferred from them directly. Recently, researchers in computer vision have been successful in extracting feature spaces that exhibit similar properties in both explicit (supervised) (Radford, Metz, \& Chintala, 2015) and implicit (unsupervised) (Reed, Zhang, Zhang, \& Lee, 2015) ways, yielding linearized semantic image transformations such as object rotations and high-level human face interpolations. The potential for applying the parallelogram model of analogy to vector space models appears to be domainagnostic, broadly applicable to both semantic and perceptual domains. This suggests a promising cognitive model and provides the opportunity to evaluate a classic theory in largescale, ecologically valid contexts.

Figure 1: The parallelogram model of analogy completes the analogy king : queen :: man : ? by adding the difference vector between king and queen to man. This forms a parallelogram in the underlying vector space.

In this paper, we evaluate the parallelogram model of analogy as applied to modern vector-space representations of words. Focusing on the predictions that this approach makes about the relational similarity of words, we provide a new dataset of over 5,000 comparisons between word pairs that exemplify 10 different types of semantic relations. We find that the parallelogram model captures human relational sim-
ilarity judgments for some semantic relations, but not others. We then show that human relational similarity judgments for pairs of words violate the geometric constraints of symmetry and triangle inequality, just as Tversky (1977) showed for judgments of first-order similarity between words. This creates a challenge for any vector space model that aims to make predictions about relational similarity.

## Relational Similarity

One way to evaluate vector space models such as word2vec and GloVe as accounts of analogy is to compare their assessments of relational similarity - the similarity of the relation between one pair of words to that of another - with human judgments. A good foundation for this task is the SemEval-2012 Task 2 dataset (Jurgens, Turney, Mohammad, \& Holyoak, 2012), which contains prototypicality scores based on human data for word pairs that exemplify 79 different semantic relations. These relations were taken from a taxonomy of semantic relations (Bejar, Chaffin, \& Embretson, 1991) and are subtypes of 10 general types, such as CLASS-INCLUSION, SIMILAR, and CONTRAST. Participants were given three or four paradigmatic examples of a relation and asked to generate additional examples of the same relation. A total of 3,218 unique word pairs were generated for the 79 relations, with an average of 41 word pairs per relation. A prototypicality score for each participant-generated word pair was calculated based on how often a second group of participants chose the word pair as the best and worst example of the relation among a set of choices. Table 1 shows examples illustrating two representative subtypes of each of the ten general types of relations.

According to the parallelogram model, two pairs of words ( $A: B$ and $C: D$ ) are relationally similar to the extent that their difference vectors $\left(v_{B}-v_{A}\right.$ and $\left.v_{D}-v_{C}\right)$ are similar. How appropriate is this geometric relationship for the various semantic relations? As a preliminary investigation of this question, we projected the 300 -dimensional word2vec vectors into a two-dimensional space using principal components analysis separately for each relational subtype in the SemEval dataset, and visualized the difference vectors for the participant-generated word pairs from each relation. Figure 2 shows the difference vectors for the 20 relational subtypes that are shown in Table 1.

Examining the difference vectors for each relation shows that the parallelogram rule does not appear to capture all relations. CASE RELATIONS Agent:Instrument (e.g., farmer : tractor) shows a nearly perfect correspondence with what we would expect under the parallelogram model, with all difference vectors aligning. However, many of the relations appear to have no clear geometric pattern. Nevertheless, simply looking at projections of the difference vectors is not sufficient to evaluate the power of geometric models of relational similarity to capture various relations, because information is lost in the projections. What is required is a detailed evaluation on judgments of relational similarity between word pairs

Table 1: Examples of word pairs instantiating each of two representative subtypes from each general relation type in the SemEval-2012 Task 2 dataset

| Relation type | Subtype | Example |
| :--- | :--- | :--- |
| 1. CLASS- <br> INCLUSION | Taxonomic <br> Class:Individual | flower $:$ tulip <br> river $:$ Nile |
| 2. PART-WHOLE | Object:Component <br> Collection:Member | car $:$ engine <br> forest $:$ tree |

within each relation.
Although the SemEval-2012 dataset contains prototypicality scores for the participant-generated word pairs within each relation, which have been interpreted as the relational similarities between the participant-generated pairs and the paradigmatic pairs, prototypicality is influenced by other factors such as the production frequencies of words (Uyeda \& Mandler, 1980). Moreover, because participants were encouraged to focus on the relation illustrated by the paradigmatic examples, the prototypicality scores may not have much to do with the particular word pairs chosen as paradigmatic examples. Experiment 1 aims to address these problems.

## Experiment 1: Benchmarking Relational Similarity

To overcome the limitations of the SemEval-2012 Task 2 dataset for our purposes, we collected a new large dataset that directly measures human judgments of relational similarity between word pairs, focusing on comparisons between word pairs with similar relations.

Participants We recruited 823 participants from Amazon Mechanical Turk. Participants were paid $\$ 2.00$ for the $20-$

Figure 2: Visualizations of difference vectors for 20 relational subtypes using two-dimensional projections of word2vec word vectors obtained separately for each relation using principal components analysis.
minute study. We excluded 158 participants from the data analysis because they failed two or more of the attention checks (see below).

Stimuli The stimuli for this study were taken from the SemEval-2012 Task 2 dataset. We were mainly interested in how people rate relational similarities between participantgenerated word pairs within each of the 79 relational subtypes. However, because the total number of such "withinsubtype" pairwise comparisons is still enormous, we selected the most representative subtype for each relation type out of the two shown in Table 1. The subtype we chose is the first of each pair of subtypes that appears in Table 1. We then randomly chose 30 word pairs out of the entire participantgenerated set for each of the 10 subtypes and formed all possible within-subtype comparisons between these word pairs. This created a set of 4,350 within-subtype comparisons. Finally, in order to encourage participants to use the entire rating scale, we added 925 "between-subtype" comparisons, which are comparisons between word pairs from different subtypes within a type (e.g., Object:Component and Collection:Member, both subtypes of PART-WHOLE), and 925 "between-type" comparisons, which are comparisons between word pairs from the representative subtypes of different relational types (e.g., Object:Component and Taxonomic CLASS-INCLUSION).

Procedure Participants were given instructions about relational similarity, which included an example of two word pairs that have similar relationships (kitten : cat and chick : chicken) and an example of word pairs with dissimilar relationships (chick: chicken and hen : rooster). Participants then viewed two pairs of words side-by-side on each page and were asked to rate the similarity of the relationships shown by the two word pairs on a scale from 1 (extremely different) to 7 (extremely similar). They rated 100 comparisons in a random order, 70 of which were within-subtype, 15 of which were between-subtype, and 15 of which were between-type. The left-right order of the two word pairs on the screen was chosen randomly (but order within pairs was of course maintained). After every 20 trials, there was an attention check question that asked participants to indicate whether two words are the same or different.

Results \& Discussion We obtained at least 10 good ratings for each comparison, with an average of 10.74 ratings per comparison. The mean rating across all comparisons was $4.52(S D=2.17)$. As expected, we obtained the highest relational similarity ratings for within-subtype comparisons ( $M$ $=5.01, S D=1.98$ ), mid-level ratings for between-subtype comparisons ( $M=4.02, S D=2.14$ ) and the lowest ratings for between-type comparisons ( $M=2.70, S D=1.93$ ).

We calculated relational similarity for each comparison us-
ing word2vec and GloVe word representations. We used the 300 -dimensional word2vec vectors trained on the Google News corpus that were provided by Google (Mikolov et al., 2013), and the 300 -dimensional GloVe vectors trained on a Common Crawl web crawl corpus that were provided by Pennington et al. (2014). We tested two measures of similarity between difference vectors, cosine similarity and Euclidean distance. Specifically, for a given comparison between two word pairs, $A: B$ and $C: D$, letting $\mathbf{r}_{1}=v_{B}-v_{A}$ and $\mathbf{r}_{2}=v_{D}-v_{C}$, we calculated the cosine similarity,

$$
\frac{\mathbf{r}_{1} \cdot \mathbf{r}_{2}}{\left\|\mathbf{r}_{1}\right\|\left\|\mathbf{r}_{2}\right\|}
$$

as well as a similarity measure based on Euclidean distance,

$$
1-\left\|\mathbf{r}_{1}-\mathbf{r}_{2}\right\|
$$

Cosine similarity is typically used to measure similarity in vector spaces such as word2vec and GloVe. However, using Euclidean distance corresponds more closely to the original parallelogram model, in which not only the directions but also the lengths of the difference vectors needed to be similar for two word pairs to be considered relationally similar.

Figure 3 shows Pearson's correlations between predicted relational similarity scores and average human relational similarity ratings on each relation type (including both withinsubtype and between-subtype comparisons) for each vector space and similarity measure. There is considerable variation in the performance of word 2 vec and GloVe in predicting human relational similarity ratings. As might be expected from examining Figure 2, cosine similarity performs the best on CASE RELATIONS (relation 7). However, cosine similarity completely fails on SIMILAR (relation 3), CONTRAST (relation 4), and NON-ATTRIBUTE (relation 6). Euclidean distance boosts performance on the latter two relations, but still underperforms overall compared to most other relations. Nevertheless, Euclidean distance does perform very well on SPACETIME (relation 9).

These results indicate that a single relational comparison strategy cannot capture all semantic relations in the spaces provided. It is unclear if such a result is a reflection of the word embeddings or actual variation in human analogical strategies. Next, we turn to the broader question of the appropriateness of the class of geometric models in general for representing human relational similarity behavior.

## Violations of Geometric Constraints

Distance metrics in vector spaces must obey certain geometric constraints, such as symmetry (the distance from $x$ to $y$ is the same as the distance from $y$ to $x$ ) and the triangle inequality (if the distance between $x$ and $y$ is small and the distance between $y$ and $z$ is small, then the distance between $x$ and $z$ cannot be very large). Cosine similarity, used to measure similarity between word2vec representations, also obeys symmetry and an analogue of the triangle inequality (Griffiths, Steyvers, \& Tenenbaum, 2007). However, psychological representations of similarity do not always obey these
constraints (Tversky, 1977). The famous example of this is that people judge North Korea to be more similar to China than the other way around, a violation of symmetry. Griffiths et al. (2007) examined the word representations derived by Latent Semantic Analysis (Landauer \& Dumais, 1997), another well-known vector space model, and found that these representations are unable to account for violations of symmetry and the triangle inequality in human word association data. Nevertheless, all prior work has focused on first-order similarity between words, and second-order (relational) similarity between word pairs might be expected to follow a different pattern. In this section, we show that human judgments of relational similarity also do not satisfy the geometric constraints of symmetry and the triangle inequality. Vector space models such as word2vec and GloVe cannot account for these violations.

## Experiment 2: Symmetry

In this experiment, we examined whether there were any pairs of word pairs for which participants' judgments of relational similarity changed when the presentation order was reversed. We might expect such asymmetry to occur when a word pair has multiple relations and shares ones of its less salient relations with another word pair. For example, when presented with angry : smile - exhausted : run, one might think, "an angry person doesn't want to smile" and "an exhausted person doesn't want to run," but when presented with exhausted : run - angry : smile, one might think,"running makes a person exhausted, but smiling doesn't make a person angry." Thus, participants might give high relational similarity ratings in the first presentation order and low ratings in the second order.

Participants We recruited 1,102 participants from Amazon Mechanical Turk, who gave informed consent and were paid $\$ 1.00$ for the 10 -minute study. We excluded 99 participants from the data analysis because they failed two or more of the attention checks (see below).
Stimuli We randomly selected 220 within-subtype, 220 between-subtype, and 60 between-type comparisons from all possible comparisons formed using the entire SemEval-2012 Task 2 dataset. We created two versions of each comparison, in which the order of the word pairs were switched.
Procedure Participants were given instructions about relational similarity and the two examples used in Experiment 1 illustrating similar and dissimilar relationships. They saw one word pair in each comparison first and were asked to think of the relationship between the words. Then after a 600 ms delay, the other word pair was shown and participants were asked to rate the similarity of the relationships on a 7-point scale. Participants rated 50 comparisons, including 22 withinsubtype, 22 between-subtype, and 6 between-type comparisons. Each participant viewed each comparison in only one of its presentation orders. After every 10 trials, there was

Figure 3: Pearons's $r$ between human relational similarity ratings and model predictions on different relation types for (a) word2vec and (b) GloVe. The name and examples of each numbered relation type are shown in Table 1.
an attention check question that asked participants to indicate whether two words are the same or different.
Results \& Discussion We obtained about 50 ratings for each comparison in each presentation order. We conducted a $t$-test for each comparison to see if the two presentation orders resulted in significantly different relational similarity ratings. 77 of these $t$-tests were statistically significant at the .05 level. The number of $t$-tests that we would expect to be significant at the $\alpha=0.05$ level if presentation order did not matter for any of the comparisons is 25 . Assuming that the $t$-tests are independent, a binomial test reveals that this deviation is statistically significant, $p<.001$.

Examining the comparisons for which different presentation orders resulted in significantly different relational similarity ratings confirms our guess as to when people's judgments of relational similarity might not obey symmetry. The previously mentioned example of angry: smile and exhausted : run indeed elicited higher ratings in the direction shown here ( 4.76 mean rating) than in the opposite direction ( 2.36 mean rating). As another example, people rated hairdresser : comb - pitcher : baseball as more relationally similar (6.10 mean rating) than pitcher : baseball - hairdresser : comb (4.84 mean rating). In the first presentation order, participants might be thinking that "a hairdresser handles a comb" and "a pitcher handles a baseball," whereas in the second presentation order, they might be thinking "a pitcher plays a specific role in baseball," which doesn't fit with hairdresser : comb.

## Experiment 3: Triangle Inequality

For this experiment, we created triads of word pairs for which we expected people's relational similarity judgments to violate the triangle inequality, such as nurse : patient, mother : baby, and frog : tadpole. This triad violates the triangle inequality because nurse : patient $::$ mother : baby is a good analogy (relationally similar), and so is mother: baby :: frog : tadpole, but nurse : patient $::$ frog : tadpole is not. In this example, the middle pair has multiple relations and shares one of them with the first pair and a different one with the last pair. We presented the two word pairs in each analogy together and asked participants to rate the quality of the analogy rather than relational similarity, because we wanted to encourage participants to consider the two relations together rather than using one relation as a reference.

Participants We recruited 71 participants from Amazon Mechanical Turk, who gave informed consent and were paid $\$ 0.50$ for the 5-minute study. This group of participants did not overlap with the participants in Experiment 2. We excluded 11 participants from the data analysis because they failed one of the attention checks (see below).

Stimuli We created twelve triads of word pairs for which analogy quality judgments are likely to violate the triangle inequality. For every triad, the analogy formed between the first and third word pairs was expected to be rated low and the other two analogies were expected to be rated highly.

Procedure Participants were given instructions about verbal analogies and the two examples used in Experiments 1 and 2 as examples of good and bad analogies, respectively. They were then asked to rate the quality of each analogy on a scale from 1 (very bad) to 7 (very good). For each of the twelve triads, each participant viewed one of the three analogies. Each participant received four analogies formed between the first and second word pairs of various triads (analogy type 1-2), four formed between the second and third word pairs (type 2-3), and four formed between the first and third word pairs (type 1-3). Because two thirds of these analogies are expected to be rated highly, participants also viewed four "filler" analogies expected to be given low ratings. Finally, there were two attention check questions that asked to participants to simply choose 1 (or 7) for a bad (or good) analogy.

Results \& Discussion We obtained 20 ratings for each analogy. We calculated the mean participant rating for each analogy and conducted a one-way between-subjects ANOVA to test if there was an effect of the analogy type (1-2, 2-3, or $1-3$ ) on the mean analogy quality rating. This revealed a significant effect of analogy type, $F(2,33)=45.57, p<0.001$. Post hoc comparisons using the Tukey HSD test indicated that the mean ratings for both type 1-2 analogies $(M=5.44$, $S D=.99$ ) and type 2-3 analogies $(M=5.43, S D=.63)$ were significantly higher than the mean rating for type 1-3 analogies $(M=2.99, S D=.46), p<.001$, whereas the mean ratings for type 1-2 and type 2-3 analogies did not differ significantly from each other. This is consistent with our expectation that types 1-2 and 2-3 analogies would both be rated highly, whereas type 1-3 analogies would be rated lowly. These results indicate that participants' analogy quality ratings violated the triangle inequality.

Figure 4: Mean human ratings and predicted relational similarities (scaled to the range 0-1) for the triad lawyer : books, chemist : beakers, and librarian : books. Error bars indicate 1 SEM for scaled human ratings.

We obtained the predicted relational similarity between the word pairs in each analogy by calculating the cosine similarity between difference vectors using word2vec and GloVe representations. Then we conducted separate ANOVAs for the two representational spaces to test whether there was an effect of analogy type on the predicted relational similarity in each space. Neither ANOVA indicated a significant effect of analogy type. For word2vec, $F(2,33)=1.20, p=.31$. For GloVe, $F(2,33)=.24, p=.79$. These results indicate that the predictions of relational similarity made by word2vec and GloVe do not violate the triangle inequality for our stimuli.

Because each participant contributed ratings to more than one analogy (although only one per triad), the observations are not entirely independent in the first overall ANOVA that we conducted on the participant data. Thus, we conducted a separate between-subjects ANOVA for each of the twelve triads to test if there was an effect of analogy type (1-2, 23 , or 1-3) on the analogy quality ratings for each triad. All twelve ANOVAs were significant, with every $p<.01$. We then conducted post hoc comparisons using the Tukey HSD test. The pattern we expected was that types 1-2 and 2-3 analogies would have significantly higher ratings than type 1-3 analogies, but would not differ significantly from each other. We observed this pattern for seven of the twelve triads. For every one of the remaining triads, the mean ratings for the type 1-2 and type 2-3 analogies were higher than the mean rating for the type 2-3 analogy, but which differences were statistically significant differed among the triads. Figure 4 shows an example of one of the seven triads with the expected pattern and compares the mean participant ratings and predicted relational similarities for the three analogies.

## Conclusions

Our results provide a clearer picture of the utility of vectorspace models of analogy. The parallelogram model makes good predictions of human relational similarity judgments for some relations, but is less appropriate for others. For example, consider the word pairs represented as vectors in Figure 2. As one would expect, relation SIMILAR seems to be best represented by a short difference vector rather than the direction of the difference vector. More generally, in more complex analogies with the source and target each consist-
ing of many points in the vector space, one could imagine many ways of describing relationships between the two sets of points.

More challenging are the constraints posed by the geometric axioms. In our datasets, we found considerable violations of two of these axioms, which cannot be overcome through better embedding methods. In light of this, it would be interesting to follow the history of models of first-order similarity in considering the use of featural representations (Tversky, 1977), exploring methods of measuring similarity in vector spaces that are no longer subject to the constraints imposed by the metric axioms (Krumhansl, 1978), or reformulating the problem as probabilistic inference (Griffiths et al., 2007).

#### Abstract

Distributional learning research has established that humans can track the frequencies of sequentially presented stimuli in order to infer the probabilities of upcoming events (e.g., Hasher \& Zacks, 1984). Here, we set out to explore anticipation of a stimulus after implicit distributional learning. We hypothesize that as people learn the category frequency information implicitly, response times will scale according to the relative frequency of the stimulus category. Twelve adult participants viewed photographs of faces, tools, and buildings while performing a simple classification task. We found that response times significantly decreased with greater frequencies in the distribution of stimulus categories. This result suggested that distributional information about the internal representations of the stimuli could be learned and indicated the possibility that participants anticipated the stimuli proportional to the probability of the category appearing and thereby reduced response times for the more frequent categories.

Keywords: statistical learning; implicit distributional learning; anticipation; classification

## Introduction

Although complicated and dynamic, our sensory environment contains regularities distributed both spatially and temporally. Previous studies have shown that humans can acquire information from a probabilistic structure, and they are able to predict the upcoming stimulus using distributional knowledge. In this study, we used behavioral methods to investigate anticipation prior to object classification after distributional learning of the object category frequencies.

People are known to be sensitive to the distributional information, and they are able to actively use this information to make complex inferences, such as identifying underlying structures in sequences. Explicit probabilistic information can aid human decision-making in many situations (Arkes, Dawes, \& Christensen, 1986; Wiggs, 1993; Lin, Kung, \& Lin, 1997). In addition to explicit distributional learning, in fact, it is well established in the fields of human development, language acquisition, attention, and perception that people are sensitive to implicit distributional information (e.g., Attneave, 1953; Fiser \& Aslin, 2002; Hasher \& Zacks, 1984; Saffran, Aslin, \& Newport, 1996; Tryk,1968; Turk-Browne, Scholl, Chun, \& Johnson, 2009; Pelucchi, Hay, \& Saffran,
2009). In these studies, distributional information was not explicitly provided to participants, but the results showed that participants could track the stimulus input to infer its underlying causal structure and therefore make accurate predictions or judgments about which stimuli potentially fit or violate this structure. Thus, even when these statistical relationships are not explicitly presented and the stimuli are too numerous to be explicitly counted, people can discover an accurate distributional model of the input.

Particularly, classification tasks have been used to test implicit distributional learning (Forster \& Chambers, 1973; Stanners, Forbach \& Headley, 1971; Stanners, Jastrzembski, \& Westbrook, 1975; Whaley, 1978). Classifying responses can reflect distributional learning processes, as learned items can be recognized and discriminated from other items faster than unfamiliar items can. For example, Whaley (1978) found that response times for word and non-word classification were substantially faster with high-frequency initial and final consonants than for words with lowfrequency consonants in initial or final position or both. Although in the context of language, this finding shed lights on the correlation between implicit distributional learning and response times, and it demonstrated the methodology of using a classification task to test this correlation.

Response time has been used to measure anticipation in many studies (Haith, Hazan, \& Goodman, 1988; Hinrichs \& Krainz, 1970; Todorovic, van Ede, Maris, \& de Lange, 2011; Turk-Browne, Scholl, Johnson, \& Chun, 2010, Poulton, 1950). Some of these studies have found that when participants were instructed to predict the upcoming stimulus, response times were faster for correct predictions than for incorrect predictions (Bernstein \& Reese, 1965; Hinrichs et al., 1970). This finding suggests that anticipation of an upcoming stimulus influences the response time in the subsequent trial.

However, the effect of adult observers' use of implicit distributional learning on anticipation of the category of an upcoming stimulus remains largely unexplored. Most studies have focused on effect of frequency information about stimulus-stimulus association (e.g. Conway \& Christiansen, 2005; Kirkham, Slemmer, Johnson, 2002; O’Brien \& Raymond, 2012; Olson \& Chun, 2001; Turk-Browne, Jungé, Scholl, 2005), and little research have looked into the effect of the overall distributional information about the internal
representation of the stimuli (e.g. the categorical representation of the object).

Here, we aimed to establish evidence for anticipatory representations of the category of the upcoming stimulus emerging from distributional learning. Turk-Browne et al. (2010) investigated implicit anticipation triggered by probabilistic information. Their behavioral result showed that when the participants observed and made classification responses to every trial, the participants reacted faster to the trials that can be predicted from their immediate preceded trials. Based on this finding, in the experiment, we measured participants' anticipation of an object category by measuring the response times in a sequential classification task. We examined the anticipatory effects of the underlying distribution and predicted that response times for classification would decrease with greater category frequencies, suggesting that as people learned the category distributional information implicitly, anticipation was scaled according to the probability of the category appearing.

## Methods

## Participants

Twelve participants were recruited ( mean age $=20$ years; $S D$ $=1.7$ years; 7 females, 5 males) and were compensated $\$ 10$ per hour. All participants were undergraduate students at the University of Rochester. All participants reported being right-hand dominant. The experiment took around 45 minutes to complete. The study procedures were approved by the Institutional Review Board of the University of Rochester, and participants received an informed consent document prior to the study.

## Materials

We chose three categories of stimuli: faces, buildings, and tools. Each category has specific brain areas that reliably respond to one of these categories but not the others (Epstein \& Kanwisher, 1998; Kanwisher, McDermott, \& Chun, 1997; Chao \& Martin, 2000). The images from each of these categories were grey-scaled and edited to be the same size ( $640 \times 480$ pixels) using Preview software in Mac OSX. The images appeared in the middle of a $27{ }^{\prime \prime}$ iMAC monitor with $1920 \times 1080$ resolution. The images appeared in the middle of the screen against a white background. Face images were acquired from the Chicago Face Database (Ma, Correl, \& Wittenbrink, 2015); Building images were downloaded by Google Image search with the keywords "building" and "house"; Tool images were obtained from the BOSS database (Brodeur, Dionne-Dostie, Montreuil, \& Lepage M, 2010).

The frequency of each category ( $60 \%, 30 \%$, or $10 \%$ ) was counterbalanced across six different distributional conditions using Latin Squares (Winer, 1962). This manipulation counterbalanced carryover effects between conditions and ensured that participants see each of the conditions in the study. We chose $60 \%, 30 \%$, and $10 \%$ as frequencies considering the number of trials in each block ( 30 trials) and condition ( 90 trials). These frequencies produce integer instead of the decimal number of trials in each condition. The
complete information about these six conditions is shown in Table 1.
Three adjacent buttons on the computer keyboard were marked as " F ", " H " and " T ". To exclude the motor-related confounds that were the interest of this study, the key mapping was counterbalanced across subjects. Subjects were asked to always use the same three fingers (index, middle, and ring fingers) for the same keys.

Table 1: Distribution of categories in each condition

|  | Faces | Buildings | Tools | Num. of <br> Trials |
| :---: | :---: | :---: | :---: | :---: |
| Condition 1 | $60 \%$ | $30 \%$ | $10 \%$ | 90 |
| Condition 2 | $60 \%$ | $10 \%$ | $30 \%$ | 90 |
| Condition 3 | $10 \%$ | $60 \%$ | $30 \%$ | 90 |
| Condition 4 | $30 \%$ | $60 \%$ | $10 \%$ | 90 |
| Condition 5 | $10 \%$ | $30 \%$ | $60 \%$ | 90 |
| Condition 6 | $30 \%$ | $10 \%$ | $60 \%$ | 90 |
| Num. of <br> Trials | 180 | 180 | 180 | 540 |

Figure 1: Illustration of the experiment experimental protocol of first three trials in one condition. After participants read the instructions, images appeared on the screen and participants responded accordingly by pressing corresponding buttons. A score would appear above the picture after the participant pressed a button.

## Procedure

Subjects were asked to perform a simple classification task. The presentation of stimuli was programmed using MATLAB Psychophysics toolbox (Brainard, 1997; Kleiner, Brainard, Pelli, Ingling, \& Murray, 2007; Pelli, 1997). The experiment took place in a behavioral testing cubicle. During each condition, the participants were instructed to press a designated key to indicate the category of each presented stimulus. A score was given based on the reaction time
immediately after each response (zero for inaccurate or missing trials), and a total score was presented after each condition. The scores were presented in order to provide feedback and motivate participants to give faster and more accurate responses, and they were not used in the analysis. Stimulus-onset asynchrony (SOA; 2000, 4000, and 6000 ms ) was varied to prevent participants from predicting when the next stimulus would appear on the screen. Each trial had a fixed image duration of 1000 ms , and the image would not disappear after a response was recorded. Inter-trial interval (ITI) varied based on the SOA of that trial. Each subject went through all 6 conditions. Each condition had 3 blocks, and each block displayed 30 images. In total 90 images were presented in each condition, and 540 images in the whole experiment. The breaks between blocks were 15000 ms , and the breaks between conditions were two minutes. Instructions between each condition were designed to cue the participants to the new distributional information of the next condition: "Thank you for finishing the task. Please take a short break. A new but similar task will start in two minutes." The illustration of the experiment experimental protocol of first three trials in one condition is shown in Figure 1.

## Results

In total, 6480 responses were recorded $(M=521 \mathrm{~ms}$; $S D=$ 107 ms ; Accuracy $=0.948$ ). For analysis, we excluded the trials with incorrect responses or no responses. And across all participants, 336 out of 6480 trials ( $0.05 \%$ ) were excluded for this reason. Paired two-tailed t-tests showed that for all twelve subjects, mean response times of block 2 for each condition were significantly less than those of block 1 , $t=2.255, p=0.038<0.05$; average response times of block 3 for each condition were significantly less than those of block 1 , $t=2.585, p=0.019<0.05$; but average response times of block 3 for each condition were not significantly less than average response times of block $2, t=-0.683, p=0.504$. It is possible that subjects needed several trials to acquire the distributional information of the current condition and to replace the carryover distributional information from previous conditions. And after obtaining the current distributional information, the participants were able to perform the task using this knowledge. Thus, we excluded all trials from block 1 of each condition. The analyses only contained correct responses from block 2 and block 3. Mean, standard
deviation, and accuracy of response times for each category in each frequency are shown in Table 2.

Using linear mixed-effects models in R , we compared response times for different stimuli in each distribution. We first used a 3-way interaction model (SOA $\times$ category $\times$ frequency), but did not find any significant 3-way interaction. Instead, a reduced 2 -way interaction model (category $\times$ frequency + SOA $\times$ category + SOA $\times$ frequency) was estimated and reported in Table 3. Face was chosen as the arbitrary baseline category by R to prevent multi-collinearity in the indicator variables for the stimulus category.

SOA did not significantly interact with Frequency, and only marginally varied across Category ( $p=0.07$ ). A main effect of SOA was also significant ( $p=0.006$ ). Therefore, although SOA was not a variable of particular interest, we retained it in the model to control for the possible effects of the pre-stimulus waiting period on the anticipatory representation and thus on the change in response times.

Similarly, no main effect for Category was found, but we retained this term due to its significant interaction with Frequency (see below) and to account for Category-specific differences in baseline response rate (e.g., participants responded to faces faster than tools and buildings).

The main effect of frequency was highly significant ( $p<$ 0.001 ), consistent with our hypothesis that response times would differ as a function of the stimulus distribution. The post-hoc paired $t$-tests on subject-level mean response times found that response times indeed significantly decrease as the frequency of the stimulus category increased ( $60 \%$ vs. $30 \%$ : $t(11)=-6.08, p<0.001 ; 30 \%$ vs. $10 \%: t(11)=-5.01, p<$ 0.001).

The interaction between frequency and condition was also significant, so we examined the frequency effects specific to each category of the stimuli. We found that within each of the categories, response times generally decreased as its frequency increased (see Figure 2 for the summary of tests), although many of these tests would not survive correction for multiple comparisons. With the results from the linear mixedeffect models and the $t$-tests, we can conclude that this effect is in line with our hypothesis that participants' response times reduced proportionally to the increasing frequency of the category.

We also looked at the estimated slopes for the frequency $\times$ category interaction in the model (Figure 3), which was

Table 3: ANOVA performed on linear mixed-effects model with 2-way interactions

|  | SS | MS | Num. DF |  | Den. DF | F | -value |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| SOA | 0.38 | 0.38 |  | 1 | 6119.5 | 7.644 | 0.006 ** |
| Category | 1.63 | 0.82 |  | 2 | 6119.3 | 0.676 | 0.509 |

highly significant in the ANOVA. Steeper slopes indicate a stronger influence of frequency on that category. It is clear that frequency influenced face more than it influenced tool, and it influenced tool more than it influenced building (slope(face) $=-2.123$; slope $($ building $)=-1.156 ;$ slope $($ tool $)=$ -1.395).

Figure 2: Average response times for each category in each frequency. The error bars were indicated by one standard error of the mean.

Figure 3: Frequency $\times$ Category Effect

## Discussion

In this study, we showed behavioral evidence that response times decreased with the higher frequency of occurrence of the upcoming stimulus. The evidence consisted of lower response times for categories with the higher frequencies of occurrence in the input as opposed to the category with lower frequencies of occurrence. Higher probability could be reasonably more predictable and therefore facilitated
classification response and reduced response times. This result could be explained if the response to each category engaged anticipatory processes that completed with the overall probability information across all categories. The results were in line with our hypothesis that the anticipatory representation acquired through distributional learning affects responses in a classification task by allowing faster response times according to the frequency of a category appearing.

Previous studies have been focused on frequency information learning between specific stimulus-stimulus associations (e.g. Conway et al. 2005; Kirkham et al. 2002; O’Brien \& Raymond, 2012; Olson \& Chun, 2001; TurkBrowne et al. 2005). However, no study, to our knowledge, has looked into the effect on distributional information about the internal representations of the stimuli. And here we present robust evidence that implicit distributional information about the internal representations of the stimuli could be learned, subsequently facilitated responses to trials of the more frequent category, and therefore caused the anticipation effect.

We also found that participants could learn new distributional information and this new information could override the previously learned distribution relatively quickly (i.e., within 30 trials or one block of the experiment). Although our finding gives a rather coarse estimate of distributional learning efficiency due to the use of response times as an index of learning with relatively low resolution, this result provides strong evidence for on-line learning, because the participants were required to give a response on every trial. Some previous studies relied on off-line learning tests so that they have not been able to study the speed of the distributional learning. Other studies that looked into the online learning of probabilistic information also suggested that probabilistic information could be obtained quickly (Abla, Katahira, \& Okanoya, 2008; Turk-Browne et al., 2009), although these studies used probabilistic information about stimulus-stimulus associations instead of the overall distributional pattern of the stimuli.

Additionally, results showed that building and tool categories were less affected by frequency than faces were. Humans are highly experienced at recognizing faces for evolutionary purposes (Leopold \& Rhodes, 2010; Little, Jones, \& DeBruine, 2010; Sheehan \& Nachman, 2014), and therefore it is possible that human faces can be more quickly recognized and distinguished than other categories can. The perception of faces might have a lower minimal response time in the high-frequency condition, and thus participants' performance for faces was far faster than the other conditions at the $60 \%$ frequency.

At the beginning of the paper, we intended to measure the anticipation of the probabilistically distributed category using comparisons between response times. The above results, using response times as the indication of the anticipation effect, showed that the participants successfully learned and used the distributional information. However, although response time has been used in some studies as an indication
of anticipation (Haith et al., 1988; Hinrichs et al., 1970; Todorovic et al., 2011; Poulton, 1950), it does not directly measure the neural response to anticipatory effect after distributional learning. It is possible that the categories were also directly encoded or primed at relative magnitudes in the brain as a function of frequency, producing this response time effect. This promising result from this behavioral experiment points to the possibility of a future experiment using neuroimaging techniques (e.g., fMRI) to test the hypothesis that probabilistically weighted brain activity also corresponds to the category frequencies, and can be found in the neural activity immediately prior to each trial.

Further studies can combine our behavioral results with the ability to detect categorical specific activation using fMRI to explore the neural basis of anticipation after implicit distributional learning. The adaptive nature of human categorization assumes that categorization reflects the optimal estimates of the probability of unseen features of objects (Anderson \& Milson, 1989). Turk-Browne et al. (2010) identified a neural mediator of anticipation for stimuli as a consequence of implicit distributional learning of paired and unpaired images using fMRI. A region of interest analysis of this study found increased activation of the category-specific brain area from the anticipation of that category and suppressed activation of the area when the predictive stimulus was from another category. These findings suggest that category-specific cortical activation due to implicit perceptual anticipation after implicit probabilistic learning is detectable in the category-specific brain regions using fMRI.

In sum, our study gave behavioral evidence that anticipation for the category of the upcoming stimulus is proportional to the distribution over all the categories. In the future, we hope to see neuroimaging experiment that shows anticipation after distributional learning can be measured in brain activity, and the representation is proportional to the learned distribution.

# Analytic Causal Knowledge for Constructing Useable Empirical Causal Knowledge: Two Experiments on Preschoolers 

Patricia W. Cheng (cheng@lifesci.ucla.edu)<br>Department of Psychology, University of California, Los Angeles, CA 90095 USA<br>Mimi Liljeholm (m.liljeholm@uci.edu)<br>Department of Cognitive Sciences, University of California, Irvine, CA 92697 USA<br>Catherine M. Sandhofer (sandhof@psych.ucla.edu)<br>Department of Psychology, University of California, Los Angeles, CA 90095 USA

#### Abstract

The present paper examines what domain-general causal knowledge reasoners need for at least some outcome-variable types to construct useable content-specific causal knowledge. In particular, it explains why it is essential to have analytic knowledge of causal-invariance integration functions: knowledge for predicting the expected outcome assuming that the empirical knowledge acquired regarding a causal relation holds across the learning context and an application context. The paper reports two studies that support the hypothesis that preschool children have such knowledge regarding binary causes and effects, enabling them to generalize across contexts rationally, favoring the causal-invariance hypothesis over alternative hypotheses, including interaction (e.g., linear) integration functions, heuristics, and biases.

Keywords: Causal induction; causal learning; causal invariance, rationality; cognitive development

## Introduction

How do we humans best represent the world so that we are able to achieve desired outcomes? A basic requirement is that the world knowledge we acquire be useable. Whenever we use our past knowledge to achieve a desired outcome (e.g., avoid a certain food to prevent a skin or intestinal reaction), we are inevitably generalizing from the learning context (e.g., items for meals at home preceding past allergic reactions) to a subsequent new context (lunch at work the next day, food during foreign travel). By contexts with respect to a cause in question, we mean occasions or settings where (known or unknown) enabling conditions and alternative causes of the target outcome may occur with different probabilities.

By adulthood, humans appear to make causal judgments that suggest they assume causal invariance - namely, that causes operate in an invariant manner across the learning and application contexts - as a default and as a criterion for revising causal knowledge (e.g., Cheng, 1997; Liljeholm \& Cheng, 2007; Lu, Rojas, Beckers \& Yuille, 2016; Lu, Yuille, Liljeholm, Cheng \& Holyoak, 2008). If the concept of causal invariance is essential to the construction of useable causal knowledge, we would expect young children to use it just as adults do. Alternatively, if the concept operates as an acquired strategy or heuristic in causalknowledge construction, young children would be less likely to use it, especially when its use requires
mathematical skills that are far beyond the children's general level of mathematical capability.

A large literature on children's causal reasoning shows that children are able to reason causally from a young age (e.g., Gopnik, 2009; Gweon \& Schulz, 2011; Legare, 2012; Rakison \& Krogh, 2012). For example, like adults, children can learn deterministic conjunctive or disjunctive causal relationships and generalize the relationship that better fits the evidence to other variables (Lucas, Bridgers, Griffiths \& Gopnik, 2014). However, there has been little work on the essentiality of the causal-invariance concept in the shaping of causal knowledge. In particular, it is not known whether children use that concept, rather than simple approximations or heuristics. Young children's use of a probabilistic form of causal invariance would provide especially strong support for its essentiality.

To see why knowledge of causal invariance is essential for constructing useable causal knowledge, consider situations in which a) there may be background causes present, b) these causes may vary from context to context, and c) the set of candidate causes under evaluation may not include one that generalizes well across contexts. Natural settings often hold these challenges. When we want to infer what cures an illness, for example, the illness must have some non-zero probability of occurring due to some background generative cause. The illness need not occur across all individuals, suggesting that background alternative preventive causes may be present. And the illness may be more or less prevalent in different contexts (e.g., countries). The fact that the "no confounding" condition is a standard principle in experimental design is an indication of the pervasive need for the influence of a target cause to be teased apart from that of background causes. A further challenge is that our initial parsing of events to isolate distinct candidate causes may not yield predictions that generalize to application contexts. Moreover, generalizability is a matter of degree (Woodward, 2000, 2003). We may encounter occasions on which a relation that we have assumed to be generalizable unexpectedly fails to hold (e.g., when on a trip up a tall mountain we find that eggs boiled the usual amount of time remain uncooked). The replicability crisis in medical research is a reminder of failures to generalize even in costly planned investigations, not to say in everyday inferences. The need to go beyond one's current set of candidate causes is ever present.

Given the goal of formulating useable causal knowledge, information about a failure to reach that goal - failure indicated by a notable deviation from the outcome expected assuming that the acquired knowledge generalizes when applied - would be useful for assessing whether to retain or revise that knowledge. Along with our colleagues, we have proposed that mathematical functions characterizing the sameness of influence of a cause across contexts - functions which differ depending on the form of the cause and effect variables (e.g., binary vs continuous) rather than their content (e.g., tobacco smoking causes lung cancer) - play a critical role in the construction of causal knowledge (e.g., Cheng, Liljeholm \& Sandhofer, 2013; Cheng \& Lu, in press). We term these causal-invariance functions. Whenever there are too many possible causal models to exhaustively evaluate, causal invariance is a helpful signal.

We have further noted that the vastness of the search space of possible causal representations renders the use of causal invariance not merely helpful but essential. A basic tenet of cognitive science -- that our perception and conception of reality are our representations -- implies that the search space of the representation of reality is infinite. In an infinite search space, an exhaustive evaluation of the possible causal models is not merely practically infeasible, but in principle impossible. Given the nature of the problem of causal knowledge construction, the need to go beyond one's current candidate causes becomes clear. Deviation from the outcome expected based on causal-invariance functions serves as an essential navigating device.

What if the need for revision is signaled instead by deviation from a causal-interaction (i.e., non-causalinvariance) criterion? In that case, that is, if candidate $c$ 's influence on target effect $e$ is expected to vary depending on the state of the background causes, there would be a deviation from expectation -- signaling a need to revise causal knowledge -- when the influence of $c$ in fact generalizes across contexts. Conversely, no deviation from expectation would confirm that $c$ interacts with background causes (its inferred influence therefore should not generalize across contexts). But no deviation from expectation means no signal to revise. Given an inverted signal to revise, in the infinite search space of possible representations of reality, the acquired causal knowledge is unlikely to hold when applied or to replicate when further tested.

If our thesis on the essentiality of the concept of causal invariance is correct, we would expect young children to use the concept, even when its use requires mathematical skills that are far beyond the children's general level of mathematical competence, and even though such usage contradicts an irrational but common practice in medical or business research. Our two studies on preschool-aged children tested their use of a causal-invariance versus a causal-interaction criterion.

## Analytic Knowledge of Causal Invariance

For all situations, every observed outcome is inherently the outcome due to the totality of its causes; the contributing
causal relations are not differentiable by observation. When background causes are present, the unobservability of causation requires that causal learners adopt an assumption (either tacitly or explicitly) regarding how the total causal influence that results in the observed outcome is decomposed into the influences by the candidate and the background causes. The functions characterizing the decomposition are often called integration functions. Causal invariance functions are integration functions that specify the sameness of causal influence across contexts. Different integration functions yield different causal conclusions (e.g., see Lu et al, 2008). Our Study 1 presents a situation where multiple integration functions yield qualitatively different causal recommendations.

One might argue, however, "Why would a particular integration function have a special status? Which integration function is appropriate depends on the domain. Although causal-invariance functions explain the results from many experiments (e.g., see Lu et al., 2008), perhaps due to reasoners' prior knowledge of how some causes combine their influences in certain scenarios, other integration functions may be more appropriate for describing how causal influences combine in other domains." Even if causal-invariance functions are the default integration functions, the argument may go, "whenever these functions do not fit the data from a domain, they would be - and should be - given up in favor of a better-fitting integration function. Causal-invariance functions may be a convenience, but the key factor is how well an integration function explains causation in a domain. Adherence to particular integration functions regardless of domain would be irrational." This argument may appear to have empirical support: Adults and even children have been shown to be able to learn various causal integration functions and generalize their learning to novel variables presented in the experiments (e.g., Lucas et al., 2014; Melchers et al., 2004).

To explain the relation between our work and work on integration-function learning, we make two distinctions: 1) a distinction between analytic and empirical knowledge (cf. Hume's, 1739, "truths of reason" and "matters of fact") and 2) a part-whole distinction, between a "whole" cause (elemental or complex) and an interactive component within a whole cause. Whereas empirical knowledge is contentspecific and justified by experience or data, analytic knowledge is content- and domain-general (i.e., formal) and is justified by reason, by what deductively follows based on the meaning of the concepts in question. Previous work has studied the generalization of acquired empirical (data-based) integration functions. In contrast, our work studies the role of a causal-invariance function as analytic knowledge, operating as a default and a revision criterion in causalknowledge construction, with both roles motivated by the (tacit) goal of formulating useable causal knowledge.

The combination of biological factors that lead to "healthy forest growth" is a whole cause of that outcome; adequate nitrates in the forest soil is an interactive component in that complex whole cause. Arsonists and the
lumber industry are two other whole causes that influence that outcome. Likewise, the gravitational force from a celestial body $y$ on a celestial $x$ is a whole cause of $x$ 's motion; the masses of bodies $x$ and $y$ and the distance between them are interactive components within that whole cause. The gravitational forces from other celestial bodies on $x$ are other contributing whole causes of $x$ 's motion, independently influencing that motion.

Note that within the same domain (e.g., gravitational force), an interaction function (i.e., Newton's law of universal gravitation) integrates the influences from specific component factors (e.g., the masses of the two celestial bodies in a pairwise gravitational force) and a causalinvariance function (vector addition) integrates the influences from multiple whole (presumably noninteracting) causes (e.g., the gravitational forces from multiple bodies on a target body simply sum up). To enable prediction, the aim of causal-knowledge construction is to formulate whole causes (elemental or complex) that are teased apart from, that do not interact with, other causes (e.g., whole causes in the background).

Because causal-invariance and causal-interaction functions exist within the same domain, empirical integration functions are content- or context-specific rather than domain-specific. Whether an acquired interactionintegration function generalizes to other candidate causes depends on the perceived similarity between the relevant causal mechanisms (e.g., Lucas \& Griffiths, 2010, Expt. 5; Wheeler, Miller, and Beckers, 2008, Expt. 3) as well as on situational variables (e.g., Wheeler et al., 2008, Expts $1 \& 2$; the demand characteristics of an experiment). In contrast, causal-invariance functions (e.g., vector addition, the noisy-AND-NOT function in Eq. 2) are formal, specific to variable types (vectors \& binary variables, respectively), but general across domains, contents, and contexts. As explained earlier, for the goal of constructing useable causal knowledge, only causal-invariance functions can serve as a default and a revision criterion for integrating the influence of ideally whole candidate causes with the influence of (potentially unknown) other causes.

## Causal-Invariance Functions for Binary Variables

The causal-invariance functions for two binary causes of a binary effect - a candidate cause of an outcome and the background causes as group - are as follows (e.g., Cheng, 1997; Pearl, 1988). There are different but logically consistent functions for potentially generative and potentially preventive candidate causes.

For a candidate cause $c$ that potentially generates effect $e$ and does so independently of alternative causes in the context, denoted $a$ as a group, the probability of observing $e$ is given by a "noisy-OR" integration function,

$$
\begin{equation*}
P\left(e=1 \mid c ; w_{a}, q_{c}\right)=q_{c} \cdot c+w_{a}-q_{c} \cdot c \cdot w_{a} \tag{1}
\end{equation*}
$$

where $c \in\{0,1\}$ denotes the absence and the presence of candidate cause $c, e \in\{0,1\}$ denotes the absence and the presence of effect $e, q_{c}$ represents the generative power of the candidate cause $c$, and $w_{a}$ represents the probability that
$e$ occurs due to all background causes, known and unknown. For a candidate cause $c$ that potentially prevents effect $e$, the probability of observing $e$ is given by a "noisy-AND-NOT" integration function:

$$
\begin{equation*}
P\left(e=1 \mid c ; w_{a}, p_{c}\right)=w_{a}\left(1-p_{c} \cdot c\right) \tag{2}
\end{equation*}
$$

where $p_{c}$ is the preventive causal power of $c$. These "noisylogical" integration functions (terminology due to Yuille \& $\mathrm{Lu}, 2008$ ), under the assumption that there is no confounding [i.e., when $\mathrm{P}(a=1 \mid c=1)=\mathrm{P}(a=1 \mid c=0)$ ], imply respectively equations for estimating $q_{c}$ and $p_{c}$. The equation for estimating preventive power $p_{c}$, for example, is:

$$
\begin{equation*}
p_{c}=\frac{P(e=1 \mid c=0)-P(e=1 \mid c=1)}{P(e=1 \mid c=0)} \tag{3}
\end{equation*}
$$

Our experiments test preschoolers' use of noisy-logical functions, the probabilistic version of disjunction, in their role as analytic knowledge of causal invariance for binary variables. Testing for knowledge of probabilistic causal invariance rather than deterministic disjunction provides a stronger test of our thesis.

## Preschooler Experiments

Our two studies with preschool children tested our causalinvariance hypothesis against alternative hypotheses, including ones in addition to the linear-integration rule tested in Liljeholm and Cheng (2007). The linear rule states that the observed value of the outcome is explained by the sum of the individual causal influences present. Our studies concern evaluating the effects of two treatments for removing (or preventing) an undesirable outcome, to decide which treatment best removes the outcome. Generalizing across contexts in the scenario involves generalizing from a farm context to a zoo context. Study 1 tested a situation in which the noisy-AND-NOT and linear integration rules yield opposite recommendations for action, and the divergence does not diminish with increased sample size.

Unlike the event frequencies in Liljeholm and Cheng's experiments, the event frequencies in Study 1 (see Table 1) were constructed so that logistic regression and the linear rule recommend the same action (see Cheng et al., 2003 for an explanation of the shared recommendation), contrary to that recommended by the noisy-AND-NOT rule. Logistic regression is a widely used statistical procedure in the medical sciences for evaluating the causal effects of treatments for binary outcome variables. Binary variables are common in medicine (e.g., whether or not a bone is fractured, a tumor is malignant, a woman is pregnant, a patient survives).

In both Studies 1 and 2, the children listened to an interactive story that concerns two brothers - a farmer and a zookeeper - who noticed that some of their animals had red dots on their faces. They were told, "The animals didn't seem sick at all, but the red dots made them look kind of funny." They heard that two "really tasty" and healthy treats, one a grain and the other leaves, might make the red dots go away. The brothers decided to figure out whether the treats work. First, they visited the farm, and fed the
grain treat to every farm animal; later they visited the zoo, and fed both treats to every zoo animal.
Table 1 displays the pattern of event frequencies at the farm and at the zoo for Study 1. The critical "transfer" question is: To relieve red dots on new farm and zoo animals that have red dots on their faces, if one has to choose one and only one treat, what is one's best bet on which treat to use, grain or leaves? Assume that neither treat has any bad effects.

Table 1: Event frequencies for Study 1

| Intervention | Farm <br> Grain <br> only | Zoo <br>  <br> leaves |
| :--- | :--- | :--- |
| Animals with dots: <br> Pre intervention | $9 / 10$ | $4 / 10$ |
| Animals with dots: <br> Post intervention | $6 / 10$ | $1 / 10$ |
| Number Cured <br> Fraction Cured | 3 | 3 |

Regardless of how "sameness of influence" is defined, the rationale underlying the choice is: Assuming the grain operates the same way across contexts (i.e., farm and zoo), then if the influence of the intervention (grain at farm vs. both treats at zoo) is observed to be the same across contexts, one's best guess would be that leaves had no influence - grain alone would already explain the outcome. But, if the influence of the intervention varied across contexts, one would attribute the difference to leaves.

Whereas the causal-invariance function predicts recommending leaves, models adopting a linear integration rule, frequentist or Bayesian, recommend using grain. Here we briefly sketch inferences according to the two rules (for prediction details see Cheng et al., 2013).

First, according to the noisy-AND-NOT integration rule (using Bayesian maximum-likelihood estimates of causal strengths as the predictor), the outcomes at the farm suggest that the grain removes red dots in a farm animal with a $1 / 3$ probability. Assuming the grain's efficacy remains the same for the zoo animals as for the farm animals, grain would be expected to remove red dots with a probability of $1 / 3$ in every zoo animal. It should be clear that the treat ingested by each animal does not "know" what the treat does in other animals (the independent-trials assumption). It follows that only $1 / 3$ of the 4 zoo animals with red dots would be expected to have their red dots removed by the grain. Because in fact 3 of these 4 animals had their red dots removed, considerably more than $1 / 3$ of the 4 , the leaves must be explaining the large difference between the expected and the observed outcome. The causal-invariance function therefore predicts recommending leaves for the new animals. Note the use here of deviation from invariance as a criterion for revising one's causal beliefs, from grain as a preventive cause to leaves as a preventive cause also.

In contrast, according to the linear integration rule, because 3 of 10 animals were "cured" both at the farm and
at the zoo, the addition of the leaves treat at the zoo does not result in any additional cured animals. This rule therefore predicts that the leaves treat is noncausal, and recommends giving the new animals grain.
The transfer question can be equivalently stated in terms of an interaction with something in the context. Both variants of the question address whether one's initial causal belief regarding relieving red dots requires revision.

## Study 1

## Method

Participants The participants were 29 children ( 13 male and 16 female) Children's mean age was 3.42 years (range 2.61 to 4.84 years, $\mathrm{SD}=.60$ years). One additional child was excluded for failure to complete the task. Children were recruited from preschools in Los Angeles, CA. All children were fluent speakers of English and were learning English as a primary language.

Procedure As mentioned, children first listened to the story about the farm and zoo animals with and without red dots on their faces. The farm animals received a grain treat intervention and the zoo animals received a simultaneous grain and leaves treat intervention. In the last part of the study, children were shown new farm and zoo animals and asked to choose between two potential interventions.

Storybook Task The task was presented in a child friendly format, as an interactive storybook. The "reader" of the book was blind to any hypotheses of the study. Children were read the following cover story:
"Once upon a time there were two brothers, one was a farmer and the other a zookeeper. The two brothers loved their animals very much and took very good care of them. One day, the brothers noticed that some of their animals had red dots on their faces."

After being reassured that the animals were not sick, the children were told about the two treats, and were asked to determine their efficacy. They were told that both tasty treats would be loved by the animals.
"The two brothers decided to figure out whether the treats work. First, they went together to the farm. Then, they went over to the zoo. Let's look at what happened and see if YOU can figure out if the grain makes the red dots go away and if the leaves makes the red dots go away."

The farm context and the zoo context were presented separately, and the change in context was highlighted and emphasized. Animals in the farm context received the grain intervention only, whereas those in the zoo context received the grain and the leaves intervention in combination.

Figure 1 depicts examples of the pre- and postintervention pictures that children saw. Because it was critical for children to attend to 1) the presence or absence of the red dots and 2) the administered intervention, those aspects of the story were interactive. For example, children were told "Here is a cow before it ate anything today" and then were asked "Does this cow have any red dots?" Children's responses were acknowledged (e.g., "You're
right he does have red dots"). Children were then handed a cut-out of the treat to feed to the animal. Next, children were asked to make a prediction (e.g., "Do you think the cow will have red dots on its face now that it ate the grain?") After the child replied, the experimenter said, "Let's see!" and showed the picture of the treat inside the animal's tummy, and the presence or absence of red dots was noted regardless of how the child answered (e.g., "Look no more red dots!"). This procedure was repeated with all twenty animals.

Figure 1: Examples of the pre- and post- intervention pictures.

Treat Selection The critical test was presented to children at the conclusion of the story. Children were shown two new animals (one farm and one zoo animal) with red dots on their faces and were asked to select only one of the treats, either the grain or the leaves, to make the animals' red dots go away.

Event Frequency Table 1 depicts the event frequencies for the Study 1. To control for primacy and recency effects, the first trial at the farm and at the zoo showed the same event type; likewise, the last trial at the two locations showed the same event type. (A replication of the study randomized trial order; see note at end of Study 2.) As explained earlier, the noisy-AND-NOT integration rule predicts choosing leaves, but the linear integration rule predicts choosing grain. Note that the linear prediction requires a subset of the arithmetic steps required by the noisy-AND-NOT prediction. The linear rule also predicts the outcome at the zoo perfectly assuming fewer causes than the noisy-AND-NOT rule, namely, a single cause rather than two causes.

## Results

Children were attentive during the storybook reading and rarely responded incorrectly about the presence or absence of red dots. Across all children and all questions there were 7 initial incorrect responses (out of 360 total queries). For these seven responses children were corrected (e.g., "Look here are red dots") and queried again.
The critical result concerned which treat children selected to make the animals' red dots go away. As Figure 2 shows, children overwhelmingly chose the leaves $X^{2}(1)=12.4, p$ $=.0004$, suggesting that children's responses fit with the
noisy-AND-NOT rule rather than with the linear rule. They did so despite the linear rule's relative arithmetic simplicity and its perfect accuracy predicting the outcome at the zoo using fewer causes.

Figure 2: Results from Study 1 depicting the number of children selecting the grain treat versus the leaves treat.

## Study 2

There are alternative explanations for why the children selected leaves in Study 1. The children's attention could be biased toward the newer second treat. The children might simply have a bias toward leaves. Or they might have used a heuristic: pick the treat uniquely associated with the fewest animals with red dots after the intervention. Previous related experiments have not ruled out analogous hypotheses. To rule out all three alternative explanations, Study 2 presented the same story but with the event frequencies in Table 2 to a separate group of preschoolers. As should be clear, the heuristics and biases still predict choosing leaves. For example, as before, fewer animals had red dots after the intervention at the zoo than at the farm (one and two, respectively). The noisy-AND-NOT rule predicts choosing grain this time; the "treatment" maintained the same preventive strength of $3 / 4$ at the farm and at the zoo. Along with the above heuristics and biases, the linear rule predicts no change from the recommended action in Study 1.
Table 2. Event frequencies for Study 2

| Intervention | Farm <br> Grain <br> only | Zoo <br>  <br> leaves |
| :--- | :--- | :--- |
| Animals with dots: <br> Pre intervention | $8 / 8$ | $4 / 8$ |
| Animals with dots: <br> Post intervention | $2 / 8$ | $1 / 8$ |
| Number Cured <br> Fraction Cured | 6 | $3 / 8$ |

## Method

Participants The participants were 28 preschool-aged children ( $M=4.38$ years, range 2.61 years -5.18 years, SD $=.66$ years). 14 were male and 14 were female. An additional two children were excluded for failure to
complete the task and/or attend to the story. Children were recruited similarly using the same criteria as for Study 1.
Procedure The procedure replicated that in Study 1 except that there were 16 trials in total, with the event frequencies for the farm and zoo animals as specified in Table 2.

Results As before, the critical result concerned which treat children selected to make the animals' red dots go away. Figure 3 shows that children's pattern of responses reversed in Study 2: children were now significantly more likely to select the grain treat, $X^{2}(1)=5.14, p=.02$.

We replicated the pattern of results in Studies 1 and 2 in a variant in which the children were randomly assigned to the two studies, and the order of trials in each context (farm and zoo) was randomized for each child.

Figure 3: Results from Study 2 depicting the number of children selecting the grain treat vs. the leaves treat.

## Discussion

Our results favor young children's use of a causalinvariance function over use of the simpler linear function, a preference for one of the candidate causes, or a heuristic to choose the candidate more frequently paired with the desired outcome. Only the noisy-AND-NOT rule representing causal invariance can explain the opposite predominant choices across both our studies. More complex alternative hypotheses, such as use of the linear function in combination with a bias toward the candidate with the more frequent pairing, await further study.

The goal of our present paper is to provide support for the essentiality of the concept of causal invariance, as a default and a criterion for belief revision, in the construction of useable causal knowledge, when the set of possible causal representations is too large to exhaustively evaluate. Our findings indicating the early use of a probabilistic causalinvariance function -- embodying the rather abstract concept of the unchanging nature of the forces of change -- suggest that the generalizability of causal knowledge, along with parsimony and logical consistency, is not a mere wish but a constraint in the rational construction of causal knowledge.

# The relationship between fairness, cognitive control, and numerical encoding 

Nadia Chernyak (chernyak@bu.edu) \& Peter R. Blake (pblake@bu.edu)<br>Department of Psychological \& Brain Sciences, Boston University<br>Boston, MA 02215 USA

#### Abstract

Fairness, or the ability to distribute resources in a manner that accords with societally recognized principles of justice, is a hallmark of human cooperation. Young children rapidly develop the ability to enact fairness, but the cognitive underpinnings of this ability remain unknown. The present study investigated 4-7-year-olds' acquisition of three principles of fairness -- equality (the principle that all parties should have the same), merit (the principle that those who work harder should get more), and starting opportunity (the principle that those who started with less should get more) -in relation to their emerging cognitive control and memory for numerical information (numerical accuracy). Cognitive control predicted children's equal sharing, whereas numerical accuracy predicted merit-based sharing. Children up through the oldest age we tested ignored starting opportunities. The results suggest that different principles of fairness may be underpinned by distinct cognitive processes.

Keywords: fairness; cognitive control; resource distribution; children; social and cognitive development

## Introduction

Fairness, or the ability to distribute resources in a manner that accords with societally recognized principles of justice, serves as a foundation for human cooperation and is a critical cognitive achievement of early childhood. In spite of the fact that the concept of fairness itself is ubiquitous, its specific manifestation varies across individuals, cultures, and social groups (Schafer, Haun, \& Tomasello, 2015). Even within a given cultural group, many possible principles of fairness exist. For example, people endorse the idea that principles of equality and merit are both fair. The key empirical question is how people shift between different potential principles of fairness and what accounts for the acquisition of these different forms of fairness. In this work, we explored the cognitive predictors of young children's fairness behavior in a third-party resource allocation task.

Recent work in developmental psychology finds that even infants possess rudimentary concepts of fairness (Sloane, Baillargeon, \& Premack, 2012; Schmidt \& Sommerville, 2012). Throughout preschool and middle childhood, children appreciate at least three distinct principles of fairness: equality (Rakoczy, Kaufmann, \& Lohse, 2016; Smith, Blake, \& Harris, 2013), merit (Baumard, Mascaro, \& Chevallier, 2012; Damon, 1975; Jara-Ettinger, Gibson, Kidd, \& Piantadosi, 2015; Kanngiesser \& Warneken, 2012), and starting opportunity (McCrink, Bloom, \& Santos, 2010; Ng, Heyman, \& Barner, 2011). However, children do not always use these principles consistently. For example, although 3-year-olds pay attention to merit-based information (Baumard et al., 2012) and are able to incorporate it into their resource allocation decisions even
when doing so is costly (Hamann et al., 2011; Kanngiesser \& Warneken, 2012), they often ignore information about merit and enact equal distributions instead (Baumard, Mascaro, \& Chevallier, 2012; Damon, 1975; Rizzo, Elenbaas, Cooley, \& Killen, 2016).

One possibility for these discrepant results may be that different principles of fairness are underpinned by unique cognitive processes. In this work, we investigated two potential cognitive processes underlying children's resource distribution: children's memory for numerical information and children's cognitive control. Accurately encoding quantitative information is essential for both equality-based and merit-based allocation. Numerical skills operate at two levels for resource distribution tasks. First, a general numerical ability is necessary for children to execute even a simple division into two equal subsets that are matched on cardinal equivalence (see Muldoon, Lewis, \& Freeman, 2009; Sarnecka \& Wright, 2013). Indeed, counting abilities have been proposed and also recently found to relate to children's abilities to share resources equally (Chernyak, Sandham, Harris, \& Cordes, 2016; Frydman \& Bryant, 1988; Squire \& Bryant, 2002).

Merit-based distribution also requires attending to quantitative information about relative effort (i.e., that one person worked twice as hard as another) and subsequently incorporating that information into decisions about resource allocation (i.e., that the harder worker must therefore receive twice as much). Similarly, information about starting opportunities must be encoded in order to be used. Thus, sharing between two recipients based on merit or starting opportunity requires trial specific numerical encoding. In this work, we looked at whether children encoded exact numerical information for each trial or whether the information was encoded only approximately.

Finally, we looked at children's emerging cognitive control. Distributing resources according to merit or starting opportunity requires holding in mind multiple -- and often conflicting -- pieces of information and "rules" regarding resource distribution (Zelazo, Helwig, \& Lau, 1996). For example, a child must keep in mind that one person worked harder, but also that that person had a greater starting opportunity to begin with (McCrink et al., 2010). Prior work has found relationships between children's inhibitory control and their abilities to execute the normatively appropriate resource allocation in costly first-party tasks (Blake, Piovesan, Montinari, Warneken, \& Gino, 2015; Steinbeis \& Over, 2017). In third-party tasks of the type that we investigated, cognitive control may serve as a behavioral tool through which they may control their behavioral responses and implement a target distribution.

In this study, we presented 4-7-year-old children with a series of trials in which children were presented with stories about animal characters that had expended either equal or unequal amounts of work in order to acquire resources that would be jointly sold. Each character also had either equal or unequal amounts of starting opportunities. After hearing each story, children were provided with a set of resources to split between these characters. We tested children's memory for numerical information by asking children to recall the amounts of work and starting opportunities for each character after each trial. We also tested children's cognitive control by administering the Happy/Sad Stroop task (Lagattuta, Sayfan, \& Monsour, 2011).

## Method

## Participants

Participants were 67 children ( 35 female, 32 male) between the ages of 4 and 7. This age-range included a younger age group of $334-5$-year-olds (Mean age $=5.00$; Range $=4.11$ 5.82 ) and an older age group of 34 6-7-year-olds (Mean age $=7.10$, Range $=6.00-8.03$ ). Children were tested either in the laboratory or at a local preschool or elementary school.

## Materials

Materials were 12 sets of storybook panels (described below), 8 sets of plastic cookies for the resource allocation tasks, and a set of 24 black and white pictures of smiley faces ( 12 representing sad faces and 12 representing happy faces) for the Happy/Sad Stroop Task.

## Procedure

Children completed 3 pretest trials, followed by 8 focal resource allocation trials, followed by the Happy/Sad Stroop Task. All children were tested in a quiet room in the laboratory or at their local school by an experimenter. All children were videotaped with the exception of 6 children whose parents did not provide video consent and 4 due to technical issues. The experimenter or a trained research assistant also transcribed answers as children during test.

Pretest Trials All children began were introduced to the structure of the storybook task via 3 pretest trials aimed at making children understand the relevant components of each story. In the first panel, the experimenter showed the child two dinosaurs and said that sometimes in the stories some characters will have different amounts. She then indicated that one dinosaur had way more candy than another, and asked the child to recount which dinosaur had more. In the second panel, the experimenter showed the child two dinosaurs and said one worked harder than another and asked the child to recount which one worked harder. Finally, in the last panel, the experimenter showed the child two dinosaurs and said both had the same and worked the same amounts. She then asked the child to recount whether either of the dinosaurs had more and also to
recount if one had worked harder. Incorrect responses were followed with corrective feedback and re-prompts.

Test Trials In each resource allocation trial, children were presented with two animal characters (e.g., two cats) who each acquired resources to achieve a shared goal (e.g., catching fish to sell at the market). The characters contributed either equal or unequal amounts of work towards the shared goal (e.g., one cat caught 4 fish the other caught 2). The characters also had either the same or different starting opportunities (e.g., one cat fished from a pond with 4 fish whereas the other cat fished from a pond with only 2 fish).
An example of the materials and wording of the task is shown in Figure 1 below.

We used a 2 (Starting Opportunity: Equal or Unequal) x 2 (Work Expended: Equal or Unequal) design in which we presented each child with 4 different trial types (2 of each type totaling 8 trials per child): (a) all equal trials (i.e., trials in which characters had exactly the same starting opportunity and expended the same amounts of effort); (b) equal opportunity, unequal work trial, (c) unequal opportunity, equal work trials (e.g., a trial in which two cats both obtain 2 fish, but one started with a pond that only had 2 and another started with a pond that had 4), and (d) unequal opportunity, unequal work trials. In these last trials, characters produced unequal amounts of work, but also had different starting opportunities. For example, one cat caught 2 out of 4 fish and another caught 1 out of 2 fish. The ratio of opportunity to work expended was thus equal.

Figure 1: Example of a Resource Allocation Trial

The types of trials and numbers used in each trial are summarized Table 1 below. As may be noted in this table, the work ratios between the two characters were $1: 1$ if equal and always $2: 1$ if unequal (i.e., the character who worked more obtained twice as much). Additionally, ratios between
a given character's starting opportunity and work expended were also either $1: 1$ or $2: 1$.

Each of these four trial types were presented in 2 blocks: a large number block in which we used relatively large numbers of starting opportunities and work expended (e.g., 8 and 4 fish), and a small number block in which we used relatively small numbers of starting opportunities and work expended (e.g., 4 and 2 fish). Within each block, the presentation of the four different trial types were counterbalanced with a Williams Latin Square design. We also counterbalanced which block type (large vs. small) was presented first as well as whether the larger vs. smaller numbers appeared on the child's right or left side. Each trial used one of four possible animal pairs: cats that fished fish, rabbits that grew carrots, bears that picked apples, and monkeys that picked bananas. Presentation of animal types and colors of animal characters were fixed.

Resource Allocation After being read each scenario (trial type), children were shown 6 plastic cookies that the characters earned from their joint effort. Children were told that they had to decide which characters should get which cookies. Cookies were arranged in a linear array in between two cardboard boxes that depicted the two animal characters. We note that we used 6 cookies specifically because they enabled either distribution according to equality (i.e., 3 cookies to each character) or distribution according to a $2: 1$ merit ratio (i.e., 4 cookies to the harder worker and 2 to the less hard worker). We recorded the amount children gave to each character.

Table 1: Numbers used in each trial type

| Trial Type | Starting <br> Opportunity | Work <br> Expended | Block <br> Type |
| :--- | :--- | :--- | :--- |
| All equal | $(8,8)$ | $(4,4)$ | large |
| Equal opportunity, <br> unequal work | $(8,8)$ | $(8,4)$ | large |
| Unequal opportunity, <br> equal work | $(8,4)$ | $(4,4)$ | large |
| Unequal opportunity, <br> unequal work | $(8,4)$ | $(4,2)$ | large |
| All equal |  |  |  |
| Equal opportunity, <br> unequal work | $(4,4)$ | $(4,4)$ | small |
| Unequal opportunity, <br> equal work | $(4,2)$ | small |  |
| Unequal opportunity, <br> unequal work | $(4,2)$ | $(2,2)$ | small |
| Numerical Accuracy <br> each trial, boxes and materials were closed and put away, |  |  |  |

and children were asked four questions to assess their memories for the numerical information presented to them in the trial: two questions asking them to recall the characters' starting opportunities (e.g. "How many fish did green Kitty have in green Kitty's pond? How about red Kitty?") and two questions asking them to recall the characters' work expended (e.g., "And how many fish did green Kitty get out of green Kitty's pond? How about red Kitty?"). For each of these, we computed a continuous accuracy measure reflecting the Percent Absolute Error that children's answers displayed (Siegler \& Booth, 2004). Percent Absolute Error (PAE) was calculated via the following formula:

$$
\text { PAE }=\frac{\mid \text { child's answer }- \text { correct answer } \mid}{\text { correct answer }}
$$

This score reflected the deviation of the child's answer from the correct answer. For example, a child who answered that there were 5 fish when the correct answer was 4 would receive a PAE score of $|5-4| / 4=25 \%$. Thus, high PAE scores indicated lower accuracy, and low PAE scores reflected higher accuracy (with a score of 0 indicating having correctly recalled the exact number). On each trial, each child was given two scores assessing trial specific numerical encoding: a Starting Opportunity PAE reflecting the average PAE of the two opportunity questions, as well as a Work Expended PAE reflecting the average PAE of the two work expended questions on that trial. These are labeled as trial specific because they reflected children's accuracy for numbers on that specific trial only.

Additionally, children received an Overall PAE reflecting numerical accuracy average across all 32 questions asked (4 per trial), which reflected general numerical memory. This was referred to as general numerical memory because it reflected children's tendency to correctly estimate numbers overall, not on any given trial.

Cognitive Control After completion of all 8 resource distribution trials, children were administered a version of the Happy/Sad Stroop Task. Following procedures used in (Lagattuta et al., 2011), children were introduced to a happy and a sad face and asked to label them. They were then told they would be playing an "opposite" game in which they had to label happy faces as "sad" and sad faces as "happy". After ensuring all children understood task instructions, children completed 4 practice trials (corrective feedback was provided) followed by 20 test trials (no corrective feedback). Children were given a Cognitive Control Score between 0-20 reflecting the number of correct test trials.

## Results

Preliminary results showed no effects of gender or block type, so we collapsed data across these variables. We first sought to characterize children's resource allocation decisions by coding the outcomes as equal, merit, or other (unequal for equal trials or against merit; see Figure 2).

We ran separate models predicting children's tendency to share resources equally. We ran a within-subjects mixed linear model using equal sharing allocation as the dependent variable and Age (entered continuously), Work Expended (equal or unequal), Initial Opportunity (equal or unequal) and all interaction effects as the predictors. There was a significant main effect of Work Expended, $F(1,528)=$ 9.102, $p=.003$ a significant Age x Work Expended interaction, $F(1,528)=18.07, p<.001$, and no other significant effects ( $p$ 's $>.15$ ). Thus, equal allocations were predicted by age and whether the characters had expended equal amounts of work.

Figure 2: Allocation Types Across Trials

Note. Merit-based sharing is impossible in Equal Work Expended Trials

We also looked at predictors of merit-based sharing. Children were coded as having given a merit-based allocation if they had given more resources to the harder working character (i.e., one who produced a greater amount of resources). Because merit-based sharing was not possible in the All Equal trial, we excluded this trial from that analysis. There was a significant Age x Work Expended interaction, $F(1,396)=4.81, p=0.03$, and no other significant effects (all $p$ 's > .09). Thus, children made more merit-based allocations with age.

To better characterize these interactions, we explored how age impacted merit-based and equality-based sharing separately in each trial type. We thus ran follow-up models for equal work expended and unequal work expended trials using Age as a predictor. The results of these analyses are summarized in Table 2 (Model 1). We ran separate models using equal sharing as a response and then merit-based sharing as a response.

As shown in Table 2, Age predicted equal sharing in the trials in which characters produced equal amounts of work (top panel of Table 2; All Equal and Unequal Opportunity, Equal Work trials), whereas Age predicted merit-based sharing in trials in which characters produced unequal amounts of work (bottom panel of Table 2).

Therefore, confirming the previous analyses, all children ignored starting opportunities. However, age predicted children's likelihood of selecting the "correct" allocation type in each trial - equal-based sharing in the trials in which
characters produced equal amounts of work, and meritbased sharing in the trials in which characters produced unequal amounts of work.

We next investigated whether these age-related changes were explained by numerical accuracy or cognitive control. In particular, we first looked at whether children's numerical accuracy predicted their resource allocation decisions. Recall that on each trial, each child was given two scores: a Starting Opportunity PAE and a Work Expended PAE. Preliminary analyses revealed no differences between the two PAE types, suggesting that children were equally adept at encoding both types of information.

We first looked at the predictors of each PAE type. For each model, we ran a mixed linear model using Age, Work Expended, and Initial Opportunity as predictors. We also included Cognitive Control Total Correct as a covariate to ensure that any potential age-related changes in encoding accuracy were not simply attributable to changes in cognitive control.

For Starting Opportunity PAE, there was a significant effect of Age, $F(1,464)=93.71, p<.001$, with older children showing lower PAE (higher accuracy) for initial opportunity and no other significant effects (all $p$ 's $>.25$ ).

For Work Expended PAE, there was a significant effect of Age, $F(1,464)=43.89, p<.001$, and a significant effect of Work Expended Trial Type, $F(1,464)=20.05, p<.001$, with children showing worse encoding of work expended when the characters put in unequal amounts of work. Therefore, both age and trial type also predicted children's recall of the work expended. Children were better at encoding numerical information when characters had expended equal amounts of work.

Finally, we looked at predictors of Overall PAE. Age significantly predicted Overall PAE, $F(1,55)=24.32, p<$ .001, and Cognitive Control did not (once accounting for age; $p=0.42$ ). Therefore, numerical accuracy and cognitive control were dissociable, despite both getting better with age. ${ }^{1}$

We next investigated whether these age-related differences in encoding accuracy might explain age-related changes in children's resource allocation decisions. Because children ignored starting opportunities, we do not further consider the Starting Opportunity PAE. Recall that each child could be coded as giving either an "equal split", "merit-based split", or neither split ("other"). For the separate analyses we coded these as equal split or not and merit-based split or not.

We first looked at predictors of equal sharing. Preliminary analyses revealed significant interactions between various predictors for the trial types. Therefore, we first considered the equal work trials only. We ran two mixed binary logistic regression models using equal sharing as a response variable and Age, Work Expended PAE, Overall PAE and Cognitive

[^302]Control as the predictors. ${ }^{2}$ The critical question was whether either Work Expended PAE or Cognitive Control might predict children's equal resource allocation.

As shown in Table 2, in the Equal Work Expended trials, Cognitive Control and Overall PAE (general numerical memory - the average error across the 32 questions asked) predicted children's equal sharing behavior. Once Cognitive Control and Overall PAE were accounted for, there was no longer any significant effect of age. Therefore, both cognitive control and general numerical memory explained age-related changes in sharing resources equally.

We then looked at predictors of merit-based allocation. As shown in Table 2, Work Expended PAE was related to the propensity to split resources meritoriously, but cognitive control and Overall PAE were not. Age continued to be related to the propensity to make merit-based splits.

Table 2: Beta Coefficients (and Standard Errors)

| Response: Equal Sharing | Equal Work Expended | Unequal Work Expended |
| :---: | :---: | :---: |
| Model 1 |  |  |
| Age | . 40 (.13)** | -. 34 (.11)** |
| Model 2 |  |  |
| Age | -. 22 (.18) | -. 50 (.14)** |
| Cognitive Control | 0.15 (.06)* | . 11 (.06)* |
| Work Expended PAE | -. 46 (.35) | -. 16 (.21) |
| Model 3 |  |  |
| Age | -. 24 (.18) | -. 50 (0.14)** |
| Cognitive Control | . 14 (.06)* | . 13 (.05)* |
| Overall PAE | -. 28 (.13)* | -. 08 (.12) |
| Response: Merit Sharing | Equal Work Expended | Unequal Work Expended |
| Model 1 |  |  |
| Age | - | -43 (.11)*** |
| Model 2 |  |  |
| Age | - | . 35 (.15)* |
| Cognitive Control | - | . 006 (.06) |
| Work Expended PAE | - | -. 89 (.40)* |
| Model 3 |  |  |
| Age | - | . 40 (.15)** |
| Cognitive Control | - | . 006 (.06) |
| Overall PAE | - | . 11 (.16) |

The Table 2 results suggest two things: first, cognitive control and general numerical accuracy predicted propensity to make equal splits. Second, trial specific numerical accuracy for work expended (ability to properly encode merit-based information specifically) predicted children's abilities to make merit-based splits on trials that called for merit-based splits (i.e., trials in which characters produced unequal splits). Both sets of results held when controlling for age, suggesting that age-related changes in

[^303]equal sharing may be explained by changes in cognitive control and numerical accuracy, and that age-related changes in merit-based sharing may be partly explained by changes in encoding of merit-based information.

## Discussion

Recent work has taken an interest in the cognitive predictors of fairness. Our findings are consistent with prior work showing a mostly equality-based principle during the preschool age shifting to a merit-based principle by middle childhood. We extend these findings by showing that 6 and 7 -year olds actively create merit-based distributions even when making equal allocations is a viable alternative. Most importantly, we point to two cognitive predictors of sharing behavior: children's numerical encoding ability, and their emerging cognitive control, each of which exerted a unique effect on children's abilities to make resource allocations.

One possibility for why young children often do not employ merit-based resource allocations may be that they fail to encode trial-specific numerical information to begin with. Our findings show that this may be the case: encoding accuracy for the amount of work that each character expended predicted merit-based resource distribution on trials that called for such distribution. Interestingly, numerical encoding accuracy for starting opportunity information did not predict allocations based on this information. Thus, 6- and 7-year olds specifically encoded information about starting opportunity but did not use this information when allocating resources.

The effect of numerical accuracy held even when controlling for changes in age and cognitive control. Prior work has found that, in third-party unequal work tasks, younger children can and do distribute resources according to merit but under simplified conditions such as when an unequal allocation is the only option (Baumard et al., 2012). Three- and 5-year olds are also capable of using merit in first person distributions but the strategies used vary widely (Kanngiesser \& Warneken, 2012).We propose that these individual differences may be explained by differences in the ability to accurately encode numerical information inherent in meritocratic situations.

In contrast to the cognitive processes for merit-based allocations, equal allocation decisions depended on general numerical encoding. This result falls in line with prior work finding that general numerical cognition (i.e., counting ability) predicts equal sharing among preschool-aged children (Chernyak et al., 2016). General numerical accuracy and counting ability may tap into the same underlying construct of numerical fluency and understanding of numbers, which may then help children with creating equal sets of resources.

We also found that children's emerging cognitive control predicted equal, but not merit-based, allocations across all trial types. This suggests that cognitive control serves as a general behavioral tool that allows children to choose equal outcomes in spite of inequalities present in the scenarios. One possibility for why this might be the case is that older
children have acquired and might therefore need to inhibit other potential principles (e.g., merit) in order to enact the equality. Alternatively, cognitive control may simply help children ensure that two equal sets have been created. Most importantly, cognitive control failed to predict merit-based resource distribution, suggesting a dissociation between the types of cognitive mechanisms required for equality and merit-based resource allocation.

Few children used the information about starting opportunities, despite encoding this information. Although work has found that children are able to make evaluations of others' work based on their starting opportunity (McCrink et al., 2010; Ng et al., 2011), to our knowledge, there is no current work that has shown that children then use those evaluations to make resource allocation decisions. We therefore propose that children may be well aware of existing inequalities, but do not actively use such information when making resource allocation decisions.

Overall, our work points to two important cognitive predictors for different fairness principles. We propose that searching for individual differences in children's cognitive abilities may help account for and ultimately shape their social preferences.

## Acknowledgments

We would like to acknowledge Elizabeth Asal, Claire Park, Javier Rivera, Eliana Roth, and Shaina Yoo for assistance with data collection and coding. This work was funded by a postdoctoral fellowship from the Greater Good Science Center and the John Templeton Foundation to NC.

#### Abstract

Prior studies on older adults' risk taking have paid little attention to the healthcare domain or social influences on decision making. This study examined age-related differences in medication risk taking and the effects of a collaborative decision-making experience on individuals' tendency to take risks. We recruited 24 younger (mean age $=19.50, S D=1.41$ ) and 24 older adults (mean age $=70.54, S D=2.30$ ), and asked them to choose between hypothetical medications that differed in probabilities and outcomes of treatment success. To investigate the effects of risk-neutral versus riskadvantageous trials, participants chose between a risky option and a sure option that had equal expected values (risk-neutral) or between a risky option and a sure option that had a lower expected value (risk-advantageous). Participants completed the decision task first individually (the pre-collaboration phase), then in dyads (the collaboration phase), and once again individually (the post-collaboration phase). During the pre-collaboration phase older adults showed a smaller increase in risk-taking tendency in response to riskadvantageous trials compared to younger adults. The pre-and post-collaboration data showed that older adults' risk preferences converged towards their partner's preference to a greater extent following collaboration relative to younger adults. These findings highlight the importance of designing decision aids to encourage older adults to take risks when risk taking is beneficial, and considering how social processes influence patients' medication decisions.

Keywords: risky decision making, health, aging, social influence

When choosing between options in health care, the degree of risk involved is an important consideration that younger and older individuals must make. For example, an individual may have to choose between painkillers that have different probabilities of treatment success. A National Health Interview Survey in 2012 showed that $86 \%$ of US older adults aged 65 or older have at least one chronic condition, and $61 \%$ have at least two chronic conditions, compared to $27 \%$ and $7 \%$ of US adults aged 18 to 44 (Ward, Schiller, \& Goodman, 2014). As older adults are more likely to have multiple chronic conditions, they may need to make more medical choices involving risks.

Individuals often discuss their health care decisions with family members, friends, or physicians. Despite the plentiful literature on shared decision making between patients and physicians, the emphasis is rarely on how a collaborative experience would affect subsequent health-related behavior of individuals. The lack of research on this area demands attention because it is common for individuals to make a number of choices on their own after their discussion with other people. There is evidence that family and friends influence the health-related attitudes and beliefs of patients, particularly those who are less educated and non-white (Thompson, 2013). Therefore, research should consider how discussions about health care decisions take place within patients' social networks and how to improve the resulting decisional outcomes. One of the most common health care decisions facing patients is medication risk taking.

## Age-related Differences in Risk Taking

## Risk-Neutral Decisions

Most studies on aging and risk taking asked participants to make risk-neutral choices, which involve a risky option and a sure option that have equal expected values. The expected value of an option is calculated by multiplying outcomes by their respective probabilities, and taking the sum of the products (Bernoulli, 1954). A higher expected value represents a higher average value in the long run assuming the same option is chosen repeatedly.

A recent meta-analysis of these studies found that older adults were more risk averse than younger adults in making positively framed decisions (Best \& Charness, 2015). Positively framed decisions refer to choices in which positive aspects of the scenarios are highlighted using wordings such as "keep" and "save". This finding can be explained by fuzzy-trace theory.

Fuzzy-trace theory postulates that people simultaneously store and access two types of representations (Reyna \& Brainerd, 2011). A verbatim representation reflects the precise information. In contrast, a gist representation captures the subjective interpretation of information based on emotion, experience, level of development, and is vague
and qualitative. In the context of the Asian disease problem (Tversky \& Kahneman, 1981), a gist representation of a sure option of "saving 200 people" would be "saving some people" whereas a gist representation of a risky option of "a one-third probability of saving 600 people and a two-thirds probability of saving no people" would be "some probability of saving some people and some probability of saving no people." Hence, fuzzy-trace theory suggests that people would choose the sure option when they represent the positively framed situation at the gist level. Older adults are more likely than younger adults to rely on gist processing because they may have learned that it is a more effective means of making decisions (Peters, Hess, Västfjäll, \& Auman, 2007). In addition, gist processing is relatively well preserved with normal aging although verbatim processing declines as people age (Reyna \& Brainerd, 2011). Older adults' decisions are more gist-based, which may account for their tendency to be more risk averse in the positive frame.

The meta-analysis revealed that the presence of the age effect depended on the amount and the scenario type (Best \& Charness, 2015). That is, the age effect was found in small-amount financial and large-amount mortality scenarios, but not in large-amount financial and smallamount mortality scenarios. Younger and older adults' levels of risk taking depended on the scenario. Owing to the primary use of either financial risk seeking scenarios or the Asian disease problem in the aging literature, past findings on age-related differences in risk taking may not generalize to medication decision making.

## Risk-Advantageous Decisions

Studies have also explored younger and older adults' risk taking tendencies in situations where risk seeking is advantageous and disadvantageous. From an economic perspective, an option with a higher expected value is better than an option with a lower expected value. Analyzing trials on which the expected value of the risky option was more favorable than that of the sure option, older adults were shown to be more risk averse than people of age 5 to 64 (Weller, Levin, \& Denburg, 2011). That is, older adults were less risk taking than younger adults when risk taking was beneficial. However, that study used very broad age ranges.

Based on Peters et al. (2007), and Reyna and Brainerd (2011), older adults have an increased tendency to use gist processing relative to younger adults. Thus, they may be less sensitive to the expected values of the sure and risky options and more likely to stick to their preferred options on risk-neutral trials than younger adults.

## Collaborative Decision Making

If we consider how common it is for people to exchange views with others in everyday situations of making health care decisions, it is necessary to understand medical decision making in a collaborative context. Collaboration in patient-physician relationships is not emphasized in the
traditional care model, which depicts patients as passive followers of the orders set by physicians. However, a new collaborative care model is replacing the traditional model (Mitzner, McBride, Barg-Walkow, \& Rogers, 2013). In the collaborative model, patients and physicians share the primary caregiving responsibility and make decisions together. Hence, investigating collaborative decision making and how it influences decision makers' subsequent decisions would help people make better use of others' opinions.

Collaborative decision making has been studied in social psychology. Group decision-making phenomena that have been observed include group polarization and group convergence. The former occurs when the decisions made by groups are more extreme than the initial position of its members (Sunstein, 2002). Group convergence was found in Bixter, Trimber, and Luhmann's (2017) study that focused on intertemporal monetary preferences. Individuals’ post-collaboration decisions converged towards their respective group decisions. The social comparison process was proposed to explain the findings. Participants might have changed their preferences in accordance with their group members' preferences because they viewed others' behavior as a source of information about normatively appropriate behavior. Using a risky decision task, another study demonstrated a similar behavioral change (Suzuki, Jensen, Bossaerts, O’Doherty, 2016). Participants' risk preferences shifted towards the observed person's preferences. Research is needed to better understand whether a group polarization or group convergence effect would be present in medication risky decision-making scenarios.

## Age Differences in Susceptibility to Social Effects

Given evidence suggesting age-related differences in decision making between younger and older adults, it is reasonable to ask whether younger and older adults' experience of making decisions in a group would influence their individual decisions differently. Age-related differences in the tendency to be influenced by others have been investigated for young age groups. In Gardner and Steinberg's (2005) study, participants made riskier decisions and exhibited more risky behavior when in peer groups, and the influence of peers on risky decision making and risk taking was stronger among adolescents and youths than adults. However, no research has assessed age-related differences between younger adults and older adults.

One finding which suggested that older adults might be more prone to social influence than younger adults in making decisions is the age-related difference in perceived decision-making competence. Older adults rated themselves as less competent decision makers than did younger adults (Bruine de Bruin, Parker, \& Fischhoff, 2012). Despite older adults' accumulation of experience, they may have rated their decision-making competence based on perceived declines in their fluid cognitive abilities. Owing to their lower perceived competence, older adults might change their decisions more easily when different views are
presented. This prediction is supported by the finding that participants who lacked confidence in their answers to health knowledge questions were significantly more likely than those who were confident to change their answer after receiving online social feedback (Lau \& Coiera, 2008). Furthermore, previous research has demonstrated that higher uncertainty strengthened social effects on memory reports (Walther et al., 2002). If older adults are less confident and thus more uncertain about their decisions, they might be more susceptible to social influence.

## Overview of Study

Although older adults often have multiple medical conditions and need to make health care choices involving risks, past research has not assessed age-related differences in risk taking for medication decision tasks. The goal of the current study was to study age differences in medication risk taking when risk taking was advantageous or neutral. Younger and older adults were asked to make choices between medications that involved varying probabilities and outcomes of treatment success. On risk-neutral trials, they chose between options that were equally favorable. On riskadvantageous trials, they chose between options that favored risk taking. To investigate the effect of collaboration on subsequent individual decisions, they were asked to complete the decision task first independently, then in dyads, and finally independently. Hypotheses were:

H 1 : older adults are less risk taking than younger adults.
H 2 : people are more risk taking on risk-advantageous trials than on risk-neutral trials.

H3: there is an age by trial type interaction such that older adults show a smaller increase in risk taking when risk taking is beneficial.

H 4 : older adults, compared to younger adults, are more likely to be influenced by others.

## Method

## Participants

Participants were 24 English speaking younger adults (14 females) between the ages of 18 and $23(M=19.50, S D=$ 1.41) and 24 English speaking older adults ( 14 females) between the ages of 67 and $74(M=70.54, S D=2.30)$. Participants in each age group formed 12 age-group matched dyads. All participants had at least $20 / 50$ visual acuity for near vision (corrected or uncorrected) to ensure that they could see the stimuli. The majority of older adults were highly educated, with $83 \%$ reporting having some college or higher. Other descriptive variables were demographics and health, numeracy (Lipkus, Samsa, \& Rimer, 2001), personality (Gosling, Rentfrow, \& Swann, 2003), social intelligence (Silvera, Martinussen, \& Dahl, 2001), perceived decision-making competence (Greene, Hibbard \& Tusler, 2005), processing speed (Wechsler, 1997), verbal working memory span (Wechsler, 1997), and verbal ability (Shipley, 1986). Due to limited space, results
involving some of these variables are not included in this paper. Table 1 provides descriptive data.

Table 1: Younger and older adults's scores on health and cognitive measures.

|  | Younger <br> Adults | Older Adults |  | $\mathrm{t}-$ <br> value |  |
| :--- | :--- | :--- | :--- | :--- | :--- |
| $M$ | $S D$ | $M$ | $S D$ |  |  |
| Health $^{\mathrm{a}}$ | 4.05 | .54 | 3.79 | .60 | 1.59 |
| Numeracy $^{\mathrm{b}}$ | 10.55 | .67 | 7.04 | 3.29 | $5.10^{* * *}$ |
| Processing <br> speed $^{\mathrm{c}}$ | 72.45 | 9.63 | 45.83 | 13.84 | $7.51^{* * *}$ |
| Verbal <br> working <br> memory | 8.86 | 2.30 | 7.63 | 2.50 | 1.75 |
| Verbal <br> ability | 32.08 | 3.28 | 32.96 | 4.85 | -.726 |

${ }^{\text {a }}$ Self-reported health (1=poor, 5=excellent); ${ }^{\text {b }}$ Numeracy (number of correct items from 0 to 11 on the numeracy scale); ${ }^{\text {c Processing speed (number of correct items on the }}$ digit-symbol substitution task from 0 to 100); ${ }^{\text {d }}$ Verbal working memory (number of correct items from 0 to 14 on the digits backward task); eVerbal ability (number of correct items from 0 to 40 on the Shipley institute of living scale); $* * * p<.001$.

## Materials

The experiment had three phases: pre-collaboration, collaboration, and post-collaboration. Participants made decisions independently in the pre- and post- collaboration phases, but in dyads in the collaboration phase.

Participants were asked to choose a medication for a family member who is the same age as them. We asked them to give advice to a family member rather than choose one for themselves because this was more ecologically valid with respect to the collaboration phase in which they have to interact with each other and reach a consensus. Every trial of the decision task consisted of a choice between two medications which had different probabilities and outcomes of treatment success. The sure option had $100 \%$ chance of some treatment success whereas the risky option had a variable outcome of treatment success.

There were two trial types, 20 risk-neutral trials and 20 risk-advantageous trials in each phase. On risk-neutral trials, the medications had equivalent expected values. On riskadvantageous trials, the medication with a sure outcome had a lower expected value than the medication with a variable outcome. Figures 1 and 2 show an example of each trial type. For both trial types, the risk magnitudes were $20 \%$, $40 \%, 60 \%$, and $80 \%$ on different trials and the number of days of sickness were $20,30,40,50$, and 60 on different trials. Within each phase of the experiment, the decision trials were presented in a randomized order to minimize
order effects. The percentage of time that participants chose the riskier option indicated their level of risk taking.

| The family member is going to experience 30 days of sickness because of a disease. Which medication would you recommend? |  |
| :---: | :---: |
| Medication A | Medication B |
| 20\% chance of protecting him/her | 100\% chance of protecting him/her |
| from 30 days of sickness and | from 6 days of sickness |
| $80 \%$ chance of protecting him/her from 0 days of sickness |  |

Figure 2: An example of a risk-advantageous trial.

## Design

Age was a grouping variable. Trial type and decisionmaking phase were the independent variables. Level of risk taking and difference in risk taking between dyad members were the dependent variables.

## Procedure

Before the experiment, participants received a consent form explaining the research study. After consent, they completed a questionnaire regarding demographics and health, and four ability tests. After that, participants were given both oral and written instructions about the decision task. Collaboration with other participants was not mentioned at this stage. The first phase of the experiment was the pre-collaboration phase. Participants made medication decisions involving risks individually. When the pre-collaboration phase was completed, participants moved on to the collaboration phase. They were notified that each of them would have to collaborate with another participant to give one answer as a group. The process of collaborative decision making was videotaped (with permission from the participants) for analysis in a separate study. When the collaboration phase was completed, participants entered the post-collaboration phase. Once again, they made similar decisions individually. After all decision trials were completed, participants filled out the self-report items, followed by other questionnaires, and then they were debriefed.

It took younger adults approximately one hour and older adults approximately two hours to complete the entire experiment.

## Results

## Individual Medication Risk Taking

First, individual risk taking data in the pre-collaboration phase were analyzed. Mixed-design ANOVA was conducted with age as the between-participants variable, and trial type as the within-participants variable.

As expected, older and young adults were significantly more risk taking on risk-advantageous trials $(M=.77, S D=$ .26) than on risk-neutral trials $(M=.41, S D=.32), F(1,46)$ $=82.66, p<.001, \eta_{\mathrm{p}}{ }^{2}=.64$. Overall, older adults $(M=.58$, $S D=.30$ ) were not significantly less risk taking than younger adults $(M=.60, S D=.18), F(1,46)=.024, p=$ $0.877, \eta_{\mathrm{p}}{ }^{2}=.001$. However, there was an age by trial type interaction such that older adults showed a smaller increase in risk taking in response to risk-advantageous trials than did younger adults, $F(1,46)=8.52, p<.01, \eta_{\mathrm{p}}{ }^{2}=.16$. Figure 3 shows the results.

Figure 3: Younger and older adults' level of risk taking on risk-neutral and risk-advantageous trials (error bars represent the standard error).

## Social Influence Effects

Risk taking data in the pre- and post-collaboration phases were compared. Mixed-design ANOVA was conducted with age as between- and phase as within-participants variable. The absolute difference between dyad members' level of risk taking was the dependent variable.

The difference in risk taking between dyad members was smaller in the post-collaboration phase ( $M=.20, S D=.19$ ) than in the pre-collaboration phase ( $M=.33, S D=.22$ ), $F(1$, 22) $=7.80, p<.05, \eta_{p}^{2}=.26$. The overall within-dyad difference in risk taking was not significantly different between younger ( $M=.22, S D=.12$ ) and older adults ( $M=$ $.31, S D=.16), F(1,22)=2.54, p=0.125, \eta_{\mathrm{p}}{ }^{2}=.10$. By contrast, the age by phase interaction was significant, $F(1$, 22) $=10.41, p<.01, \eta_{\mathrm{p}}{ }^{2}=.32$. Older adults' risk preferences converged towards their partner's preferences to a greater extent following collaboration relative to younger adults'. Figure 4 shows the results.

Figure 4: Younger and older adults' within-dyad difference in risk taking in pre- and post-collaboration phases (error bars represent the standard error).

## Discussion

Findings from the present study provide insights into younger and older adults' individual risky decision making for medications, and the effects of collaborating with a partner on subsequent risk-taking tendency. Confirming our expectation, younger and older adults took more risks when risk taking was beneficial than when risk taking and risk aversion were equally favorable. However, this effect of trial type differed between the two age groups such that the increase in risk taking among older adults was smaller than the increase in risk taking among younger adults when the risky option was favored. Regarding social influence effects, dyad members' risk-taking tendency was more similar to each other's after the collaborative decision-making experience compared to their initial difference. Older adults demonstrated a convergence effect, whereas the younger adults did not.

## The ore tical Implications

The present study adds to the literature in that it investigated age differences in risk taking in the medical domain, which has heretofore been understudied. Based on fuzzy-trace theory, when people represent positively framed scenarios at the gist level, they tend to be risk averse. Therefore, we predicted that older adults would be less likely to take risks than younger adults when choosing between medications that had different probabilities and outcomes of treatment success, consistent with the recent meta-analytic findings on age differences in the risky-choice framing effect (Best \& Charness, 2015). In our study, which focused on decision making in the medical domain, older adults were not significantly less risk taking than younger adults in making medication decisions. Because prior research mainly focused on financial and mortality domains, the pattern of finding in the present study could be additional evidence that age differences in risk preferences are context dependent (Best \& Charness, 2015).

Additionally, an interaction was found in the present study between age and trial type. Younger adults exhibited a substantially larger increase in risk taking than did older adults when comparing risk-advantageous trials with riskneutral trials. This finding is consistent with our expectation that younger adults are more sensitive to the expected values of options. When presented with a risky option and a sure option with a lower expected value, younger adults were more likely to choose the risky option that maximized their expected value gain in terms of the number of days protected from sickness. Relative to younger adults, older adults showed a more similar risk-taking tendency on riskneutral and risk-advantageous trials, suggesting that they were not as sensitive as younger adults to the expected values of options. This is consistent with the idea that older adults are more likely to use gist processing whereas younger adults are more likely to use verbatim processing in making medication risky decisions.

The present study demonstrated that people's medical risk taking propensities were prone to social influence effects. In addition, it explored the effects of collaborative decisionmaking on subsequent individual decisions in two different age groups. Consistent with prior studies on intertemporal choices (Bixter et al., 2017) and financial risky decisions (Suzuki et al., 2016), we found a group convergence effect following collaboration in older adults' medication risky decisions. Importantly, older adults' convergence effect was larger than younger adults'. This might reflect their greater tendency to conform to others. Older adults might change their decisions more easily when different views are presented because of their lower perceived decision-making competence (Bruine de Bruin et al., 2012). However, it could also be due to the greater initial difference within older dyads observed in the present sample. Future research should attempt to better understand age differences in social influence effects in risky decision-making contexts.

## Limitations and Future Directions

Several limitations have to be noted. The decision task may not resemble an everyday medical context and thus makes the results less generalizable to ecological settings. Asking participants to make third-person medication decisions might introduce bias. Moreover, people might perceive avoiding sickness as categorically different than shortening the duration of sickness. Additionally, numeracy differed between the age groups, and could be an alternative explanation for the individual risk taking and social influence findings. Future research should address these issues.

## Practical Implications

Findings from the current study offer some insights into how age and collaboration influence medication risk taking. Examining age differences in medical risk seeking would enable us to devise appropriate decision aids for people of different ages. In particular, it is important to encourage older adults to take risks when risk taking is beneficial.

Examining age differences in choice shift due to social influence would inform the public how social interactions alter patients' subsequent decisions as a function of their age. Current findings suggest that other people might be able to play a significant role in influencing older patients and helping them make improved decisions.

## Acknowledgments

This research was supported in part by a pilot grant from the National Institutes of Health (National Institute on Aging) Grant P01 AG17211 under the auspices of the Center for Research and Education on Aging and Technology Enhancement (CREATE; www.create-center.org), and by the Ruth L. Kirschstein National Research Service Award (NRSA) Institutional Research Training Grant from the National Institutes of Health (National Institute on Aging) Grant 2T32AG000175-26A1.

# Finding Creative New Ideas: Human-Centric Mindset Overshadows Mind-Wandering 

Yung-Yi Juliet Chou (juliet.chou@columbia.edu)

Barbara Tversky (btversky@stanford.edu)<br>Teachers College, Columbia University<br>New York, NY 10027 USA

#### Abstract

Finding creative new ideas requires both release from fixation and a productive search mindset. Recent research has shown that messy desks, walking, and mind-wandering can lead to more new uses for old objects. Here we show that a humancentric mindset is superior to mind-wandering for generating more alternative uses and more creative uses because it provides both release from fixation and an effective search strategy. A human-centric mindset entails perspective-taking, and perspective-taking is likely to be an effective general strategy for enhancing creativity, problem-solving and innovation.

Keywords: creativity; design; mindset;

## Introduction

How do you get an original idea? One way to catalyze the creative process is to recombine or transform old ideas into new ones. But starting with established ideas can often be counter-productive, leading to fixation (e.g., Jansson \& Smith, 1991; Finke, Ward, \& Smith, 1992; Smith, Ward, \& Schumacher, 1993; Purcell \& Gero, 1996; Chrysikou \& Weisberg, 2005). Finding new associations is regarded as key to overcoming fixation (e. g., Finke, 1990; Finke, Ward, \& Smith, 1992; Jansson \& Smith, 1991; Mednick, 1962; Smith, Ward, \& Finke, 1995).

Recent studies have shown a variety of ways to stimulate new ideas for alternative uses of ordinary objects, a classic creativity task (Guilford, Christensen, Merrifield \& Wilson, 1978) that is also frequently used in design classes as a warm-up activity. Messy desks in contrast to tidy ones have enabled people to think of more new uses for ping-pong balls (Vohs, Redden, \& Rahinel, 2013). Messy desks create ambiguous configurations and ambiguous configurations are deliberately used by designers to generate new ideas and successful in doing so (Tversky \& Suwa, 2009). Taking a walk rather than sitting has helped people generate more novel uses for common objects (Opezzo \& Schwartz, 2014); taking a walk exposes people to new stimuli that might inspire new associations. Mind-wandering has facilitated creative incubation for finding new uses for common objects (Baird, Smallwood, Mrazek, Kam, Franklin, \& Schooler, 2012; Smallwood \& Schooler, 2006) though this strategy has not always been successful (Hao, Wu, Runco, \& Pina, 2015). The proponents of mind-wandering use neuroscience research on the default network to argue for mind-wandering (Baird, et al., 2012). The default network
is activated when the mind turns inward rather than responding to external stimuli (Mason, Norton, Van Horn, \& Wegner, 2007; Smallwood, Beach, Schooler, \& Handy, 2008). Wandering in the mind, like wandering in the world, can bring new stimuli, and consequently new responses.
Messy desks, taking a walk, and mind wandering succeed in releasing thinkers from fixation by bring in new stimuli. An even simpler manipulation, interleaving different design problems rather than blocking them, accomplishes the same (Tversky \& Chou, 2010)—remember the old adage: Take a break. But bringing in new stimuli doesn't by itself provide a productive way to search for new ideas. Innovators need effective search strategies as well as release from fixation. Designers in prominent design firms, notably IDEO, have developed a systematic approach, Human-Centric design, to do exactly that. They have instituted elaborate practices to enable their designers to put themselves in the shoes of potential users in order to design effective systems, procedures or products for the target community (Kelley \& Littman, 2006). Although widely adopted, the humancentric approach has not been systematically evaluated.
Here we evaluate the Human-Centric approach by using a design task that laypeople frequently need to do, finding new uses for everyday objects. In our daily lives we often find ourselves improvising, to grasp an object out of reach by twisting a coat hanger or to tie a shoe together with a paper clip when a shoelace has snapped. This improvised design requires finding new uses for familiar objects. The new uses task has been used in considerable previous research, including the studies that stimulated our own. It is also used as a warm-up exercise in design course typically asking students to come up with many ways to use a brick. We asked participants to find new uses for ordinary objects under three mindsets: Human-Centric, Mind-Wandering, and a control condition with no special mindset. For the Human-Centric mindset, for each object, we directed participants to think of how different human roles might use the object. We chose roles that participants would be familiar with in their everyday interactions, such as artist, chef, physician, mechanic, and athlete. We pretested the roles to make sure our intuitions were correct. We selected six objects, also after pretesting to make sure that laypeople could generate alternative uses for the objects.
Adopting the perspectives of many roles should fulfill both requirements for original ideas. Changing perspective should lead to release from fixation and taking new
perspectives should provide effective ways to search for new ideas. The Human-Centric group was asked "to imagine how different people in different roles might reuse the objects in their activities." The Mind-Wandering group was given the instructions of Baird et al. (2012) "to simply relax and let your mind wander." The control group was given no special mindset.

## Measuring Fluency and Originality of Ideas

Here ideas generated by participants were evaluated on quantity or fluency and on creativity, that is degree of originality. The primary interest is in fluency, as in design evaluating suitability can only come after ideas are generated. Evaluating originality or creativity has typically been based either on judgments of creativity or on statistical rarity in the larger group (e.g. Hennessey \& Amabile, 2010; Runco \& Jaeger, 2012; Runco, 2004). Judgments of creativity can be biased and unstable (e.g. Kaufman, Baer, Cole, \& Sexton, 2008). Here we use the Sample-Specific Percentage Score of Mouchiroud and Lubart (2001) derived from Torrance's classic paradigm (1968). One point is given to each idea given by $2-5 \%$ of the sample and two points to each idea given by less than $2 \%$ of the sample. This method has been criticized for failing to differentiate the quality of originality from the fluency of responses. For example, a participant who gave 10 common responses might get a higher total originality score than a participant who gave only 2 answers, even if the 2 answers were more unusual. However, this did not seem to be a problem in the present study as the people who gave original ideas also gave many ideas.

## Methods

## Participants

Participants $(\mathrm{N}=105)$ were recruited through Amazon Mechanical Turks Web service, receiving $\$ 5$ for approximately 40 minutes of time. Participants' ages ranged from 21-65, with a mean of 33.19 and came from a wide range of educational backgrounds. Participants were randomly assigned to the three mindset conditions. There were 18 women and 17 men in the Mind-Wandering Group, 15 women and 20 men in the Human-Centric Group, 18 women and 17 men in the Control Group.

## Stimuli

The objects were selected from a review of objects in previous research and from a pilot study to make sure that they could be decomposed and would stimulate new uses from ordinary people: broom, flashlight, chair, umbrella, shoe, and smartphone. A smartphone is representative of contemporary and future design challenges.

## Procedure

The first screen that greeted participants described everyday ingenuity, such as using a hanger to grab an out of reach
object or rolling up a magazine to swat flies. Then participants were invited to discover and generate uncommon uses for six ordinary objects. All three mindset conditions next read general instructions: "On each trial you will be presented with the name of the object. Your job is to produce as many different novel uses as you can, uses that are different from the normal use. You will type your ideas in a text box, using only a few words, one idea at a time. Please do not repeat ideas. Eventually, you may run out of new ideas and then you will have a chance to proceed to the next object and generate new ideas for it. There are SIX objects. You will have 5 minutes to generate novel uses for each object. Please do not use any resources besides your own creative mind in this task." Participants were also told: "It's OK to use more than one of the objects and it's OK to use parts of the object."

Participants in the Mind-Wandering group were told that "One proven way to generate new ideas is to simply relax and let your mind wander. Please use that mindset to generate as many new uses as you can think of." Participants in the Human-Centric group were told that "One proven way to generate new ideas is to imagine how different people in different roles might reuse the objects in their activities. Other roles might include various kinds of athletes, gardeners, artists, chefs, musicians, mechanics, craftspeople, dancers, teachers, police, firefighters, plumbers, tailors, architects, physicians, writers and more. Please imagine the mindset of a variety of roles to generate as many new uses as you can think of." The Control group was not given any specific strategy or exemplars. Each participant had a practice trial with clothes hanger for 3 minutes before starting the real experiment. The screenshot of the human-centric mindset condition are shown after participants entered responses in Figure 1. Each response was assigned a position number by the system.

Figure 1: Screenshot of the Human-Centric mindset condition after entering new responses.

Participants were then presented with the names of six objects, one at a time, for the unusual uses task: Broom, Flashlight, Chair, Umbrella, Shoe, and Smart Phone. Each of those 5 objects except for Smart Phone was randomly ordered for each participant. For each object, the common use was presented under the name of the object on the screen After generating ideas for those 5 objects, the Smart

Phone was presented along with a new instruction by adding a paragraph, "Now that you've warmed up generating new uses for old objects, try your mind at generating new uses, including new apps, for a smart phone."

After participants finished generating new uses, participants responded to a questionnaire asking whether they used the mindset strategy suggested and how easy, how helpful it was to follow. The control group was asked if they used a mindset strategy, and if so, what?

## Results

Coding Counting ideas was a two-step process. Responses were first put through a spreadsheet that (a) counted the total number of answers, and (b) identified the likely original answers by eliminating all duplicates (repeated identical answers). During the initial examination, all duplicate answers were removed; total numbers generated for each participant were accurate, and all the unusual / unique answers were identified. Generalized items (e.g., "a broom to clean off the cobweb on the ceiling") were counted toward a participant's total number of responses but were not coded as original. To measure the originality of ideas, the task was coded with Sample-Specific Percentage scoring method derived from the classic Torrance's (1968) paradigm. Examples of both original and ordinary examples are provided in Figure 2.

| Objects | More Original Examples | Most Ordinary Examples |
| :---: | :---: | :---: |
| Broom | Mini golf course with multiple brooms; Wood flavoring source by shaving the stick; Fragrance holder; | Clean cobwebs off the ceiling; Animal deterrent; Weapon; |
| Flashlight | Martini Shaker; Meat Tenderizer; Wrapping longhair with decorative lighting; | Weapon; Signal; Starting a fire; |
| Chair | Use folding chair hinges in extending arm array; Spokes for a ring loom; Water Strainer; | Step stool; Weapon; Firewood; |
| Shoe | Stack up to use as soundproofing; Voice disguiser; Bottling lace grommets as a baby rattle; | Weapon; Planter; Animal Deterrent; |
| Umbrella | Cutting the fabric into strips to tie things together; Use mental spokes as shish kabobs; | Weapon; Walking cane; Protection from the Sun; |
| Smartphone | Physical obj.: Wrist splint; Cutting board in wilderness; Digital/Physical obj.: Smoke detector; Stud finder; Steak doneness tester; | Paperweight; Flashlight; Camera; |

Figure 2: Examples of original and ordinary ideas
Fluency of Ideas The 3 mindsets differed substantially in fluency (i.e. total number of ideas); the Human-Centric group ( $M=54.06, S D=27.30$ ) generated far more ideas than the Mind-Wandering ( $M=38.77, S D=15.52$ ) and Control groups ( $M=36.54, S D=17.05$ ) in Figure 3. Because Levene's test was significant ( $p<.001$ ), revealing that variances in the Human-Centric group were differed, violating the assumption of homogeneity of variance, a more robust Games-Howell method (instead of Tukey HSD)
was applied to interpret the F statistics for the post hoc results.

Welch's Robust ANOVA showed significant differences in fluency of three mindset groups, $F(2,65.38)=5.407, p=$ .007. Continuing, the Games-Howell post hoc testing revealed that the Human-Centric mindset group generated more ideas than the mind-wandering mindset group a mean increase of $15.229,95 \%$ CI [ 2.18 to 28.27]. There was also a mean increase of $17.514,95 \%$ CI [ 4.42 to 30.61 ] between the Human-Centric and Control groups, but there was no significant mean difference between the Mind-Wandering and Control groups, 2.229, $95 \%$ CI [-7.11 to 11.57]. The mean number of ideas generated by each mindset condition for each object can be viewed in Figure 4.

Figure 3: The Human-Centric mindset group generated more uses than Mind-Wandering and Control groups.

Figure 4: The Human-Centric mindset group generated more uses than the other groups for each object.

Originality of Ideas For originality, Levene's test was significant, and the assumption of homogeneity of variance was violated. The Welch test table was applied. There was a significant effect for the three mindset conditions differed significantly in originality of ideas $F(2,67.21)=4.34, p=$ .017. The post-hoc comparison using the Games-Howell test indicated that the mean score of originality for the HumanCentric group ( $M=31.89, S D=21.67$ ) was significantly different from the Mind-Wandering group $(M=20.43, S D=$
16.61) and from the Control group ( $M=18.77, S D=17.12$ ) . There were no differences between the Mind-Wandering and Control conditions, as shown in Figure 5.

Fluency of Original Ideas Two Pearson's product-moment correlations were run to assess the relationship between the quantity and originality of ideas. The first correlation refers to the total number of ideas, a summation of the number of ideas that each participant generated across 6 objects ( 5 min per object) and the sum of the originality score for those ideas. There was a strong correlation between the quantity of ideas generated by a participant and the overall originality scores irrespective of mindset conditions in the study, $r(103)=.885, p<.001$. The overall originality score (i.e. 2 points for each idea given by less than $2 \%$ of the sample; 1 point for each idea with a frequency seen in $2 \%$ to $5 \%$ of the sample; 0 points for ideas given more than $5 \%$ of the sample) is a summation of the originality score for 6 objects. The average participant generated approximately 43 ideas in the 30 minutes of the idea generation task. The second correlation refers to the total number of ideas and the average originality of ideas for each participant. There was a moderate positive correlation between the quantity of ideas and the mean originality score (sum of originality score divided by total number of ideas), $r(103)=.434, p<.001$.

There were no differences in quantity of ideas and originality of ideas for the different objects.

Figure 5: The Human-Centric mindset group generated more original ideas than the Mind-Wandering and Control groups.

Figure 6: Participants who generated at least 10 ideas for any object were more likely to produce more original ideas.

Position of Ideas: Original Ideas Come Later Many studies have found that ideas generated later tend to be better than early ideas since Christensen, Guilford, \& Wilson (1957) first demonstrated the effect. This result aligns with those from prior studies (Beaty \& Silvia, 2012).

Two methods were used to confirm that original ideas do come later. The graph in Figure 6 shows the mean score of originality (from 0 to 2 ) for ideas that appear in the ith position, $i=1,2, \ldots 10$, regardless of conditions and objects for this study. It was reasonable to choose 10 positions, because about half of the sample size generated at least 10 ideas. It appears that participants came up with more original ideas at the later position. Another bar graph Figure 7 is to show the percentage of ideas that were original (less than $5 \%$ of the sample generated the idea) for each position.

Figure 7: Original ideas tended to come later.
Self Report / Manipulation Check Regarding whether participants used the suggested mindset strategies to generate ideas; it appears that more than $75 \%$ of participants in both Human-Centric and Mind-Wandering groups claimed that they did follow the instruction. $69 \%$ of participants in the Human-Centric group and $60 \%$ of participants in the Mind-Wandering group did think it was helpful with the suggested strategy. Regarding how easy participants used the suggested mindset strategies to generate ideas; it appears that more than $50 \%$ of participants in both Mind-Wandering and Human-Centric groups self-reported it was easy for them to use the mindset. $89 \%$ of participants in the Control group self-reported that they simply let things come to mind, using a mindwandering mindset strategy.

## Discussion

Designers and problem solvers--and we are all designers and problem solvers--often get stuck. They/we get fixated on one idea or a set of them and then thinking goes in circles. Breaking fixation, breaking that circle, finding new ideas requires new associations. Messy desks, walks, and mind-wandering have all proven helpful for finding new uses for familiar objects. They work because each leads to new stimuli and new stimuli can bring new associations and perhaps new ideas.

Although wandering eyes, wandering bodies, and wandering minds can expose us to new stimuli, the paths of
search are still wandering, not directed in any meaningful way. There is no guarantee that the meandering and the associations are in any way related to the design or problem. Designers and problem solvers also need productive ways to search for and generate new ideas that are relevant to the problem at hand. The human-centric mindset does just that. The human-centric approach entails taking the perspectives of others, here diverse roles that participants are familiar with. Participants could make use of their knowledge of the roles to generate relevant uses: what could a gardener do with an umbrella? An artist with a shoe? An athlete with a chair? Participants with the Human-Centric mindset did use the roles that we gave them, and invented new roles of their own. Using a high criterion for relevance, nearly half the ideas generated by the group using the Human-Centric approach were directly related to one of the roles provided and another $10 \%$ derived from roles they invented, presumably because they used the mindset to take the perspectives of various roles. The most productive role was artist, followed by gardener, athlete, policeperson, mechanic, chef, and musician.

Consistent with that analysis, the Human-Centric mindset yielded more ideas than either the Mind-Wandering mindset or the no-mindset control. In fact, the Mind-Wandering mindset was no more successful than the no-mindset control group at generating new uses. This turns out to be unsurprising; in response to a question about how they searched for new ideas, many in the control group reported that they just let their minds wander.

Participants using the Human-Centric mindset generated more new uses and also generated more original new uses than those who adopted the other mindsets. Original new uses tended to come later; it's as if participants have to first get the ordinary alternative uses out of their heads in order to free their minds to find unusual ones. Sadly, one of the most common uses suggested for most of the objects was weapon. The vast majority of original responses were not only reasonable and appropriate, but clever, even if unusual. Remember that the instructions allowed using more than one of the objects. For a shoe, sound-proofing; for a chair, a water strainer; for a smart phone, a wrist splint, for a flashlight, a martini shaker.

Because of the overall quality of the original ideas, it is apparent that participants were editing their own responses. That process, of generating ideas and evaluating them, is supported by neuroscience research (Beaty, Benedek, Silvia, \& Schacter, 2016; Chrysikou, in press; Ellamil, Dobson, Beeman, \& Christoff, 2012; Mason, Norton, Van Horn, Wegner, Grafton, \& Macrae, 2007). The neuroscience findings suggest that creative problem solving is characterized by alternating activation in the default network, indicative of internal processing, and the frontal system, indicative of executive control. This iterative process, of generating ideas and evaluating them coincides with the experience of designers and problem solvers. It remains to be seen whether the neuroscience tools are sensitive enough to detect the large differences in mindset
demonstrated here. In the meantime, it should be clear that Mind-Wandering is not to be recommended as a general mindset for finding innovative ideas. A Human-Centric mindset is far more productive.
The Human-Centric mindset clearly has wide applicability. Diplomats negotiating peace agreements take the perspectives of each party, as do lawyers. Writers of books and screenplays take the perspectives of their readers or viewers. Product designers think deeply about the ways different users will interact with their products. Using the Human-Centric mindset entails adopting relevant and varying human roles. Yet there are many problems that demand creative solutions but do not involve humans, except as thinkers. Problems in mathematics or physics. Design of machines or robots for tasks that do not involve humans, except as designers. Taking different human perspectives might help, but that is probably not be the best way for those problems. However, taking different human perspectives is at its foundation taking different perspectives, and that mindset might just work for everything. Or nearly everything. Mathematicians reframe problems algebraically or geometrically. Temple Grandin, in designing runways for cattle, famously adopts the perspective of the cattle (Grandin \& Deesing, 2008). Taking different perspectives might sound simple, but deciding which alternative perspectives are relevant and productive also requires creative thought.

#### Abstract

Perceptual learning is a key perceptual skill that people possess, in particular, it contributes to their ability to distinguish between faces thus recognize individuals. Recently, we showed that anodal transcranial Direct Current Stimulation (tDCS) at Fp3 abolishes the inversion effect (that would otherwise exist) for familiar checkerboards created from a prototype. Because of the close analogy between the inversion effect obtained with checkerboards, which we use as a marker for perceptual learning, and the traditional face inversion effect (upright faces recognized better than inverted ones), we investigated the effects of anodal tDCS at Fp3 during an old/new recognition task for upright and inverted faces. Results showed that stimulation significantly reduced the face inversion effect compared to controls. The effect was strongest in reducing recognition performance to upright faces. This result supports our account of perceptual learning and its role as a key factor in face recognition.

Keywords: TDCS; Perceptual learning; Face inversion effect; Old/new recognition task; Face recognition

## Introduction

Perceptual learning refers to an enhanced ability to distinguish between similar stimuli as a consequence of experience with them or stimuli like them. It also plays a key role in learning to identify stimuli as specific exemplars of a category, and not confuse one stimulus with another similar one (e.g. wine experts and wines, or bird watchers and warblers; James, 1890; see Hall, 1980 for a review). We know that people (and other animals) can improve their perceptual skills as a result of experience with stimuli, and recent studies have shown this phenomenon to be responsible for some key perceptual skills that people possess. In particular, it contributes to our ability to distinguish between faces and recognize individuals. For example, if we pre-expose someone to a set of checkerboards, all of which are produced by imposing random variation on one original prototype checkerboard, then this will have the effect of making them better able to distinguish between exemplars generated in this way -a
basic perceptual learning effect. They will now be able to tell two otherwise similar checkerboards apart where once they might have found it difficult to do so, and such preexposure improves their ability to identify checkerboards they have been asked to memorize in a subsequent recognition test (McLaren, Leevers \& Mackintosh, 1994). McLaren (1997) extended this result to show that the same procedures could also produce an inversion effect, with upright exemplars discriminated better than inverted ones.

Civile et al. (2014) further developed the case for perceptual learning as a contributor to the face inversion effect (i.e. that upright faces are recognized much better than inverted ones), by showing that these results can be obtained with the kind of old/new recognition paradigm conventionally used in such studies (Yin, 1969; Diamond \& Carey, 1986; see Maurer, Le Grand, \& Mondloch, 2002 for a review). Participants were trained to categorize (categorization task) checkerboard exemplars from two prototype-defined categories (the pre-exposure phase), before being shown an equal number of checkerboard exemplars (which they had not previously encountered) drawn from either one of the now familiar categories or a novel category, half of which were upright and half inverted. Participants were then tested for recognition of these exemplars after this study phase. The results confirmed the inversion effect for checkerboard exemplars drawn from a familiar category, and its absence for exemplars drawn from a novel category, strengthening the case for perceptual learning contributing to the inversion effect found with faces.

In a recent study, Civile et al. (2016) demonstrated that tDCS to dorsolateral prefrontal cortex (DLPFC) at Fp3 site significantly affected perceptual learning and reduced the inversion effect that can otherwise be obtained with checkerboards. The authors adopted the same old/new recognition task as in Civile et al. (2014)'s study which uses a categorization task to pre-expose participants to the stimuli i.e. checkerboards. A previous study by Ambrus et al., (2011) had found that anodal tDCS (compared to sham)
applied to the Fp 3 during the training phase of a categorization task where participants had to identify prototype and low-distortion patterns as category members reduced classification accuracy for the prototype. Thus, as Civile et al. (2014)'s study used prototype-defined checkerboard categories and formation of a strong representation of the prototype is a prerequisite for perceptual learning (McLaren, Kaye, \& Mackintosh,1989), Civile et al. (2016)'s study adopted the same Fp3 montage as that adopted by Ambrus et al. (2011). Civile et al. (2016) showed that the control condition (sham tDCS stimulation over Fp 3 delivered during the pre-exposure phase, i.e. the checkerboard categorization task) replicated the usual inversion effect for checkerboards drawn from a familiar category, but, as expected, not for checkerboard exemplars drawn from a control (novel) category that had not been preexposed. Critically, anodal tDCS to the same brain region changed this pattern, as there was now no inversion effect for stimuli drawn from either familiar or unfamiliar category, and the upright exemplars drawn from a familiar category were less well recognized than those drawn from the novel category, an indication that perceptual learning may even have been reversed. This remarkable and informative result suggested that perceptual learning in humans could be turned 'on' and 'off".

Civile et al.'s (2016) study is the first evidence that anodal tDCS administered during the pre-exposure phase can affect perceptual learning later on when participants are asked to memorize and recognize exemplars of checkerboards drawn from the checkerboard categories seen in during the pre-exposure phase (categorization task). The next important question to address is whether or not the same tDCS procedure would also affect perceptual learning that has already taken place. Given the lifelong expertise we have for faces, and given the already established analogy between the inversion effect obtained with checkerboards (McLaren, 1997; McLaren \& Civile, 2011; Civile et al., 2014; Civile et al., 2016) and that usually obtained with faces (for a review see Maurer et al., 2002), in the current study we extended the tDCS paradigm used in Civile et al.' (2016) to the inversion effect for faces. We expected to obtain a strong inversion effect for familiar faces in the sham tDCS group, but a significantly reduced inversion effect for familiar faces in the anodal tDCS group because, as was the case for Civile et al.'s (2016) familiar upright checkerboards, we expected anodal tDCS over Fp3 to disrupt recognition performance for familiar upright faces.

[^304]tDCS stimulation could reduce our ability to recognize upright familiar faces.

## Method

We adopted the tDCS montage used in Civile et al. (2016). Each subject was randomly assigned to either sham or anodal tDCS conditions. In the sham condition, the tDCS stimulation was only delivered for 30 s, to evoke the sensation of being stimulated, without causing neurophysiological changes that may influence performance. In the anodal tDCS condition, the stimulation was delivered for 10 mins while the subjects were completing an old/new recognition computer task that used images of faces. In both sample groups, the sham and tDCS stimulation started when the computer task began. In the first part of the computer task, the study phase, subjects were asked to memorize a set of upright and inverted faces presented one at a time. Following this, subjects were given a recognition task where they pressed one key if they thought they had seen the face before, and another key if they thought they had not seen the face before. All the faces seen in the study phase were presented again intermixed with an equal number of new faces of each type (i.e. upright faces, and inverted faces). This old/new recognition task is a standard method of assessing face processing and the inversion effect (Yin, 1969; Diamond \& Carey, 1986; Civile, McLaren, \& McLaren, 2016; Civile, McLaren, \& McLaren, 2014). Our main measure was accuracy scores during recognition converted into signal-detection d-prime " $d$ '". We also examined reaction time responses to check for any speed-accuracy trade-off that could affect our interpretation of the results.

## Subjects

Forty-eight students ( 39 women; mean age $=18.9$, age range $=18-22$ years) from McMaster University participated in this experiment. Twenty-four subjects were randomly assigned to each of two groups (sham tDCS, anodal tDCS). All subjects were right-handed and were given course credits for their participation. The experiment was approved by the research ethics committee at McMaster University. Written informed consent was obtained after the nature and possible consequences of the study were explained. Sample size was determined in advance based on previous studies (Civile et al., 2014; McLaren 1997) that found the original inversion effect for checkerboards and that showed a clear effect of tDCS on perceptual learning (Civile et al., 2016; McLaren, Carpenter, Civile, McLaren, Zhao, Ku, Milton, Verbruggen, 2016), as well as previous studies that adopted the same old/new recognition task and face stimuli that we used here (Civile, McLaren, McLaren, 2014; and Civile, McLaren, McLaren, 2016 obtained a strong face inversion effect with group samples of 24 subjects). Additionally, we conducted a post-hoc power analysis using G*power software (Faul, Erdfelder, Lang, \& Buchner, 2007) that revealed a statistical power of 0.92 , in
line with the recommended 0.80 level of power (Cohen, 1988).

## Materials

The study used 128 images of male faces. Only male faces were used because they allowed the inclusion of ears in the images as well. Men tend to have shorter hair with ears visible whereas women often have longer hair covering the ears, making the visibility of these features rather variable. The faces were standardized in gray-scale format and cropped around the hairline in Adobe Photoshop. The same set of faces was previously used in studies that adopted the same old/new recognition task with upright and inverted faces that we used in the study here reported (Civile, McLaren, \& McLaren, 2014; Civile, McLaren, \& McLaren, 2016).

## Transcranial Direct Current Stimulation (tDCS)

All participants first completed a brain stimulation safety screening questionnaire. Stimulation was delivered by a battery driven, constant current stimulator (Neuroelectrics) via a pair of surface sponge electrodes ( $25 \mathrm{~cm}^{2}$ ), soaked in a saline solution $(0.9 \% \mathrm{NaCl})$, and applied to the scalp at the target areas of stimulation. Electrodes delivered a constant current of 1.2 mA (current density: $0.048 \mathrm{~mA} / \mathrm{cm}^{2}$ ); the choice of the intensity is in line with Civile et al. (2016)'s study (see Neuroelectics website for a review of clinical studies that suggest keeping the average current densities in electrodes below $0.06 \mathrm{~mA} / \mathrm{cm} 2$ ). As in Civile et al. (2016)'s study, we adopted a bilateral bipolar-non-balanced montage with one of the electrodes (anode/target) placed over the left PFC ( Fp 3 ) and the other (Ambrus et al., 2011; Kincses et al., 2003) was placed on the forehead, just above the right eyebrow. In the anodal tDCS condition, the current was applied for 10 mins (fade-in and fade-out of 5 s ) from when the subjects began the computer task and throughout the old/new recognition task. Sham received the same 5 s fadein and fade-out, but only 30 s stimulation between them, which terminated shortly after the computer task started. The electrodes were left on the participant throughout the experiment (see Figure 1, Panel A).

## Behavioral Task

The old/new recognition task consisted of two parts: a 'study phase' and an 'old/new recognition phase' (Civile, McLaren, \& McLaren, 2014; Civile, McLaren, \& McLaren, 2016). In the study phase, each subject was shown upright and inverted faces with 32 images for each type ( 64 images in total). Faces were presented one at a time in random order. In the old/new recognition phase, 64 novel faces split into the same stimulus types were added to the 64 faces seen in the study phase, and all 128 images were presented one at a time in random order. Each face never appeared in more than one condition during the experiment for the same participant.

## Trial Structure

Following the instructions, in each trial of the study phase subjects saw a fixation cross in the center of the screen presented for 1 second. After this, one of the faces was presented on screen for 4 seconds. The next trial started with the presentation of a fixation cross again. After all 64 faces had been presented, the program displayed another set of instructions, explaining the recognition task. In this task, subjects were asked to press the '. ' key if they recognized the stimulus as having been shown in the study phase on any given trial, or press ' $x$ ' if they did not (the keys were counterbalanced). During the recognition task, the faces were shown for 4 seconds during which time subjects had to respond. The experiment was implemented using SuperLab 4.5 installed on a PC (see Figure 1, Panel B).

Figure 1: Panel a shows the electrode configuration of the tDCS and the stimulation set up on the Neuroelectrics software (NIC). Panel b shows the structure of the trials presented during the old/new recognition task.

## Data Analysis

Our primary measure was performance accuracy in the two recognition tasks. The data from all the participants was used in the signal detection $d^{\prime}$ analysis of the recognition task (old and new stimuli for each stimulus type) where a $d^{\prime}=$ of 0.00 indicates chance-level performance (Stanislaw \& Todorov, 1999). Each p-value reported in this paper is two-tailed, and we also report the F or t value along with measures of variability (SE or $S E M$ ) and effect size (Cohen's $d$ followed by the $95 \%$ confidence interval [CI] for d). The study had a $2 \times 2$ mixed model design using as a within-subjects factor Face Orientation (upright, inverted) and the between-subjects factor $t D C S$ (sham, anodal). Follow up, paired $t$-tests analyses were conducted to compare performance on upright and inverted faces (the inversion effect) in each tDCS group (sham, anodal). We also assessed performance against chance ( $d^{\prime}$ of 0 ) to show that both upright and inverted faces in the tDCS sham and anodal groups were recognized (for all four conditions we found a $p<.001$ ).

## Results

The statistical analysis (ANOVA) using the factors Face Orientation (upright/inverted) x $t D C S$ (anodal/sham) revealed a significant interaction, $F(1,46)=7.45, M S E=$ $0.12, p=.009, d=0.78, \mathrm{CI}=0.98,0.58$. We decomposed the interaction by looking at the inversion effect (upright faces - inverted faces) in each tDCS group (sham, anodal) separately. Following Civile et al's (2016) study, we expected to find the usual inversion effect for faces in the tDCS sham group. As predicted, a planned comparison showed a significant inversion effect with upright faces ( $M$ $=1.09, S E=0.11$ ) being recognized significantly better than inverted faces $(M=0.35, S E=0.07), t(23)=7.48, S E=$ $0.09, p<.001, d=1.59, \mathrm{CI}=1.78$, 1.41. Critically, we found a reduced (but still significant) inversion effect in the tDCS anodal group, recognition of upright faces ( $M=0.78$, $S E=0.11)$ compared to inverted faces $(M=0.44, S E=$ $0.08), t(23)=3.19, S E=0.11, p=.004, d=0.69, \mathrm{CI}=0.89$, 0.49 (see Figure 2). Thus, the inversion effect in the tDCS sham group was significantly greater than that in the tDCS anodal group, a similar result to that previously found in Civile et al. (2016)'s study using prototype-defined categories of familiar checkerboards.

Importantly, in Civile et al. (2016)'s study (Experiment 1) statistical analysis showed recognition of upright familiar checkerboards in the tDCS anodal group was reduced compared to that for familiar checkerboards in the tDCS sham group. We computed an additional analysis in our study to directly compare the recognition performance for upright faces in the two tDCS groups (sham, anodal). The results were that recognition for upright faces in the tDCS anodal group was reduced compared to that in the tDCS sham group, $t(46)=1.95, S E=0.14, p=$ .028 (1-tail), $d=0.56, \mathrm{CI}=0.78,0.34$. Thus, in both Civile et al. (2016)'s study (Experiment 1) and in our current
study, we have some evidence that anodal tDCS may affect the recognition of upright familiar stimuli (checkerboards in Civile et al, 2016, and faces in the current study). We calculated the Bayes factor using the procedures outlined by Dienes (2011) for this effect with faces using the effect for checkerboards in Civile et al. (2016)'s study (Experiment 1) as the prior, setting the standard deviation of $p$ (population value |theory) to the mean for the difference between recognition for familiar upright checkerboards in the tDCS sham group vs that in the tDCS anodal group (0.359). We used the standard error and the mean difference for tDCS sham upright faces vs tDCS anodal upright faces effect found in our study and assumed a one-tailed distribution for our theory and a mean of 0 . This gave a Bayes factor ( $B$ ) of 3.65. This factor is greater than 3, providing good support for this component of the reduction in the inversion effect (for Bayes factor calculator see Dienes, 2011).

Statistical analysis (ANOVA) of the response latencies was also conducted. Simple comparisons showed a significant inversion effect for both Anodal (p <.001) and Sham ( $\mathrm{p}=.009$ ) groups, and the inversion effect was numericaly larger for the Anodal group, but no significant interaction ( $p=.63$ ) was found. For completeness, we report the mean latencies for each stimulus condition: Sham upright faces, 1.37 s ; Sham inverted faces, 1.47 s ; Anodal upright faces, 1.48 s ; Anodal inverted faces, 1.61 s .

Finally, we also report here the SDT Bias estimates for each of the four stimulus' conditions: Sham upright faces, $\beta=1.33$; Sham inverted faces, $\beta=1.12$; Anodal upright faces, $\beta=1.70$; Anodal inverted faces, $\beta=1.04$.

Figure 2: The $y$-axis gives d' means for the old/new recognition task (higher _ better, $0_{\sim}$ chance), and the different stimulus' conditions in the two tDCS groups (sham, anodal) are shown on the $x$-axis. The dimensions of the stimuli were $6.95 \mathrm{~cm} \times 5.80 \mathrm{~cm}$. Participants sat 1 m away from the screen on which the images were presented.

## Discussion

We adopted the same procedures used in Civile et al. (2016) employing the old/new recognition task for faces that is a standard in the literature. The results indicate that anodal tDCS impaired recognition performance for upright faces, and as a consequence, the inversion effect was significantly reduced compared to the usual inversion effect found with faces that can be seen in the sham condition.

The MKM model (McLaren, Kaye and Mackintosh, 1989) and its later development in McLaren and Mackintosh (2000) and McLaren, Forrest and McLaren (2014) can explain the inversion effects reported by McLaren (1997) and Civile et al (2014) by appealing to perceptual learning as a consequence of experience with the category. But if the salience modulation based on prediction error implemented by this model is disrupted (by anodal tDCS ), then the MKM model turns into one more akin to McClelland and Rumelhart's (M\&R) (1985) model of categorization, and enhanced generalization between exemplars as a consequence of familiarity with that category is predicted rather than the enhanced discriminability that is the hallmark of perceptual learning. The result is the elimination of the inversion effect seen with artificial stimuli (that we take to be entirely due to perceptual learning), and even some reversal of the perceptual learning effect, explaining the pattern observed by Civile et al (2016). This interpretation of the results from Civile et al. (2016)'s study also applies to Ambrus et al. (2011)'s finding that tDCS reduces learning to the prototype, and increases generalization to random patterns. This would result in the elimination of the prototype effect, which is what we would expect if the MKM model of perceptual learning were, in effect, to be turned into the M\&R model of categorization by turning off the error-based modulation of salience that is the hallmark of MKM.

Our present data imply that anodal tDCS to Fp3 not only affects perceptual learning for artificial stimuli (the checkerboards in Civile et al., 2016) that were novel until encountered in the experimental setting but can also affect the long established perceptual learning for faces that is a result of experience over many years. This is a truly striking result that suggests that perhaps anodal tDCS over Fp3 may prevent individuals from exploiting "expertise" when called on to discriminate between stimuli of a class they are very familiar with.

These data strengthen the analogy between our checkerboard experiments and those with faces. In both cases, anodal tDCS reduces the inversion effect and reduces performance on upright exemplars taken from a familiar category. This suggests that the inversion effect obtained with what were novel, artificial stimuli, and that we attribute to perceptual learning, is at least one component of the face inversion effect. True, the inversion effect was completely eliminated by anodal stimulation in Civile et al (2016) but is still present in our stimulation group when we use faces. This could mean that any disruption of perceptual learning (which might be expected to be stronger after many years of
experience) is not complete in the current experiment, or it might be that there is a component of the face inversion effect that is not due to perceptual learning. We cannot say at present. What we can say is that the theory we have of how anodal tDCS to Fp3 works predicted a reduced inversion effect, and our salience modulation via error account of perceptual learning is, to that extent, further validated. We have also shown that we can turn perceptual learning in humans on and off, which opens the door to future applications.

These data also contribute to a recent line of studies that tested that effects of tDCS stimulation delivered at occipital brain regions on face recognition tasks. In one study the authors tested tDCS stimulation on an orientation judgment task for faces while recording brain activity with EEG. Results showed that anodal tDCS compared to sham, significantly reduced the N170 for both upright and inverted faces, despite not affecting the size of the inversion effect (Yang et al., 2014, Experiment1). In the same study (Experiment 2) the authors also showed that the same tDCS paradigm applied before a composite face effect task (the effect refers to an impairment at recognizing the top half of a familiar face when matched with the bottom half of another face) can significantly reduce the composite effect by enhancing performance for incongruent faces (composite faces created by mismatched top and bottom halves). In a similar vein, another study found that off-line (stimulation delivered before the task) anodal tDCS enhances memory performance for both upright faces and objects (inversion was not tested). In contrast, no enhancement was found for online (stimulation delivered during task execution) and sham tDCS stimulation (Barbieri et al., 2016). Together, the results from these studies show that tDCS at occipital regions seems to be effective at enhancing recognition performance (at least when tDCS is delivered off-line). Thus, this suggests that tDCS at occipital brain regions could possibly enhance perceptual learning in our experimental paradigm (either with checkerboards or faces). Future studies should test this and directly compare the effect of tDCS at Fp3 with that of tDCS at occipital sites during (and off-line) using Civile et al. (2016)'s checkerboard paradigm and our face paradigm.

# Beliefs about sparsity affect causal experimentation 

Anna Coenen ${ }^{1}$, Neil R. Bramley ${ }^{1}$, Azzurra Ruggeri ${ }^{2}$, and Todd M. Gureckis ${ }^{1}$<br>${ }^{1}$ Department of Psychology, NYU, New York; ${ }^{2}$ MPRG iSearch, Max Planck Institute for Human Development, Berlin<br>\{anna.coenen, neil.bramley, todd.gureckis\}@nyu.edu, ruggeri@mpib-berlin.mpg.de

#### Abstract

What is the best way of figuring out the structure of a causal system composed of multiple variables? One prominent idea is that learners should manipulate each candidate variable in isolation to avoid confounds (known as the "Control of Variables" strategy). Here, we demonstrate that this strategy is not always the most efficient method for learning. Using an optimal learner model which aims to minimize the number of tests, we show that when a causal system is sparse, that is, when the outcome of interest has few or even just one actual cause among the candidate variables, it is more efficient to test multiple variables at once. In a series of behavioral experiments, we then show that people are sensitive to causal sparsity when planning causal experiments.

Keywords: information search; causal learning; hypothesis testing

## Introduction

To develop a causal understanding of the world, we often need to find out how multiple candidate variables affect an outcome of interest. This problem arises in everyday situations (e.g., "Which of these switches can turn on the bathroom fan?"), during scientific exploration ("Which of these chemicals affect reaction $x$ ?"), and plays a role in answering economic and social questions ("How do these policies affect GDP?"). Often, the quickest and most effective method of resolving the causal relationships between variables and outcomes is to conduct experiments that manipulate variables (e.g., turning switches on or off) and help to decouple causation and correlation (Pearl, 2009).

In this paper, we explore how people interact with a novel causal system to understand how it works by manipulating multiple independent variables over a series of trials. We start by introducing two strategies for causal experimentation, one of which is so well known that it is codified in contemporary STEM education standards. We then describe an analysis of an optimal experimenter (i.e., an ideal actor model) which shows how the most informative strategy for learning critically depends on a learner's knowledge about the number of causes among the variables. We then evaluate the predictions of this model in three behavioral experiments.

## Test one variable at a time

The problem of disambiguating the effects of multiple variables has a long history in developmental psychology and education. Starting with Piaget (Inhelder \& Piaget, 1958), many educators and psychologists have stressed the importance of controlling or isolating variables. One important procedural component of this approach is the experimental strategy of changing one variable at a time and observing its effect while holding all other variables constant. In the STEM education
literature, considerable emphasis has been placed on teaching children this controlling variables strategy (e.g., Chen \& Klahr, 1999; Kuhn \& Brannock, 1977). In fact, it even appears in national standards for science education (National Academy of Sciences, 2013). A common finding from empirical studies is that children require extensive training to acquire the CV principle (e.g., Kuhn et al., 1995; Klahr, Fay, \& Dunbar, 1993; Kuhn \& Phelps, 1982). Adults and adolescents, although more likely to use the strategy spontaneously, sometimes also have a tendency to test multiple features at once instead of testing them one-by-one (Kuhn et al., 1995). Interesting exceptions have been found in more complex tasks. For example, Bramley, Dayan, Griffiths, and Lagnado (2017) tested people's intervention strategies in completely unconstrained multivariate systems (with no distinction between potential causes and outcomes) and found that participants often focused on testing one causal relationship at a time by holding most variables at a constant value.

In sum, CV is a widely regarded epistemic principle for learning about causal systems composed of multiple variables. A key advantage of a CV strategy is that it results in unconfounded data that is easy to interpret. Empirical work suggests that acquiring the ability to use the CV principle can be challenging, but adults sometimes adopt it more in complex tasks.

## Test half or test multiple variables

Changing variables one-by-one has the benefit of isolating the effect of every variable without confounding influence of the others. It is therefore particularly helpful when one believes that many variables are causes of the outcome. However, consider the case in which a learner expects only very few, and perhaps just a single variable to have a causal relationship to the outcome, but is faced with a number of equally plausible candidate variables. In that case, an alternative strategy is to test multiple variables at once to see if any of them affect the outcome at all. For example, imagine trying to figure out which out of 20 switches in a poorly labeled basement fusebox controls the bedroom fan. An optimal strategy for finding this switch is to turn on exactly half (10) of the switches to find out which half contains the target switch and then continue halving the remaining possibilities until only one switch remains. Compared to testing switches one-by-one, this will dramatically reduce the number of trips needed for checking what effect the current switch setting has on the fan.

This Test Multiple or (more specifically) Test Half strategy has been studied by psychologists in a slightly different type of information-seeking task, often based on popular games as "Twenty questions" or "Guess who?". In these games, chil-
dren or adults have to identify a target object, person or cause among a given set by asking as few yes/no questions as possible. Here too, the optimal strategy (in terms of expected information gain, see next section) is to ask about features that apply to half the possibilities under consideration (e.g., "Is the person female?", if the hypotheses are people and half are each sex), since it can reduce the number of possibilities more rapidly than asking about specific identities directly (e.g., Navarro \& Perfors, 2011). Both children and adults have been shown to use this method successfully (Nelson, Divjak, Gudmundsdottir, Martignon, \& Meder, 2014; Ruggeri \& Lombrozo, 2015). Interestingly, any Test Multiple strategy would be considered an error from the perspective of the education literature (e.g., a student adopting this strategy might be coded as failing an STEM education assessment), because by changing many things at once it momentarily confounds the influence of individual variables.

The Test One and Test Multiple/Half strategies are typically studied in different kinds of psychological tasks. However, as the switch example from above illustrates, they can both be reasonable approaches for testing the causal impact of multiple variables. Next, we show how the effectiveness of each strategy depends on the structure of the task.

## Sparsity determines effectiveness of strategies

As the switch example shows, an important factor that determines the effectiveness of a Test One or a Test Multiple strategy is the sparsity of a causal system. We define sparsity as the proportion of causes among variables (for related definitions and discussions of the importance of sparsity for hypothesis testing, see e.g., Navarro \& Perfors, 2011; Langsford, Hendrickson, Perfors, \& Navarro, 2014). In sparse environments (e.g., when we know that only one in 20 switches controls the fan), a learner can quickly narrow in on an effective cause by trying many variables at once. In contrast, if there are (known to be) many causes, trying many things at once will tend to be uninformative as the effect will almost always be generated and little will be learned about which variable(s) were responsible. The choice of an effective testing strategy in a particular situation is thus a question of ecological rationality.

Modeling the effect of sparsity To formalize this intuition, assume that a learner is faced with a simple causal system with $N$ binary independent input variables, $I$, and a single binary outcome, o. Given the subset of input variables, $C \subseteq$ $I$ that, when active, can cause the outcome to happen, the probability of the outcome given the current setting of inputs is

$$
P(o=1)= \begin{cases}1, & \text { if } \exists c \in C(c=1) \\ 0, & \text { otherwise }\end{cases}
$$

In other words, the outcome occurs if and only if any of the input variables in $C$ are currently active.

The learner must now decide how to manipulate the input variables to best figure out which of them are causes (i.e.,

Figure 1: Effect of the number of causes, $|C|$, and the number of variables, $N$, on the number of variables tested.
which are members of $C$ ). We assume that the learner's optimal strategy lies in choosing a switch setting, $s \in S$, that maximizes the expected Information Gain with respect to the system. Information gain is a common metric for quantifying the value of information-seeking actions, including causal interventions. It is computed as the expected difference of a learner's current uncertainty over their hypotheses $H$, and their expected new uncertainty after having made an intervention on the system and observed an outcome. In this case, a learner's hypotheses $H$ are all possible compositions of the set of causes, $C$, and there are two possible outcomes ( $o=1$ or $o=0$ ). Thus a learner's expected information gain is

$$
\begin{equation*}
E I G(s \mid H)=S E(H)-\sum_{j=0}^{1} P(o=j \mid s) S E(H \mid s) \tag{1}
\end{equation*}
$$

where SE denotes the Shannon Entropy over a distribution of beliefs (Shannon \& Weaver, 1949). To investigate the impact of causal sparsity, we use this model to explore how a learner's belief about sparsity affects the optimal strategy.

Figure 1 shows model predictions for the number of variables an optimal learner should manipulate upon their first encounter with a system of variables, based on their knowledge about the number of causes, $|C|$, and the number of variables in the system, $N$, assuming a uniform belief over all remaining hypotheses. In line with the intuition outlined above, when a learner expects only one cause the model predicts a Test Half strategy. As the number of causes increases (that is, as causal sparsity decreases), the optimal number of manipulated variables decreases and quickly reaches the strategy of changing only a single variable. This relationship is modulated by the total number of variables, which increases the degree of causal sparsity and consequently the number of variables that should be manipulated.

These results show that the causal sparsity of an environment should affect a learner's strategy for manipulating binary variables to find out how they affect some outcome of interest. This means that, even in the same task, there can exist a continuum of optimal strategies with respect to the num-

Figure 2: Wooden box used in Experiment 1.
ber of variables changed, which ranges from a Test Half to a Test One method. This observation leads to the core prediction we test in this paper. We hypothesize that when learning a causal system, people will use different strategies depending on their belief about the sparsity of the system. This result would offer a further demonstration that human intervention strategies are ecologically rational, in the sense of being well matched to the environment within which they are needed.

## Experiments

We now present three experiments that investigate how knowledge about sparsity affects people's causal testing strategies. Sparsity is manipulated in two ways, both suggested by the model results shown in Figure 1. We first vary the number of causes (i.e., variables that affect the outcome) in a system (Exp. $1 \& 2$ ) and second the number of total variables available for testing (Exp. 2). We also investigate what strategies people select given no prior instructions about sparsity (Exp. 3).

## Experiment 1 - manipulating number of causes

Participants 30 participants were recruited via the subject pool of New York University's Department of Psychology. Participants were paid at a rate of $\$ 5$ per hour and could win an additional bonus of up to $\$ 3$ (see below).

Stimuli Participants were presented with the wooden box depicted in Figure 2. The box had six different switches (inputs), a yellow wheel (output) and a red activation toggle. Each switch could be turned to the left (off) or the right (on). The activation toggle controlled whether the entire box was turned on or off. Participants were randomly assigned to one of two experimental conditions. In the sparse condition, only one of the switches caused the wheel to spin, whereas the remaining five switches were broken. In the non-sparse condition, five switches caused the wheel to spin and one switch was broken. A single working switch was sufficient to activate the wheel, and the position of the broken switches had no effect whatsoever. The wheel could only be activated if the activation toggle was currently in its on-position. Otherwise, participants were told that the box was turned off. The working and broken switches were chosen randomly for each participant. At the beginning of the experiment, participants
were given six plastic tokens, each of which was worth $\$ 0.50$. Participants had to pay one token every time they wanted to turn on the box via the activation toggle (see below).

Procedure Participants were first familiarized with the components on the box. They were told about the the binary (on/off) nature of the switches, and the difference between broken and working switches. Depending on the condition, participants were then told that they had to to identify the one broken switch (non-sparse condition) or the one working switch (sparse condition). Before starting the task, participants in both conditions were shown the same two demonstration trials. First, while the activation toggle was turned off, the experimenter turned all six switches to their on position and subsequently turned on the activation toggle, causing the wheel to spin. Second, after turning the activation toggle off again, the experimenter set all switches to their off state and turned the activation toggle back on, which did not cause the wheel to spin. In the main part of the experiment, participants could repeatedly test different settings of the switches to find out which one was broken/working. On each trial, they could change the switches in any way they liked while the activation toggle was off. They could then test their chosen switch setting by turning the activation toggle on and observing the effect on the wheel. Before the start of each new trial, the activation toggle had to be turned off again.

To incentivize participants to use as few trials as possible, they had to pay one of their six plastic tokens (worth $\$ 0.50$ each) for each time they performed a test by inserting it into a coin slot on the box. Participants could test the box up to six times (hence the use of six tokens), but could stop whenever they thought they had identified the one broken/working switch. After their final test, they indicated to the experimenter which of the switches was broken/working. If their choice was correct, they could trade in any remaining tokens for their corresponding monetary value. If it was incorrect or they used up all their tokens, they received no bonus.

Results To characterize participants' trial-by-trial behavior at a strategy level, we used the following classification scheme. In the non-sparse condition, participants' strategies were classified as Test One if they turned on one switch on every trial, while leaving all other switches turned off. If a participant manipulated multiple switches or kept testing the same switch more than once, their strategy was classified as Other. In the sparse condition, participants' strategies were classified as Test One if participants turned on one new switch each trial, even when they left previously tested, but ineffective, switches turned on. This is because these past switches would have shown to be broken and therefore could not contribute confounding evidence on future tests. Participants' strategies were classified as Test Multiple if participants tested half or multiple of the switches. As a sequential strategy, Test Half does not have a meaningful definition for participants in the non-sparse group, who would al-

Figure 3: Strategy use in Experiment 1
ways encounter confounding evidence when changing multiple switches. Note that we also classified participants as Test One or Test Multiple if they had some interspersed trials with zero Information Gain (e.g., from repeating the same test twice), assuming that they were using a more noisy version of the respective strategy. ${ }^{1}$

Figure 3 shows the number of participants using each testing strategy in the two conditions. For the purposes of this figure, the classification was based on a participant's sequence of tests up to the point at which an optimal learner would have been able to correctly identify the working or broken switch (some participants made further unnecessary tests). Note that, among participants classified as "Test Multiple", everyone actually manipulated exactly half of the switches (i.e., they used the optimal strategy according to our optimal model). We kept the more general classification as Test Multiple, to stay consistent with the results presented in the next experiment. The number of participants using a Test One strategy was lower in the sparse condition (4 in 15 vs. 14 in 15 , Fisher's exact $p<0.001$ ). However, even in the sparse condition around a quarter of the participants decided to change one variable at a time.

In sum, as predicted by the optimal learner model presented above, Experiment 1 found that instructing participants to expect either a sparse (one cause) or a non-sparse (five causes) environment, had an effect on how they proceeded to manipulate a set of six variables. However, even in the sparse condition, we found that some use of the less effective Test One strategy persists. The following experiments explore possible explanations for this finding.

## Experiment 2 - manipulating number of variables

Experiment 2 explores whether increasing the amount of sparsity by adding more variables would lead to more participants to adopt a Test Half strategy. In Experiment 1, the benefit of testing multiple variables over testing variables one-byone was relatively modest. In fact, testing half of the variables in the sparse condition would save participants less than one

[^305]

Figure 4: Expected number of trials needed to find the working switch in the sparse condition, when using a Test One or Test Half strategy.
step ( $2 / 3$ of a step) on average, compared to testing variables individually (this difference translated to an average saving of $\sim \$ 0.33$ ). This may have not provided sufficient incentive for participants to realize that a Test Half strategy would be more advantageous. As discussed above, one way to amplify the sparsity manipulation is to add more variables (see Figure 1). To illustrate the effect on the expected payoff from the two strategies, Figure 4 shows the average number of tests needed to find the working switch for a learner in a sparse (one cause) environment employing either a Test One or a Test Half strategy. It shows that as the number of switches increases, so does the benefit of the Test Half strategy over the Test One strategy.

To test if people are sensitive to the degree of sparsity, Experiment 2 manipulated the number of variables (switches). Participants on Amazon Mechanical Turk completed the same task as in Experiment 1, but were presented with either $4,6,10$, or 20 switches (all manipulations were betweensubjects). As before, they were given either sparse (one switch working) or non-sparse (one broken) instructions. Although adding variables should have no effect on behavior in the non-sparse condition, we decided to keep the manipulation to ensure that adding variables does not encourage a general increase in the number of variables participants would test on each trial. By including the 6 switches condition again, this experiment also served to replicate the results from Experiment 1 with an online sample.
Participants 120 participants were recruited on Amazon Mechanical Turk. Recruitment was restricted to AMT workers within the United States aged 18 or above. Participants were paid $\$ 0.50$ for their participation, with the possibility of earning an additional bonus of up to $\$ 1$ (see below).
Stimuli The task from Experiment 1 was adapted as faithfully as possible to be run on the web with some minor changes. Instead of a wheel, the outcome of interest was a light bulb, which lit up when it was turned on, and re-

Figure 5: Strategy use in Experiment 2
mained gray otherwise. All switches were of the same kind and would turn green when on and red when off.
Procedure The experiment followed a $4 \times 2$ betweensubjects design. Participants received different versions of the task with either $4,6,10$, or 20 switches, and were given either the sparse or the non-sparse instructions. The procedure was the same as in Experiment 1. Participants received similar instructions and were also asked to perform two demonstration trials in which first all and then none of the switches were turned on, to show that the light bulb would turn on and stay off, respectively. The per-trial payment was adjusted depending on condition, such that participants had to pay either $\$ 0.25, \$ 0.16, \$ 0.1$, or $\$ 0.05$ per additional test in the $4,6,10$, or 20 switches conditions, respectively. These payments were chosen so that the total potential bonus (starting at \$1) would be zero if participants decided to test every single switch in isolation.
Results Figure 5 shows the frequency of the Test One, Test Multiple, and Other strategies by condition. In the non-sparse group a large majority of participants changed a single variable at a time, irrespective of the number of switches. In the sparse condition, however, the proportion of Test One users varied with the number of switches (Fisher's exact, $p<.05$ ), such that participants confronted with more switches (10 or 20) were less likely to test individual switches than those confronted fewer (4 or 6). This development was also accompanied by the expected increase in strategy efficiency, such that the number of trials participants saved on average in the sparse condition compared to the non-sparse condition increased from 0.15 trials in the 4 variable condition to 6.53 trials in the 20 variable condition, in line with the predictions in Figure 4.

These results provide further evidence that information about sparsity affects how people learn actively in multiplevariable settings. Again, participants in the sparse group were more likely to manipulate multiple variables at a time, whereas those with in the non-sparse group chose to manipulate variables one-by-one. Furthermore, participants in the sparse condition, in which there is only one cause, were sensitive to the total number of variables. The more switches were presented to participants (the more sparse the environment),
the more prominent was their use of a Test Multiple strategy. Nevertheless, this experiment also replicated the finding from Experiment 1 that in the absence of a strong incentive to do otherwise, people have a tendency to change single variables, rather than multiple. In fact, the web sample revealed, if anything, an even stronger tendency to use a Test One strategy in the sparse condition, particularly when the number of switches was small.

## Experiment 3 - no sparsity information

Experiments 1 and 2 suggest that testing one variable at a time might serve as a default strategy that is only overridden, to some degree, by knowledge about the number of causes. To explore this possibility further, Experiment 3 asked what strategy people would use to test a multi-variable system when they had no prior information about the number of causes to begin with. By giving participants vague instructions, we aimed to instill an approximately flat "prior" over all possible combinations of working and broken switches.

Participants 57 participants were recruited on Amazon Mechanical Turk. Recruitment was restricted to AMT workers within the United States aged 18 or above. Participants were paid $\$ 0.50$ for their participation, with the possibility of earning an additional bonus of up to $\$ 1$.

Stimuli Materials were the same as the 6-switch condition of Experiment 2. In a between-subject design participants were again randomly assigned to a switchboard that either had one broken or one working switch.

Procedure The procedure was the same as in the previous Experiment, with the exception that participants were given the same set of instructions about the number of causes in both conditions. Instead of being told to find the one broken or one working switch, they were instructed to "find out which switch(es) are working or broken". After the switch testing phase, participants were asked to indicate which switch(es) were working or broken, now being able to make multiple selections.

Results Figure 6 shows the proportion of participants that chose to turn on any possible number of switches on the very first trial. Data is collapsed over both conditions, since the initial instructions were the same and hence the first trial should not lead to different behaviors. The vast majority of participants (\%58) chose to manipulate a single switch, with only a small number (\%10) manipulating half.

This experiment verified that with no instructions about sparsity, the majority of participants chose to manipulate variables one-by-one. Note that an optimal learner initialized with a flat prior (which translates into $2^{6}$ hypotheses, given 6 switches, each with a prior probability of $\frac{1}{2^{6}}$ ) also assigns higher expected Information Gain to testing one over testing

Figure 6: Number of switches tested on the first trial of Experiment 3.
multiple variables. Therefore, the Test One "default" shown by some participants in earlier experiments, could stem from them ignoring the constrained prior that they were instructed on and instead acting as if they knew nothing about the sparsity of the system. This behavior would still be in line with the optimal learner analysis presented above.

## General Discussion

In a series of experiments, we found that, in line with an optimal learner model, people's strategies to manipulate multivariate causal systems take into account the causal sparsity of the system. In non-sparse environments (e.g., only one non-cause) the majority of participants adhered to a strategy of testing one variable at a time, in line with a "Controlling Variables" principle (Kuhn \& Brannock, 1977). When causes were sparse (e.g., only one cause) participants were more likely to manipulate multiple (often half) of the candidate variables. We also found that increasing the degree of sparsity, by increasing the total number of variables, amplified this effect on people's strategy choices.

These findings demonstrate that people adaptively change their causal experimentation strategies in response to knowledge about the environment. Our study thus offers an example of the importance of "ecological learning" that allows people to flexibly adapt their inquiry strategies to the information structure of the task (Ruggeri \& Lombrozo, 2015). This idea tallies with other recent work on causal interventions showing that people's strategy choices were made adaptively with respect to internal constraints, like cognitive load, and external factors like the match of a strategy and the task environment (Coenen, Rehder, \& Gureckis, 2015). In finding that sparsity affects behavior, the experiments above also add to recent evidence from other (spatial) information search tasks, in which hypothesis sparsity was shown to affect people's hypothesis testing strategies (Hendrickson, Navarro, \& Perfors, 2016).

Interestingly, we also found that even in sparse environments a proportion of participants chose to test variables individually, despite the fact that changing multiple variables would have been more efficient. This is somewhat surprising since prior work has often found that the Controlling Variables principle is difficult to teach and often violated even
by adults (Kuhn et al., 1995). It is thus intriguing to think about why we found such pervasive use of a CV strategy. One possibility is that a Test One strategy is less risky than changing multiple variables under a wide range of possible prior beliefs about the system. If the underlying system is not sparse, changing multiple variables can result in ambiguous evidence and often no information gain. However, changing variables one-by-one will be informative even in a sparse environment. With some degree of uncertainty about the current environment, a learner might therefore just be better off testing one variable at a time. Another contributing factor might be the that changing one variable at a time is explicitly taught in schools as a principle of scientific experimentation (National Academy of Sciences, 2013). It is interesting to consider whether this curriculum standard might actually in some cases hinder efficient experimentation by promoting a narrow focus on the idea of testing variables individually, irrespective of situation specifics.

# Path salience in motion events from verbal and visual languages 

Neil Cohn (neilcohn@visuallanguagelab.com), Vivian Wong, Kaitlin Pederson \& Ryan Taylor<br>Tilburg center for Cognition and Communication (TiCC)<br>P.O. Box 90153, 5000 LE Tilburg, The Netherlands

#### Abstract

Languages differ in the way they convey paths. S-languages conveying manner of motion directly in a main verb, while Vlanguages require a separate verb. This difference has been shown to influence the conceptualization and narration of motion events. We therefore asked: would this difference arise in the paths that people draw, particularly in visual narratives? We annotated the representations of path information (source, trajectory, goal) in a corpus of 35 comics from S- and Vlanguages. We found that panels from S-languages depicted the path of an action more often than those from V-languages, consistent with previous research on increased motion event salience for S -languages. These findings suggest that the conceptualization of paths from spoken language may influence the graphic depiction of paths.

Keywords: visual language; motion events; linguistic relativity; paths; attention

## Introduction

Expressing information about the paths of actions is a challenge to communication systems. Spoken language expresses spatial relations with symbolic units. Languages break down actions as moving from a source (starting point) to a goal (endpoint) with some sort of manner (characteristic of the path, i.e., bouncing, wiggling, sauntering, etc.) (Talmy, 1985). This can be encoded in a sentence using a satelliteframed construction, which places both manner and motion into one verb (go, run), while a "satellite" expresses the path in a preposition (out, in), as in She ran out of the room. Alternatively, a verb-framed construction includes both motion and path in a verb (Spanish: salir-"exit", entrar"enter"), and separating manner into an additional verb (corriendo-"running"), as in She exited the room running. Corpus analysis has suggested that languages differ in which of these constructions they primarily use (see Slobin, 2003 for summary). Satellite-framed "S-languages" (English, German, Dutch, Mandarin) allow a main verb to contain information about manner of motion, while verb-framed "Vlanguages" (Spanish, French, Japanese, Hebrew) express this in a separate verb.

This difference in typology thus varies the salience of paths in motion events between languages. For example, in a sentence like He ran out of house, across the street, into the bar, an S-language can easily covey one main verb, and extend the manner of the path (running) across several event segments using prepositions. In contrast, V-languages would require a separate verb for each path (He exited the house,
crossed the street, entered the bar) and would need to add a verb repeatedly to each clause to specify manner (running).

Because V-languages frame manner in a separate verb, they demand extra effort and attention in contrast to the increased salience of paths in motion events by S-languages (Slobin, 2000, 2003). This difference in salience has manifested in studies of mental imagery, translation, and narration-often elicited from reading wordless visual narratives. Narratives told by speakers of S-languages tend to create units of successive events and draw focus to the manner of motion, while those by speakers of V-language often frame the setting and environment where motion events happen, leaving both paths and their manner to inference (Slobin, 2000, 2003).

Given that much previous work examined participants' verbalized narration of wordless, drawn visual narratives, would path salience be reflected in the drawing systems that appear in visual narratives themselves? In drawings, motion needs to be converted from dynamic movement into a static depiction. Such information is implied by the postures of figures in actions, and further clarified by graphic devices, like motion lines, which overtly depict the path of an action by trailing a moving object (Cohn, 2013; McCloud, 1993). Motion lines differ in the "visual languages" used to draw visual narratives throughout the world (Cohn, 2013; McCloud, 1993) and their understanding is learned over time (Friedman \& Stevenson, 1975) and conditioned by experience with comics (Cohn \& Maher, 2015; Nakazawa, 2016). In addition, both behavioral and neurocognitive research suggests that actions are more easily understood when motion lines depict their paths than without motion lines (Cohn \& Maher, 2015; Ito, Seno, \& Yamanaka, 2010).

Given that S - or V-languages differ in how they encode properties of paths, might this salience of paths in visual depictions differ based on a drawer's spoken language? That is, might the conceptualizations from one domain (e.g., speaking) "permeate" those of another domain (e.g., drawing) as a reflection of shared conceptual resources (Cohn, 2016)?

A study by Tversky and Chow (2009) sampled panels out of one comic each from Japan, Italy, America, and China. These books crossed distinctions of Western cultures (America and Italy) and Asian cultures (China and Japan), in addition to crossing linguistic typology of S-languages

Figure 1. A path depicted by a motion line segmented into its component parts.
(Chinese and English) and V-languages (Japanese and Italian). Panels were then rated on a scale of "action" vs. "setting the scene" by American and Japanese participants. Participants rated panels from China and America (Slanguages) as more "active" than those from Japan and Italy (V-languages), but within these contrasts panels from Asian countries (China, Japan) were rated as more active than those from Western countries (America, Italy). These results provide preliminary evidence that path information encoded differently in S- and V-languages could influence the drawings of speakers of those languages. Nevertheless, this work was limited in that it included panels from only single comics per group, and did not directly examine the depiction of paths within those works, instead using "action" as a proxy for paths.

We therefore further investigated this issue by coding the component parts of paths directly in panels from various comics from around the world. Paths were analyzed for their component segments: a source (the start of the path), the goal (the endpoint of the path), and the trajectory (the path traversed). The manner is typically encoded in the trajectory. In Figure 1, the ball is bouncing, but without that middle segment, the ball would appear to move in a straight path. As in Figure 1, an image could depict all three of these path segments at once, or a panel could frame isolated segments of a path (imagine each dotted box as images on their own, or combining them for Source-Trajectory or Trajectory-Goal segments).

We coded the properties of path information in 35 comics from around the world, drawn by speakers of S-languages (English, Mandarin, German) and V-languages (Japanese, Korean, French). However, we also considered the possibility
that path information could vary as a function of the influence of comics traditions. For example, American and Japanese comics have been observed to use different types of motion lines to depict the paths of moving objects (Cohn, 2013; McCloud, 1993, 1996). Yet, motion lines were a highly borrowed element from the Japanese Visual Language into mainstream American comics during the influx of manga into America in the 1990s. In addition, Original English Language (OEL) manga are comics drawn in the "style" of Japanese manga, but are created by speakers of English (an Slanguage). This is contrasted by Korean "manhwa," which are also imitative of the visual language of Japan, but come from Asia and speakers of Korean-another V-language. Chinese manhua (including "wuxia" from Hong Kong) are also from Asia, but do not necessarily imitate the Japanese Visual Language.

Following previous work, we reasoned that representations from visual narratives produced by speakers of S-languages (and optimized for those readers) would depict more paths than those from V-languages. Specifically, they should depict more trajectories, since that path segment illustrates its manner.

## Methods

## Materials

We selected 35 books for analysis, with 5 from each of our primary groups which varied in their continent of origin

Table 1. Characteristics of comics included in our corpus study.

| Comic type | Continent | Original <br> Language | Language <br> path type | Total <br> pages | Total <br> panels | Average <br> panels/page |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| American Mainstream | America | English | S-language | 106 | 541 | 5.16 |
| OEL Manga | America | English | S-language | 137 | 768 | 5.62 |
| Chinese manhua | Asia | Mandarin | S-language | 131 | 772 | 5.92 |
| German comics | Europe | German | S-language | 136 | 772 | 5.78 |
| French bande desinée | Europe | French | V-language | 100 | 769 | 7.73 |
| Japanese manga | Asia | Japanese | V-language | 106 | 563 | 5.62 |
| Korean manhwa | Asia | Korean | V-language | 118 | 579 | 5.2 |
| TOTAL |  |  |  | $\mathbf{8 3 4}$ | $\mathbf{4 , 7 6 3}$ | $\mathbf{5 . 8 6}$ |

(America, Europe, Asia) and path language type (S-language, V-language), as listed in Table 1. A full listing of works analyzed appears in the Appendix. We attempted to retain the same general genre (action, adventure, superhero, fantasy, sci-fi) throughout all the books as best as possible. Coders analyzed either a single issue, chapter, or episode in each book, 25 pages, or 150 panels, whichever came first. This amounted to an average of 23.8 pages and 136.1 panels per book, across a total of 4,763 panels in 834 pages (see Table 1). All annotations were incorporated into the Visual Language Research Corpus (VLRC: http://www.visuallanguagelab.com/vlrc/index.html).

## Data Analysis

Trained coders independently analyzed each book panel-by-panel across the areas of analysis with $60 \%$ of books were annotated by two coders. Coders were trained through an extensive course on visual language linguistics and prior to coding scored above an $85 \%$ agreement on assessments of their coding ability.

Coders identified whether a represented path depicted its source (starting point), trajectory (midpoint and the path itself), and/or goal (endpoint). Panels could involve an isolated path segment (just source, trajectory, or goal) or multiple segments together (ex. source-trajectory, trajectorygoal). We also annotated the cues used to signal these paths, be they graphic devices like motion lines, or the postural cues of figures in motion. We recorded the total number of path segments in a given panel, and calculated the mean number of instances by dividing the sum of path segments divided by the total number of panels per book. Final analyses averaged the means for each book between coders' scores.

Our analyses looked at panels which included any path segments (e.g., a panel with a trajectory, and/or both a trajectory and goal), and those that panels depicting only an isolated path segment (source, trajectory, or goal). Path segments were analyzed using repeated-measures ANOVAs that set path segment (i.e., source, trajectory, goal) as the

Figure 2: Path segments isolated to individual panels averaged across language types. Standard error is depicted.
within-groups factor and comic type (Table 1), continent of origin (America, Asia, Europe) or language type (S- vs. Vlanguage) as the between-groups factor. Follow up analyses examined the differences of each area of analysis within and between groups.

## Results

Our initial $2 \times 3$ repeated-measures ANOVA examined the difference between path segments (source, trajectory, goal) between different language types (S- vs. V-). We found main effects of path segments and language type, as well as an interaction between them (see Table 2). These analyses were carried out both for panels with any path segment, and those with isolated path segments. The main effect of path segment arose because, across language types, trajectories were used more than goals, which were used more than sources (all $p \mathrm{~s}<.05$; see Figure 2). However, across both analyses comics originally produced by speakers of S-languages used significantly more trajectories than those by V-languages (all $F \mathrm{~s}>7.3$, all $p \mathrm{~s}<.01$ ), but neither sources nor goals differed on the basis of language types (all $p \mathrm{~s}>.134$ ).

In line with Tversky and Chow's (2009) contrasts between cultures, we also analyzed path segments collapsed across continents (America, Europe, Asia) with a $3 \times 3$ repeatedmeasures ANOVA. Consistent with our other analyses, we again found main effects of path segments, but found no significant main effects of continent or interaction between path segments and continents. This held for analyses of all path segments and isolated path segments (Table 2).

Figure 3: Path segments isolated to individual panels from various comics. Standard error is depicted.

Finally, to assess the differences between each comic type, we used a $3 \times 7$ repeated-measures ANOVA to compare path segments across all comic types. We found main effects of path segments and comic type, and an interaction between them (Table 2). As in Figure 3, in almost all types of comics, trajectories appeared more than goals, which appeared more than sources (all $p s<.05$ ). The exception to this was Japanese manga, which depicted near equal amounts of trajectories and goals. Follow up analyses showed comic types did not differ in their depiction of isolated sources or goals when isolated in panels (all $p s>.364$ ), but did differ for trajectories in both analyses (all $F \mathrm{~s}>7.3$, all $p \mathrm{~s}<.001$ ) and between goals in panels depicting any paths, $F(6,28)=2.6, \mathrm{p}<.05$. Specifically, the difference in isolated trajectories seemed to be motivated by Chinese manhua, which used more trajectories than all other comics (all $t \mathrm{~s}>4.1$, all $p \mathrm{~s}<.01$ ) except French and German comics (all $p \mathrm{~s}>.16$ ), while panels with any paths including trajectories were higher in Chinese manhua than all other comics (all $t \mathrm{~s}>3.5$, all $p \mathrm{~s}<.05$ ), except trended higher than German comics ( $p=.076$ ). In addition, isolated trajectories in Japanese manga and Korean manhwa were fewer than in French and German comics (all $t \mathrm{~s}>3.1$, all $p \mathrm{~s}$ <.05).

## Discussion

This corpus analysis examined comics from seven different types of comics from around the world to investigate whether the depiction of path information varied on the basis of culture and/or spoken language typology. Though we found that path segments differed between comics, such variation did not vary based on the comics' continent of origin.

However, they did vary based on a comics' original language type.

On the whole, the trajectories of paths-i.e., the path itself-were depicted more than the goals (endpoint) of the paths, which in turn appeared more than the sources (starting point). The prominence of goals over sources aligns with findings that the endpoints of paths are more salient than starting points in verbal language, and in perception and attention (Lakusta \& Landau, 2005; Regier, 1996, 1997). However, the fairly consistent depiction of trajectories beyond sources and goals suggests an importance for the visual depiction of paths themselves in motion events, more than their start or endpoint. This is consistent with the idea that motion lines disambiguate actions by depicting their paths (Cohn \& Maher, 2015).

In addition, we found that trajectories isolated to their own panels appeared more in the depictions of paths from visual narratives from S-languages than V-languages. These findings are also consistent with findings that the conceptualization and narration of motion events are more salient for speakers of S-languages than those of V-languages (Slobin, 2000, 2003), and with previous work (Tversky \& Chow, 2009) showing panels from S-languages (English, Chinese) are as rated more action-oriented than those from V-languages (Japan, Italy). These findings support the idea that the framing of path information in a spoken language may influence its depiction in a drawn visual language.

Despite our finding of differences between comic panels on the basis of spoken language typology, we found no significant differences based on the comics' continent of origin. This differed from Tversky and Chow's (2009) finding of a split between how "active" panels were rated in

Western and Asian comics. However, inspection of Tversky and Chow's reported data suggests that Chinese panels may have driven the effect of higher ratings of "action" compared to all others type. We too found that manhua exceeded the depiction of paths of all other types of comics, though here it may have offset differences between continents given the relational similarities otherwise between pairs of books from Asia (Korean, Japanese), America (US mainstream, OEL manga) and Europe (French, German). The difference between manhua and other types of comics-including those from other S-languages - may support the classification of Mandarin as variant from the binary split of S- and Vlanguage types (Chen \& Guo, 2009).

The absence of variation between depictions of paths on the basis of culture contrasts from findings across other aspects of structure from the visual languages used in comics. For example, previous corpus analyses have suggested differences between cultures on the basis of comic panels' attentional framing structure (Cohn, Taylor-Weiner, \& Grossman, 2012), narrative patterns across panels (Cohn, In press), semantic transitions between panels (McCloud, 1993), and visual morphology like speech balloons (Forceville, Veale, \& Feyaerts, 2010). Combined with prior findings, our results suggest that cross-cultural variation in visual narrative systems may involve a diverse number of factors including cultural specificity, visual language patterns, and possibly influence from spoken languages.

Finally, given the differences between depictions of paths on the basis of S- versus V-languages, this work hints at "permeability" between the conceptualization made in expressive domains, here between spoken languages and drawings. This initial work could thus be followed by more extensive corpus research, in addition to experimental methods further examining these preferences. For example, both behavioral and neurocognitive work has shown that comic panels containing motion lines are easier to process than those omitting such visualized paths (Cohn \& Maher, 2015; Ito et al., 2010). While comic reading expertise modulated these costs (Cohn \& Maher, 2015), our findings here might suggest cross-cultural variation in such processing. Given the greater salience of paths for S languages, would speakers of these languages be more sensitive to the absence of motion lines than speakers of Vlanguages, for whom depicted paths may be less salient? Might path information thus be a factor in translations or interpretations of comics across languages? This work can hopefully sponsor further research into the potential permeability between the conceptualizations in spoken and visual languages.

#### Abstract

The predictive performance equation (PPE) is a mathematical model of learning and retention that uses regularities seen in human learning to predict future performance. Previous research (Collins, Gluck, Walsh Krusmark \& Gunzelmann,, 2016) found that prior data could be used to inform PPE's free parameters when generating predictions of a group's aggregate performance, allowing for more accurate initial performance predictions. Here we investigate an extension of this methodology to predict performance of individuals, rather than aggregate samples. This paper documents the results of that investigation, which is on the critical path to the use of this cognitive technology in education and training.

Keywords: Mathematical model; Performance predictions; Skill learning; Parameter generalization; Educational data mining, Individual predictions

## Introduction

It is typical in training and education for instructors to have little to no information about the people who are about to begin the curriculum. Rather, individuals must complete some portion of the curriculum before for their knowledge can be assessed. This assessment period can lead to an increase in the overall amount of time that training and education takes, and can lead to individuals practicing skills that have already mastered (Beck \& Chang, 2007). Ideally, instructors could be able to estimate the future performance of both the incoming cohort of students as a whole in addition to the specific individuals based on the past performance of those who learned the same curriculum. This would allow instructors to better adjust a given curriculum to fit the needs of the cohort and of specific students.

In cognitive science, models of learning and retention have been developed to account for particular regularities in human learning such as the power law of learning (Newell \& Rosenbloom, 1981) and power law of decay (Rubin \& Wenzel, 1996), and the spacing effect (Bahrick, Bahrick, Bahrick, \& Bahrick, 1993 Although many of these models were created based on basic laboratory phenomena, they can also be used to generate predictions of future human performance (Anderson \& Schunn, 2000; Jastrzembski, Gluck, \& Gunzelmann, 2006; Mozer, Pashler, Cepeda, Lindsey, \& Vul, 2009; Pavlik \& Anderson, 2008; Raaijmakers, 2003). These models hold promise in training and education to increase mastery and /or decrease instruction time.

## The Predictive Performance Equation

The model discussed in this paper is the Predictive Performance Equation (PPE; Walsh et al, submitted). PPE is a mathematical model of human learning and retention that can generate performance predictions on declarative (know-what) and procedural (know-how) tasks. Prior research has validated PPE across a variety of different laboratory tasks (Walsh et al., submitted) as well as complex human performance data from F-16 fighter pilot training research (Jastrzembski et al., 2006) and education and training data (Collins, Gluck, \& Jastrzembski, 2015).

PPE represents the effects of three factors on knowledge acquisition and retention: recency of practice, frequency of practice, and the distribution of practice over time (i.e., spacing). The first factor, recency ( $T_{n}$ ), captures the amount of elapsed time since training began. $\mathrm{T}_{\mathrm{n}}$ is calculated as a weighted sum of the elapsed time since each of each previous training opportunities $\left(t_{i}\right)$ (Equation 1). The weight $\left(w_{i}\right)$ applied to the amount of time that has passed since a particular event decreases exponentially with time (Equation 2). Although in principle a free parameter, prior model exploration has found that the exponent, $x$, can be set to 0.6 , which we do in the analyses presented here.

$$
\begin{align*}
& T=\sum_{i=1}^{n} w_{i} * t_{i}  \tag{1}\\
& w_{i}=-t_{i}^{-x} \sum_{j=1}^{n} \frac{1}{t_{j}^{-x}} \tag{2}
\end{align*}
$$

The second factor, frequency $\left(\mathrm{N}_{\mathrm{n}}\right)$, represents the number of times that a particular knowledge or skill has been rehearsed. These two factors, elapsed time and frequency of practice, have a multiplicative effect on activation $\left(M_{n}\right)$, which is the strength of a particular memory or skill (Equation 3). Amount of practice is scaled by the learning rate $c$, which is fixed to 0.1 . As the amount of practice increases, activation rises at a decreasing rate, producing the power law of learning. The second term, comprised of $T$ and $d$, captures the effects of the power law of decay. The decay rate, d , captures spacing effects (Equation 4).

$$
\begin{gather*}
M_{n}=N^{c} * T^{-d}  \tag{3}\\
d_{n}=b+m *\left(\frac{1}{n-1} * \sum_{j=1}^{n-1} \frac{1}{\log \left(\operatorname{lag}_{j}+e\right)}\right)
\end{gather*}
$$

The precise effect of spacing on performance is determined by the summation term within the decay parameter. When lags between successive training opportunities $\left(\right.$ lag $\left._{j}\right)$ are
short, the summation term in Eq. 4 approaches 1 and decay increases, leading to a greater amount of forgetting. When the lags between training opportunities are long, and the summation term approaches 0 , the decay term decreases, leading to less forgetting over time. The decay rate equation includes a decay intercept parameter (b) and a decay slope parameter $(m)$. The activation value from Eq. 3 is scaled to performance through a logistic function (Equation 5). The function contains two additional free parameters controlling its slope $(s)$ and the intercept $(\tau)$.

$$
\begin{equation*}
P_{n}=\frac{1}{1+\exp \left(\frac{\tau-M_{n}}{s}\right)} \tag{5}
\end{equation*}
$$

In summary, PPE has four free parameters (i.e., $b, m, \mathrm{~s}, \tau$ ). These parameters can be calibrated based on existing performance data. Once a set of best fitting parameters have been found, PPE can use these parameters to predict future performance.

## Motivation

Reliable and valid parameter estimates for PPE cannot be found with PPE when calibrating to fewer than three training opportunities. There are two reasons for this. First, when fewer than three data points are available, multiple combinations of free parameter values that can fit the available training data equally well. This makes it difficult to determine which set of parameter values should be used to generate out-of-sample predictions (Beck \& Cheng 2007). Second, when calibrating PPE to so little data, PPE will likely fit to both the performance of the individual as well as to noise in the data (Geman, Bienenstock, \& Doursat, 1992). This overfitting, in turn, will reduce the accuracy of out-of-sample predictions. The combination of these two factors are likely to lead to inaccurate and uncertain out-of-sample performance predictions. To overcome this limitation, Collins et al. (2016) developed a method for using prior data (i.e., records of performance data collected from previous classes) to inform a subset of PPE's free parameters (prior predictions), under cases where there were not enough data points for accurate calibration. By using prior data to inform a subset of PPE's free parameters, PPE fits the available training data with a constrained parameter set. In circumstances where there is little training data, this increases PPE's prediction accuracy for early performance events.

This prior-informed prediction method was based on work from the Educational Data Mining (EDM) literature. EDM research applies data mining and statistical learning methodologies to educational data to improve student learning outcomes (Romero, Ventura, \& Baker, 2010). EDM methods are primarily data driven, meaning they require large amounts of data to develop predictions within a specific domain (Webb, Pazzani, \& Billsus, 2001). In contrast PPE is primarily theory driven, meaning that its predictions are based on mechanisms that account for general characteristics of human learning and retention.

The development of PPE's prior-informed prediction method balances the data-driven and theory driven approach of these two methods.

Although Collins et al. (2016) found that prior data could be used to generate predictions of the aggregate performance of multiple students attempting a single skill, their results did not indicate how accurate the predictions are at an individual student level of analysis. Using prior data to predict the initial performance at a finer level of aggregation is more difficult for two reasons. First, the performance of a single individual is characterized by greater variability, as compared to learning curves aggregating across the performance of multiple students, making performance of a single student more difficult to predict. Second, students are likely to learn skills at different rates, meaning that best fitting parameters for an aggregate learning curve may not generalize to account for the performance of a specific student attempting a particular skill.

In spite of these additional complexities when predicting the performance of individual students, educational data mining research has shown that prior data can be used to inform valid model parameter estimates for models used to account for the performance of individual students on single skills (Cen, Koedinger \& Junker 2007; Beck \& Chang 2007; Ritter et al., 2009). These findings suggest that prior data can serve as a useful tool that can be used to inform predictions of individual students and not just aggregate samples. In summary, we sought to expand our previous research by examining the extent to which our method for predicting early performance of groups of students generalizes to the individual student level of analysis. To evaluate the prior-informed method, we compare it against predictions to PPE's standard non-prior predictions during an individual student's first 4 attempts on a new skill.

## Method

The data used in this report were obtained from Learnlab.com's DataShop (Koedinger, Baker, Cunningham, Skogsholm, Leber, \& Stamper 2010), which is an online educational data repository for student $\log$ data. DataShop contains a collection of publicly available datasets from different math, science, and English classroom and tutoring studies. The data used in our analyses, consisted of $\log$ files of performance metrics of students completing their homework for an introductory physics class during six different semesters. Students used the ANDES tutoring system to complete their homework (VanLehn et al, 2005) at the United States Naval Academy (USNA). We chose these datasets because they contain the largest collection of data from multiple semesters collected from the same domain currently available on DataShop, allowing us to better investigate the utility of using prior data to inform PPE's performance predictions.

A single semester's worth of data on DataShop is called a dataset, which is composed of a record of the
performance of individuals who attempted to solve problems in a specific domain within a specific period of time. Each dataset contains the record of all of the students' actions across the curriculum's content. A curriculum is made up of problems, defined as "a task [attempted by] a student usually involving several steps." An example of a problem would be calculating the difference in velocity between trains A and B. Successfully solving a problem involves completing a series of steps, which are "an observable part of a solution to a problem", such as finding the velocity of train A. We choose to examine the performance of students while completing particular steps for two reasons. First, steps were the smallest level of resolution of data available on Datashop. Second, each step isolates a particular knowledge component. Because learning occurs at the level of individual knowledge components (Anderson \& Schunn, 2000), comparing analogous steps across problems is the proper way to observe the change in performance over time.

## Prediction Procedure

We systematically selected one of the six datasets as the prediction sample, and used the remaining five datasets as prior data to inform predictions for an individual on a particular step. Then the performance data of a single student on a particular skill was selctecd, from the prediction sample. All of the students from the prior data who also attempted the same skill were selected (relevant sample) and used to inform PPE's predictions. Due to the fact that the data collected from the ANDES tutoring system are data from homework assignments, the students' first exposure to the curriculum was during class and was not their first attempt on a particular step within the tutoring system. For this reason, we assumed a six-hour lag between class and when a student began to complete their homework. This assumption of a lag between class and home time allowed for a better estimation of PPE's model time as calculated from PPE's time variables (Eq. 1and 4). For the relevant sample to be able to inform a prediction, the average performance and model time variables across each participant during each event was calculated. Based on aggregate performance and model time computed from the relevant samples, PPE model parameters were estimated, and then used to make individualized predictions of a student's performance on a particular skill on the $2^{\text {nd }}, 3^{\text {rd }}$, and $4^{\text {th }}$ event.

For the analysis in this paper, we used PPE to generate predictions for two metrics of the students' performance: time to complete a particular step (seconds) and the number of incorrect attempts made by a student during a particular event. To generate a prior prediction, PPE first calibrated to the performance (i.e., completion time in seconds or number of incorrect attempts) of the first two events from the aggregate performance of the relevant sample. This yields a set of best fitting parameters values. The best fitting $b\left(\mathrm{~b}_{\text {prior }}\right)$ and $m$ ( $\mathrm{m}_{\text {prior }}$ ) parameters are then generalized to inform PPE's prior informed prediction of
an individual student's performance on the $2^{\text {nd }}$ event given their performance on the $1^{\text {st }}$ event. This is done by setting PPE's $b$ and $m$ free parameters to the $\mathrm{b}_{\text {prior }}$ and $\mathrm{m}_{\text {prior }}$ values and fitting PPE's remaining two free parameters $s$ and $\tau$ to the student's performance during the first event. After PPE is fitted to the student's performance on the $1^{\text {st }}$ event, the model is used to generate a prediction of the student's performance on the second event. This procedure was then repeated to generate predictions of the $3^{\text {rd }}$ and $4^{\text {th }}$ event, by increasing the number of events that PPE is calibrated to with the prior sample and the predicted individual before generating a performance prediction of the next event.

In addition to generating prior predictions, we used PPE to generate predictions of each student's performance on the 2nd, 3rd, and 4th events without using data from past participants. This involved fitting the model with the sparse, individual-specific data, and using the model to predict performance for the following event.

Across all of the six datasets collected from Datashop, a total of 10,499 predictions were made across 430 students and 161 individual steps across the $2^{\text {nd }}, 3^{\text {rd }}$, and $4^{\text {th }}$ performance event.

## Results

To examine the accuracy of PPE's prior and non-prior predictions the average model predictions from the $2^{\text {nd }}, 3^{\text {rd }}$, and $4^{\text {th }}$ events were compared to the average observations from students whose performance was predicted (Figure 1).

In addition to the looking at the average performance, the students' performance and PPE's predictions were separated in to two groups (i.e., canonical and noncanonical learning). The students in the canonical learning groups were students whose performance either improved or remained the same over the four observed learning events (Figure 2-A, 2-C). Students in the non-canonical learning group were students whose performance decreased during at least one of the four learning events (Figure 2-B, 2-D). The students' performance was separated into canonical and non-canonical learning groups, due to the fact the variability in the students' performance effects PPE's performance predictions. Additionally, we wanted to observe to test if PPE's could account for the two types of learning profiles.

## Completion Time

As seen in Figure 1, when predicting a student's performance on the $2^{\text {nd }}$ event, given their performance on the $1^{\text {st }}$ event, there is a significant difference between the mean completion time between PPE's prior ( $M=45.50$, $S D=85.50$ ) and non-prior ( $M=192.199, S D=196.78$; $t(10497)=90.932, p<.01)$ predictions compared to the students' average completion time $(M=37.85, S D=$ 70.43). Examining the root mean squared deviation $(R M S D)$ between PPE's prior $(R M S D=98.49)$ and nonprior predictions $(R M S D=250.18)$, we see that PPE's prior-informed predictions were more accurate than nonprior predictions. These results show that informing PPE's

Figure 1. The average performance metric, completion time (seconds) (left plot) and number of incorrect attempts (right plot) on the $2^{\text {nd }}, 3^{\text {rd }}$, and $4^{\text {th }}$ event, across human data (solid black line), prior informed predictions (dashed blue line), and non-prior informed predictions (dashed red line).
predictions using prior data can improve prediction accuracy when prediction performance of the $2^{\text {nd }}$ event

When predicting the students' performance on the $3^{\text {rd }}$ event, given their performance on the first 2 events, again a significant difference between PPE's prior ( $M=36.79$, $S D=81.76$ ) and non-prior ( $M=66.85, S D=143.21$; $t(10497)=22.78, p<.01)$ predictions is observed, compared to the students' average performance ( $M=$ $73.96, S D=179.11$ ). As was seen when predicting the students' average performance on the $2^{\text {nd }}$ event, a similar pattern is seen when predicting the $3^{\text {rd }}$ event. A lower RMSD was found between the students' average performance and PPE's prior $(R M S D=99.66)$ compared to non-prior predictions $(R M S D=151.80)$.

Finally, when predicting the students' performance on the $4^{\text {th }}$ event, given their performance on the previous 3 events, again a difference between the PPE's prior ( $M=$ $35.76, S D=73.11$ ) and non-prior ( $M=71.63, S D=172.86$; $\mathrm{t}(10497)=22.63, p<.01)$ predictions are observed, compared to the students' average performance ( $M=$ 33.56, $\mathrm{SD}=68.26$ ). Again PPE's prior informed predictions had a lower RMSD $(R M S D=92.13)$ compared to the non-prior predictions $(R M S D=181.53)$ when predicting the students' performance on the $4^{\text {th }}$ event.

## Correct Attempts: Canonical and Non-Canonical Learning Profile

Separating the students' performances into those who displayed canonical and non-canonical learning profiles, reveals two different sets of completion times. The performance of students who displayed a canonical learning profile was found to be monotonically improve over the course of the three events (Figure 2-A). Students who the non-canonical learning profile, on average

Figure 2. The average performance metric, completion time (A, B) and number of incorrect attempts (C, D) for both students who fit the canonical (A, C) and non-canonical (B D) learning profile, for both the human data (solid black line), non-prior predictions (dashed red line) and prior predictions (dashed blue line) on the $2^{\text {nd }}, 3^{\text {rd }}$, and $4^{\text {th }}$ event.
displayed non-monotonic improvement in their performance over the four events (Figure 2-B). Additionally, it is seen that the accuracy of PPE's prior and non-prior predictions varied based on the performance of the students' learning profile. When predicting the performance of students' who showed a canonical learning profile, PPE's prior and non-prior predictions became more accurate as PPE was calibrated to additional events before generating a prediction, during the $2^{\text {nd }}$ (Prior: $R M S D=$ 117.97; Non-prior: $R M S D=310.42$ ), $3{ }^{\text {rd }}$ (Prior: $R M S D=$ 82.90; Non-prior: $R M S D=132.78)$, and $4{ }^{\text {th }}$ (Prior: $R M S D=$ 56.31;Non-prior: $R M S D=91.52$ ) event (Figure 2-A). However, PPE's accuracy decreased when it was calibrated to each additional event when predicting performance of students' whose performance was found to have a noncanonical learning profile. When predicting the performance of students' who showed a non-canonical learning profile, PPE's prior and non-prior prediction accuracy decreased as PPE calibrated to additional events, during the $2^{\text {nd }}$ (Prior: $R M S D=41.26$; Non-prior: $R M S D=$ 95.67), $3^{\text {rd }}$, (Prior: $R M S D=101.62$; Non-prior: $R M S D=$ 154.06 ) and $4{ }^{\text {th }}$ (Prior: $R M S D=95.80$; Non-prior: $R M S D$ $=190.80$ ) event (Figure 2-B). Although, PPE's prediction accuracy varied based on the students' learning profile, PPE's prior performance predictions were more accurate than PPE's non-prior predictions.

## Number of Incorrect Attempts

Examining the average students' number of incorrect attempts on the $2^{\text {nd }}$ event given a students' previous performance on the first event (Figure 2), a large difference is observed in the predicted average number of incorrect attempts in PPE's prior ( $M=.47, S D=1.25$ ) and non-prior
$(M=2.19, S D=4.58 ; \mathrm{t}(10496)=38.97, p<.01)$ predictions, compared to the students' average number of incorrect attempts ( $M=.38, S D=1.09$ ). Looking at the RMSD between PPE's predictions and the students' performance, PPE's prior $(R M S D=1.51)$ predictions had a lower RMSD than PPE's non-prior informed predictions ( $R M S D=4.87$ ).

When predicting the students' average number of incorrect attempts $(M=.39, S D=1.63)$ on the $3^{\text {rd }}$ event, again a significant difference between PPE's prior ( $M=$ .49, $S D=1.63$ ) and non-prior predictions is observed ( $M=$ $1.20, S D=3.58 ; t(10496)=20.92, p<.01)$. However, unlike when predicting performance on the $2^{\text {nd }}$ event, the RMSD of PPE's prior informed predictions increased $(R M S D=2.14)$. While as well as PPE's non-prior ( $R M S D$ $=3.91$ ) decreased slightly.

Finally, when predicting the students' number of incorrect attempts on their $4^{\text {th }}$ event, given their performance on the previous three events, a similar pattern of predictions is seen. A significant difference was observed between PPE's prior $(M=.52, S D=2.13)$ and non-prior predictions $(M=1.24, S D=3.79 ; t(10496)=$ 22.62, $p<.01$ ), compared to the students' average performance was observed $(M=.39, S D=1.63)$. Additionally, the RMSD between the PPE's prior (RMSD $=2.22)$ and non-prior predictions $($ RMSD $=3.87)$ were not seen to improve. However, the PPE's prior informed predictions were lower than PPE's non-prior informed predictions.

## Incorrect Attempts: Canonical and Non-Canonical Learning Profile

Separating the students' performance into those who displayed canonical and non-canonical learning profiles, two different sets of the students' number of incorrect attempts are seen. From students who displayed a canonical learning profile, number of incorrect responses decreased over the course of the four learning events (Figure 2-C). Conversely, students who displayed a noncanonical learning profile on average displayed a nonmonotonic performance over the four events (Figure 2-D). The accuracy of PPE's prior and non-prior predictions varied based on the type of learning displayed by the students. When predicting the performance of students who showed a canonical learning profile, PPE's prior and nonprior predictions became more accurate when PPE calibrated to additional events, during the $2^{\text {nd }}$ (Prior: $R M S D$ $=1.04$, Non-Prior: $R M S D=4.69$ ), $3^{\text {rd }}$, (Prior: $R M S D=.68$ Non-Prior: $R M S D=2.27$ ) and $4^{\text {th }}$ (Prior: $R M S D=.56$ NonPrior: $R M S D=1.29$ ) event (Figure 2-C). However, PPE's accuracy decreased when it calibrated to additional events of students with a non-canonical learning profile. When predicting the performance of students' who showed a noncanonical learning profile, PPE's prior and non-prior predictions became less accurate as PPE calibrated to additional events, during the $2^{\text {nd }}$ (Prior: $R M S D=2.03$; NonPrior: $R M S D=5.14$ ), $3^{\text {rd }}$ (Prior: $R M S D=3.30$; Non-Prior:
$R M S D=5.57$ ), and $4^{\text {th }}$ (Prior: $R M S D=3.34$; Non-Prior: $R M S D=5.96$ ) (Figure $2-\mathrm{D}$ ). Although, prediction accuracy varied based on the students' average performance based on the learning profile of the student, PPE's prior performance predictions were more accurate than PPE's non-prior predictions.

## Discussion

The primary goal of this paper was to describe our assessment of the accuracy of PPE predictions of performance in the tutoring data available on DataShop, both with and without the use of informative priors. We find evidence that incorporating prior data into PPE's predictions at a lower (individual student) level of aggregation, slightly improves prediction accuracy, depending on the performance measure, the event being predicted, and the student's learning profile.

When predicting a student's completion time on the $2^{\text {nd }}$, $3^{\text {rd }}$, and $4^{\text {th }}$ event, we found that PPE's prior informed predictions were more accurate than PPE's individualized predictions. Additionally, we found that PPE's predictions varied based on the student's learning profile. When predicting the performance of students' who were found to have a canonical learning profile, the accuracy of PPE's increased as PPE was calibrated to additional events. However, the opposite results were observed when predicting the performance of students' who were found to have a non-canonical learning profile. Here it was observed that PPE's ability to predict performance depended on the variability of the students performance history in their performance. When variability in a student's performance history was low and improved regularly (i.e., canonical learning profile), PPE was better able to predict their future learning. When variability was high and a student's performance history showed both improvement and forgetting (i.e, non-canonical learning), the increased uncertainty in performance hindered the PPE's predictions from accurately predicting future performance. Although, the benefit of using priors was observed in PPE's predictions in each of these cases.

These results are partially consistent with results from Collins et al. (2016), where we found an initial benefit of using prior predictions to generate initial performance predictions of the $2^{\text {nd }}$ event, as was found when predicting the student's completion time. Without information from prior data, PPE's parameters must be estimated with sparse data from the student's prior performance during the first event. Because the model is under constrained in this case, the parameter estimates are likely unreliable.

Additionally, when predicting the average completion time and the number of incorrect attempts, a benefit of using a priors was found. When predicting a student's future performance, PPE is able to utilize information from other students who have previously performed the skill before, allowing for a better estimate of the student's future performance will be. These findings are in line with our
previous findings that PPE's prior predictions benefit PPE's predictions beyond the $2^{\text {nd }}$ event.

## Conclusion

The benefits of using prior data are not new to cognitive science. However, within the context of the PPE line of investigation, little previous research has been conducted on how prior data can be used to inform predictions, especially within the context of early performance predictions of individual students. In summary, we find evidence that our previously proposed method of incorporating information from prior data into PPE's free parameters (Collins et al. 2016), can add some benefit to prediction accuracy when attempting to predict the performance of individual students on particular skills. The results suggest that prior data is a useful source of information about the performance of individual students when generating predictions with PPE. Future work should attempt to incorporate information from prior data to generate initial performance predictions in order to decrease overall training or education time.

# Determinants of judgments of explanatory power: Credibility, Generalizability, and Causal Framing 

Matteo Colombo (m.colombo@uvt.nl)<br>Tilburg Center for Logic, Ethics and Philosophy of Science (TiLPS), Warandelaan 2, 5037 AB Tilburg<br>Tilburg, The Netherlands<br>Leandra Bucher (bucher@uni-wuppertal.de)<br>Department of Biological and General Psychology, Bergische Universität Wuppertal, Max-Horkheimer-Str. 20, 42119 Wuppertal, Germany<br>Jan Sprenger (j.sprenger@uvt.nl)<br>Tilburg Center for Logic, Ethics and Philosophy of Science (TiLPS), Warandelaan 2, 5037 AB Tilburg<br>Tilburg, The Netherlands

#### Abstract

This study investigates how judgments of explanatory power are affected by (i) the prior credibility of a potential explanation, (ii) the causal framing used to describe the explanation, and (iii) the generalizability of the explanation. We found that the prior credibility of a causal explanation plays a central role in explanatory reasoning: first, because of the presence of strong main effects on judgments of explanatory power, and second, because of the gate-keeping role prior credibility has for other factors. Highly credible explanations were not susceptible to causal framing effects. Instead, highly credible hypotheses were sensitive to the generalizability of an explanation. While these results yield a more nuanced understanding of the determinants of judgments of explanatory power, they also illuminate the close relationship between prior beliefs and explanatory power and the relationship between abductive and probabilistic reasoning.

Keywords: Explanation; Prior credibility; Causal framing; Generalizability; Abduction

## Introduction

Explanation is a central concept in human psychology. It supports a wide array of cognitive functions, including reasoning, categorization, learning, inference, and decisionmaking (Lombrozo, 2006; Keil \& Wilson, 2000; Keil, 2006). When presented with an explanation of why a certain event occurred, how a certain mechanism works, or why people behave the way they do, both scientists and laypeople have strong intuitions about what counts as a good explanation. Yet, more than sixty years after philosophers of science began to elucidate the nature of explanation (Hempel \& Oppenheim, 1948; Hempel, 1965; Salmon, 1989), the determinants of judgments of explanatory power remain unclear.

In this paper, we present three experiments on factors that may affect judgments of explanatory power. Motivated by a large body of theoretical results in epistemology and philosophy of science, as well as by a growing amount of empirical work in cognitive psychology (for respective surveys see Woodward, 2014; Lombrozo, 2012), we
examined how judgments of explanatory power are affected by (i) the prior credibility of a potential explanation, (ii) the causal framing used to describe the explanation, and (iii) the generalizability of the explanation.

First we hypothesized that the prior credibility of a causal explanation predicts judgments of explanatory power. Thus, throughout all three experiments, we manipulated the prior credibility of different explanations, and examined the effects of this manipulation on explanatory judgments.

Our focus on the prior credibility of causal explanation was motivated by the fact that most philosophical and psychological analyses of explanatory power agree that powerful explanations provide information about credible causal relationships. Credible causal information facilitates the manipulation and control of nature (Pearl, 2000; Woodward, 2003; Strevens, 2008) and plays distinctive roles in human psychology (Lombrozo, 2011; Sloman \& Lagnado, 2015). For example, credible causal information guides categorization (Carey, 1985; Murphy \& Medin, 1985; Lombrozo, 2009), supports inductive inference and learning (Holyoak \& Cheng, 2011; Legare \& Lombrozo, 2014; Walker et al. 2014), and calibrates metacognitive strategies involved in problem-solving (Chi et al., 1994; Aleven \& Koedinger, 2002).

Our second, related hypothesis was that presenting an explanatory hypothesis in causal terms predicts judgments of its explanatory power. Thus, we wanted to find out whether people's explanatory judgments are sensitive to causal framing effects.

The importance of this issue should be clear in the light of the fact that magazines and newspapers very often, even when it's not warranted, describe scientific explanations in terms of causal language (e.g., 'Processed meat causes cancer' or 'Economic recession leads to xenophobic violence') with the aim of capturing readers' attention and boosting their sense of understanding (Entmann 1993; Scheufele \& Scheufele, 2010). By combining prior credibility and causal framing as predictors of judgments of explanatory power, Experiment 1 and 2 examined the
impact of causality on the explanatory power of scientific hypotheses.

With Experiment 3, we tested the hypothesis that the generalizability (or scope) of a hypothesis determines its explanatory power. While the generalizability of scientific results is an obvious epistemic virtue that figures in the evidential assessments made by scientists, its relation to explanatory power is less clear. Previous psychological findings about the role of generalizability in explanatory reasoning are mixed. Read \& Marcus-Newhall (1993) found that generalizability predicts explanatory judgments. Preston \& Epley (2005) showed that hypotheses that apply to a wide range of observations are judged as more valuable. However, these studies involved no uncertainty about whether or not a causal effect was actually observed (cf., Khemlani, Sussman, \& Oppenheimer, 2011). So, whether or not generalizability is a robust determinant of explanatory judgment remains unclear.

In summary, bringing together different strands of research from philosophy and psychology, our study asks: How do the credibility, causal framing, and generalizability of a hypothesis influence judgments of explanatory power?

The pattern of our experimental findings supports the hypothesis that the prior credibility of a causal explanation plays a central role in explanatory reasoning: first, because of the presence of strong main effects on judgments of explanatory power, and second, because of the gate-keeping role it has for other factors. Highly credible explanations were not susceptible to causal framing effects. Instead, highly credible hypotheses were sensitive to the effects of factors which are usually considered relevant from a normative point of view like the generalizability of an explanation.

## Overview of the experiments and pre-tests

To warrant the validity of the experimental material, we conducted a series of pre-studies, where participants evaluated different levels of causal framing, credibility, and generalizability. Materials which corresponded to high, low, and neutral levels of these three factors were implemented in the vignettes of our three experiments, either as independent variables or as control variables.

Material evaluation and main experiments were both conducted online on Amazon Mechanical Turk, utilizing the Qualtrics Survey Software. We only allowed workers with an approval rate $>95 \%$ and with a number of HITs approved > 5000 to submit responses. Instructions and material were presented in English.

## Causal Framing

A sample of $\mathrm{N}=44$ participants (mean age 30.5 years, $S D=$ $7.3,28$ male) from America ( $\mathrm{n}=27$ ) and other countries rated eight brief statements, expressing relations between X and Y of the type " X co-occurs with Y "; "X is associated with Y", and so on. Participants judged how strongly they agreed or disagreed that a certain statement expressed a causal relation between X and Y. Judgments were collected
on a 7-point scale with options: "I strongly disagree" (-3), "I disagree", "I slightly disagree", "I neither agree nor disagree" (0), "I slightly agree", "I agree", "I strongly agree" (3). Based on participants' ratings, we selected three types of statements for our main experiments: statements with a neutral causal framing ("X co-occurs with Y"), with a weak causal framing (" X is associated with Y "), and with a strong causal framing ("X leads to Y " and " X causes Y ").

## Prior Credibility

We identified the prior credibility of different hypotheses by asking a new sample of $\mathrm{N}=42$ participants (mean age 30.7 years, $S D=7.5,16$ male) from America $(\mathrm{n}=29)$ and other countries to rate a list of 24 statements. Participants judged how strongly they disagreed or agreed that a certain hypothesis was credible. For all hypotheses, we used the phrasing "... co-occurs with..." to avoid the influence of causal framing. Based on participants' ratings, we selected four statements to use in our main experiments: two were highly credible, two were highly incredible (Table 1).

Table 1: The four hypotheses rated as least credible and as most credible.

| Credibility | Hypothesis |
| :---: | :--- |
| Low | Eating pizza co-occurs with immunity to flu. |
| Low | Drinking apple juice co-occurs with <br> anorexia. |
| High | Well-being co-occurs with frequent smiling. |
| High | Consuming anabolic steroids co-occurs with <br> physical strength. |

## Generalizability

This pre-study included two questionnaires, which were administered to two different groups of participants. One questionnaire presented descriptions of the samples used in scientific studies, which varied with regard to the number of people involved. The other questionnaire presented sample descriptions that varied with regard to the type of people in the sample.

Forty-two participants (mean age 33.5 years, $S D=10.8$, 27 male) from America ( $\mathrm{n}=38$ ) and other countries were presented with a list of six statements about a sample of a certain number of participants, e.g. "The study investigates five people"; "The study investigates 500 people".We found that the perceived generalizability of a study increased with the number of people in the sample of the study.

A new group of $\mathrm{N}=41$ participants (mean age 33.0 years, $S D=9.7,26$ male $)$ from America $(\mathrm{n}=36)$ and other countries was presented with a list of nine statements about samples of particular types of people, e.g. "The study investigates a group of people who sit in a park"; "The study investigates a group of people who work at a university". However, focusing on the number instead of the type of people in the sample allowed for a neater distinction between narrowly and widely generalizable results. Therefore, we characterized generalizability as a function of the number of participants in the main vignettes of the experiment.

## Vignettes of the Main Experiment

All experiments were performed using a $2 \times 2$ (withinsubject) design with explanatory power as dependent variable and prior credibility of the hypothesis being one of the independent variables. The other independent variable was either causal framing, or generalizability.

Participants were presented with four short reports about fictitious research studies. Two of these reports involved highly credible hypotheses, the other two reports involved incredible hypotheses. Two reports showed a high level of the other independent variable, while the other two reports showed a low level of that variable.

Each vignette in our experiments followed the same format as in this sample vignette.

## Consuming anabolic steroids leads to physical strength

A recent study by university researchers investigated the link between consuming anabolic steroids and physical strength. The researchers studied 240 persons. The level of physical strength was higher among participants who regularly consumed anabolic steroids than among the participants who did not regularly consume anabolic steroids. Family health history, age, and sex, which were controlled by the researchers, could not explain these results. The study therefore supports the hypothesis that consuming anabolic steroids leads to physical strength.

In all experiments, we varied the level of prior credibility of a hypothesis. In Experiment 1 and 2, we also varied the causal framing and interchanged "leads to" with "causes" and "is associated with", while we kept generalizability at its control. In Experiment 3, we varied the sample size (=generalizability) and controlled for causal framing by using the predicate "co-occurs with" in the headline and the conclusion. Participants were asked to rate our dependent variable: the explanatory power of the stated hypothesis for the results of the study.

## Experiment 1 and 2. Credibility x Causal Framing

## Participants, Design, and Material

Two-hundred-three participants (mean age 34.7 years, $S D=$ 10.5; 121 male) from America ( $\mathrm{n}=130$ ), India $(\mathrm{n}=67$ ) and other countries completed Experiment 1 for a small monetary payment. A new sample of two-hundred-eight participants (mean age 34.56 years, $S D=9.97$; 124 male) from America $(\mathrm{n}=154)$, India $(\mathrm{n}=43)$, and other countries completed Experiment 2 for a small monetary payment.

In both experiments, participants were presented with four short reports about fictitious research studies along the lines of the above vignette. Across vignettes, we manipulated the causal framing of the relationship between hypothesis and evidence as well as the choice of the hypothesis (credible vs. incredible). Generalizability was controlled for by setting it to its medium value (i.e., 240 participants). Two of the four reports involved highly
credible hypotheses, the other two involved incredible hypotheses. Similarly, two of these reports used weak causal framing (Experiment 1 and 2: "X is associated with Y") while the other two used strong causal framing (Experiment 1: "X leads to Y", Experiment 2: "X causes Y"). In other words, Experiment 1 used implicit causal language and Experiment 2 used explicit causal language, while the experiments were identical with respect to design, materials, and procedure.
To account for the possible influence of the content of a particular report, we counterbalanced the allocation of weak and strong causal framing conditions to the credibility conditions across the items, and created two versions of the experiments. The order of reports was individually randomized for each participant.
Participants judged each report in terms of the explanatory power of the hypothesis it described. Specifically, participants considered the statement: "The researchers' hypothesis explains the results of the study", and expressed their judgments on a 7 -point scale with the extremes (-3) "I strongly disagree" and (3) "I strongly agree", and the center pole (0) "I neither disagree nor agree".

## Analysis and Results

Separate two-way ANOVAs were calculated with the factors Credibility (low, high) and Causal Framing (weak, strong). ANOVA of Experiment 1 (implicit causal language) revealed a main effect of Credibility, $F(1,202)=$ 84.5; $p<.001 ; \eta_{\text {part }}^{2}=0.30$. There was no main effect of Causal Framing ( $p=.37$ ), and no interaction ( $p=.08$ ). Pairwise comparisons showed that incredible hypotheses were rated significantly lower than credible hypotheses, independently of the value of Causal Framing (incredible hypotheses: $M=0.26 ; S E M=0.10$; credible hypotheses: $M$ $=1.14 ; S E M=0.09 ; t$-test: $t(202)=-9.2 ; p<0.001 ; d=$ 0.67 ). The results of Experiment 1 therefore indicate that the prior credibility of a hypothesis was a strong predictor of judgments of explanatory power (Figure 1). Instead, framing a hypothesis with implicit causal language did not have effects on explanatory judgment.

Figure 1: Explanatory power ratings for credible and incredible statements in Experiment 1. Error bars show standard errors of the mean, and are expressed numerically, in parentheses next to the mean value.

ANOVA of Experiment 2 (explicit causal language) revealed main effects of Credibility $(F(1,207)=286.9 ; p$ <.001; $\left.\eta_{\text {part }}^{2}=0.58\right)$ and Causal Framing, $F(1,207)=31.0$; $p<.001 ; \eta_{\text {part }}{ }^{2}=0.13$, as well as a significant interaction Credibility x Causal Framing, $F(1,207)=37.6 ; p<.001$; $\eta_{\text {part }}{ }^{2}=0.15$. Figure 2 shows the effect sizes and the interaction between both factors as well as the relevant descriptives.

Figure 2: How explanatory power ratings vary with regard to Credibility and Causal Framing (Experiment 2). Error bars show standard errors of the mean and are expressed numerically, in parentheses next to the mean value.

The results of Experiment 2 confirm that the prior credibility of a hypothesis is a strong predictor of judgments of the hypothesis' explanatory power. Incredible hypotheses received negative explanatory power ratings, credible hypotheses receive positive ratings. The results also showed that explicit causal framing can increase ratings of explanatory power, but only for incredible hypotheses. While this effect may lead explanatory judgment astray, in most practical cases of explanatory reasoning, people are interested in the explanatory power of hypotheses which they find, at least to a certain extent, credible. As Figure 2 shows, there was no effect of causal framing on explanatory power in this important case.
This pattern of results confirms that the prior credibility of a hypothesis plays a gate-keeping-role in explanatory reasoning: only credible causal hypotheses qualify as explanatorily valuable. By contrast, implicit or explicit causal framing plays a small to negligible role in influencing judgments of explanatory power.

## Experiment 3: Credibility x Generalizability

## Participants, Design, and Material

Two-hundred-seven participants (mean age 33.4 years, $S D=$ 9.1; 123 male) from America ( $\mathrm{n}=156$ ), India $(\mathrm{n}=37)$ and other countries completed Experiment 3 for a small monetary payment.

The experiment resembled Experiment 1 and 2. Four vignettes, each of which included a headline and five sentences, presented credible and incredible hypotheses. The relation between hypothesis and evidence was expressed by using the causally neutral wording "X co-
occurs with $\mathrm{Y}^{\prime \prime}$. The critical manipulation concerned the sample descriptions used in the vignettes, which expressed either narrow or wide generalizability of the study's result. For narrowly generalizable results, the second sentence of a report indicated that the sample of the study encompassed around 5 people (e.g. "The researchers studied 6 people"). For widely generalizable results, the sample included about 10,000 people (wide generalizability condition, e.g. "The researchers studied 9891 people").
To control for the possible influence of the content of a particular report, we counterbalanced the allocation of narrow and wide generalizability conditions to the credibility conditions across the items, and created two versions of the experiments. The order in which reports were presented to the participants was individually randomized for each participant.

Participants were asked to carefully assess each report with regard to Explanatory Power. Participants’ ratings were collected on 7-point scales, with the extreme poles (-3) "I strongly disagree" and (3) "I strongly agree", and the center pole (0) "I neither disagree nor agree".

## Analysis and Results

The ratings were analyzed with a two-way ANOVA with the factors Credibility (low, high) and Generalizability (narrow, wide). ANOVA revealed significant main effects of Credibility, $F(1,206)=83.830 ; p<.001 ; \eta_{\text {part }}{ }^{2}=0.289$; and Generalizability, $F(1,206)=29.593 ; p<.001 ; \eta_{\text {part }}{ }^{2}=$ 0.126 , and no interaction Credibility x Generalizability ( $p=$ .085, n.s.).

As with Experiment 1 and 2, credible hypotheses achieved significantly higher ratings than incredible hypotheses (incredible hypotheses: $M=-0.01$; $\mathrm{SEM}=0.10$; credible hypotheses: $M=0.95$; SEM $=0.08$; $t$-test: $\mathrm{t}(206)=$ $-9.2 ; \mathrm{p}<.001 ; \mathrm{d}=0.72$ ). Furthermore, reports with wide generalizability achieved significantly higher ratings compared to reports with narrow generalizability (narrow: $M=0.21$; SEM $=0.10$; credible hypotheses: $M=0.73$; SEM $=0.08$; $t$-test: $\mathrm{t}(206)=-5.4 ; \mathrm{p}<.001 ; \mathrm{d}=0.40)$. Figures 3 and 4 show the main effects for both variables.

Figure 3: Explanatory power ratings as a function of Credibility. Error bars show standard errors and are also expressed numerically, next to the mean value.

Figure 4: Explanatory power ratings as a function of Generalizability. Error bars show standard errors and are also expressed numerically, next to the mean value.

## Discussion

We examined the impact of three factors---prior credibility, causal framing, and generalizability---on judgments of explanatory power. In a series of three experiments, we varied both the subjective credibility of an explanation and one of the other factors: causal framing and generalizability. In Experiments 1 and 2 we found that the impact of causal language on judgments of explanatory power was small to negligible. Experiment 3 showed that generalizable explanations with wider scope positively affected judgments of explanatory power.

Across all experiments, we found that the prior subjective credibility of a hypothesis had a striking effect on how participants assessed explanatory power. In particular, the credibility of an explanatory hypothesis had an important gate-keeping function: the impact of generalizability on explanatory power was more significant when credibility was high. On the other hand, the high credibility of a hypothesis controlled for the potentially misleading effect of causal framing on explanatory judgment.

This pattern of findings is consistent with existing psychological research demonstrating that people resist endorsing explanatory hypotheses that appear unnatural and unintuitive, given their background common-sense understanding of the physical and of the social world (Bloom \& Weisberg 2007). Our findings are also consistent with the idea that stable background personal ideologies (often referred to as "worldview") can reliably predict whether people are likely to reject well-confirmed scientific hypotheses (Lewandowsky et al., 2013; Colombo, Bucher, \& Inbar, 2016).

So, scientific hypotheses that are inconsistent with our prior, background, common-sense beliefs or in tension with personal ideologies are likely to be judged as implausible, and may not be endorsed as good explanations unless they are supported by extra-ordinary evidence gathered by some trustworthy source. On the other hand, for hypotheses that fit our prior, background belief or ideology, we often focus on information that, if the candidate explanatory hypothesis is true, would boost its goodness (Klayman \& Ha 1987).

This kind of psychological process of biased evidence evaluation and retention might have led participants to give
the highest ratings of explanatory power, across different experiments, when, in addition to a credible hypothesis, the report was widely generalizable. In comparison, the impact of causal framing was negligible in these cases. This result confirms that a good explanation has to be credible and widely generalizable, and that credible, widely generalizable explanations are not subject to misleading causal framing effects.

The interplay we observed between prior credibility and explanatory power is also relevant to understanding the relationship between abductive and probabilistic reasoning. Highly credible hypotheses were sensitive to the effects of factors which are usually considered explanatory virtues like the generalizability of an explanation.

In abductive reasoning, explanatory considerations are taken to boost the credibility of a target hypothesis while inducing a sense of understanding (Lipton, 2004). Previous psychological studies investigated the effect on people's assessments of explanatory power of factors like simplicity (Lombrozo, 2007; Bonawitz \& Lombrozo, 2012) and coherence (Koslowski et al. 2008). Our results advance this body of literature by suggesting that the generalizability of a hypothesis will boost the acceptability of the hypothesis, when the hypothesis has a high prior subjective credibility.

High prior credibility may also insulate an explanation from causal framing effects, which may produce a deceptive sense of understanding leading to erroneous explanatory judgments (Rozenblit \& Keil, 2002; Trout, 2002).

Overall, our experiments show that explanatory power is a complex concept, affected by considerations of prior credibility of a (causal) hypothesis, and its generalizability. These factors also figure prominently in (normative) philosophical theories of explanation. For instance, the D-N model (Hempel, 1965) stresses the generality of the proposed explanation, and the causal-mechanical account (Woodward, 2003) requires a credible causal mechanism.

On the other hand, the multitude of relevant factors in explanatory judgment explains why it has been difficult to come up with a theory of abductive inference that is both normatively compelling and descriptively accurate: after all, it is difficult to fit diverse determinants of explanatory judgment into a single unifying framework. In that spirit, we hope that our results will promote an interdisciplinary conversation between empirical evidence and philosophical theorizing, and about the "prospects for a naturalized philosophy of explanation" in particular (Lombrozo 2011, 549; Schupbach, 2015; Colombo, 2016).

# PACKER: An Exemplar Model of Category Generation 

Nolan Conaway (nconaway@wisc.edu)<br>Joseph L. Austerweil (austerweil@wisc.edu)<br>Department of Psychology, 1202 W. Johnson Street<br>Madison, WI 53706 USA

#### Abstract

Generating new concepts is an intriguing yet understudied topic in cognitive science. In this paper, we present a novel exemplar model of category generation: PACKER (Producing Alike and Contrasting Knowledge using Exemplar Representations). PACKER's core design assumptions are (1) categories are represented as exemplars in a multidimensional psychological space, (2) generated items should be similar to exemplars of the same category, and (3) generated categories should be dissimilar to existing categories. A behavioral study reveals strong effects of contrast- and target-class similarity. These effects are novel empirical phenomena, which are directly predicted by the PACKER model but are not explained by existing formal approaches.

Keywords: Categorization, exemplar models, category generation, creative cognition, computational modeling.

## Introduction

The creation of new concepts and ideas is among the most interesting - yet infrequently studied - capabilities of human cognition. This paper focuses on one topic within the broader field of creative cognition: category generation. Foundational work on this topic (e.g., Smith, Ward, \& Schumacher, 1993; Ward, 1994, 1995; Ward, Patterson, Sifonis, Dodds, \& Saunders, 2002) has focused on the role of prior knowledge in generating novel concepts. A core phenomenon is that people generate categories with similar distributional properties as existing categories. For example, Ward (1994) asked participants to generate species of plants and animals that might exist on other planets. Generation was strongly constrained by prior knowledge of Earth species: People generated species with the same features as those found on Earth (e.g., eyes, legs, wings) and possessing the same feature correlations observed on Earth (e.g., feathers co-occur with wings).

Recent work has proposed and tested formal models to explain these observations. Jern and Kemp (2013) trained participants on experimenter-defined categories composed of exemplars within an artificial three-dimensional domain. After a short training phase, participants were asked to generate exemplars from a new category. Participants were provided with a set of scales to adjust the feature values of each generated stimulus, and were given unlimited time to create each example. As in the classic Ward (1994) experiment, Jern and Kemp (2013) found that generated categories possessed the same feature variance and correlations as the experimenterdefined categories in the domain.

Jern and Kemp (2013) tested several different computational models on their data. Most relevant to the present investigation, they tested a 'copy-and-tweak' model that generates items by copying and changing previous observations, and a hierarchical Bayesian model that uses the structure of
known categories to infer the structure of new ones. They found that the hierarchical Bayesian model provided the strongest account of the behavioral results.

In this paper, we introduce a novel exemplar-based approach to category generation, PACKER (Producing Alike and Contrasting Knowledge using Exemplar Representations), which creates categories by balancing two constraints: (1) new categories should be different from known categories (minimizing between-class similarity), and (2) new categories should be internally coherent (maximizing withinclass similarity). As such, PACKER is a significant departure from previous accounts of generation - rather than proposing that people create categories by abstracting and re-using knowledge of related categories, PACKER first considers how the generated category should differ from related categories. Further, it does so using the well-studied mechanics of exemplar representations and therefore possesses a rich connection to the wider body of research on category learning.

In the sections below, we formally describe the PACKER model and explore its predictions in a behavioral experiment. We compare its performance to copy-and-tweak and hierarchical Bayesian models by examining their fits to aggregate results and individual differences.

## PACKER: An Exemplar Model

The PACKER model is an extension of the Generalized Context Model of category learning (GCM; Nosofsky, 1984). It assumes that each category is encoded by a set of exemplars within a $k$-dimensional psychological space, and that generation is constrained by both similarity to members of the target category (the category in which a stimulus is being generated) as well as similarity to members of other categories.

As in the GCM, the similarity between two examples, $s\left(x_{i}, x_{j}\right)$, is an inverse-exponential function of distance:

$$
\begin{equation*}
s\left(x_{i}, x_{j}\right)=\exp \left\{-c \sum_{k}\left|x_{i k}-x_{j k}\right| w_{k}\right\} \tag{1}
\end{equation*}
$$

where $w_{k}$ is the attention weighting of dimension $k\left(w_{k} \geq 0\right.$ and $\sum_{k} w_{k}=1$ ), accounting for the relative importance of each dimension in similarity calculations, and $c(c>0)$ is a specificity parameter controlling the spread of exemplar generalization. For simplicity, our simulations will use uniform attention weights, except when otherwise noted.

To generate a new example, the model considers both the similarity to examples from contrast categories as well as the similarity to examples (if any exist) in the target category.

Figure 1: PACKER generation of a category ' B ' example, following exposure to one member of category ' A ' and category ' B '. The panels differ in how the trade-off between within- and between-category similarity is managed (via the $\gamma$ parameter).

The aggregated similarity $a$ between generation candidate $y$ and stored exemplars $x$ is:

$$
\begin{equation*}
a(y, x)=\sum_{j} f\left(x_{j}\right) s\left(y, x_{j}\right) \tag{2}
\end{equation*}
$$

where $f\left(x_{j}\right)$ is a function specifying the extent to which each exemplar contributes to the generation. A negative value for $f\left(x_{j}\right)$ produces a 'repelling' effect (items are less likely to be generated nearby $x_{j}$ ), and a positive value produces an 'attracting' effect (items are more likely to be generated nearby $x_{j}$ ). When $f\left(x_{j}\right)=0$, the exemplar does not contribute to generation.

PACKER sets $f\left(x_{j}\right)$ depending on exemplar $j$ 's category membership: $f\left(x_{j}\right)=\gamma$ if $x_{j}$ is a member of the target category, and $f\left(x_{j}\right)=\gamma-1$ if $x_{j}$ is a member of a contrast category. $\gamma$ is thus a free parameter $(0 \leq \gamma \leq 1)$ controlling the trade-off between within- and between-category similarity. PACKER's core proposal is that new categories should be different from existing categories, and same-category exemplars should be similar to one another. This is realized when $\gamma$ assumes an intermediate value: For example, when $\gamma=0.5, f\left(x_{j}\right)=0.5$ for members of the target category and $f\left(x_{j}\right)=-0.5$ for members of other categories; thus, the model is likely to generate items that are similar to members of the target category but are not similar to members of other categories. However, more extreme values can be used to produce different behavior, see Figure 1.

The probability that a given candidate $y$ will be generated is evaluated using an Exponentiated Luce (1977) choice rule. Candidates with greater values of $a$ are more likely to be generated than candidates with smaller values:

$$
\begin{equation*}
p(y)=\frac{\exp (\theta \cdot a(y, x))}{\sum_{i} \exp \left(\theta \cdot a\left(y_{i}, x\right)\right)} \tag{3}
\end{equation*}
$$

where $\theta(\theta \geq 0)$ controls response determinism.

## Summary

The proposed PACKER model suggests people generate categories by minimizing between-category similarity and maximizing within-category similarity. The underlying processes assumed by PACKER are highly similar to those in the GCM.

The main difference is that PACKER aggregates positiveand negative-valued similarities, rather than only aggregating positive-valued similarities. In later sections, we will explore the unique predictions yielded by these design principles. First, however, we contrast PACKER with other category generation models.

## Previous Accounts of Category Generation

Previous models of category generation focus on capturing the tendency for people to produce new categories that have similar distributional properties to existing categories. To the best of our knowledge, Jern and Kemp (2013) were the first to evaluate computational models of generation. Based on their work, we describe two alternative models: a formalization of the Path of Least Resistance hypothesis (later termed copy-and-tweak, see Jern \& Kemp, 2013), and the hierarchical sampling hypothesis (Jern \& Kemp, 2013).

## Copy-and-Tweak

The copy-and-tweak model, based broadly on the earlier Path of Least Resistance view (Ward, 1994, 1995), proposes that participants generate categories by retrieving an observation of the target class from memory, and then tweaking it to make something new. Jern and Kemp (2013) interpreted this proposal in terms of an exemplar model using the GCM (Nosofsky, 1984). Formally, their model is equivalent to PACKER with $\gamma=1$ (see Figure 1). In this case, $f\left(x_{j}\right)=1$ for members of the target category and $f\left(x_{j}\right)=0$ for members of other categories; thus, the model considers only target-class similarity, and when no members of the target class are known, the model generates items at random.

In our work we provide simulations from the copy-andtweak account, realized as a variant of PACKER with a fixed $\gamma$ parameter. Formalizing a model family where PACKER and copy-and-tweak are different parameterizations within the same framework is useful because comparison between the models provides a test of the explanatory value of the contrast mechanism: The account provided by copy-and-tweak will only equal that of PACKER if the contrast mechanism does not offer an advantage (i.e., if $\gamma<1$ significantly improves model fits).

## Hierarchical Sampling

Based on several results inconsistent with the copy-and-tweak account, Jern and Kemp (2013) advocated a hierarchical Bayesian model. Exemplars of each category were generated from a multivariate Normal distribution over the dimensions of stimulus space. The mean of each category was independently generated, but the covariance matrix (encoding feature variances and correlations) was generated from a common prior distribution. New categories are produced by generating a new mean (uniform over stimulus space) and covariance matrix from the common prior distribution. Because the shared prior distribution's parameters were unobserved, a hierarchical Bayesian model uses information from the previous categories (their feature variances and correlations) to generate the covariance matrix of the new category.

Each category's exemplars are assumed to be a multivariate Normal distribution with parameters $(\mu, \Sigma)$. Each category's covariance matrix is assumed to be inverse-Wishart distributed with parameters $\left(v, \kappa\right.$, and $\left.\Sigma_{D}\right) .{ }^{1} \quad \Sigma_{D}$ is the covariance matrix shared between categories. We assume the shared covariance matrix $\Sigma_{D}$ is generated from a Wishart distribution (for conjugacy) with parameters $v_{0}, \kappa_{0}$, and $\Sigma_{0}$. We set $v_{0}=4$, and $\Sigma_{0}=\lambda \mathbf{I}$, where $\lambda$ is a free parameter controlling the expected variance of dimensions (dimensions of the shared covariance matrix are expected to be uncorrelated) and $\mathbf{I}$ is the identity matrix.

To simplify the model predictions, we used maximum a posteriori (MAP) estimates for the hidden parameters and then generated new categories based on those estimates. Due to conjugacy, the MAP estimate for the shared covariance matrix $\Sigma_{D}=\Sigma_{0}+\sum_{c} C_{c}$, where $C_{c}$ is the empirical covariance matrix of category $c$. The MAP estimate of the covariance matrix for the target category $B$ is

$$
\begin{equation*}
\Sigma_{B}=\left[\Sigma_{D} v+C_{B}+\frac{\kappa n_{B}}{\kappa+n_{B}}\left(\overline{x_{B}}-\mu_{B}\right)\left(\overline{x_{B}}-\mu_{B}\right)^{T}\right]\left(v+n_{B}\right)^{-1} \tag{4}
\end{equation*}
$$

where $v(v>k-1)$ is an additional free parameter (from the Inverse-Wishart prior on $\Sigma_{B}$ ) weighting the importance of $\Sigma_{D}$. When the target category has no members (i.e., $n_{B}=0$ ), items are generated at random.

Generated exemplars are drawn from a multivariate Normal distribution specified by $\left(\mu_{B}, \Sigma_{B}\right)$. Thus, $p(y)$ is

$$
\begin{equation*}
p(y)=\frac{\exp \left(\theta \cdot \operatorname{Normal}\left(y ; \mu_{B}, \Sigma_{B}\right)\right)}{\sum_{i} \exp \left(\theta \cdot \operatorname{Normal}\left(y_{i} ; \mu_{B}, \Sigma_{B}\right)\right)} \tag{5}
\end{equation*}
$$

where $\theta$ is a response determinism parameter and $\operatorname{Normal}(y ; \mu, \Sigma)$ denotes a multivariate Normal density evaluated at $y$.

## Behavioral Experiment

The copy-and-tweak and hierarchical sampling models were designed to explain effects of prior knowledge on the struc-

[^306]

Figure 2: Conditions tested in the behavioral experiment.
ture of categories, but they do not make any assumptions about the role of between-category contrast. Indeed, when there are no known examples of the target category, both models assume that generation is random. PACKER is thus unique in its prediction that contrast categories should influence both the structure and location of generated categories. The behavioral experiment described below was designed to test this key prediction.

The experiment follows the paradigm developed by Jern and Kemp (2013): first, participants learn members of a known category ('Alpha', or 'A'), and are then asked to generate exemplars belonging to a new category ('Beta', or 'B'). We developed two Alpha categories (see Figure 2): the 'Bottom' Alpha category is a tight cluster in the bottom-center of the space, and the 'Middle' Alpha category is identical except that it lies in the center of stimulus space.

Although our manipulation is minimal, the PACKER model predicts strong between-condition differences. According to PACKER, the nature of the space not occupied by the Alpha category should determine where members of the Beta category are likely to be generated. Thus, the lower areas of the stimulus space should be less frequently used for generation in the Bottom condition compared to the Middle (as these areas possess greater similarity to the Bottom Alpha category). Conversely, the upper areas of the stimulus space should be used for generation more frequently in the Bottom condition compared to Middle.

More generally, PACKER proposes that the probability a stimulus $y$ will be generated is a function of its similarity to contrast categories and to members of the target category. Two more general predictions (not specific to either condition) follow from this proposal: (1) the location of Beta examples should be positively related to distance from the Alpha category, and (2) Beta examples should be more similar to one another than they are to members of the Alpha category.
Participants \& Materials We recruited 122 participants from Amazon Mechanical Turk from the US equally assigned to each condition. Stimuli were squares varying in color (grayscale $9.8 \%-90.2 \%$ ) and size ( $3.0-5.8 \mathrm{~cm}$ ). The assignment of perceptual features (color, size) to axes of the domain space ( $x, y$ ) was counterbalanced across participants.
Procedure Participants began the experiment with a short training phase ( 3 blocks of 4 trials), where they observed ex-

Figure 3: Sample generated categories.
emplars belonging to the 'Alpha' category. Participants were instructed to learn as much as they can about the Alpha category, and that they would answer a series of test questions afterwards. On each trial, a single Alpha category exemplar was presented, and participants were given as much time as they desired before moving on. Exemplars were randomly ordered within each block. Participants were shown the range of possible colors and sizes prior to training.

Following the training phase, participants were asked to generate four examples belonging to another category called 'Beta'. Participants were instructed that members of the Beta category could be quite similar or different depending on what they think makes the most sense for the category, but that they were not allowed to make the same example twice. As in Jern and Kemp (2013), generation was completed using a sliding-scale interface. Two scales controlled the features of the generated example. An on-screen preview of the example updated whenever one of the features was changed. Participants could generate any example along an evenly-spaced $9 \times 9$ grid, except for any previously generated Beta exemplars. Neither the members of the Alpha category nor the previously generated Beta examples were visible during generation.

Results Several sample Beta categories are depicted in Figure 3. Because the conditions differ only in their location along the $y$-axis, we first focus on how Beta exemplars are generated above and below the contrast category. As is evident in Figure 3, we observed broad individual differences in generation strategy: Whereas some participants generated all four Beta examples within a narrow y-axis range, others generated Beta examples along a wide range.

To evaluate the key predictions of PACKER, we determined the number of participants in each condition who placed at least one Beta exemplar on the top and bottom 'rows' of the space (the maximum and minimum possible $y$ axis value, respectively). The resulting contingencies data are shown in Table 1. Fisher's Exact Tests reveal that more Middle participants generated a Beta exemplar in the bottom row , $p<0.001$, but the conditions did not differ in use of the top of the space, $p=0.16$. More Middle participants placed Beta exemplars in the top and bottom rows, $p=0.038$.

To evaluate PACKER's other predictions, we computed the

Table 1: Behavioral results.

| Middle | Used top row | No top row |
| :--- | ---: | ---: |
| Used bottom row | 28 | 18 |
| No bottom row | 11 | 4 |
|  |  |  |
| Bottom | Used top row | No top row |
| Used bottom row | 16 | 8 |
| No bottom row | 31 | 6 |

number of exemplars produced at different distances to the center of the Alpha category. These data (Figure 4 left) reveal a strong preference for stimuli that are dissimilar to the Alpha category members: maximally distant items were by far the most frequently generated.

Finally, we computed for each participant the average distance between exemplars belonging to the same and opposite categories. These data (Figure 4 right) show that, as observed by Ward (1994), most people generated Beta categories in which members are closer to one another than they are to members of the Alpha category (i.e., more between- than within-category distance). We did however, observe a notable subset of individuals with greater within-class distance. These individuals tended to adopt a 'corners' approach, in which Beta examples were placed almost exclusively in the corners of the space.

## Summary

Our results support PACKER's predictions: People tend to generate items that are dissimilar from the contrast category and similar to the target category. We observed considerable differences in generation between the Middle and Bottom conditions: Participants in the Bottom condition were less likely to use the bottom row of the stimulus space for generation, and participants in the Middle condition were more likely to create categories spanning the entire $y$-axis (utilizing the top and bottom row of the space). This latter result is especially interesting as it conflicts with previous results: Qualitatively different types of categories were generated, depending only on the location of the Alphas.

Some aspects of the results described above are somewhat commonsense: They demonstrate that the location of existing categories imposes constraints on generation because people tend to generate examples in areas not occupied by existing categories. This principle, however, is novel and not predicted by existing models of generation - these models were designed to explain distributional correspondences between generated and existing categories, not effects of contrast.

## Model Evaluation

To obtain an overall sense of each model's ability to explain our results, we fit each model by maximizing the loglikelihood of the model's predictions of the human results. The $c, \gamma$, and $\theta$ parameters were fitted for PACKER; $c$, and $\theta$

Figure 4: Behavioral results. Left: Frequency of exemplar generation as a function of distance from the Alpha category normalized by the maximum possible distance. Right: Within- vs. between-category distance for every participant.
were fitted for the copy-and-tweak model ( $\gamma$ was fixed at 1 ), and $\kappa, \lambda, v$, and $\theta$ were fitted for the hierarchical sampling model. Note that each model possess a $\theta$ parameter fulfilling the same role (response determinism). Attention in PACKER and copy-and-tweak was set uniformly. Parameters were not allowed to vary between participants or conditions - the goal was to obtain the best-fitting values to our entire dataset.

Each model's best-fitting parameterization is shown in Table 2. Overall, PACKER outperformed copy-and-tweak and the hierarchical sampling model by a considerable margin ( $\sim 11 \%$ improvement in log-likelihood). The parameter settings associated with PACKER's best fit are exactly as expected: a strong preference for items that are similar to members of the target category but are dissimilar to members of the contrast category. A similar pattern of results was obtained when we only considered the second to fourth exemplars generated by each participant.

Our model-fitting results make sense given the assumptions made by each model. As the copy-and-tweak and hierarchical sampling models are not influenced by the location of contrast categories within the space, they do not capture the broad tendency for generated items to be dissimilar to existing classes.

## Relation Between Category Structure \& Location

Generally, our behavioral results showed that members of generated categories are dissimilar to opposite categories, and similar to members of their own category. However, we also observed a great deal of individual differences in generation style. Manually inspecting the data reveals four typical patterns (see Figure 3): 'corners' categories with one Beta example in each corner of the space, tight clusters, 'column'-like categories, and 'row'-like categories. This informal inspection also reveals that each of these category types tended to be generated into distinct regions of the domain, suggesting a link between category location and distributional structure.

To more systematically evaluate this possibility, we computed, for each stimulus in the domain, the difference in range between the features (range (size) - range(color)) across every generated category that had the stimulus as member. Ag-

Table 2: Model-fitting results.

| PACKER | Copy \& Tweak | Hierarchical <br> Sampling |
| :--- | :--- | :--- |
| $A I C=3474$ | AIC $=3914$ | AIC $=3972$ |
| $c=0.565$ | $c=4.894$ | $\kappa<0.001$ |
| $\gamma=0.469$ | $\gamma=1$ (fixed) | $\nu=4.660$ |
| $\theta=6.632$ | $\theta=3.712$ | $\lambda=0.423$ |
|  |  | $\theta=2.771$ |

gregating over these range differences yields a gradient describing how categories tended to distributed for each stimulus. These data (Figure 5) reveal a systematic relationship between category structure and location. Whereas column-like categories more often include stimuli to the left or right of the Alpha class, row-like categories appear above and below the Alpha class. Thus, participants modify the distributional structure of new categories to the maximize distance from the contrast category.

To simulate this finding, we set the attention weight parameters in PACKER and copy-and-tweak per participant. The other free parameters were set as in Table 2. While there exist methods to find the optimal attention weights for a given classification (see Vanpaemel \& Lee, 2012), for simplicity we approximated the weights using proportionally to inverse of each feature's range: Thus, the Alpha and Beta categories are assumed to be distinct along dimensions that the Betas do not vary on. To simulate the hierarchical sampling model we set the domain covariance prior, $\Sigma_{0}$, proportional to the range (not inverted) of each feature: Thus new categories were distributed more widely along the features that each participant used more widely. We then simulated 50 Beta categories with each participant's weighting scheme to obtain a sense of how the relative importance of each dimension affects what types of categories are generated and where they are generated. The results of these simulations are depicted in Figure 5.

When the x -axis is weighted more, PACKER creates column categories to the sides of the Alphas. Conversely, when the $y$-axis is weighted more, PACKER creates row categories above and below the Alphas. This behavior falls out from the nature of selective attention: Dimensions weighted more have a sharper similarity gradient. For example, when the xaxis is weighted more, PACKER favors Beta categories with more within-class similarity (less range), and less betweenclass similarity along the x-axis, resulting in column-like categories that differ from the Alphas along the x -axis.

Although differentially weighting the features results in different types of categories from the hierarchical sampling and copy-and-tweak models, the location of the Alpha category does not affect where items will be generated by these models. Thus, row- and column-like categories are not systematically generated in different areas of the stimulus space, resulting in the uniform predictions shown in Figure 5.

Figure 5: Generated category structure as a function of location. Orange areas in each gradient correspond to stimuli that were commonly generated into category possessing greater y-axis range (columns). Purple areas correspond to categories possessing greater x -axis range. White areas correspond to equal range along both features (or infrequent generation).

## Discussion

The creative use of conceptual knowledge is a fascinating yet understudied topic in categorization. In this paper, we presented a novel exemplar-based approach to explaining category generation. The PACKER model proposes that categories are represented as a collection of exemplars stored in memory, and that members of generated categories should be similar to one another, yet dissimilar to members of opposing categories. Exemplar models can be viewed as ImportanceSampling approximations of Bayesian models (Shi, Griffiths, Feldman, \& Sanborn, 2010). So, PACKER can be viewed as a rational process model, approximating the expected density of a new category based on a contrast category.

In a behavioral study and subsequent formal modeling, we found broad support for the PACKER model. Participants in our study more frequently generated items that are distant from members of contrast categories, and they tended to generate categories with more within-class than between-class similarity. Likewise, we found that the location of contrast categories (as opposed to their structure) shapes generation by imposing constraints on the areas of space that remain available for a new category. Formal simulations reveal that existing models (see Jern \& Kemp, 2013), making no assumptions about category-contrast, do not account for these effects.

The PACKER model is, in general, highly expressive in its performance. Under different parameter settings it is capable of generating tightly clustered or highly distributed categories, and adjusting the distribution of categories along each feature. Future work will focus on exploring the broad degree of individual differences we observed in generation, and whether PACKER can explain previous results in the field (Jern \& Kemp, 2013; Ward, 1994).

## Acknowledgments

Support for this research was provided by the Office of the VCRGE at the UW - Madison with funding from the WARF. We thank Kenneth Kurtz for helpful comments, and Alan Jern and Charles Kemp for providing code and data.

# Opening Up and Closing Down Discussion: Experimenting with Epistemic Status in Conversation 

Shauna Concannon (shauna.concannon@qmul.ac.uk),<br>Patrick G. T. Healey (p.healey@qmul.ac.uk) \& Matthew Purver (m.purver@qmul.ac.uk)<br>Cognitive Science Research Group<br>Queen Mary University of London, United Kingdom

#### Abstract

Managing disagreement in conversation requires subtle linguistic and pragmatics skills. One key dimension is the degree of 'knowingness' with which people present their stance on an issue. It has been hypothesised that framing stances as 'knowing', i.e. with higher implied levels of speaker certainty limits the potential for challenge by others. We present the first experimental test of this hypothesis. Using a text based chat-tool paradigm and a debating task we are able to systematically manipulate how 'knowing' people's turns appear to one-another. The results show that 'knowing' stances tend to close off discussion leading to less carefully formulated, truncated turns, but do not reliably affect the range of solutions considered. Unknowing stances, by contrast, do not affect turn length or formulation but do encourage more deliberation and include more signals of certainty in the message contents.

Keywords: Dialogue; Interaction; Disagreement; Stance; Deliberation.

## Introduction

During a debate people have choices about how they present their contributions. Amongst other things they can simply assert their position, they can modify it with a propositional attitude verb such as 'know' or 'think' or they can turn an assertion into a question rephrasing "'I think X" as "Do you think X?". These choices of attitude and modality all help to establish what a person's stance is and, in combination with the choices made by their interlocutor, set the tone and direction of a debate. One of the most important hypotheses about the impact of different stance markers on dialogue relates to expressions of epistemic certainty; framing of a stance as 'knowing' or 'unknowing' appears to significantly alter the deliberative quality of a discussion Heritage (2012a).

Although the interactional dimensions of stance have been discussed in some detail (Du Bois, 2007; Englebretson, 2007; Kärkkäinen, 2003), this work is based on case studies and corpus analyses. The causal effects of adopting different stance markers on the subsequent trajectory of a dialogue has not, as far as we are aware, been directly tested. One key reason for this is the practical difficulty of manipulating stance markers in a live dialogue. Here we use a technique introduced by Healey et al. (2003) that takes advantage of the potential of text-chat for enabling selective manipulation of people's turns, including the addition of stance markers, without their awareness. We use this technique to to assess how the epistemic status of a stance, i.e. whether it is framed as either unknowing or knowing, impacts on the quality of the joint action and deliberation in discussion dialogues.

## Knowing vs unknowing epistemic status

Heritage (2012a) defines 'epistemic status' as the relative positioning in which "persons recognize one another to be more or less knowledgeable concerning some domain of knowledge". Knowing all $(\mathrm{K}+)$ is typically conveyed through declaratives, while interrogative grammatical format is the most explicit way that a speaker can embody an 'unknowing' (K-) epistemic status. For example, the question 'what time is your appointment' positions the speaker in request of information, where as 'your appointment is at 3 pm ' positions the speaker in a K+ position. However, as highlighted by Drew (2012), how much speakers know relative to one another is not only encoded in the grammatical format, but also in incongruities between epistemic status and grammatical format, for example in posing a question to which you already know the answer (e.g. 'Aren't you going to be late?'). Speakers' relative positioning can alter from moment to moment, and be "disassembled by persons who deploy epistemic stance to appear more, or less knowledgeable than they really are" (Heritage, 2012a). There are significant potential social and interactional implications of positioning ourselves or others as either knowing or unknowing (Levinson, 2012).

In issuing a question the requester assumes an unknowing epistemic status and positions the recipient in a knowing one (Heritage, 2012a), creating an obligation for the recipient to respond (Levinson, 2012). Levinson (2012) observes that people prefer polar questions to other forms that require more knowledge-rich responses and often disguise them as assertions, thus demonstrating an unwillingness to locate oneself in an unknowing position, nor to impose too greatly upon an interlocutor by demanding a response. However, in a discussion context, in which individual contributions on the topic under discussion are warranted and expected, the ways in which requests are made could be influential to the deliberative quality of the discussion.

Furthermore, between the most explicit formats of K+ and K- constructions (i.e. declaratives and interrogatives), there are a range of other ways that speakers can encode epistemic stance, such as modals, hedges and epistemic adverbs, which can convey levels of speaker certainty, e.g. 'It was definitely red', and commitment 'I absolutely think...' and evidential markings which convey the source of a knowledge claim (i.e. direct evidentials based on sensorial/ visual evidence and indirect evidentials, such as inference and hearsay). Particularly within a discussion context the management of imbal-
ances in epistemic status is particularly pertinent as participants' contributions must necessarily negotiate alternative stance positions.

## Stance and Disagreement

Work in the emergent field of interactional linguistics posits that stance-taking is a fundamentally intersubjective process, with stance positions being co-constructed through interaction (Englebretson, 2007; Du Bois, 2007). This process of stance co-construction relies upon the expression of oppositions and alternatives. Disagreement is one perspicuous social activity which denotes the negotiation of differing stances and a potential process by which a shift in stance can occur. Disagreement is generally minimised in conversation (Pomerantz, 1984; Concannon et al., 2015a), and tends to be problematic when issued without mitigation (Chiu, 2008; Concannon et al., 2015b). However, in certain contexts, such as problem solving and discussion tasks, it can be important for advancing the deliberative quality of a dialogue and encouraging novel contributions (Chiu, 2008).

There is thus a delicate balance between mitigating the socially problematic aspects of disagreement while still being able to identify and resolve differences of opinion. This balance can be achieved in many different ways. Resources such as 'well'-prefacing (Pomerantz, 1984), stance markers such as 'I think' (Kärkkäinen, 2003) and reported speech (Holt \& Clift, 2007; Concannon et al., 2015b) all provide less explicit ways of marking what follows as potentially incongruous or in opposition to what went before.

## Marking Stance in the Balloon Task

The task chosen for the experiment reported below is the Balloon Task. Participants are presented with a fictional scenario in which an hot air balloon is losing altitude and about to crash. The only way for any of three passengers to survive is for one of them to jump to a certain death. The three passengers are: Dr. Nick Riviera, a cancer scientist, Mrs. Susie Derkins, a pregnant primary school teacher, and Mr. Tom Derkins, the balloon pilot and Susie's husband. The advantages of this task are that it is effective at generating debates between subjects and there is good scope for deliberation. To ensure we chose a relatively natural manipulation of epistemic stance for this task an initial analysis was conducted using control condition transcripts from previous balloon task discussions. Twelve transcripts were analysed for markers that conveyed 'knowing' or 'unknowing' states in relation to stance marking. 'I think' was frequently used as a resource to mark a stance position. 'I think' has been attributed a dual function, and can can also act as a hedge (Holmes, 1990), however in the discussion context it was used most frequently to convey a knowing stance, particularly when at the beginning of a turn.
(1) a. I think Tom should definitely stay in the balloon
b. I think Nick should definitely be the one to go
c. I think because there's an element of risk with whether Nick will actually end up coming up with a cure for cancer ... There's no point taking two risks by then letting go of Tom
d. ithink we have a couple mins left
e. A: so tom has to jump?

B: i think so
In $1 \mathrm{a}, 1 \mathrm{~b}$ and 1 c the marker 'I think' serves to accentuate the propositional content and emphasise the speaker's commitment to their proposition and focuses on a substantive aspect, namely, who should be sacrificed. In $1 d$ and $1 e$, however, the marker performs the opposite effect and suggests a lack of speaker commitment and acts as a hedging marker. There were 44 instances of 'I think' in the transcripts, 34 instances $(77.27 \%)$ served to emphasise the propositional content it was associated with, eight instances (18.18\%) acted in a 'hedging' or unknowing capacity, and the two remaining instances made manifest the cognate processes (e.g."whenever i think that nick should go, i think 'Are susie and tom really that important?'"). Of the 44 instances, 25 were turn-initial ( $56.82 \%$ ), 19 of which served to emphasise the speaker's ownership and commitment to the content that followed. Four instances of turn-initial 'I think' ( $20 \%$ ) were constructed in such a way that 'I think' functioned as a hedging marker and two instances were not possible to classify due to insufficient context (e.g. 'I think overall'). Closer inspection of the use cases showed that all instances of turn-initial 'I think', in which the proceeding content featured a character from the scenario, conveyed a 'knowing' stance. As such, using 'I think' as a turn-initial insertion for turns which contain a mention of one of the scenario's characters, should increase the likelihood of a consistent effect of framing the utterance as 'knowing', rather than performing a hedging effect.

While looking for markers which served to downgrade the epistemic strength of assertions, 'do you think' was one such 'unknowing' device that was used in the transcripts.

A: do you think the married couple would gang up on the doctor and throw him out
B: maybe. he is their friend though
'Do you think' makes a minimised contrast pair with 'I think' and can be inserted at a turn-initial position without changing the content of the turn. Consequently, 'I think' and 'do you think' were selected as our turn-initial inserts, to perform the role of framing the proceeding content as more or less 'knowing'.

## Hypothesis

Following Heritage (2012b) our general hypothesis is that framing a proposition as unknowing invites elaboration, sequence expansion and further discussion of the topic at hand (Heritage, 2012b). Conversely, a more knowing epistemic
stance, creates pressure for confirmation and sequence closing. As such, we predict that inserting 'knowing' and 'unknowing' stance markers will have different impacts on the course of a conversation even where, counterfactually, nothing about the content of the modified assertions is changed.

The analysis of previous dialogues enables us to operationalise our general hypothesis about the level of knowingness with which opinions are presented and inform the following predictions:

1. Fewer possible solutions will be considered when contributions are framed as knowing and responses will be less considered; this should affect turn formulation, with shorter typing times and less editing of turns. Framing contributions as knowing will close down the dialogue, as indicated by shorter and fewer turns.
2. Framing contributions as unknowing will open up dialogues, leading to longer turns and more possible solutions considered.
3. More possible solutions will be considered and more care will be taken in the construction of turns, as evidenced by slower typing times and more edits when contributions are introduced with an unknowing preface ('do you think X').
4. Framing contributions as unknowing will lead to higher frequencies of certainty and uncertainty markers.

## Method

In this experiment, to see how the epistemic framing of a contribution affects levels of deliberation in dyadic text-based conversations, participant contributions were manipulated using the DiET chat tool.

## The DiET chat tool

The participants communicate via a specially programmed chat tool, similar to other instant messenger interfaces they may have used previously. The Dialogue Experimental Toolkit (DiET) chat tool is a text-based chat interface facilitating real time manipulations of the dialogue. It is possible to programme several different types of interventions using the chat tool: turns may be altered prior to transmission, turns may not be relayed, and additional turns may be added, (e.g. Healey et al. (2003), insertion of spoof clarification requests). These manipulations occur as the dialogue progresses, thus making them minimally disruptive to the sequence of dialogue.

## Design

The experiment was conducted in pairs, with 10 dyads per condition. Pairs of participants were presented with a discussion task and instructed to discuss for 30 minutes and attempt to come to an agreement. Each pair of participants was assigned at random to one of three conditions; i) Control ii) Knowing iii) Unknowing. In the Control condition there were no interventions performed by the server; participants
received the dialogue turns exactly as they were typed. In the Knowing condition turn-Initial 'I think' insertions were made and in the Unknowing condition 'Do you think' insertions were added turn-initially. Manipulations were carried out every four turns, if and only if the turn included a reference to one of the characters in the scenario (e.g. Doctor, Susie, etc.). Interventions are not visible to the individual whose turn has been manipulated, only the recipient, so that there is no awareness that turns are being intercepted before being relayed. A pilot study was conducted to establish the acceptable frequency of interventions.

## Subjects and materials

The experiment was carried out on thirty pairs of students (41 females and 19 males) from the University of London who each received $£ 7.50$ or course credits for providing an hour of their time. They were invited to attend with someone they already knew to increase the likelihood that inter-pair participants were acquainted. All subjects were native speakers of English. Pairs of participants were seated at separate computers, at opposite ends of shared office ${ }^{1}$ and given an instruction sheet detailing the balloon task (see above for a description). Participants were told to take as much time as they needed to read the summary of the situation and then discuss with their partners via a chat tool set up on the computer at which they were seated.

## Analysis

The DiET chat tool records all interventions and key presses, including edits made before participants press ENTER. For a simple measure of authorial commitment counting frequencies of epistemic adverbials, modals and hedges were collected. Epistemic adverbials are separated into two categories (adapted from Biber et al. (1999); Biber \& Finegan (1988)): those which express certainty (e.g., surely, obviously) and those which express anything less than certainty, such as possibility or probability (e.g., maybe, probably). Our separation between those that express certainty and possibility is to acknowledge that through probability there is less authorial commitment. Uncertainty Markers therefore include uncertainty adverbials as well as modals ('may', 'might' and 'could') and hedges ('quite', 'sort of', etc.), but certainty and uncertainty adverbials are also presented individually for comparison ${ }^{2}$ Obvious typographical errors were corrected to

[^307]increase the accuracy of the frequency counts (e.g. possibiliyt $->$ possibility). The inserted fragments were also removed from the transcripts before frequency counts were conducted, to ensure that the figures reflected only what the participants actively contributed.

The decision processes were hand labelled for each conversation to detect the decision patterns for each participant. The transcripts were hand coded for the solutions being considered (for example, Undecided, Kill Tom, Kill Susie, Kill Nick) and the number of shifts from one solution to another during the conversation (e.g. Kill Susie $->$ Undecided $->$ Kill Tom). Furthermore, turns were counted in which participant A and B had matching or opposing stance states. Time spent in an undecided state, even if both participant A and B both were undecided is not counted as a matching stance as it is unclear what their current stance is. A matching stance would only be A: Tom B: Tom; A: Nick B: Nick or A: Susie B: Susie.

## Results

Table 1 provides the means for total number of words typed, turns and average words per turn per participant, the mean typing time in milliseconds, the speed of typing and details of the various self-edits participants made during turn construction, such as deletion and insertion of characters before pressing send to relay the message to their partner. Standard Deviations are provided in parentheses.

Table 1: Message construction data, per participant

|  | Control | Unknowing | Knowing |
| :--- | :--- | :--- | :--- |
| Total Words | 618.30 | 641.95 | 649.05 |
|  | $(182.12)$ | $(160.28)$ | $(196.08)$ |
| Total Turns | $81.05(35.91)$ | $74.35(34.57)$ | 94.65 |
|  |  |  | $(37.50)$ |
| Words/Turn | $8.71(4.43)$ | $9.45(3.62)$ | $6.65(1.87)$ |
| Type Time | 16005.50 | 17279.88 | 12988.29 |
|  | $(8118.06)$ | $(10793.22)$ | $(5300.58)$ |
| Type Speed | $3.09(0.88)$ | $3.71(1.17)$ | $3.26(0.81)$ |
| Self- | $0.25(3.79)$ | $0.31(0.68)$ | $0.03(0.10)$ |
| edits(Ins) |  |  |  |
| Self- <br> edits(Del) | 53.32 | 73.38 | 20.41 |
|  | $(125.10)$ | $(169.25)$ | $(49.01)$ |

Word counts A nonparametric Kruskal Wallis independent samples test shows that there is a significant omnibus effect of condition on the number of words typed per turn $\left(H_{(2)}\right.$ $=7.475, \mathrm{p}=0.02$ ). A post hoc pairwise comparison using Dunn's test shows that there is a significant difference in the number of words per turn between the Knowing and Unknowing cconditionondition, with Knowing dialogues containing fewer words per turn and Unknowing dialogues containing more words per turn ( $\mathrm{p}=0.02$ ). There is no significant difference between the number of words typed per turn in the

Control and Unknowing conditions ( $\mathrm{p}=0.74$ ), nor Knowing and Control conditions $(\mathrm{p}=0.35)$. A nonparametric Kruskal Wallis independent samples test shows that the total number of words typed was not significantly affected by the condition $\left.H_{(2)}=0.283, \mathrm{p}=0.87\right)$ and there is no significant effect of condition on the number of turns per dialogue $\left(H_{(2)}=3.556\right.$, $\mathrm{p}=0.17$ ).
Typing time Typing time averaged by participant was analysed using a Generalised Linear Mixed Models analysis (GLMM) with a Gamma distribution because the timing data was positively skewed. Participants was included as a random factor and condition as a fixed factor. This shows a clear main effect of condition $(\mathrm{F}(2,59)=13.18, \mathrm{p}<0.00)$. The estimated marginal means are: Control: 12,139, Unknowing: 13,404 and Knowing: 8,813. Pairwise Contrasts show that the Knowing condition has shorter typing times than Control $(\mathrm{t}=-3.606, \mathrm{p}<0.00)$ and shorter than the Unknowing condition ( $\mathrm{t}=-4.87, \mathrm{p}<0.00$ ) but Unknowing and Control are not reliably different ( $\mathrm{t}=1.16, \mathrm{p}=0.25$ ).
Self-edits The mean number of self-edit insertions per turn is substantially lower in the Knowing condition than the Control and Unknowing conditions. A Kruskal Wallis test shows that there is a significant omnibus effect of condition on the number of Self-edits (Inserts) per participant $\left(H_{(2)}=7.761\right.$, $\mathrm{p}=0.02$ ). A post hoc pairwise comparison using the Dunn's method shows that there are significantly fewer Self-edits (Inserts) in the Knowing condition than the Unknowing condition ( $\mathrm{p}=0.04$ ), but no significant difference between Knowing and Control ( $\mathrm{p}=0.06$ ), nor Unknowing and Control condition ( $\mathrm{p}=1.0$ ). The mean number of self-edit deletions per turn is higher in the Unknowing condition than the Control and Knowing conditions. However, a non-parametric Kruskal Wallis test shows that there is no significant effect of condition on the number of Self-edits (Deletions) $\left(H_{(2)}=4.560\right.$, $\mathrm{p}=0.10$ ).
Epistemic Strength Table 2 provides mean frequencies of epistemic markers, adverbials of certainty, adverbials of uncertainty and combined uncertainty markers (adverbials,hedges,modals) per 100 words. A non-parametric

Table 2: Epistemic marker mean frequencies

| Condition | Certainty <br> Adverbials | Uncertainty <br> Adverbial | Uncertainty <br> Markers |
| :--- | :--- | :--- | :--- |
| Control | $0.28(0.25)$ | $0.54(0.32)$ | $4.69(1.12)$ |
| Knowing | $0.33(0.34)$ | $0.55(0.21)$ | $4.60(1.19)$ |
| Unknowing | $0.67(0.35)$ | $0.65(0.39)$ | $4.69(0.88)$ |
| Total | $0.43(0.35)$ | $0.58(0.31)$ | $4.66(1.04)$ |

Kruskal Wallis test shows that there is an omnibus effect of condition on the frequency of certainty adverbs $\left(H_{(2)}=\right.$ $7.501 \mathrm{p}=0.02$ ). A post-hoc pairwise comparison Dunn's test shows that there are significantly more certainty adverbs in
the Unknowing condition compared to the Control condition ( $\mathrm{p}=0.04$ ), but no significant difference in frequencies between the Control and Knowing ( $\mathrm{p}=1.00$ ), nor Knowing and Unknowing conditions ( $\mathrm{p}=0.08$ ). A non-parametric Kruskal Wallis test shows that there is no omnibus effect of condition on the mean frequencies of uncertainty adverbials $\left(H_{(2)}\right.$ $=0.742 \mathrm{p}=0.690)$ or combined uncertainty markers $\left(H_{(2)}=\right.$ $0.148 \mathrm{p}=0.93$ ).

Deliberation quality Table 3 details the mean number of changes from a given stance position to another per participant over the course of the dialogue for each condition, as well as the total number of possible alternatives considered.

Table 3: Mean stance shifts during dialogue and possible solutions considered per participant by condition

| Condition | Shifts in Stance | Solutions Considered |
| :--- | :--- | :--- |
| Control | $4.85(1.84)$ | $3.10(0.97)$ |
| Unknowing | $6.80(2.63)$ | $3.30(0.66)$ |
| Knowing | $4.55(1.61)$ | $2.75(0.55)$ |
| Total | $5.40(2.27)$ | $3.05(0.77)$ |

There are a third more stance shifts in the Unknowing condition than the Control and Knowing conditions. A Kruskal Wallis non-parametric test shows that there is a significant omnibus effect of condition on the number of stance shifts traversed by a participant $\left(H_{(2)}=9.559 \mathrm{p}=0.008\right)$. A planned pairwise post hoc comparison using the Dunn's test shows that there are significantly more stance shifts in the Unknowing condition than the Knowing condition ( $\mathrm{p}=0.01$ ) but no confirmed significant effect between Unknowing and Control ( $\mathrm{p}=0.06$ ). There is an omnibus effect of condition on number of possible solutions considered $\left(H_{(2)}=6.146 \mathrm{p}<0.05\right)$. There are more possible solutions considered in the Unknowing condition than the Knowing condition ( $\mathrm{p}=0.044$ ). There is no significant difference between Knowing and Control ( $\mathrm{p}=0.33$ ) and nor Control and Unknowing ( $\mathrm{p}=.1 .00$ ).

Table 4 provides details of the mean percentage of turns in which participant A and B had matching and opposing stance states across conditions.

Table 4: Mean percent of dialogue in which participant A and B had matching and opposing stances

| Condition | Turns: Matching | Turns: Opposing |
| :--- | :--- | :--- |
| Control | $39.42 \%$ | $60.58 \%$ |
| Unknowing | $48.27 \%$ | $51.73 \%$ |
| Knowing | $32.74 \%$ | $67.26 \%$ |
| Total Mean | $40.15 \%$ | $59.85 \%$ |

Although, the distributions show approximately $16 \%$ difference in the ratio of opposing and matching stances between Knowing and Unknowing conditions, with more turns covered with opposing stances in the Knowing condition and
more matching stances in the Unknowing condition. A nonparametric Kruskal Wallis test find no significant effect of condition on the distribution of oppositional and matching stance states amongst participants $\left(H_{(2)}=3.850 \mathrm{p}=0.15\right)$.

## Discussion

In line with our prediction, the results show that framing statements as unknowing led to more deliberation in the dialogues. Not only was there a higher numbers of shifts in stance, indicating a thorough deliberation going back and forth over the possible solutions, there was also a fuller exploration of the total possible solutions (i.e. participants in the Unknowing condition were more likely to consider all of the four possible outcomes, and consider each person to be ejected rather than just sticking to one or two).

The results show that the introduction of the knowing stance marker 'I think' leads to fewer words per turn, i.e. shorter, or more terse responses. In part this may be so to the declarative format, compared to the question format of 'do you think', which obligates a reply. The greater efficiency in the construction of dialogue turns suggests that the introduction of the knowing stance marker leads to more direct exchange of opinions, which is supported by the fewer edits during turn construction in this condition. Less care is taken in the Knowing condition to alter the message prior to relaying it to a conversational partner, perhaps leading to less delicately constructed or polite turns, but more direct and less guarded opinion exchange. The results show that prefacing statements with a knowing preface (i.e. 'I think') forecloses the conversation, while the framing of the contribution with do you think leads to more considered and extended responses.

Counter to our predictions there was no significant effect of condition on the frequency of expressions of uncertainty. However, significantly more certainty adverbials are employed by participants in the Unknowing condition compared to the Control condition. This suggests that framing contributions as unknowing creates an environment in which participants are more likely to make manifest their commitment to a stance by upgrading the epistemic strength of a statement through certainty adverbials; as solutions are discussed more and potentially co-constructed, once a stance is established it can be committed to with greater conviction by participants in the Unknowing condition. So, although the Knowing condition features less guarded and more direct messages as indicated in the manner in which they are constructed, it is in the Unknowing condition that participants commit more firmly to the substantive essence of their utterance.

Interpreting these results together suggests that the introduction of 'Do you think' opens up the dialogue, inviting further elaboration of the topic at hand, while introducing 'I think' closes down the dialogue and limits the deliberative quality of the discussion. 'Do you think' positions the speaker in a position of unknowing epistemic status, and also directly invokes the hearer to collaborate in the co-construction of a
joint stance. In the Unknowing condition stance positions are more explicitly emphasised through certainty adverbials, i.e. when something is important, participants take care to make clear the focus of their stance and their strength of commitment to a given proposition. In part this may be due to the fact that 'do you think' directly invites input and therefore greater care is taken to make clear exactly what the opinion to which they are attaching themselves is. The interactive negotiation of the stance is more exaggerated. Conversely, the introduction of 'I think' to the dialogue has the opposite effect: the presentation of a knowing stance, leads to less consideration and more conviction among participants, demonstrated through fewer edits when constructing responses and more terse and direct turns. Opinions are expressed plainly and without additional specification.

## Conclusion

In this paper the causal effects of epistemic status, as expressed through particular stance markers, on the deliberative quality of a dialogue were investigated using an experimental approach. Framing a statement as unknowing has a significant impact on the deliberative quality of a dialogue and increases the likelihood that participants will consider multiple possible solutions, shifting their opinion more times before reaching a concluding stance. Furthermore, participants in the Unknowing condition, spent a larger proportion of dialogues considering one another's stance. This suggests that, within a discussion dialogue, the framing of a statement in a unknowing way can lead to a more flexible deliberation process and a greater willingness to engage with alternative viewpoints. Furthermore, while being more considerate of one another's views, this was not to the detriment of expressing a position with conviction, and actually led to greater displays of speaker commitment to a stance through certainty adverbials.

Framing a statement as knowing affects the ways in which individuals produce messages; specifically, they construct shorter and less edited responses. This suggests that there is less care taken in the construction of messages, and less conscientious effort put into producing polite, or considered turns. Shorter messages are typically more direct and the lack of editing may reflect decreased guardedness. By prefacing statements with 'I think', the context is set for the exchange of opinions; by introducing a stance with a knowing marker, the appropriateness for a response which is equally direct is established. Overall it seems that marking stances with a knowing preface leads to more direct and unguarded exchanges, but does not improve the deliberative quality of the dialogues. Conversely, prefacing statements with the unknowing preface 'do you think' encourages a more collaborative deliberation, in which more possible solutions are considered in turn before a final decision is reached.

#### Abstract

Research on the continued influence effect has consistently shown that people continue to rely on false causal information despite being corrected by more recent information. Corrections are most effective when paired with an alternative explanation that 'fills the causal gap' left by the correction. However, it may not always be possible provide an alternative explanation. Previous research suggests people more readily discount unreliable information. Two experiments examined whether corrections to false causal information in a news report are more effective when the correction explains why the source of the false information was unreliable. The results showed that a correction did not fully eliminate reliance on false information and that an explanatory correction was no more effective than a non-explanatory correction. People also continued to rely on false information when there was limited information to support its validity. Possible explanations for the ineffectiveness of explanatory corrections are discussed.

## Introduction

Many news organizations now report breaking news via social media platforms. Although social media helps to keep people up to date, breaking news can be based on mistaken, inaccurate, or incomplete information. When false information ${ }^{1}$ is reported news organizations would ordinarily issue a correction, revising their original account. Provided that the false information has not proliferated, being aware of a correction should normatively neutralize belief in the false information. In contrast, numerous experiments on the continued influence effect (CIE) have shown that causal false information continues to be influential beyond a correction (Ecker, Lewandowsky, \& Apai, 2011; Ecker, Lewandowsky, Swire, \& Chang, 2011; Ecker, Lewandowsky, \& Tang, 2010; Johnson \& Seifert, 1994; Wilkes \& Leatherbarrow, 1988).

The standard experimental paradigm for studying the CIE involves reading a series of messages describing a fictional news story over time. Explanatory target information is presented and subsequently corrected for one group of participants, but remains uncorrected for a control group. Inferences and memory for the news report are then assessed through a series of open-ended questions. In Johnson and Seifert (1994), participants read a story about a warehouse fire wherein target information implies that

[^308]carelessly stored flammable materials (oil paint and gas cylinders), were a likely cause of the fire. Later in the story, some participants learn that no such materials had actually been found. A comprehension test follows, which includes indirect inference questions (e.g., "what could have caused the explosions?"), and questions assessing recall of basic facts (e.g., "what was the cost of the damage done?"). Inference responses are then coded in order to measure the extent to which the target information (oil paint and gas cylinder) has been discounted. Responses are coded according to whether they are consistent with the explanatory theme implied by the target information (e.g., "exploding gas cylinders") or not (e.g., "electrical short circuit").

The key finding from CIE studies (for reviews see (Lewandowsky, Ecker, Seifert, Schwarz, \& Cook, 2012; Seifert, 2014) is that corrections do not fully eliminate reliance on false information. People continue to rely on false information despite recalling the correction, when given prior warnings about false information in news reports; whether corrections are repeated, or appear immediately after the false information (Ecker, Lewandowsky, \& Apai, 2011; Ecker et al., 2011; Ecker et al., 2010; Johnson \& Seifert, 1994). The CIE has been replicated using various types of news stories, types of false information (e.g., Ecker et al., 2011), and using direct or indirect measures of reliance on false information (Connor Desai \& Reimers, 2016; Rich \& Zaragoza, 2016). Identifying the cognitive mechanisms underlying the successful correction of false information has timely, realworld implications in a wide variety of domains (e.g., news stories, public health information, in the courtroom).
Filling the causal gap One explanation for the CIE is that corrections are ineffective because a correction alone leaves a causal gap in a person's mental model of the reported event (e.g., Johnson \& Seifert, 1994; Wilkes \& Leatherbarrow, 1988; Lewandowsky et al., 2012). In this view, people maintain the false information because they prefer an inconsistent to an incoherent mental event model. In the warehouse fire example, an individual might infer that a fire started by an electrical short circuit was a result of negligence, based on information suggesting that flammable liquids were carelessly stored. Correcting a key piece of causal information (i.e., no flammable liquids) results in an incoherent mental model. People might continue to draw causal inferences from the false information because it is the only explanation available to them. In line with the mental models account, combining a correction with an alternative
explanation to 'fill the causal gap' considerably reduces the degree to which people rely on false information (e.g., there was evidence the fire was caused by arson; Ecker et al., 2011; Johnson \& Seifert, 1994a; Rich \& Zaragoza, 2016; Tenney, Cleary, \& Spellman, 2009).

In the real world it is not always possible to provide a single, coherent, alternative explanation to replace corrected false information (e.g., the true cause the Flight MH370 disappearance still remains unknown). Due to the fact that alternative explanations are not always available, it is important to identify other means of increasing the effectiveness of corrections.
Explanatory corrections One way of increasing the impact of corrections is to explain why the original information is no longer relevant or useful. For example, Bush, Johnson, and Seifert (1994) found that explaining that target information had been of poor quality (the storeroom actually contained cans of coffee and soda canisters), or was no longer relevant (a delivery of paint and gas cylinders was expected but never arrived), enhanced the effectiveness of the correction statement compared to a correction alone, but an explanatory correction was still not as effective an offering an alternative explanation. Bush et al., also found that ruling out the involvement of the corrected information (there was clear evidence that no paint or gas were ever on the premises) without providing an explanation actually decreased the effectiveness of the correction. These findings can be understood by the pragmatic inferences people draw about the conversational implications of the original statement (cf. Seifert, 2014). The validity of corrected information might be reinforced because people assume that a speakers only offer true (maxim of quality) and relevant (maxim of relevance) information (Grice, 1975). Bush et al's findings suggest that the person issuing the correction must explain why the original information should no longer be believed in order ensure the correction is understood. Legal decision-making studies support the idea that explaining why initial information is unreliable can enhance the effectiveness of a correction. For example, Kassin and Sommers (1997) found that mock-jurors who learned a key piece of incriminating evidence was inadmissible because it was unreliable (a taped confession secured without a warrant) were more likely to convict a defendant than mock-jurors who were told that the evidence was unreliable (the tape was inaudible). Similarly, Fein, McCloskey and Tomlinson (1997) found mock-jurors discounted inadmissible incriminating testimony when its reliability was called into question. Finally, Lagnado and Harvey (2008) showed that people providing evidence that an eyewitness has a 'longstanding grudge' against the suspect resulted in participants discounting that testimony. These studies suggest that explanatory corrections could be as effective as combining a correction with an alternative explanation when the correction explains why the initial source of the false information is unreliable.

## Pilot study

The pilot study tested whether explanatory corrections are more effective than a correction alone when the correction explains why the original source of the false information is unreliable (i.e., mistaken or intentionally deceptive). There were two main predictions: 1) Explanatory correction groups would produce fewer target information consistent inferences than the correction alone group, and 2) Correction only group would produce fewer target information consistent inferences than a group who was never exposed to a correction.

## Methods

Participants Forty-five U.S. based participants were recruited from Amazon Mechanical Turk (17 female, age $36.3 \pm 9.70$ ). Participants were paid $\$ 1$ and took an average of 14 minutes to complete the experiment.
Design Participants were randomly assigned to either the no correction (11), correction only (10), explanatory correction error (10), or explanatory correction lie (14) correction groups. There were four main dependent measures: 1) references to target information on inference questions, 2) recall on filler items, and 3) awareness of the correction.
Materials and Procedure Participants read a news story describing a warehouse fire, displayed as a series of sequentially presented short messages. Materials were reconstructed from an experiment by (Johnson \& Seifert, 1994; Exp 3a). There were 12 discrete messages (1, target message, 1 critical message, 1 causal detail message, 9 additional messages), in the style of 'Tweets' from the social media platform Twitter, an approach inspired by Hardwicke, Manning and Shanks (2016). The 'Tweets' originated from the same fictional news outlet, called "news now" and each message was no longer than 140 characters. Messages appeared one a time for a minimum of 5 seconds each; there was no maximum time. Participants clicked a button to proceed to the next message; they were unable to return and view previous messages.

Participants completed an instructional attentional check (e.g., Oppenheimer, Meyvis, \& Davidenko, 2009) before starting the experiment. The explanatory theme implied by the target message was that flammable materials had been carelessly stored in a storeroom. The target message, containing information about a possible cause of the fire (there were cans of oil paint and gas cylinders present in a storeroom), was presented at Message 5. The causal detail containing information consistent with the explanatory theme implied in the target message (thick, oily smoke + sheets of flames hinder firefighters efforts, intense heat has made the fire difficult to bring under control) appeared at Message 8. The critical message varied depending on condition and appeared at Message 11. The remaining (filler) messages provided event information, which was neutral with respect to the explanatory theme implied by the target message (e.g., Three warehouse workers working overtime, have been taken to St Columbus Hospital, due to smoke inhalation).

Table 1 Example questions and responses from pilot study

| Question | Example response to <br> receive score of 1 on false <br> information measure |
| :--- | :--- |
| What aspect of the fire <br> should the police focus on <br> in their investigation? | They should focus on the <br> chemical aspects because <br> it seemed to have started <br> from paint or gas. |
| What was the most likely <br> overall cause of the fire? | The oil paint cans and <br> pressurized gas cylinders. |
| Is there any evidence of <br> careless management in <br> relation to this fire? | Yes the pressurized <br> cylinders should not have <br> been kept indoors next to <br> paint cans. |

In the three correction conditions Message 11 corrected earlier information about the contents of the storeroom; participants in the no correction condition learned instead that warehouse workers taken to hospital had been released. The explanatory correction groups either learned that the target information had been corrected because an employee confused the soda canisters and coffee cans for paint and gas (error) or that an employee lied that there were flammable materials in the storeroom (lie). There were four narrative versions in total.

After reading all of the 'Tweets' participants completed a questionnaire consisting of seven inference questions, seven filler questions and two questions assessing awareness and understanding of the correction. Inference and filler questions were presented in a random order. Inference questions asked participants about information not explicitly mentioned in the news report (e.g., "Is there any evidence of careless management in relation to this fire?"), and included a question querying participants about what they thought the most likely cause of the fire was. Filler questions enquired about the explicit details included in additional (filler) messages included in the news story (e.g., "Which hospital were the workers taken to?"). Two further questions assessed awareness and understanding of the correction message. Participants typed a response to each of 16 questions in a text box, were required to use a minimum of 25 characters, and encouraged to answer using full sentences.

## Pilot study: Results

## Coding of Responses

The main dependent variable extracted from inference question responses was 'references to target information'. References that explicitly stated, or strongly implied, that the fire was caused by gas and oil paints were scored a 1 on the target information measure, and were otherwise scored as 0 . The maximum individual score for inference questions was 7. Filler question responses were scored for accuracy. Correct or partially correct responses were scored 1 and a score 0 was given for an incorrect response. The maximum individual score for filler questions was also 7. Awareness

Figure 1: Mean target information inference scores (left panel), filler accuracy scores (top right panel), and awareness of correction scores (bottom right panel) as a function of correction. Error bars represent $95 \%$ confidence interval of the mean.
of correction scores were computed using the same criteria; the maximum individual awareness of correction score was 2. One-way ANOVA analyzed differences between the correction conditions for all three measures. ${ }^{2}$ Fig 1 shows mean inference, filler and awareness of correction as a function of correction condition.
Inference scores There was significant effect of correction on the number references to target information, $F(3,41)=$ 3.32, $p<.05, \eta^{2}=$.20. Planned contrasts showed a correction reduced references to target information compared to no correction, $t(19)=-2.98, p<.01, d=1.46$. However, neither an error explanatory correction, $t(19)=-$ $0.55, d=0.23$, nor a lie explanatory correction, $t(23)=-$ $1.45, d=0.53$, reduced references to target information compared to no correction.
Filler recall accuracy There was a significant effect of correction on filler recall accuracy, $F(3,41)=4.39, p<.01$, $\eta^{2}=.24$. Tukey's tests showed the no correction group recalled significantly more filler details than the lie explanatory correction group, $t(23)=-3.34, p=.009, d$ $=1.14$. None of the other differences were significant ( $p$ 's $>$ .05).
Awareness of correction There was a significant effect of correction on awareness of correction scores, $F(2,31)=$ $6.52, p<.01, \eta^{2}=.30$. Tukey's tests revealed that the correction only group showed more awareness of the correction than the error, $t(18)=-3.09, p=.01 d=1.62$, or lie, $t(22)=-3.24, p<.01, d=1.22$ explanatory correction groups. The two explanatory correction groups did not significantly differ, $p=.10$.

[^309]

Figure 2: Content of critical messages in main experiment. In contrast to previous studies, the critical message in each of the correction conditions explicitly stated that the message was a correction.

## Interim Discussion

A correction alone reduced, but did not fully eliminate, target information references when compared to no correction. Pilot results also showed that an explanatory correction did not reduce references to target information compared to no correction. On average both explanatory correction groups made more target information references than the correction only group, although these differences were not significant. These results are inconsistent with previous findings showing that an explanatory correction was more effective at reducing reliance on target information than a correction alone (cf. Bush, Johnson \& Seifert, 1994).

The most likely reason that an explanatory correction was less effective than a correction alone is that participants in the explanatory correction groups showed poorer awareness and understanding of the correction, than the correction only group. Only $40 \%$ of the error explanatory correction group, and $21 \%$ of the lie explanatory correction group understood and were aware of the correction, compared to $90 \%$ of the correction only group. Both explanatory correction groups also recalled fewer story details on average than the correction only group. Some participants' responses indicated doubts about the credibility of the correction message (e.g., questioning whether the employee really lied about the contents of the storeroom), and other responses suggested misunderstanding of the correction message (e.g., the employee thought there was soda and coffee but there was actually paint and gas). A lack of clarity of the explanatory correction messages could explain poorer awareness and understanding in explanatory correction conditions could also explain why the current results do not replicate previous findings (cf. Bush et al., 1994). The main experiment sought to rectify these issues by enhancing the clarity of the correction messages.

Figure 3: Mean target information inference score as a function of condition in main experiment. Error bars represent the $95 \%$ confidence interval of the mean.

## Main Experiment

The same general setup was employed in the main experiment except that a number of changes were made to rule out explanations identified in the interim discussion. The hypotheses and predictions were also the same as the pilot study.
Participants Three-hundred and twelve U.S. based participants were recruited from Amazon Mechanical Turk (146 female, age $39.67 \pm 12.31$ ). Participants were paid $\$ 1$ and took an average of 20 minutes to complete the experiment.
Design, materials and procedure Participants were randomly assigned to either the no correction (71), correction only (87), explanatory correction error (71), or explanatory correction lie (83) groups. Dependent measures were the same as in the pilot study.

Content of the critical messages was modified from the pilot study in order to make it unequivocally clear that the target information was being corrected (see Fig 2). Unlike previous studies, the critical message for the correction conditions explicitly stated that the target information was being corrected.

## Results

Additional coding and analysis was performed on one of the filler questions to the total number of references indicating flammable substances had been in the storeroom before the fire. The additional 'discounting' measure further assessed the extent to which the false information had been disregarded. Responses were scored 1 if the response indicated there were flammable substances in the storeroom before the fire and 0 otherwise. One-way ANOVA analyzed differences between conditions for all four dependent measures.
Inference scores There was a significant effect of correction on references to the target information, $F(3,308)$ $=23.23, p<.001, \eta^{2}=.18$. Planned contrasts revealed a correction significantly reduced the number of references to target information, $t(156)=-6.84, p<.001, d=0.98$.

Likewise, the error, $t(140)=-6.90, p<.001, d=1.02$, and lie, $t(152)=-6.99, p<.001, d=1.01$., explanatory correction groups, made significantly fewer references to the target information than the no correction group. Mean target information inference scores are shown in Fig 3.
Filler recall accuracy There was no effect of correction on filler recall accuracy, $F(3,308)=0.64, p=.90, \eta^{2}=.01$, so it was not necessary to perform contrast analysis. Mean filler recall scores ranged from 4.58 to 4.96 (out of 7 ).
Awareness of correction No correction group responses were excluded from analysis because their responses to awareness of correction questions were meaningless. There was a significant effect of correction condition on awareness of correction scores, $F(2,238)=3.76, p<.05, \eta^{2}=.03$. Tukey's tests showed a significant difference between the correction only and explanatory correction error group, $t$ $(168)=-2.39, p=.05, d=0.37$. There were non-significant differences between the explanatory correction error and correction only groups ( $p=.06$ ), and both the explanatory corrections groups ( $p=1$ ). Given the small effect size the difference is considered negligible.
Discounting false information The inference scores suggest that explanatory corrections are treated the same as a correction alone. If this is the case, then the number of references indicating the storeroom contained flammable substances before the fire should be equivalent to inference scores. There was a significant effect of correction on the number of responses indicating the storeroom contained flammable substances before the fire, $F(3,308)=57.25, p$ $<.001, \eta 2=.36$. Planned contrasts confirmed the same pattern of results as inference scores; there were significantly higher number of references stating that flammable substances had been in the storeroom before the fire in the no correction than the correction only group, $t$ $(156)=9.22, p<.001, d=1.49$, the error correction group, $t$ (140) $=-12.27, p<.001, d=2.81$, or the correction lie group, $t$ (152) $=-9.99, p<.001, d=1.68$. A closer inspection of the responses suggested that explanatory corrections were not treated the same as a correction alone. Fig 4 shows the mean number of responses indicating that flammable substances were in storeroom before the fire. Tukey's tests showed that the explanatory correction error group significantly differed to the correction only, $t(156)=$ $-3.66, p<.01, d=0.55$, and explanatory correction lie group, $t(152)=-2.75, d=-.45$. The difference between the correction only and explanatory correction lie groups was not significant, $p=.80$.

## Discussion

The results show a clear continued influence effect; a correction significantly reduced, but did not eliminate, references to target information. A correction appeared to have a similar impact on inferences whether accompanied by an explanation as to why the original source of the false information should not be trusted, or not. A closer inspection of responses suggested fewer people continued to think that flammable substances had been in the storeroom

Figure 4: Mean number of references to presence of flammable substances in the storeroom before the fire as a function of correction condition. Error bars represent 95\% confidence interval of the mean.
before the fire when the correction replaced the contents of the storeroom (i.e., there were soda cans and gas canisters in the storeroom) than when the correction left the storeroom empty before the fire (i.e., the employee had lied about flammable materials in the storeroom). In addition, the continued influence effect was still observed despite the fact that the correction to target information was explicitly stated in the correction message.

## General Discussion

The experiments reported in this paper examined the impact of explanatory corrections on inferences about false information in the context of breaking news reports on social media. The findings reported here are consistent with previous studies showing that corrections do not fully eliminate reliance on false information (Ecker, Lewandowsky, Swire, et al., 2011; Ecker et al., 2010; Johnson \& Seifert, 1994; Wilkes \& Leatherbarrow, 1988). These results also provide a novel contribution to the literature on the continued influence effect. Specifically, a correction that explained why the original source of the false information was unreliable was no more effective in reducing reliance on false information, than a correction alone. Participants made an equivalent number of references to target information whether the correction provided an explanation for why the target information should no longer be believed (i.e., the current inaccuracy of the target information was directly attributed to a mistaken or a deceptive individual), or not.

Despite this finding there was evidence to suggest that corrections were not treated equally. People were less likely to say that flammable substances (oil paint and gas canisters) were in the storeroom before the fire when the contents of the storeroom were replaced with other objects (soda canisters and coffee cans) than when the contents of the storeroom were not replaced (i.e., the employee lied that there were flammable items in the storeroom). One explanation for this inconsistency between inferences and
memory of the storeroom contents is that people who received the error correction updated their representation of the contents of the room whilst maintaining an inconsistent mental model of the event. In contrast, people did not update their representation of the storeroom when the contents were not replaced with alternative materials. These results do not support previous findings showing that explanatory corrections are more effective than a correction alone (Bush, Johnson, \& Seifert, 1994).

The main methodological difference between the current study and previous study is that the explanatory correction conditions in this study involved an additional source of information. In addition to making a judgment about whether the correction sufficiently negated the false information participants had to establish why or how the original source of the information (i.e., the employee) provided the information in the first place. Without knowing why the employee lied about the flammable materials or how the employee was able to confuse flammable for nonflammable substances, people might still assume the false information is relevant. Another possible reason for the inconsistent results could be that in at least one of Bush et al's conditions the correction made it logically impossible to continue to rely on the false information whereas this was not the case in the current study. These findings further demonstrate that pragmatic inferences play an important role in successfully correcting false information.

The current studies also showed evidence of the continued to rely on false information even though the report only contained one piece of information that reinforced the false information explanatory theme. This suggests that people construct a mental model of the incident on the basis of limited causal information. If there is no information to indicate an alternative explanation then people fall back on the only explanatory information available to them. It is also possible that people interpret (or re-interpret) information as supporting their leading hypothesis (e.g., Carlson \& Russo, 2001). Future studies are necessary to address whether people re-interpret neutral information to fit false causal information or whether people construct their mental event model based on limited information.

While the current study provides initial steps, there is a lot more left to explore. It will be necessary to further explore why explaining why the information was unreliable was no more effective than withdrawing the false information and why the current findings are discrepant with previous continued influence (Bush et al., 1994) and legal decision making studies (e.g., Lagnado \& Harvey). Future studies will further investigate the role of source reliability in correcting false information, and use a wider range of scenarios as well as types of false information.

## Acknowledgments

We thank Dr. Tom Hardwicke for his insights and expertise regarding the continued influence effect paradigm.

# Learning Relational Concepts through Unitary versus Compositional Representations 

Daniel Corral (daniel.corral@colorado.edu) \& Matt Jones (mcj@colorado.edu)<br>Department of Psychology and Neuroscience, University Colorado Boulder, Boulder, CO 80309 USA

#### Abstract

Current theories of relational learning on structure mapping emphasize the importance of compositional representations, based on the concept's components and the relations among them. We consider the possibility that relational concepts can also be represented unitarily, whereby the concept is a property of the stimulus as a whole. The distinction between compositional and unitary representations of relational concepts is a natural consequence of structure-mapping theory, but its psychological implications have not been explored. We report two experiments in which we examine how encouraging subjects to represent relational concepts compositionally versus unitarily affects learning on classification- and inference-based category learning tasks. Our findings show that unitary representations lead to better learning than compositional representations, especially for the inference task. We conclude that unitary representations incur less cognitive load than structural alignment of compositional representations, and thus may be the default for everyday relational reasoning.

Keywords: Relational Learning; Relational Structure; Concept Representation; Category Learning; Inference.

## Introduction

On a daily basis, people encounter many complex concepts that are defined by a relational structure - the specific pattern in which two or more objects are bound together by interconnected relations (Corral \& Jones, 2014). For instance, consider a simple scenario in which a dog chases a cat. In this example, the $\operatorname{dog}$ and the cat share a specific relationship with one another, such that it is the dog that fills the role of the chaser and the cat fills the role of being chased (chase (dog, cat)). Critically, this structure is different from a scenario in which a cat chases a dog (chase (cat, dog)). These types of concepts differ from those that are defined by features, which can be identified by the presence of a given set of attributes (Estes, 1986). For example, a bird might be identified by the presence of certain prototypical features, such as \{feathers, beak, wings $\ldots\}$. Although feature-based representations can provide extensive knowledge about a given scenario, they do not convey structural information (Markman, 1999). Thus, a feature-based representation does not allow one to readily distinguish a simple scenario in which a dog chases a cat from an instance in which a cat chases a dog (Markman \& Gentner, 2000), as both would be represented as an unstructured set: $\{d o g$, cat, chase $\}$.

The ability to recognize and reason about structured concepts has been posited to be one of the cornerstones of human cognition (Penn, Holyoak, \& Povinelli, 2008). According to structure-mapping theory, the dominant theory
of relational learning, structured concepts are acquired via structure mapping, wherein the elements of two analogous scenarios are put into alignment in a way that preserves their common roles. For example, in the hypothetical scenarios described below, the dog in the first scenario maps to the cat in the second scenario because both fill the role of the chaser. Alignment of two scenarios highlights their common structure and facilitates abstraction of new relational concepts (Gentner, 1983; Hummel \& Holyoak, 2003).

Importantly, structure-mapping theory ${ }^{1}$ makes the implicit assumption that a relational concept can be represented in two fundamentally different ways: (1) as a system of relations, with meaning derived both from the identities of those relations and from how they are interconnected by shared role-fillers (Corral \& Jones, 2014); or (2) as a primitive, atomic relation that is explicitly represented. We refer to these as compositional and unitary representations. Although this logical distinction has been noted (Gentner, 1983), its potential psychological implications have largely been neglected.

To elaborate further, the first of these representational assumptions is premised on the idea that representations are constructed from two basic types of building blocks: objects and relations. The second assumption is based on the idea that a relation operates on a set of $n$ objects, that is, for every ordered set of $n$ objects, the relation returns a truthvalue indicating whether the objects satisfy the relation. Equivalently, for every ordered set of $n$ objects $\left(o_{1} \ldots, o_{n}\right)$ for which the relation holds, there is an explicit token of that relation: $R\left(o_{1} \ldots, o_{n}\right)$. We refer to any relation of this sort as a unitary relation.

In recent work, Corral, Kurtz, and Jones (under revision) raise the possibility that subjects might indeed represent some relational concepts unitarily, such that the concept is a component or a property of the stimulus as a whole. This type of representation would lack explicit structure and could be recognized directly in a stimulus, similarly to a feature. This idea is perhaps best exemplified in language comprehension, where people appear to seamlessly understand a multitude of rich relational concepts, without explicitly representing their substructure. For example, consider the concept of investigation. An investigation consists of an agent, a given question, the approach the agent takes to answering that question, and the specific

[^310]pattern of interconnections among these components. Nevertheless, people can likely recognize this concept without explicitly representing its structure. Likewise, a $t$ test involves a complex structure of mathematical elements and relations (as many hapless introductory statistics students will attest), but for experienced scientists it is easily conceived of as a unitary event-one can hear the sentence "I ran a $t$-test" and immediately comprehend its meaning without needing to invoke the concept's substructure.

The literature on structure-mapping theory has focused on compositional representations, through its emphasis on the alignment process. Furthermore, it has been proposed that people must use compositional representations in order to learn relational concepts (Markman \& Gentner, 2000). Compositional representations are computationally expensive (Forbus, Gentner, \& Law, 1995) and can place a high strain on working memory (Kintsch \& Bowles, 2002). They are also unnecessary for learning feature-based concepts (Markman, 1999), which can be recognized (without regard to structure) by attending to a stimulus' defining attributes (e.g., Nosofsky, 1986). Similarly, relational concepts that are represented unitarily can be explicitly recognized as a global attribute of the given scenario, and thus can be learned in an unstructured manner. Such representations allow for computationally efficient processing (Forbus et al., 1995), and based on principles of cognitive economy, it follows that people should avoid compositional representations and structural alignment whenever a unitary representation and setwise (featurestyle) comparisons are adequate.

Evidence from related literatures suggests that people in fact do not use compositional representations as much as might be expected based on structure-mapping theory. One prediction that follows from compositional representations is that people should be able to report the structural elements of the relational concepts they are familiar with. However, despite subjects reporting high confidence in their comprehension of various types of common relational systems (e.g., how helicopters fly), they are often mostly unaware of their structural elements (Keil, 2003; Rozenblit \& Keil, 2002). Another prediction from compositional representations is that, because relational structure must be explicitly represented (Kintsch \& Bowles, 2002), it should take longer to comprehend and recognize structured information than information that is not structured. However, various studies have found no differences in the time it takes subjects to comprehend structured (metaphors) and non-structured statements (e.g., "the ball is blue") (Glucksberg, Gildea, Bookin, 1982). Related work has shown that subjects can often understand metaphors automatically, with minimal explicit processing (Glucksberg, 2003). Taken together, these findings suggest that many relational concepts may not typically be represented compositionally.

Due to the representational flexibility that humans possess (Chalmers, French, Hofstadter, 1992), it seems plausible that relational concepts can be represented both unitarily
and compositionally. For instance, a person might represent a concept such as investigation based on a global attribute (e.g., an inspection), but can also likely represent its relational substructure when necessary (explicitly representing the agent, question, line of inquiry, and their interrelations). This idea leads to the question of which type of representation people use by default when learning a relational concept. The main hypothesis of the present paper is that, because unitary representations should allow for more efficient processing, subjects will use such representations when they are available. We test this prediction by giving subjects relational category learning tasks and encouraging them to represent the stimuli either compositionally or unitarily. If people typically learn relational concepts from structural alignment, then encouraging subjects to use compositional representations should aid learning. However, if people instead learn more efficiently with unitary representations, than the opposite outcome should be expected.

Half the subjects in our experiments were given a classification task, in which they were shown a series of stimuli and asked to make categorization judgments. Unitary representations seem especially well-suited for such a task, because they should enable subjects to directly recognize the diagnostic property in a stimulus, just as with feature-based categories. The other subjects were given an inference task, in which they were asked on each trial to determine a missing property of a stimulus that was presented together with its category label. Research with feature-based categories has shown that classification and inference learning tend to yield different category representations, with inference tasks encouraging learning of internal category structure, such as correlations among features (Markman \& Ross, 2003; Yamauchi \& Markman, 2000). This finding suggests that compositional representations should be particularly well-suited for inference learning with relational categories, as such representations highlight the internal structure of stimuli. The inference conditions of our experiments thus provide a more stringent test of our hypothesis that people can learn relational concepts better through unitary representations.

## Experiment 1

Experiment 1 examines how providing unitary and compositional descriptions of relational concepts affects learning on classification and inference tasks (description and task type both manipulated between subjects). Subjects were provided either a unitary or compositional hint at the start of learning and again after every third error, in order to assess whether each type of hint can improve learning. Control groups who were given no hints were also included in order to assess baseline performance in both tasks.

The stimuli used in this study were taken from Corral, et al. (under revision), which were adopted and modeled after those used by Rehder and Ross (2001). A stimulus consisted of three sentences, each of which describes a different component of a machine that works to remove waste
material: (1) the location of where the machine operates, (2) the waste material the machine removes, and (3) the instrument the machine uses.

Stimuli were sampled from two categories: coherent and incoherent. Each category consisted of 18 exemplars. The categories were determined by how a machine's components were related to one another. For exemplars from the coherent category, the machine's instrument is suited for collecting the waste material that the machine works to remove, which can be found in the location where the machine operates. Consider the following example: "Operates on the seafloor, works to remove lost fishing nets, and has a hook." This exemplar is coherent because of the secondary relations among the machine's component parts (presumed to be known by subjects), such that lost fishing nets can be found on the seafloor and a hook can be used to retrieve lost fishing nets. In contrast, exemplars from the incoherent category do not satisfy either of these secondorder relations (i.e., the machine's tool cannot be used to collect the machine's target waste material and that material cannot be found where the machine operates). Non-Morkels were thus made to be as incoherent as possible so as to maximally differentiate the categories and better facilitate learning of the task. Figure 1 illustrates the abstract relational structure of the two categories.

Half of the subjects completed an $A / \neg A$ classification task (in which each stimulus was to be categorized as either a category member or a nonmember), and the other half completed an inference task. On each trial, the subject was presented a single stimulus and asked to make an inference or classification judgment (depending on the condition). After the response, the subject was shown whether the response was correct along with the correct answer.
Operates on the surface of the water
Operates on the surface of the water
Works to clean spilled oil
Works to clean spilled oil

Coherent Item

Operates on the surface of the water Works to collect dangerous gaseous ions Has a shovel

Incoherent Item

Figure 1. Illustration of the relational structure for items in the coherent and incoherent categories in Experiment 1. The structures differ in that coherent items satisfy the relations indicated by diagonal lines: the machine's implement can remove the target, and the target is found in the machine's location. Recreated from Corral et al. (under revision).

## Method

Two hundred eighteen undergraduates from the University of Colorado Boulder participated for course credit in an introductory psychology course. Subjects were randomly
assigned to six conditions. Type of hint (compositional vs. unitary vs. control) was crossed with task type (classification vs. inference).

Subjects were told that they would be shown short descriptions of various types of cleaning machines, some of which were made by the Morkel Company (coherent category) and some were not (incoherent category). Subjects were provided a positive example of a Morkel (randomly selected) and told that all Morkels share a certain commonality and it was their job to figure out what it was.

Subjects in the unitary condition were shown the following hint: "On each trial try to think about how "well suited" the machine is for performing its task. Keep in mind that consumers say machines from Morkels are built "intuitively" in a way that makes sense." This hint was intended to shift subjects' attention toward finding a global attribute of the stimulus and away from the explicit relationships among its components. Using this hint, it is possible for subjects to learn how to distinguish the categories without explicit knowledge of their relational structure. This hint can therefore be said to encourage subjects to represent each stimulus unitarily.

Subjects in the compositional condition where shown the following hint: "On each trial try to think about the specific manner in which the machine's $1^{\text {st }}$ property relates to its $2^{\text {nd }}$ and $3^{\text {rd }}$ properties, as well as how its $2^{\text {nd }}$ property relates to its $3^{\text {rd }}$ property." This hint was intended to focus subjects' attention on the relationships among the component parts of the stimulus, and thus to encourage them to represent the stimulus compositionally.

Subjects were presented the appropriate hint during the initial task instructions, after the first trial, during rest breaks, and following every third error the subject committed (on a blank screen after corrective feedback was shown). Subjects were asked to read the hint carefully and press the spacebar when they were ready to continue. Subjects in the control group were not shown a hint and were instead asked to continue to try their best; this reminder was presented on every third error the subject committed and on rest breaks.

Each subject completed 72 trials. The order in which the items were presented was randomized for all subjects. In each block of 18 trials, all 18 stimuli appeared in a random order. After each block, subjects were given a self-paced rest break and were shown the proportion of correct responses they answered correctly over those trials, along with the number of trials they had completed and the number that remained.

On each trial in the classification condition, a single, complete stimulus was presented and the subject was asked to type "A" if the machine was a Morkel or "L" if it was not. On each trial in the inference condition, the category label for a stimulus was shown (Morkel or non-Morkel) directly above an incomplete stimulus consisting of two of its three components (i.e., sentences). Below the stimulus were two response options, one of which was the missing component and the other was a lure. The component the
subject was asked to infer (i.e., implement, target material, or location) was randomly selected on each trial. Subjects were asked to select which was the missing component by typing "A" if the correct choice was the top option or "L" if it was the bottom option. The order in which the two options were presented was randomized on every trial. For items that were Morkels, the correct response was the option that shared secondary relations with the given stimulus components. The lure did not share secondary relations with either of the stimulus components. For items that were nonMorkels, the correct response was the component that did not share any secondary relations with either of the stimulus components. The accompanying lure shared at least one secondary relation with one of the stimulus components. Figure 2 shows an example trial from the inference condition.

Figure 2. Example of a stimulus display from the coherent category (Morkels) from the inference task in Experiment 1.

## Results \& Discussion

Figure 3 shows average learning curves for subjects in each group. An ANOVA was conducted to examine differences in performance among groups. The analysis showed a main effect of hint, $F(2,212)=42.14, p<.0001, M S E=.014$, and an interaction, $F(1,212)=8.90, p=.0002, M S E=$ .014 , indicating that the main effect of hint depends on the type of task that subjects completed. On the classification task, control subjects $(M=.61, S E=.017)$ were outperformed by subjects in the compositional ( $M=.775$, $S E=.014 ; p<.0001$ ) and unitary groups $(M=.83, S E=$ $.016 ; p<.0001$ ). In the inference condition, only subjects who received a unitary hint $(M=.716, S E=.012)$ performed better than control subjects $(M=.585, S E=.012$; $p<.0001$ ), as no differences were observed between subjects who were presented a compositional hint ( $M=$ $.587, S E=.011$ ) and subjects in the control group.
Planned $t$-tests were conducted to compare the unitary and compositional groups, separately for each task. On the classification task, subjects in the unitary condition ( $M=$ $.83, S E=.014$ ) outperformed subjects in the compositional condition $(M=.775, S E=.014), t(71)=1.85, p=.068, d=$ .45. This same pattern was observed in the inference condition (unitary $M=.716, S E=.012$; compositional $M=$ $.587, S E=.012), t(67)=5.28, p<.0001, d=1.29$. An
additional 2 (unitary vs. compositional) $\times 2$ (classification vs. inference) ANOVA was conducted, which excluded control subjects. This analysis revealed an interaction, $F(1$, $138)=4.01, p=.047, M S E=.013$, indicating that the unitary advantage was stronger in the inference task than in the classification task.

Taken together, the findings presented here suggest that unitary and compositional representations can both be used to acquire relational concepts. However, subjects who were encouraged to represent the stimuli unitarily showed more robust learning than subjects who were encouraged to represent the stimuli compositionally, especially in the inference task. These findings thus provide support for our main hypothesis that, when both types of representations are available, subjects learn better with unitary than with compositional representations.

Figure 3. Average learning curves and standard errors across blocks of nine trials for each condition in Experiment 1.

## Experiment 2

Experiment 2 builds on the findings from Experiment 1 and examines how category learning is affected when subjects represent a relational concept one way (either unitarily or compositionally) and are subsequently made aware of an alternative representation. Experiment 2 used the stimuli from Experiment 1, and all subjects performed the classification task. All subjects were either provided a unitary or compositional hint prior to the start of learning. For half of the subjects, the hint was changed after the $18^{\text {th }}$ trial (i.e., the unitary hint was replaced with the compositional one and vice versa). For the other half of subjects, the hint they were shown remained the same throughout the study. These latter conditions were identical to the unitary and compositional classification conditions in Experiment 1.

## Method

One hundred fifty-seven subjects were randomly assigned to four conditions: unitary/switch $(N=40)$, compositional/switch $(N=39)$, unitary/no-switch $(N=39)$, and compositional/no-switch $(N=39)$. After the $18^{\text {th }}$ trial (i.e., in the first rest break), the screen was cleared and subjects in the switch conditions were shown a prompt that
notified them that Morkels could be represented differently from the initial hint and were shown the other hint. Following the $19^{\text {th }}$ trial, this hint was presented once more and subjects were reminded to use it to try to figure out what constitutes a Morkel. Subjects in the switch conditions were shown this hint for the remainder of the study (i.e., on rest breaks and following every $3^{\text {rd }}$ error), whereas noswitch subjects continued to see the hint they had seen at the beginning. The rest of the procedure was identical to that of Experiment 1.

## Results \& Discussion

Figure 4 shows average learning curves for subjects in each condition. A $t$-test showed that subjects in the unitary/noswitch condition ( $M=.79, S E=.017$ ) outperformed subjects in the compositional/no-switch condition $(M=.716, S E=$ $.017), t(76)=2.23, p=.03, d=.50$. This finding directly replicates the results from the classification condition in Experiment 1, which showed a unitary learning advantage.

Figure 3. Average learning curves and standard errors across blocks of nine trials for each condition in Experiment 2.

In addition to this analysis, a series of planned comparisons were conducted to examine differences among groups from the point at which subjects were introduced to the other hint (trials 19-72). The first analysis showed that subjects in the compositional/switch condition ( $M=.82, S E$ $=.017$ ) outperformed subjects in the compositional/noswitch condition $(M=.743, S E=.017), t(76)=2.26, p=$ $.027, d=.51$. Additionally, subjects in the unitary/switch condition ( $M=.802, S E=.018$ ) marginally outperformed subjects in the compositional/no-switch condition, $t(77)=$ 1.77, $p=.08, d=.45$. However, no differences in performance were observed among any of the three groups that were presented a unitary hint at some point in the study. Thus, it seems that as long as a unitary hint is presented, regardless of whether it is the only hint that is shown or if it is presented before or after a compositional hint, subjects are able to benefit from it. Taken together, these findings support the conclusion from Experiment 1 and suggest that subjects indeed learn better when they rely on unitary representations.

## General Discussion

We report two experiments that test how encouraging subjects to represent relational stimuli unitarily or compositionally affects concept learning. The findings from Experiment 1 showed that both types of hints can aid learning on a classification task, but only the unitary hint was a useful learning aid on the inference task. These findings provide support for the idea that subjects can indeed use both types of representations to understand and learn relational concepts, but that unitary representations are as or more effective than compositional ones. This latter conclusion challenges the emphasis on compositional representations at the core of most research on analogical reasoning.

Experiment 2 used only a classification task and was able to replicate the findings from the classification condition in Experiment 1, as subjects who received only a unitary hint outperformed subjects who received only a compositional hint. Furthermore, the results from this study showed that subjects who received a unitary hint at any point in the study (with a compositional hint coming before, after, or not at all) outperformed subjects who did not receive a unitary hint at all. No differences in performance were found among subjects in the groups who received a unitary hint. These results lend more support to the dominance of unitary representations, in that subjects will abandon or ignore suggestions for compositional representations if they have discovered a unitary one.

One surprising finding from Experiment 1 was that the unitary advantage was stronger for the inference task than for classification. The effect size for the inference task was actually quite dramatic (Cohen's $d$ of 1.29 ). We had predicted that, if anything, the interaction would go in the opposite direction, given that inference tasks encourage learning the relationships among a concept's components (Markman \& Ross, 2003; Yamauchi \& Markman, 2000). One speculative possibility is that inference learning encourages a top-down approach, in that subjects must reason from the category label to the stimulus, whereas classification encourages a bottom-up approach of reasoning from the stimulus to the category label. Likewise, a unitary representation is top-down in that it embodies a global property of a stimulus that can be used to deduce its internal structure, whereas a compositional representation is bottomup in that the local structure is explicitly represented and the global property emerges only implicitly from the relational system. Under this view, there might be a congruency effect between the stimulus representation and the processes involved in carrying out the task. In particular, a unitary representation might be more congruent with an inference task, because it facilitates conceiving of a concept by a single attribute that can then be used to infer missing parts of a stimulus.

These speculations aside, the main conclusion of the present studies is that, although relational concepts are defined by the interconnections among their component parts, subjects seem to learn these concepts better when they
can be represented unitarily, which might facilitate a global understanding that is easier to discover and use than an explicitly structured one. Furthermore, although compositional-based instruction can help subjects classify a given concept, it might not be optimal for inference-based reasoning.

These findings seem particularly applicable to education and instruction, as they might provide insight into how different types of descriptions for a given relational concept can affect students' representations, as well as how such representations affect learning. Indeed, students are often required to learn various types of structured concepts, and must often engage in both classification and inference. For instance, in mathematics, students must recognize various instantiations of a given problem type, a process that relies on classification, and must also make inferences about how to apply a given solution. These findings thus hold the potential to improve how relational concepts are taught in the classroom.

Furthermore, the present findings have theoretical implications for relational concept learning and representation, and have the potential to affect current theories of analogical reasoning and learning. In particular, research within the theoretical framework of structure mapping (Doumas, Hummel, \& Sandhofer, 2008; Hummel \& Holyoak, 2003) has placed a heavy emphasis on alignment processes operating on compositional representations, but our findings suggest that subjects more naturally represent such concepts unitarily, and that such representations produce a greater and more robust benefit to learning. During comparison of two scenarios, if the critical information can be represented unitarily, then there is no need for structural alignment, because the two can be recognized through the same sort of processing that is possible with feature-based representations, that is, flat (setwise) comparison to identify which properties they have in common. To be clear, this proposal is not intended to argue against the idea that structural alignment of compositional representations plays a prominent role in the more impressive feats of human reasoning (e.g., creativity or scientific discovery), but rather to point out that in more mundane cases, simpler processes and representations may be involved. Nevertheless, further work is necessary to better understand which conditions facilitate unitary and compositional representations.

Lastly, we note one potential shortcoming of the present studies. Although subjects were encouraged to represent the stimuli unitarily or compositionally, we cannot know for certain whether subjects adopted either of these representations. This issue has historically plagued researchers in this domain of study and highlights the need for improved assessment on concept representation. We welcome suggestions in helping us to address this challenge.

#### Abstract

Conversation partners' assumptions about each other's knowledge (their partner models) on a subject are important in spoken interaction. However, little is known about what influences our partner models in spoken interactions with artificial partners. In our experiment we asked people to name 15 British landmarks, and estimate their identifiability to a person as well as an automated conversational agent of either British or American origin. Our results show that people's assumptions about what an artificial partner knows are related to their estimates of what other people are likely to know but they generally estimate artificial partners to have more knowledge in the task than human partners. These findings shed light on the way in which people build partner models of artificial partners. Importantly, they suggest that people use assumptions about what other humans know as a heuristic when assessing an artificial partner's knowledge.

Keywords: knowledge estimation, human-computer interaction, partner modelling, theory of mind, human-computer dialogue

## Introduction

Psycholinguistic research on human-human dialogue (HHD) has shown that our language choices are affected by the assumptions we make about our partners as communicative and social beings (i.e. our partner models) (Branigan, Pickering, Pearson, McLean, \& Brown, 2011): People tend to estimate their conversational partner's knowledge and communicative abilities, and formulate their utterances accordingly. This complex set of judgements is simplified by using a range of heuristics such as accent and social cues (Clark, 1996; Nickerson, 1999) as well as our beliefs about the social distribution of knowledge, i.e., assumptions about what information is likely to be known to whom (e.g., students, residents of Dublin, opticians, birdwatchers) (Fussell \& Krauss, 1992a).

Such perspective taking is critical to successful communication and is not solely the preserve of HHD. People consistently perceive the flexibility and ability of automated artificial (computer) partners as far lower than those of a human dialogue partner, leading us to categorise them as 'at risk' listeners in dialogue (Oviatt, MacEachern, \& Levow, 1998). Moreover, our initial expectations about artificial partner's abilities affect our language choices in Human-Computer Dialogue (HCD) (Branigan et al., 2011; Edlund, Gustafson, Heldner, \& Hjalmarsson, 2008). Yet we know little of how people come to have these expectations: What factors impact people's preconceptions and expectations about what an artificial partner is likely to know, before they have even begun to interact with it? In other words, what determines people's initial partner models for artificial partners?

Understanding what governs and impacts our partner models when interacting with artificial partners, especially in speech-based interactions, has important theoretical and applied implications (e.g., in developing robust and effective speech-based interfaces). In this paper, we investigate whether our initial assumptions about what an artificial speech-based interaction partner knows are related to the sense we have of the social distribution of knowledge. We also look at how our initial beliefs about partner knowledge are influenced by (1) partner type (humans vs. artificial) as well as (2) the partner's signalled nationality.

## Perspective-Taking in Dialogue

Imagine that a stranger asks for directions to a local landmark. How do we ensure that the information we include and the language we use to communicate the message is appropriate for them? Research suggests that we
use verbal and non-verbal cues to assess our conversational partner's characteristics, e.g. where they are from, their language proficiency, their age, profession etc., and use these cues to construct a partner model to guide our language choices (Nickerson, 1999).

This initial global partner model (Brennan, Galati, \& Kuhlen, 2010), which is consulted at the stage of initial interaction, is formed through relatively superficial cues (e.g., stereotypes and pre-conceived expectations and assumptions that are in place prior to the dialogue) and assumptions about the social distribution of knowledge (Fussell \& Krauss, 1992a). These initial inferences act to give a speaker an initial model of common ground between interlocutors, i.e., a representation of mutual knowledge, assumptions and beliefs shared between the interlocutors in a conversation, crucial to successful and effective communication (Bromme, Rambow, \& Nückles, 2001; Clark, 1996). Although our partner models may be subsequently updated by local experiences within the dialogue interaction (e.g. feedback about comprehension, via verbal and non-verbal cues) (Brennan et al., 2010), the global model acts as a guide for our initial interaction, especially before feedback has been gathered from within the dialogue (Fussell \& Krauss, 1992a).

Understanding how we develop and form these initial models is important, as research shows that they guide our language choices. We tend to adjust our language based on our assumptions about our addressees' knowledge. For instance, when people are asked to describe items for their friends, they adapt their descriptions to their friend's knowledge - and these adjustments lead to better communication, i.e., higher accuracy in identification (Fussell \& Krauss, 1989). Crucially, studies also show that we are very accurate at assessing others' knowledge and that these assessments guide how we construct our initial message in communication (Fussell \& Krauss, 1991, 1992a).

Similar effects of partner models on language choice are thought to drive our dialogue interactions with artificial dialogue partners. People tend to see artificial partners as poorer interlocutors and alter their language choices and speech behaviours as a result (Branigan et al., 2011; Oviatt, Bernard, \& Levow, 1998). For example, people are more likely to converge (or align) with their partner's choice of referring expression when they believe their partner to be a computer rather than a human. In addition, they adjust their behaviour more in this way when they are led to believe that the artificial partner is a 'basic' interlocutor with restricted capability than a partner with more advanced capability (Branigan et al., 2011). Similarly, people's linguistic choices in a telephone conversation concerning air-fares and timetables change depending on whether they believe their partner to be a human or a computer (Amalberti, Carbonell, \& Falzon, 1993). Similar findings have been reported in
other work (Bell \& Gustafson, 1999; Kennedy, Wilkes, Elder, \& Murray, 1988). Compared to HHD, users tend to use simpler grammatical structures, use more words in their descriptions, use fewer pronominal anaphors (e.g. her/him; $h e / s h e$ ), and use simpler lexical choices (Amalberti et al., 1993; Kennedy et al., 1988). Such research assumes that people's perceptions and beliefs about their partner's abilities affect their language choices in these contexts. Yet it is not clear what factors determine these beliefs in the first place, and thus what may be driving people's global partner model during their initial interaction with an artificial partner. Our work aims to shed light on this question.

Research on robotic agents has shown that the perceived nationality of the agent, and the content that it is being asked to process, both influence participants' judgements about its abilities (Lee, Lau, Kiesler, \& Chiu, 2005). Participants used these cues in a similar way to that which they are used in HHD: When they were asked to judge the likelihood that a robot 'from New York' or 'from Hong Kong' would know and recognize a set of New York and Hong Kong landmarks, they judged that the robot would be more likely to identify landmarks associated with its perceived nationality (Lee et al., 2005). In this context, accent can play an important role. It acts as a strong signal of identity and a speaker's linguistic background (Ikeno \& Hansen, 2007), and allows listeners to identify characteristics such as age, gender and geographic affiliation, as well as stimulating specific stereotypes (Ryan, Giles, \& Sebastian, 1982).

## Research Aims and Hypotheses

There is currently little understanding of what factors affect people's assumptions about partner knowledge and abilities in HCD contexts. The limited existing research on people's perceptions of artificial dialogue partners tends to focus on affective factors such as interface likeability rather than on assumptions about a computer's knowledge and abilities. Other work in tangential fields such as HRI cannot be assumed to hold more widely as the embodiment of robots tend to facilitate the mapping of human abilities to a robot partner (Kiesler, 2005).

We present a study using a similar method to previous work investigating how people initially estimate human partners' knowledge (Fussell \& Krauss, 1992a), in order to investigate how people estimate artificial partners' knowledge. People are asked to name landmarks and judge the identifiability of those landmarks' names to others. We hypothesise that people will use the same heuristics to estimate partner knowledge for artificial partners as they use for human partners. That is, people will rate both human and artificial partners as more likely to know the name of those landmarks that are generally more accurately identified by other people (H1). This would be evidence that people have a sense of the spread of knowledge about a topic in the population (i.e., the social distribution of knowledge) with
this being related to their assessment of a partners’ likely knowledge, including artificial partners. We also expect a strong positive correlation between judgements of humans' and artificial partners' knowledge (H2), giving support to the idea that our judgements of artificial agents are related to our judgements of humans in this context. Based on the intimated difference in partner models between humans and artificial partners in the literature we also hypothesise that there will be a statistically significant difference between people's judgements of how likely a person versus an artificial agent is to know the name of the stimuli (H3). We also hypothesise that people will make different judgements about partner knowledge based on the relation between the system's signalled nationality (UK or US) and the type of content being judged in the experiment (i.e., UK landmarks) (H4).

## METHOD

## Participants

32 ( 16 F, 16 M) Native British English speakers with a mean age of 32.0 years (S.D.=12.1) from a UK university community took part in the study. The majority ( $\mathrm{N}=26$ ) of participants had previously spoken to an automated system. Those who had used such systems were asked to rate how frequently they used them on a 7 point Likert scale (Very Infrequently-Very Frequently). The mean rating suggests that their level of experience with these types of interfaces was low ( $\mathrm{M}=2.73$, $\mathrm{SD}=1.43$ ).

## Items

Fifteen UK landmarks were used as the stimuli in the study, selected based on the frequency of accurate naming in a prestudy. This was to ensure that there was variation in the frequency of accurate naming across the items in the experiment.

## Conditions

Partner Type All participants were asked to judge both an artificial partner's (i.e. automated agent) and a human partner's (within participants) likely knowledge of the landmark names. The order in which participants were asked to judge the artificial and the human partner was randomised. Participants judged all 15 landmarks in each condition. The display of the 15 landmarks in each partner condition was randomised to reduce potential order effects.

Nationality Participants were asked to judge how likely either an American $(\mathrm{N}=14)$ or British $(\mathrm{N}=18)$ partner (between participants- randomly assigned) would be to know the landmarks. When in the human partner condition, participants were asked to rate how identifiable the landmarks' names would be to either a British or American person (participants were told that 'identifiable' referred to the likelihood of knowing the landmark name). When in the artificial partner condition, participants were told that the
researchers were developing a British-based (British nationality condition) or a US-based (US nationality condition) automated agent. They then listened to a sample audio clip taken from the system. Participants listened to a sample audio introduction from the agent (e.g. "Hello, my name is Laura. How can I help you?"), simulating the type of content that would guide people's initial partner models in these types of interactions. To further emphasise the nationality, the introductory message from the service was played in either a British or a US accent. This procedure was used to make sure that participants who lacked previous experience with agents had a frame of reference for their ratings.

## Measures

Participant's ability to name landmarks To identify the spread of knowledge within the sample, all participants were initially asked to name the 15 landmarks used in the study. A $300 \times 250$ pixel image of each landmark was displayed along with a textbox. Participants were asked to name the item. They were informed that if they did not know the name of the item they could leave this box blank. The lead author then marked the names given by the participants as either accurate or inaccurate.

Others' knowledge of the landmark names Based on scales used in previous research on perception of others' knowledge in HHD (Fussell \& Krauss, 1992b) and humanrobot interaction (HRI) (Lee et al., 2005), participants were asked to judge how identifiable they felt the name of each landmark would be to others. This was measured using a 7point Likert scale from Not Identifiable (1) to Very Identifiable (7).

## Procedure

Participants were recruited via email from a British university community. Upon responding to the email participants were sent a link to the online survey. Participants completed the demographic section of the survey. They were then asked to name the 15 landmarks, and subsequently asked to judge how identifiable the name of the landmarks would be to a human (either a British or US person), and then how identifiable the name of the landmark would be to a computer (either British or US accented automated agent). Again, the order of these was randomised. They were then debriefed as to the purpose of the experiment.

## RESULTS

## Social Distribution of Knowledge

Following previous work on knowledge estimation in HHD (Bromme et al., 2001; Fussell \& Krauss, 1992b) we ran analysis on the item level data to test H1 and 2. Using the item level data means we can see whether landmarks that were more accurately named across the sample were rated
as more likely to be known to both human and artificial partners. This would give us a sense of how people's assumptions of knowledge for each item relate to actual levels of knowledge in the group of participants for each item. This type of fine grained insight would not be possible using the participant level data as we would only have a measure of accuracy for each participant, giving us no sense of the spread of knowledge of each item in the sample as a whole.

Figure 1: Relationship between percentage accurate item naming and human partner identifiability rating

There was a strong positive correlation between the percentage of accurate responses for an item and participants' mean judgements of other people's [r (13)= .85, p $<.001$ ] (Figure 1) as well as an artificial partner's knowledge of its name [r (13)=.86, p<.001] (Figure 2). There was also a strong positive correlation between judgments of other people's knowledge of the names and an artificial partner's knowledge $[\mathrm{r}(13)=.78, \mathrm{p}<.001]$ (Figure $3)$.

Figure 2: Relationship between percentage accurate naming and artificial partner identifiability rating

These correlations support our hypotheses (H1 and 2). They suggest that people have relatively accurate awareness of the actual distribution of knowledge (with respect to which
knowledge is more or less likely to be known) and that this has a strong relationship to their judgements of how likely the name is to be known to a person and an artificial partner.

Figure 3: Relationship between human and artificial partner identifiability ratings

Moreover, people's assessment of how identifiable a landmark's name is to an artificial partner seems related to how identifiable they believe it is to a human partner. This supports the idea that people's initial model of an artificial partner's knowledge is related to their initial model of other people's knowledge, with both closely reflecting people's actual rates of accuracy in naming each item.

## The Effect of Partner Type \& Nationality

To test H3 and H4, we analysed the data at the participant level using a $2 \times 2$ Mixed ANOVA looking at the effects of partner type (Human vs. Artificial -within participants) and nationality (US vs. British- between participants) on people's knowledge estimation. We saw a statistically significant main effect of partner type on people's knowledge estimations $\left[\mathrm{F}(1,30)=6.43, \mathrm{p}=.016, \eta_{\mathrm{G}}^{2}=\right.$ $0.058]$. People rated item names in general to be more identifiable to an artificial partner ( $\mathrm{M}=4.60$, S.D. $=1.06$ ) than to a human partner $(M=4.19$, S.D. $=0.74)$, supporting our hypothesis but contradicting the direction intimated by previous HCD work. There was no statistically significant main effect of nationality $[\mathrm{F}(1,30)=0.31, \mathrm{p}=.58$, $\left.\eta^{2}{ }_{G}=0.007\right]$ or interaction effect between partner type and nationality $\left[\mathrm{F}(1,30)=2.94, \mathrm{p}=.097, \eta_{\mathrm{G}}{ }^{=}=0.028\right]$. Therefore a partner's nationality did not affect people's knowledge judgements of human or artificial partners in relation to the landmarks; H4 was therefore not supported.

## DISCUSSION

We found that people have a strong sense of the social distribution of knowledge and this relates to people's judgements about others' knowledge, irrespective of the other being an artificial agent or a human. The number of times each item was named correctly correlated strongly and
positively with people's estimations of both artificial and human partners' knowledge of landmark names. We also found that people in general judged the names of the landmarks in the experiment to be more identifiable to a computer than a person. Surprisingly, partner nationality did not have statistically significant effects on knowledge estimation.

Our research highlights that people are relatively accurate at estimating what other people are likely to know based on a sense of the general distribution of that knowledge, similar to previous research (Fussell \& Krauss, 1992b; Lau, Chiu, \& Hong, 2001). But importantly, these effects also apply to our estimates of artificial partners' knowledge. The actual percentages of correct responses for each item correlated highly and positively with the knowledge estimates for both artificial and human partners. We therefore seem to use our estimates of what other people will know to inform our judgements of what an artificial partner will likely know. That is, people seem to use their perceptions of the social distribution of knowledge among humans to anchor their perceptions of an artificial partner's knowledge.

We also see that people judged an artificial partner as being more likely to know the name of the landmark in the study than a human partner. It is important to note that our finding may reflect users' assumptions about one specific dimension of an artificial partner's abilities (i.e., their knowledge of proper names) rather than their communicative capabilities or knowledge as a whole. Participants were asked to judge how identifiable the name of a landmark (e.g., Stonehenge) would be. Proper names pick out unique entities in the world. As such, they do not require any complex inferencing, knowledge of ontologies, conceptual relations between categories. They can (usually) be captured by a simple association between the name and a unique object, the kind of data that are prototypically perceived as easy for computer systems to store, index, and retrieve. This may explain why a computer was judged more likely than a human to know the name of the landmarks that we used. Other types of knowledge that involve more complex conceptual relationships, or operations over elements might not show the same pattern. Note however that people did not attribute complete omniscience to the artificial partner; their judgements about its knowledge were strongly related to the social distribution of knowledge.

There is also likely to be a distinction between what we perceive artificial partners to know and what we believe they can do with this knowledge in dialogue, or even whether these names will be recognised effectively in the first place. For instance people may assume that artificial partners know the proper names of landmarks but may not be sufficiently confident that these names will be recognised during speech recognition. Although vast improvements on error rates have been made in speech technology research, there may still be a perception within people's partner
models that recognition is poor and inflexible. Hence rather than artificial partners being seen as 'at risk' dialogue actors, people's partner models are likely more nuanced and multi-dimensional, presumably encompassing assumptions about both underlying knowledge and processing abilities.

To be clear, this study focused on how people establish estimates of knowledge in their initial global partner models, in the absence of dialogue interaction with the system. Our findings are particularly relevant to how people form a priori partner knowledge assumptions in a dialogue context. Yet when in dialogue, our perspective taking is likely to be informed by both the global models we create of our partner (e.g. assumptions of their knowledge and abilities formed by stereotypes and expectations before interaction) and local experiences within the dialogue (e.g. feedback of comprehension via verbal and non verbal cues) (Brennan et al., 2010). Indeed these factors are likely to interact in dialogue interactions. Work on HHD interaction has shown that behaviours within a dialogue that do not match our expected partner models impact our speech (Kuhlen \& Brennan, 2010). Research suggests that these models should be considered as being dynamic and adaptable over time (Fussell \& Krauss, 1991; Nickerson, 1999). Investigating the dynamism of partner models across the course of an interaction is a critical issue for future research in HCD as it has been in HHD.

In addition, although partner models are assumed to be important in influencing people's language choices and linguistic processing in HCD (Edlund et al., 2008), more research is needed to fully explore the role that they play. This question has received considerable attention in research on HHD, with particular reference to the extent to which our partner models impact processing: Is their influence immediate and pervasive, or delayed and restricted? (see Brennan et al., (2010) for summary of the main theoretical positions). Within HCD research, partner models have been invoked to explain the differences in language use between HHD and HCD (Branigan et al., 2011; Edlund et al., 2008), but recent research has shown that this may not be true in all contexts (Cowan \& Branigan, 2015; Cowan, Branigan, Bugis, Obregon, \& Beale, 2015). Clearly, partner models affect language choice and processing in both HHD and HCD - but it is not yet clear whether they do so in the same ways and to the same extent. An interesting possibility for future research is that partner models may play a more pervasive and far-reaching role in HCD than in HHD.

## Implications \& Conclusions

Our research set out to investigate the factors that affect people's expectations about what an artificial partner is likely to know, before they have begun to interact with it. Our findings suggest that we come to interactions with an existing presumption of what an artificial partner is likely to know that is based on assumptions of how knowledge is socially distributed. Moreover we found that under some
circumstances they may have the preconception that an artificial partner knows more than a human partner. These results suggest that models of human-human communication are applicable in important ways to communication with artificial agents. They also have important applied implications for HCD, by casting light on factors that can lead users towards or away from an appropriate mental model of a partner's abilities and intentions, with implications for successful communication (Kiesler, 2005). When designing artificial systems, developers should be aware that people bring with them assumptions about the social distribution of knowledge, which could significantly affect their interaction.

# Folk Attributions of Control and Intentionality Over Mental States 

Corey Cusimano (cusimano@sas.upenn.edu)<br>Geoffrey P. Goodwin (ggoodwin@psych.upenn.edu)<br>Department of Psychology, University of Pennsylvania, 3720 Walnut St Philadelphia, PA 19104 USA

#### Abstract

Influential theories in social psychology, philosophy, and linguistics assume that ordinary people judge many mental states as outside voluntary control, yet few studies have directly investigated these claims. We report four studies suggesting that, contrary to several prominent models, ordinary people attribute at least moderate intentional control to others over a wide variety of mental states. Furthermore, it appears that perceived control may vary systematically according to mental state type (e.g. emotions vs. desires vs. beliefs). These results point to several important directions for future research in behavior explanation and moral judgment.

Keywords: mental states; control; intentionality; agency

## Introduction

Mental states are not just used to explain and predict others' observable behavior, they are also often treated much like behaviors themselves in that we talk about them, care about them, and try to influence them (Frankfurt, 2004). For instance, when we learn that someone doesn't like us or respect us, it hurts and we feel angry (Leary, Springer, Negel, Ansell, \& Evans, 1998). When we dislike certain attitudes, either our own or someone else's, we try to change them (DeMarree, Wheeler, Briñol, \& Petty, 2014). And when we're exposed to someone's highly immoral emotions, desires, and thoughts, we form negative impressions of that person and try to avoid them (Ames \& Johar, 2009; Gromet, Goodwin, \& Goodman, 2016; Cohen \& Rozin, 2001).

Despite the importance of mental state evaluation and regulation in social life, very little research has studied how ordinary people think about others' agency over their own minds. This omission is particularly striking in light of years of research demonstrating that perceptions of behavioral control predict judgments of blame and responsibility, feelings of anger or pity, and helping or punishing behavior (see, Alicke, 2000; Malle, Guglielmo, \& Monroe, 2014; Weiner, 1995 for reviews).

One possible reason for this omission is a long-held assumption, based on early work in linguistics, that mental states are perceived as involuntary. In one of the first investigations on this topic, Katz and Postal (1964) argued, based on the observation that mental state verbs seem to be ungrammatical in the imperative form (e.g. compare "Want this pear!" and "Pick up this pear!"), that "being in such psychological states as belief, understanding, wanting and hoping is not subject to a person's will" (p. 77; see also Miller \& Johnson-Laird, 1978). Despite other work arguing that many mental states can be used in the imperative form (e.g. Huddleston, 1970), many linguists continued to assume that
mental states are involuntary (e.g., Brown \& Fish, 1983; Corrigan, 1988).

This work also influenced social psychology. For instance, Gilovich and Regan (1986) assumed that, unlike actions, mental states "do not necessarily involve any choice on the part of the person from among alternatives; they just happen" (p. 349). Similarly, Malle and Knobe (1997a) took as given that "prototypical actions... are both intentional and observable, whereas prototypical experiences (e.g. 'Ben is excited') are both unintentional and unobservable" (p. 289; emphasis added). These claims about ordinary attributions of intentionality and voluntariness play an important role in psychological models of behavior explanation. For instance, Malle \& Knobe (1997a) argued that people will be less motivated to try and explain others' mental states because they are unintentional. Gilovich \& Regan (1986) argued that, because mental states are involuntary and uncontrollable, people offer more dispositional (as opposed to situational) explanations for them (see also Lock \& Pennington, 1982). Finally, Malle (2004)'s model of behavior explanation posits that people provide mechanistic cause explanations (as opposed to reason explanations) for emotions, desires, beliefs, and other mental states, on the premise that ordinary people judge these as unintentional.

Scholars in philosophy and anthropology also frequently make assumptions about ordinary people's judgments of mental state voluntarism, but they often differentiate between mental states types. In his 'folk model of mind', D'Andrade (1987) claimed, similarly to Katz and Postal (1964), that people view desires as entirely involuntary and uncontrollable. However, D'Andrade (1987) also claimed that people view emotions as somewhat controllable and beliefs as highly controllable. A similar pattern emerges in philosophical theories. For instance, the idea that ordinary people judge beliefs as voluntary is echoed in Alston (1988), who invoked this point to explain why people blame each other for unjustified beliefs, while the idea that people view desires and other attitudes as involuntary is common in moral philosophy (see, e.g. Adams, 1985; Smith, 2008).

Despite the ubiquity of claims about the perceived controllability of mental states, only a handful of studies have been conducted which directly ask people about how they perceive them, and the evidence from these studies conflicts. In one study, Malle and Knobe (1997b) asked participants to rate the intentionality of 20 behaviors, three of which were mental states (e.g. "Anne was in a great mood"). Each of those mental states was rated low in intentionality (e.g. $M=$ 2.54 on a 1-7 scale). In contrast, Schlesinger (1992) asked people to rate how much control (Studies 1-4, 6) or
intentionality (Study 5) the experiencer of a mental state had over that state and found that people attributed a moderately high degree of control and intentionality (e.g. $M=4.58$ on a 1-7 scale, Study 6). However, Schlesinger (1992) relied on scenarios that were interpersonal and highly abstract (e.g. "A fears B"), making it unclear whether the results reflect prototypical attributional processes.

In light of this, we sought to test how much control and intentionality people typically attribute to others over their mental states. We improved over prior studies by testing a wide range of mental states and, following the possibility raised by D'Andrade (1987) and others, testing for differences between mental state categories. In the studies below, we also include observable behaviors including intentional acts (e.g. talk, avoid), accidents (e.g. slip, fall), and uncontrollable behaviors (e.g. sneeze, shiver), as foils. These foils acted as benchmarks, allowing us to test how judgments of mental states compared with judgments of prototypical controllable and uncontrollable behaviors, while also ensuring that participants used the control measure concepts in a predictable way.

## Study 1

The purpose of Study 1 was to measure prototypical judgments of control for a variety of mental states, and to compare these judgments with those for clearly intentional, unintentional, and uncontrollable behaviors. To obtain ecologically valid materials, we solicited vignettes from one sample of our population (University of Pennsylvania undergraduates), selected frequent examples, and then used them in a rating task for a separate sample from the same population.

## Methods

Stimulus generation and selection. We solicited stimuli for 43 items in total. These items consisted of 28 mental states, including four beliefs (believe that, conclude that, feel that, think that), four desires (crave, desire, hope, want), four emotions (anger, anxiety, embarrassment, happiness), four intentions (goal, intend, plan, resolve), four deliberations (consider, deliberate, speculate, think about), four evaluations (value, love, hate, appreciate), two imaginations (imagine, visualize), and two memory events (forget, remember). In addition to these 28 mental states, we included five intentional acts (play with, eat, say, search for, avoid), five accidents (fall off of, trip over, slip on, run into, drop), and five uncontrollable behaviors (sneeze, yawn, sweat, shiver, faint) as our foils.

80 University of Pennsylvania students participated (57 female) in a sentence completion task for course credit. Participants were provided with sentence fragments containing an ambiguous subject and a mental (or behavioral) verb, but no object (e.g. "He believed that...", "She wanted...", "He intended to..."). They were instructed to complete each sentence fragment in a way that made sense given the words provided and to avoid humor. The mental states were split across five lists and combined with
observable behaviors and 12-13 filler trials. Participants were randomly assigned to one of these lists, yielding 13-17 contents per item.

As expected, many of the topics participants wrote about were relevant to their lives as undergraduate students, including concerns about school (e.g. "She felt anxious about her upcoming exam", "He planned to do better on the next test"), romantic relationships (e.g. "She felt angry with her boyfriend", "She thought that she wasn't good enough for him"), and food (e.g. "He craved chocolate", "She thought about the lunch she would be having soon"). Similar responses appeared across item categories.

We selected five completions for each of the 28 mental states and 15 behavior foils, yielding 215 scenarios total, based on the frequency of similar completions. For items that produced few or no duplicate responses, we selected responses so as to maximize the diversity of content.

Main rating task. 143 University of Pennsylvania students (94 female) were recruited for an experiment about "understanding others' behavior" and completed the task for course credit.

The 215 scenarios were distributed across five lists. Each list contained one scenario from each of the 28 mental states and 15 behaviors yielding 43 trials total. Scenarios were presented on separate pages in a random order. For each trial participants responded to eight questions which, to avoid possible order effects, were presented in a new random order for each trial.

Four questions assessed how much agency participants attributed to the agent for the ascribed mental state. Two of these questions assessed general control: (1) How much control the agent had over that behavior; and (2) Whether, if desired, the agent could have done otherwise. The other two probed intentionality: (3) Whether the agent acted intentionally; and (4) Whether the agent chose to act/think/feel (etc.) that way.

Two questions probed participants' evaluations of the mental state, including (5) How good or bad the agent's behavior was; and (6) Whether the agent should have behaved in the manner described. Two final questions probed judgments of agent themselves: (7) How responsible the agent was for the behavior or mental state; and (8) How revealing it was of the agent. All questions used a 7-point rating scale.

To minimize ambiguity, all questions contained explicit reference to the mental or physical content (e.g., "How much control did she have over believing that she did well on the exam?"). At the end of the experiment, participants reported demographic variables including age, sex, political orientation, religiosity, and religious affiliation.

## Results

We combined our two control ( $1-2, r \mathrm{~s}=0.74-0.81$ ), and two intentionality (3-4, $r s=0.83-0.89$ ) measures into single measures of control and intentionality (Table 1 shows means and standard deviations for each behavior and mental state

Figure 1: Mean ratings (and standard errors) for each of the 43 item categories (black) with mean rating for each of the five scenarios (color) from Study 1. Each shape represents the mean one of the five scenarios.
category). To test degrees of agency, we ran a series of mixed-effect linear models comparing mental state categories to uncontrolled, accidental, or intentional behaviors, on bysubject means for each category.

Participants used the control concepts expected: accidents were seen as more controlled ( $b=0.78, S E=0.11, t=7.26$, $p<0.001$ ) but not more intentional ( $b=-0.15, S E=0.11, t$ $=-1.39, p=0$. 165) than uncontrollable behaviors. With two exceptions, mental states were seen as more controlled and intentional than the uncontrollable and unintentional behaviors ( $p s<0.001$ ). Only intentions were not see as less controlled ( $p=0.338$ ) or intentional ( $p=0.832$ ) than intentional action foils (see Figure 1).

We also conducted a set of exploratory analyses to test whether any mental state categories were significantly different from one another. We conducted a regression comparing each mental state category to its adjacent category based on the overall control and intentionality means. Results showed that, on average, most mental state category ratings were different from their adjacent category: emotions were less intentional than desires $(b=0.79, S E=0.08, t=10.07, p$

Table 1: Means (and SD) for agency responses in Study 1

| Behavior | Control | Intentionality | Responsibility |
| :--- | :--- | :--- | :--- |
| Uncontrolled Act | $2.51(1.53)$ | $2.13(1.40)$ | $2.66(1.70)$ |
| Accident | $3.30(1.51)$ | $2.29(1.41)$ | $3.72(1.73)$ |
| Emotion | $3.71(1.51)$ | $3.32(1.58)$ | $3.89(1.68)$ |
| Memory | $3.53(1.52)$ | $2.94(1.52)$ | $4.13(1.67)$ |
| Desire | $4.03(1.63)$ | $4.11(1.71)$ | $4.28(1.70)$ |
| Evaluation | $4.59(1.63)$ | $4.62(1.64)$ | $4.70(1.65)$ |
| Belief | $4.54(1.56)$ | $4.50(1.61)$ | $4.70(1.60$ |
| Deliberation | $4.99(1.43)$ | $5.04(1.39)$ | $5.07(1.43)$ |
| Imagination | $5.05(1.35)$ | $5.16(1.37)$ | $5.03(1.41)$ |
| Intention | $5.88(1.22)$ | $5.97(1.15)$ | $5.89(1.19)$ |
| Intentional Act | $5.98(1.18)$ | $5.99(1.13)$ | $5.86(1.28)$ |

$<0.001$ ), desires were less intentional than beliefs ( $b=0.39$, $\mathrm{SE}=0.08, t=4.92, p<0.001)$. Beliefs and evaluations were not significantly different from each other ( $b=0.11, S E=$ $0.08, t=1.42, p=0.157$ ), however evaluations were different from deliberations ( $b=0.44, S E=0.08, t=5.58, p<0.001$ ). This pattern was replicated in participants' control ratings.
Finally, we examined item-level means for each of the 28 mental state concepts and found that judgments of control and intentionality were highly correlated with one another $(r(26)$ $=0.95)$, and with judgments of responsibility $(r(26)=0.98$ and $r(26)=0.92$, respectively).

## Discussion

Results from this study provide evidence that, contrary to the theories cited above, many ordinary mental states are perceived to be moderately controllable and intentional. It also suggests that perceived agency might differ as a function of the type of mental state: emotions were judged as less voluntary than desires, beliefs, and other states.
However, this study has several notable shortcomings. First, the mental state scenarios were presented without the immediate context in which they occurred. It is possible that when possible proximate or situational causes for mental states are made salient, perceived control and choice is diminished. Second, the nature of our design was such that the content of the mental states was not held constant across mental state type: desires tended to be "about" different things than beliefs, evaluations, and so on. It is therefore possible that differences in control were due to what the mental states were about. Study 2 was designed to address these limitations.

## Study 2

Study 2 used a set of experimenter-generated stimuli to investigate judgments of three different measures of
voluntariness with more detailed and comparable vignettes. Because control measures were divided between subjects, Study 2 comprised three separate experiments: Study 2a investigated judgments of intentional choice, Study 2b investigated general control, and Study 2c investigated the ability to choose to stop thinking, feeling, or wanting something once it has started.

We predicted that, despite the additional constraints imposed in this experiment (see below), participants would still view mental states as moderately voluntary - more controllable than passive behaviors such as coughing or sweating - but not as fully controllable as intentional actions and, second, that there would be a step-wise increase in perceived control between emotions, desires, beliefs, and thoughts.

## Methods

Participants. A total of 442 participants were recruited from Amazon's Mechanical Turk to participate in Study 2. 146 individuals ( 65 female, 81 male; mean age $=35$ ) participated in Study 2a ("Choice"), 149 (66 Female, 78 Male, 5 unreported; mean age $=34$ ) participated in 2 b ("Control"), and the remaining 147 ( 60 Female, 85 Male, 2 unreported; mean age $=35$ ) participated in 2c ("Choose to stop"). No participants were excluded.

Stimuli. To generate contexts, we constructed 30 scenarios describing someone in an ordinary or believable situation (such as repairing a bike, photographing a wedding, walking down the street, and so on). Unlike Study 1, each scenario provided a great deal of context about the person and situation leading up to the mental state or behavior. Our primary manipulation was the last element of each scenario, which was either (1) an observable uncontrollable reaction, (2) an emotion, (3) a desire, (4) a belief, (5) thinking or ruminating on some idea, or (6) an observable intentional action. Below is one of the 30 scenarios with each of the six conditions:

Katy is nearing the end of her third year in college. She's studying chemistry and biology in order to eventually apply to medical school. Any low grade will hurt her chances at getting into the top medical schools. Today, however, she struggled through the final exam in her chemistry class. She did not complete it in time and had to guess on the entire last page of questions.
Walking out of the exam, Katy...

1. begins shivering in the cold. (uncontrollable reaction)
2. feels angry at her professor. (emotion)
3. wants to leave her professor a poor course evaluation. (desire)
4. believes that her professor deserves a poor course evaluation. (belief)
5. thinks about leaving her professor a poor course evaluation. (thinking)
6. fills out a negative course evaluation on her phone. (intentional act)

As this example illustrates, the context prior to the manipulation was held constant, and the attitudinal content of each mental state (and the intentional behavior) was also held as constant as possible (e.g., in the item above, a negative and retaliatory attitude towards the professor is conveyed in each case). There was, of course, no such content for the uncontrollable foils (shivering, sneezing, coughing, etc.). We varied the kind of emotion experienced by the agent in the scenario: across the 30 sets, the emotion condition featured the agent feeling either angry, sad, afraid, excited, or pleased. Given 30 scenarios, each of which split into six behavior conditions, there were 180 items in the whole experiment.

Design. The items were distributed across six lists (of 30 items each) using a Latin-square design. Each list had one item category from each of the 30 scenarios, yielding a total of five trials within each list for each item category. We balanced the distribution of emotion trials so that each of the five different emotions appeared in each list.

Dependent measures. In Study 2a, the main dependent variable was whether the agent chose the particular mental state he/she had at the end of the story. Participants indicated their answer on a rating scale ranging from 1 (definitely did not choose) to 7 (definitely did choose). As in Study 1, the full content of each item was included in each question and was italicized (e.g. "Did Katy choose to feel angry at her professor?").

Study 2 b measured perceptions of how much control the agent had over whether he/she had the particular mental state (or over the behavior). For instance, in the Katy vignette above, participants were asked "How much control did Katy have over whether she felt angry at her professor?" on a scale from 1 (no control at all) to 7 (complete control).

Finally, 2c, measured perceptions of the degree to which the agent could stop the particular mental state (or behavior) once it had started. In the Katy vignette above, participants were asked "Can Katy choose to stop feeling angry at her professor?" on a scale from 1 (definitely can not choose) to 7 (definitely can choose).

Procedure. At the beginning of the experiment participants were randomly assigned to one of the six stimulus lists. Participants were provided brief instructions that they would read 30 stories about different characters and answer a question about a behavior that the character performed. Each trial was presented on a separate page in a new random order for each participant. At the end of the study, participants filled out a brief demographics questionnaire. No other data was collected.

## Results

All analyses were performed by running a linear mixed-effect model (LMEM) regressing ratings on the within-subject, within-scenario behavior manipulation. We included random intercepts for participant and scenario ratings, as well as

Figure 2: Mean (and SE) ratings for (A) Choice, (B) Control, and (C) Choose to stop measures of agency across behavior conditions in Study 2
random slopes for by-subject and by-scenario variation in the effect of condition. For each control measure, Intentionality, Control, and Stopping, we ran three sets of analyses. One analysis compared the means of the four mental state categories to the uncontrollable behavior foil (dummy coded as the reference level); one analysis compared the means of the four mental state categories to the intentional act behavior foil; and finally one analysis compared mental state categories to each other following our hypothesized stepwise increase in control through emotions, desires, beliefs, and thinking. See Figure 2 for condition means and standard error across control measures.

2a: Choice. Replicating results from Study 1, emotions ( $M=$ 3.95, $S D=2.08$ ), desires $(M=5.48, S D=2.08)$, beliefs $(M$ $=5.43, S D=1.73)$, and thinking $(M=5.29, S D=1.77)$ were all judged significantly more intentional than uncontrollable reactions $(M=1.67, S D=1.37 ; p \mathrm{~s}<0.001)$. These states were also all judged significantly less chosen than intentional acts ( $M=6.45, S D=1.13 ; p \mathrm{~s}<0.001$ ). Also replicating Study 1, emotions were rated as less chosen than desires $(b=1.534$, $S E=0.08, t=19.243, p<0.001$ ) but, contrary to expectations, there were no differences between desires and beliefs or beliefs and thinking ( $p \mathrm{~s}>0.07$ ).

2b: Control. Emotions ( $M=4.26, S D=1.44$ ), desires ( $M=$ 4.96, $S D=1.85$ ), beliefs ( $M=5.09, S D=1.72$ ), and thinking ( $M=5.00, S D=1.81$ ) were all judged significantly more controllable than uncontrollable reactions ( $M=2.09, S D=$ 1.44; $p \mathrm{~s}<0.001$ ) and significantly less controllable than intentional acts ( $M=6.32, S D=1.23 ; p \mathrm{~s}<0.001$ ). Similar to Study 2 a , we observed a significant difference between emotions and desires ( $b=0.692, S E=0.076, t=9.125, p<$ 0.001 ), but not between desires, beliefs, or thinking ( $p \mathrm{~s}>$ 0.07).

2c: Choosing to Stop. Again, Emotions $(M=4.44, S D=$ 1.99), desires $(M=4.74, S D=1.98)$, beliefs $(M=4.77, S D=$ 1.93), and thinking ( $M=5.08, S D=1.84$ ) were all judged significantly easier to stop than uncontrollable reactions ( $M$
$=2.03, S D=1.58 ; p \mathrm{~s}<0.001)$ and significantly harder to stop than intentional acts $(M=6.08, S D=1.54 ; p \mathrm{~s}<0.001)$. Participants judged emotions as more difficult to stop than desires $(b=0.306, S E=0.084, t=3.662, p<0.001)$, and beliefs more difficult to stop than thinking ( $b=0.305, S E=$ $0.084, t=3.638, p<0.001$ ) but did not distinguish between beliefs and desires ( $b=0.03, S E=0.084, t=0.359, p=0.72$ ).

## Discussion

Study 2 replicated the main findings from Study 1: people attribute moderate to high agency to others over their emotions, desires, beliefs, and deliberative thoughts, whether that agency is conceptualized as "choice", general "control", or an ability to "choose to stop". This finding replicated in spite of more explicit portrayals of relevant situational constraints. We also replicated the finding that this control is not perceived as complete: individuals were granted less agency over all mental states (even traditionally "active" processes such as thinking) compared to observable intentional acts.

We also found that emotions were perceived as less voluntary than desires. Unexpectedly, once holding mental state content constant, the other differences in perceived agency, namely, those between desires and beliefs, and between beliefs and thinking, did not replicate except in the "choose to stop" condition. This may reflect the improved design in this study (i.e., the fact that background context and focal content were held constant), but suggests that some variation in general control may come from the kinds of content different mental states are usually about.

## General Discussion

Our results pose a challenge to a common assumption in linguistics, anthropology, and social psychology, namely that people view others' mental states as largely uncontrollable. Contrary to this assumption, we report that people judge many mental states to be quite controllable: they clearly do not perceive mental states as just happening (cf. Gilovich \& Regan, 1986), completely outside voluntary control (cf. Katz
\& Postal, 1964), nor as uniformly unintentional (cf. Malle \& Knobe, 1997a).

In line with models like those proposed by D'Andrade (1987), our results also suggest that people attribute different degrees of voluntary control to different mental state categories (even holding context and content constant). However, as D'Andrade (1987) never empirically tested his model, his specific predictions were wrong: for instance, we found that people viewed desires as moderately controllable, more controllable, on average, than emotions, whereas D'Andrade (1987) posited that desires were uncontrollable (while emotions were partially controllable). Future work should investigate the sources of variation in control both between (e.g. why beliefs easier are to control than emotions), and within mental state categories (e.g., why particular beliefs differ in their perceived controllability).

Finally, a great deal of work has shown that people are held accountable for their moral wrongs (e.g. Alicke, 2000; Malle et al, 2014). To date, however, notwithstanding some related work inferring poor character from knowledge of noxious mental states (see, e.g. Ames \& Johar, 2009; Gromet et al., 2016), no one has investigated the possibility that people hold each other accountable (i.e., blameworthy) for their immoral beliefs, desires, or emotions. Given that people apparently do attribute agency to others over everyday mental states, and control predicted judgments of responsibility in Study 1, future work should investigate whether these results replicate for immoral mental states, and whether perceived agency predicts blame, anger, and punishment.

To conclude: assumptions about the perceived agency of mental states are common, yet direct empirical investigations are rare. Across several studies, we found that these assumptions fail to track ordinary judgments of the controllability of mental states. Accordingly, our results may have important implications for a range of debates in social and cognitive psychology, and open up new questions about the sources of variation in perceptions of mental control.

# Judgment Before Emotion: <br> People Access Moral Evaluations Faster than Affective States 

Corey Cusimano (cusimano@sas.upenn.edu)<br>Department of Psychology, University of Pennsylvania, 3720 Walnut St Philadelphia, PA 19104 USA

Stuti Thapa Magar (stuti_thapa_magar@brown.edu) and Bertram F. Malle (bfmalle@brown.edu)<br>Department of Cognitive, Linguistic, and Psychological Sciences, Brown University, 190 Thayer Street, Providence, RI 02912 USA

#### Abstract

Theories about the role of emotions in moral cognition make different predictions about the relative speed of moral and affective judgments: those that argue that felt emotions are causal inputs to moral judgments predict that recognition of affective states should precede moral judgments; theories that posit emotional states as the output of moral judgment predict the opposite. Across four studies, using a speeded reaction time task, we found that self-reports of felt emotion were delayed relative to reports of event-directed moral judgments (e.g. badness) and were no faster than persondirected moral judgments (e.g. blame). These results pose a challenge to prominent theories arguing that moral judgments are made on the basis of reflecting on affective states.

Keywords: affect, emotion, moral judgment, reaction time

## Introduction

There is broad agreement that affective phenomena play an important role in moral cognition; there is widespread disagreement, however, over the particular role that affect plays. Many theories suggest that emotion acts as an input to moral judgment: that affective states help distinguish moral from non-moral events (Nichols, 2002), indicate the severity of the transgression (Haidt, 2001), or bias downstream cognitive processes (Alicke, 2000). In contrast to these "emotion-as-input" (em-in) models, "emotion-asoutput" (em-out) models argue that, very often, considerations of rules, norms, risk or caused harm, and causal and mental information, guide moral judgments without any necessary causal precedence of affect (Huebner, Dwyer, \& Hauser, 2009; Mikhail, 2011). According to these models, emotions are typically connected to moral judgments because as they motivate and scale our social responses.

The focus of our paper is on a prominent subset of the emin theories, which claim that emotions precede and influence moral judgment through felt affect. For example, Schnall Haidt, Clore, and Jordan (2008) claim, "When making evaluative judgments, people attend to their own feelings, as if asking themselves: How do I feel about it?" (p. 1097, emphasis added). Similarly, Miller et al (2012) argue that "the likelihood of judging an action wrong is determined... by how upsetting you consider the action itself to be" (p
574). That is, moral judgments of some event are formed by recognizing and reporting one's emotional response to that event. This is why, according to these theories, the experience of negative affect on its own (i.e. absent appraisals of harm or risk) can yield negative moral evaluations (e.g. Haidt, 2001). The primary source of evidence for this comes from affect misattribution experiments in which inducing feelings of disgust (unrelated to the stimulus) both amplified the perceived wrongness of target behaviors (Schnall, et al., 2008; Cheng, Ottati, \& Price, 2013) and appeared to cause ordinarily permissible behaviors to be judged as wrong (Wheatley \& Haidt, 2005).

Though initially promising, many of the findings in favor of the em-in model of moral judgment have been called into question. First, it appears as though many moral judgments can be made absent any affective experience (Niedenthal, Rohmann, \& Dalle, 2003) and, conversely, many strong emotional reactions occur without any corresponding moral judgment (Royzman, Goodwin, \& Leeman, 2011). Additionally, the primary source of evidence for the causal role of felt affect has been called into question: a recent meta-analysis reports that, across dozens of experiments, there is not reliable effect of incidental disgust on moral judgment (Landy \& Goodwin, 2015).

However, even though these findings are consistent with em-out models, a major challenge in assessing any of the theories regarding the role of emotion in moral judgment is the dearth of experimental paradigms that get at the heart of the causal primacy question-whether the routine causal sequence is, according to one set of theories, event $\rightarrow$ emotion $\rightarrow$ moral judgment or, according to the other set of theories, event $\rightarrow$ moral judgment $\rightarrow$ emotion. What is needed are independent and time-locked measurements of the relevant moral and affective processes as they emerge in response to a range of different moral violations.

Because causality implies temporal precedence, we reasoned that if attended emotions cause moral evaluations, then participants ought to experience (and be able to report) certain emotions (such as feeling angry or upset) before being able to judge the moral status of that behavior. In contrast, if moral judgments guide affect or emotions based on perceived norm violations, causal and mental information, and so on, then felt emotions should follow moral judgments.

## Experimental Paradigm

To examine questions of causal primary, we conducted a series of reaction time experiments to test the relative speed of moral, non-moral, and affective reactions to value-laden events. We relied on a variant of the simultaneous inference paradigm (SIP, Smith \& Miller, 1983; Malle \& Holbrook, 2012) to measure the speed at which people make different judgments in response to short descriptions of moral transgressions. In the SIP, participants learn to associate a question with a short cue (or, hereafter, "probe") which is then used to elicit responses in a speeded-judgment task. These probes minimize the latency between the presented question and the participant's comprehension, as well as differences in the length and complexity of full questions.

Prior research using the SIP trained participants on dichotomous Yes-No judgments (e.g. "Did the behavior reveal a certain goal the actor has?"), which required modification for two reasons: First, many moral and affective reactions are graded: stabbing someone is worse than keying their car, which is worse than stealing their pencil. A simple Yes-No judgment does not indicate that someone is sensitive to these differences. Second, and relatedly, a prediction of em-in models is that the extremity of the affective reaction predicts the perceived severity of the transgression (e.g. Miller et al, 2012), which makes the best test of these models one in which both moral and affective judgments require reporting this more specific, nuanced information. To do this, we presented each probe along with a 7 -point rating scale from which participants selected their response as quickly as they could.

We also varied the type of moral scenario participants would react to. Different kinds of events reliably lead to different moral and affective reactions (e.g. people blame transgressors more for intentional harms relative to unintentional ones), and these different outputs are thought to reflect different underlying cognitive processes (Cushman, 2013; Malle et al, 2014). Furthermore, variation in encountered behavior better reflects the experience of encountering random morally relevant behaviors in the real world and generates variation that requires participants' attention. To this end, studies 1-2 mixed intentional and unintentional violations, while studies 3 and 4 mixed intentional, unintentional, and non-agent caused events.

Across four experiments, we measured reaction times for four response types: (1) non-moral judgments (e.g "Intentional?"), (2) moral evaluations of the event (e.g., "Bad?" or "Good?"), (3) moral judgments of the person (e.g., "Blame?"), and (4) reports of one's own affective state (e.g., "Angry?"). As argued above, the em-in models predict that people's responses to the affective probes should be faster than the responses to the moral probes, whereas the em-out models predict the opposite. For the purpose of the current report, we will focus on these a priori contrasts of response times, setting aside the speed of other probes and the specific ratings people provided.

## Study 1

## Methods

Participants. 241 people ( 130 self-reported as female, mean age $=35$ ) recruited from Amazon's Mechanical Turk (AMT) participated in this experiment.

Stimuli. We constructed 24 short descriptions of an agent causing harm either intentionally or unintentionally (e.g. "When she walked by a homeless man asking for money, Lisa spit on the ground in front of him"). Intentionality was verified through pretesting (mean intentionality ratings for intentional and unintentional descriptions were 8.17 and 2.35 respectively on a $1-9$ scale). The 12 intentional and unintentional sentences were matched on length (15.3 and 15.8 words for intentional and unintentional conditions, respectively) and varied in moral severity (valence ratings 1.1 to $-4.0, M=-2.45$, for intentional transgressions, and 0.65 to $-3.88, M=-2.00$ for unintentional transgressions on a -4 to +4 scale).
Judgments. Our non-moral, social judgment probed intentionality (Cue: INTENTIONAL? Full: Was the main character's behavior INTENTIONAL?) on a [1] definitely not intentional to [7] definitely intentional scale. Our eventdirected moral evaluation probed "badness" (Cue: BAD? Full: How BAD was the thing that happened? Scale: [1] not at all bad - [7] the most bad possible), while our persondirected moral judgment probed judgments of blameworthiness (How much BLAME does the main character deserve? Scale: [1] no blame at all - [7] the most blame possible). Finally, to assess participants' affective states, we used a general feeling probe (Cue: FEEL? Full: How much did the story make you FEEL something? Scale: [1] no feeling at all - [7] the most feeling possible).
Design. The study crossed two within-subject factors: behavior type (intentional vs unintentional) and judgment type (INTENTIONAL, BAD, BLAME, FEEL). The 24 experimental stimuli and four judgments types were distributed over participants such that they were probed for each judgment type 6 times, (three for intentional behaviors, three for unintentional behaviors). We used a Latin-square design to pair each of the four judgments with each of the 24 stories across four lists. The order of stimuli and probes was randomized for each participant within each list.

Procedure. The entire experiment was conducted through the participant's web browser. At the beginning of the experiment, participants received instructions, including a description of the cues and their associated meanings, as well as the fact that they would be doing a speededjudgment task and so would have limited time to read and respond to the vignettes. They then completed a training session in which they were taught the single-word cues for the associated judgments (e.g. "BAD?" for "How bad was the thing that happened?").

During the experiment, for each trial, a one-sentence description of a transgression was displayed in the center of
the screen. It remained for 4.5 s and was replaced by the probe and a seven-point rating scale (participants did not know which probe would be displayed for any trial). Participants were instructed to place their fingers on the number row of the keyboard and press the corresponding number to respond. Once they indicated their response, the cue and scale disappeared and the next trial automatically started. At the end of the experiment, participants filled out a brief demographics questionnaire indicating their gender, age, and language background.

## Results

We removed all trials with reaction times greater than 10 seconds ( $0.7 \%$ data loss). Otherwise, no other trials or participants were removed from data analysis.

Following previous studies (Malle \& Holbrook, 2012), we conducted simple effects tests comparing RTs for the affect probe with RTs for other judgment types separately within intentional and within unintentional behaviors. Our primary question was whether reaction times to the affective judgment probe were slower than to other judgment probes. We used linear mixed-effect models (LMEM) to regress RTs on judgment type, which was dummy coded with affective judgment (here, FEEL) as the baseline. Finally, due to the within-subject design, each model included random intercepts and slopes for each participant as well as a random intercept for each scenario.

When judging intentional behaviors, reaction times for FEEL judgments ( $M=2563, S D=1246$ ) were significantly slower compared to INTENTIONAL $(M=2113, S D=985, \mathrm{~b}=$ $-452.52, \mathrm{SE}=62.9, t=-7.19, p<0.001)$, BAD $(M=2332$, $S D=1204, \mathrm{~b}=-233.04, \mathrm{SE}=57.49, t=-4.054, p<0.001)$, and BLAME $(M=2355, S D=1211, \mathrm{~b}=-214.44$, $\mathrm{SE}=$ 55.964, $t=-3.832, p<0.001$ ). However, when judging unintentional transgressions, we observed no significant difference between FEEL ( $M=2640, S D=1267$ ) and INTENTIONAL $(M=2540, S D=1240, \mathrm{~b}=-98.71$, $\mathrm{SE}=$ 59.936, $t=-1.647, p=0.1)$, BAD $(M=2545, S D=1244, \mathrm{~b}=$ -96.17, $\mathrm{SE}=59.09, t=-1.63, p=0.104$ ), or BLAME ( $M=$ 2647, $S D=1339, \mathrm{~b}=13.88, \mathrm{SE}=60.93, t=0.23, p=0.82$ ).

## Discussion

Study 1 provides preliminary support against em-in models in favor of em-out models. Reaction times for the emotion probe FEEL were slower than those for judgments of INTENTIONALITY, BAD, and BLAME, at least when considering intentional norm violations. There were no comparable RT differences between the affect probe and the remaining probes in response to unintentional violations, perhaps because relevant moral rules are more difficult to access, harm more difficult to calculate, or responsibility more complicated to assess (e.g. Malle, et al., 2014).

One possible reason for the slow unfolding of affective reactions is that participants found it difficult to respond to a vague probe such as "feel". To address this possibility, we conducted another experiment using a more concrete easily identifiable and morally relevant emotion probe: angry.

Figure 1: Reaction time (and standard error) for participants' responses to probes in study 1 (A) and 2 (B)

## Study 2

## Methods

Participants, Materials, \& Procedure. 237 people (134 self-reported as female, mean age $=35$ ) recruited from Amazon's Mechanical Turk (AMT) participated in this experiment. Study 2 was identical to Study 1 except that the affective judgment probe assessed anger (Cue: ANGRY? Full: How ANGRY are you at the main character? Scale: [1] not at all angry to [7] the most angry possible).

## Results

Reaction times from Study 2 were analyzed identically to Study 1. Before conducting analyses, we removed all trials with RTs greater than 10s ( $2.8 \%$ data loss). No other data were removed.

Replicating Study 1, we found that, in the intentional condition, INTENTIONAL $(M=2111, S D=1119)$ and BAD ( $M$ $=2133, S D=1091$ ) judgments were both significantly faster than ANGER judgments $(M=2313, S D=1150$; INTENTIONAL: $\mathrm{b}=-203.90, \mathrm{SE}=52.32, t=-3.90, p<0.001$; BAD: $-183.18, \mathrm{SE}=52.90, t=-3.46, p=0.001$ ). We did not observe significant differences between ANGER ( $M=2448$, $S D=1300$ ) and other judgments for unintentional violations
(INTENTIONAL: $M=2358, S D=1189,-88.43, \mathrm{SE}=56.65, t$ $=-1.561, p=0.119$; BAD: $M=2382, S D=1291, \mathrm{~b}=-61.22$, $\mathrm{SE}=59.91, t=-1.02, p=0.307)$. Finally, we detected no significant difference between ANGER and BLAME for either intentional $(M=2231, S D=1214, \mathrm{~b}=-80.41, \mathrm{SE}=52.94, t$ $=-1.52, p=0.129)$ or unintentional $(M=2426, S D=1229$, $\mathrm{b}=-18.10, \mathrm{SE}=55.28, t=-0.33, p=0.743$ ) behaviors (see Figure 1).

## Discussion

Study 2 largely replicated the findings from Study 1. However, both studies are limited in several respects. First, the behaviors were always negative, and the agent in every description always a causer of harm. It is possible under these conditions that moral norms become more salient and accessible or that expectations of high causal agency sped up moral evaluations. Additionally, anger is typically directed at persons, and a different emotion term may be more appropriate for affective reactions to events. Finally, the studies did not limit participants' response time. While most responses occurred within several seconds, it is nevertheless possible that judgments are consciously accessible before then without an incentive to reveal these judgments as soon as they are accessible. The next two studies were designed to address these shortcomings.

## Studies 3 and 4

## Methods

Participants. 111 people ( 58 self-reported as female, mean age $=37.4$ ) in Study 3 and 193 people ( 90 self-reported as female, mean age $=33.4$ ) in Study 4, recruited from AMT participated in this experiment.

Stimuli. We constructed 28 single-sentence descriptions, 14 featuring a good event and 14 featuring a bad event. For each valence condition, we constructed four stimuli that had an agent with no causal role (Non-causal) in the good or bad event, four in which an agent unintentionally did a good or bad thing (Unintentional), and a final six in which an agent intentionally did something good or bad (Intentional). Pretesting ensured that these items were matched on intentionality and length across valence, and that all agency conditions were comparable (see Table 1).

Judgments. We modified the full questions associated with
Table 1: Pretest ratings for stimuli in Studies $3 \& 4$

| Behavior Types |  | Pretest Values |  |  |
| :--- | :--- | :---: | :---: | :---: |
| Valence | Agency | Intentionality | Valence | Words |
| Negative | Intentional | 8.41 | -2.58 | 16.83 |
|  | Unintentional | 2.40 | -2.57 | 16.00 |
|  | Non-causal |  | -2.70 | 13.75 |
| Positive | Intentional | 8.22 | 2.57 | 15.17 |
|  | Unintentional | 2.03 | 2.64 | 18.75 |
|  | Non-causal |  | 2.79 | 12.50 |

each cue to accommodate the greater variety of stimulus events. Similar to Studies 1-2, we included measures of (1) intentionality (Cue: INTENTIONAL? Full: "Was it intentional (what the character did)?" Scale: [1] definitely not intentional - [7] definitely intentional), and (2) the badness of the event (Cue: BAD? Full: "How bad was it (what happened)?" Scale: [1] not at all bad - [7] extremely bad). We also included a measure of (3) the goodness of the event in order to accommodate the positive valence items (Cue: GOOD? Full: "How good was it (what happened)?" Scale: [1] not good at all - [7] extremely good).

Studies 3 and 4 were identical except for the affective judgment probe. Study 3 measured anger (Cue: ANGRY? Full: "How angry were you (about what happened)?" Scale: [1] not at all angry - [7] extremely angry), whereas Study 4 measured "upset" (Cue: UPSET? Full: "How upset were you (about what happened)?" Scale: [1] not upset at all - [7] extremely angry).

Design. Studies 3 and 4 crossed two within-subject factors: event type (non-causal, intentional, and unintentional) and judgment type (INTENTIONAL, BAD, GOOD, and UPSET or ANGRY). The 28 experimental stimuli and four judgment types were distributed over participants in the following pattern: across the 28 items, participants responded to eight INTENTIONAL probes, four for intentional behavior conditions, two for unintentional behavior conditions, and two in the non-caused behavior conditions. This distribution meant that roughly half the probes would results in low intentionality ratings and the other half would result in high intentionality ratings. Affect probes were also distributed this way: four for intentional behavior stimuli, two for unintentional behavior stimuli, and two for non-caused. These probes were evenly divided between valence conditions. Finally, participants saw six BAD probes and six GOOD probes, which were matched to valence. That is, participants made BAD judgments only following negatively-valenced stimuli and GOOD judgments only following positively-valenced stimuli. The twelve moral evaluation probes ( 6 BAD and 6 GOOD) were evenly divided between event type conditions.

Probes were distributed across four stimulus lists according to a Latin-square design. At the beginning of the experiment, participants were randomly assigned to one of the four lists and, during the experiment, the order of the stimulus sentences and probes was randomized.

Procedure. The training and overall experiment procedures were the same as in Studies 1 and 2, with one exceptions: For each trial, the judgment screen containing the cue (e.g. "BAD?") and the rating scale disappeared after five seconds after being displayed. If no response was offered before then, no response was recorded for that trial. Participants were informed of the time restriction in the instructions. Prior to the experiment, participants conducted five practice trials to get accustomed to the procedure.

## Results

We removed all trials in which the participant did not provide an answer within the time constraint ( $1.6 \%$ data loss in Study 3, 3\% data loss in Study 4). No other data were removed. Similar to Studies 1 and 2, we conducted separate analyses on the Intentional, Unintentional, and Non-Causal behaviors, using the same mixed-effect regression models and adding the Valence (positive vs. negative) term, which predicted changes in the dummy variable (affect) as a function of positive or negative behaviors. Across all models in both studies, valence was not significant and did not improve model fit, and so was removed as a predictor.

Figure 2: Reaction time (and standard error) for participants' responses to probes in study 3 (A) and 4 (B)

Intentional Behaviors. In Study 3, moral evaluations were faster than ANGER ( $M=1746, S D=739$; BAD: $M=1601$, $S D=647, \mathrm{~b}=-178.46, \mathrm{SE}=37.35, t=-4.78, p<0.001$; GOOD: $M=1438, S D=645, \mathrm{~b}=-294.32, \mathrm{SE}=38.32, t=-$ 7.68, $p<0.001$ ), while INTENTIONAL ratings were not ( $M=$ 1687, $S D=739, \mathrm{~b}=-57.65, \mathrm{SE}=36.01, t=-1.60, p=$ 0.109). Similarly, in Study 4, intentional ( $M=1656, S D=$ $675)$, BAD $(M=1560, S D=607)$, and GOOD $(M=1456, S D$ $=642$ ) judgments were significantly faster than UPSET ( $M=$ 1822, $S D=682$; INTENTIONAL: $\mathrm{b}=-163.51, \mathrm{SE}=42.7, t=-$ 3.83, $p<0.001$; BAD: $\mathrm{b}=-273.68, \mathrm{SE}=48.50, t=-5.64, p<$ 0.001 ; GOOD: $\mathrm{b}=-366.28, \mathrm{SE}=48.19, t=-7.60, p<0.001$ ).

Unintentional Behaviors. In Study 3, moral evaluations were significantly faster than the ANGER ratings ( $M=1837$,
$S D=714 ;$ BAD: $M=1682, S D=694, \mathrm{~b}=-174.2, \mathrm{SE}=$ 43.07, $t=-4.05, p<0.001$; GOOD: $M=1601, S D=647, \mathrm{~b}=$ -193.3, $\mathrm{SE}=43.86, t=-4.41, p<0.001$ ), while INTENTIONAL was slower ( $M=1932, S D=775, \mathrm{~b}=115.11$, $\mathrm{SE}=41.88, t=2.75, p=0.006$ ). In Study 4, UPSET ( $M=$ 1760, $S D=617$ ) was significantly slower than GOOD ( $M=$ 1603, $S D=624, \mathrm{~b}=-157.62, \mathrm{SE}=53.89, t=-2.93, p=$ 0.003 ), and significantly faster than INTENTIONAL ( $M=$ 1972, $S D=769, \mathrm{~b}=212.92, \mathrm{SE}=53.78, t=3.96, p<$ $0.001)$, but not reliably different from $\operatorname{BAD}(M=1673, S D=$ $686, \mathrm{~b}=-82.75, \mathrm{SE}=53.86, t=-1.54, p=0.124$ ).

Non-Caused Behaviors. Moral evaluations of uncaused good and bad events were significantly faster than the ANGER judgments $(M=1728, S D=653$; BAD: $M=1561$, $S D=611, \mathrm{~b}=-163.31, \mathrm{SE}=38.24, t=-4.27, p<0.001$; GOOD: $M=1335, S D=541, \mathrm{~b}=-390.61, \mathrm{SE}=37.89, t=-$ 10.31, $p<0.001$ ), while INTENTIONAL ratings were slower ( $M=1969, S D=749, \mathrm{~b}=241.79, \mathrm{SE}=39.55, t=6.11, p<$ 0.001). In Study 4, UPSET ( $M=1659, S D=616$ ) was significantly slower than GOOD $(M=1340, S D=505, \mathrm{~b}=-$ 309.67, $\mathrm{SE}=50.41, t=-6.14, p<0.001)$ and $\operatorname{BAD}(M=$ 1556, $S D=639, \mathrm{~b}=-103.24, \mathrm{SE}=50.39, t=-2.05, p=$ $0.04)$, but significantly faster than INTENTIONAL ( $M=1947$, $S D=723, \mathrm{~b}=292.20, \mathrm{SE}=50.56, t=5.78, p<0.001)$.

## Discussion

Results from Studies 3 and 4 replicated our previous findings (see Figure 2): Moral evaluations of intentional violations were reliably faster than reports of felt anger and upsetness. For unintentional violations, reporting feeling upset was not significantly slower than negative moral evaluations, but anger was. Perhaps upset feelings are more globally sensitive to any unfortunate outcome and therefore converge with (but on average do not precede) badness judgments. Lastly, intentionality judgments were slowed in response to unintentional and uncaused events-which is not entirely surprising given that those events are clearly not intentional; the detection of negation may take time.

## General Discussion

Across four experiments, participants were reliably slower at reporting their emotional states in response to norm violations compared to reporting their moral judgments. More specifically, the results from these studies showed a clear speed advantage for event-directed judgments of badness and, often, intentionality judgments. These results fit both with theoretical models of moral judgment arguing that moral appraisals precede emotion, as well as prior work showing that intentionality and norm violation detection can occur extremely quickly (Malle \& Holbrook, 2012; Van Berkum et al, 2009). These findings did not extend to person-directed moral judgments (blame), consistent with theories that blame is more complex than event-directed evaluations (e.g. Cushman, 2013; Malle et al, 2014).

One important limitation of these studies comes from the observation that, while we are interested in characterizing
the cognitive processes underlying moral judgment when people are exposed to a morally relevant stimulus, we measured people's reaction times to probes that were displayed after the stimulus had been shown. It is possible that participants attended to their affective reactions when they were first exposed to the stimulus, which resulted in a moral judgment, which they later more quickly retrieved during the post-stimulus probe. However, while we cannot rule this out, it is not clear why affect would be more difficult to retrieve post-stimulus as opposed to duringstimulus (when one's attention is presumably directed outward toward reading the stimulus). Additionally, this account does not explain why the speed of retrieving affective information would change as a function of the behavior (Study 4). Finally, prior work using a simultaneous inference paradigm found that post-stimulus reaction times directly recapitulated online measures (Malle \& Holbrook, 2012).

Second, affect may have been slower relative to moral and social judgments because of an attention switching cost: the non-affect judgments targeted the stimulus while the affect judgment targeted oneself. Because em-in models explicitly predict a shift in attention from the behavior to one's affective state, a delay in reporting due to switching attention is not, in principle, a confound for our test. That said, this cost may have been exacerbated by the relative balance of event-directed (75\%) versus self-directed (25\%) probes, and future studies should use an even balance of affect and moral judgments.

Finally, even if we accept that felt emotions do occur after explicit moral judgment, our data do not rule out the possibility that pre-conscious affective processes play a role in moral judgment formation (say, by interfering with cognitive processes, Alicke, 2000). It is also possible that conscious affect may play a causal role when judging more ambiguous situations, in which relevant harm or rule information is difficult to access. Consistent with this, badness and blame judgments were not reliably faster than emotion reports when judging accidental bad behavior. Thus, our results may only hold for relatively common or extreme, but not unusual or novel situations.

In summary, we found that people could report moral evaluations of norm-violating events more quickly than their emotional reactions to these events. These results pose a challenge to models claiming that felt affect plays a necessary role in forming moral judgment.

## Acknowledgments

The authors would like to thank Fiery Cushman, John Voiklis, members of the SCSRL and anonymous reviewers for valuable feedback on this project. This research was funded in part by a grant from the Office of Naval Research (ONR), N00014-13-1-0269.

# The Lego hands: changing the affording location of graspable objects 

Da Silva Fabrice (fabrice.da-silva@univ-montp3.fr) \& Brunel Lionel (lionel.brunel@univ-montp3.fr)<br>Epsylon Laboratory, Paul Valéry University, Montpellier, 34190, France

#### Abstract

The present study examined throughout three experiments the nature of stimulus-response compatibility (SRC) effects related to affordance perception in situations wherein object affordances and response effectors are irrelevant to each other. In the first experiment, using a foot-press response dispositive, we found a SRC effect between the orientation of the graspable part of the presented object and the laterality of the response. In Experiment 2a, we showed that constraining the subject hands in a given position (i.e., a Lego hand shape) during the same task interfered with the SRC effect. In Experiment 2b, participants performed a short training phase with their hands constrained before performing the experiment. This resulted in an inversion of the direction of the SRC effect previously observed. We discuss these results and provide arguments in favor of a specific motor activation account.

Keywords: Visual Perception; affordances; categorization; motor constraints

## Introduction

In stimulus-response compatibility (SRC) paradigms related to affordance perception (see Michaels, 1988), participants are usually faster and more accurate to categorize stimuli when the response hand and the presented objects are located on the same side (i.e., compatible) rather than on the lateral opposite side (i.e., incompatible). The present study aimed at disentangling between two alternatives explanations of this specific SRC effect.

## The affordances

Stimulus-response compatibility paradigms were first designed to highlight affordance effects. These affordances were defined as what a given environment offers the animal, what it provides or furnishes in terms of action possibilities (Gibson, 1979). These action possibilities are properties of the subject-environment system and emerge from the relation between an object and a subject (Stoffregen, 2003). For instance, stairs can afford an action of climbing only when their size does not exceed a certain proportion of the riser leg height (Warren, 1984). In SRC paradigms, participants generally performe a perceptual categorization task using a specific motor response. The critical manipulation is the compatibility (or congruence) between the motor response setting and the perceptual configuration of this object. For instance, Tucker and Ellis (1998) showed that participants were faster and more accurate to categorize the orientation (i.e., upright or downright) of daily life graspable objects when object handles and motor responses referred to the same side (i.e., compatible) than when they referred to the opposite side (i.e., incompatible). These results were interpreted as evidences of the affordance
effects. This interpretation was further supported by electrophysiological recording such as analyses of lateralized readiness potentials (LRP) during categorical judgments (Goslin, Dixon, Fischer, Cangelosi, \& Ellis, 2012), or studies about the link between the affordance perception and the dorsal stream activation through transcranial mental stimulations (Buccino, Sato, Cattaneo, Rodà \& Riggio, 2009).

## Specific motor activation versus abstract space coding

Despite the multiplication of experimental works concerning affordance perception for about twenty years, the nature of affordance-related SRC effects is still debated. For Tucker and Ellis (1998), SRC effects were observed because interactions with an object involve a representation about the range of actions that we can perform with and thereby, potentiate them. The nature of these representations was discussed in later works by the same authors including through micro-affordances (e.g. Tucker \& Ellis, 2001). However, other authors provided evidences that an alternative explanation of SRC effects might be considered. (Anderson, Yamagishi, \& Karavia, 2002). These authors interpreted such effects as a consequence of an attentional bias induced by a stimuli perceptual asymmetry (i.e., attention might be oriented to the left or the right depending on the perceptual configuration of the stimulus). This attentional orientation could be responsible for spatialrelated motor activations without requiring the potentiation of action-related properties of an object. This hypothesis is also in line with location-coding theories (e.g., Cho \& Proctor, 2011). In order to disentangle between specific motor activations and abstract location coding as mechanisms responsible for affordance related SRC effects, Phillips and Ward (2002) developed a method wherein a prime graspable object and the orientation of its handle were irrelevant to the participants' task. In this study, the handle of the priming object was oriented to the left or to the right side. Furthermore, the object handle was presented with an apparent depth towards or away from the participant. Participants had to respond to a target that appeared in the center of a computer screen. Authors found a main effect of the handle orientation congruent with common SRC studies but no significant effects involving its apparent depth. Nevertheless, this result could be attributed to methodological issues. Indeed, such proximity-related effects have been reported since (see Fischer \& Dahl, 2007). A more interesting point is that Phillips and Ward (2002) proposed another experiment in which participants had to respond to the same task pressing using foot switches with their left or their right foot. Like in the first experiment,
authors found a significant main effect of correspondence. Therefore, participants were faster to categorize stimuli when both the foot and the handle of the object were localized on the same side. The authors concluded that response facilitation effects arise from an abstract location coding.

However, if observing SRC effects with feet during the presentation of graspable objects seem to be inconsistent with the motor specific activations account, this is not sufficient to reject it. Indeed, grasping an object does not imply a single hand gesture but a more global engagement of the body. It is unclear in what extend the body is engaged during the perception of graspable objects and further investigations are necessary to question the implications of such generalized activations. Therefore, finding SRC effects while the response effector (i.e., the foot) and the action associated with the presented object (i.e., hand use) are seemly not directly related is not sufficient to conclude that no specific motor activations occurred.

## The current study

In the present study, we aimed at showing that motor activations could constitute the core mechanism of SRC effects. For this purpose, we conducted three experiments in which subjects had to categorize a common graspable object with foot-press responses. The experimental design was similar to the one used by Tucker and Ellis (1998) and consisted in a classical SRC paradigm. In the three experiments, participants had to categorize with their feet the orientation (i.e., upright or inverted) of a common mug displayed on a computer screen. In the first experiment, they responded while keeping their hands placed on the table in front of them. In the second experiment, participants were wearing gloves during the task, constraining their hands in an opened position (i.e., such as the Lego hand shape). Finally, in a third experiment, a last group responded while wearing the same gloves but after performing a short training phase.

## Experiment 1

The aim of this experiment was to replicate the SRC effects observed in Tucker and Ellis (1998) tasks using Phillips and Ward (2002) response setting.

## Method

Participants Twenty undergraduates students (17 women) from Paul Valéry Montpellier University aged from 18 to 36 years old ( $M=23.1, S D=4.72$ ) took part to this experiment and received course credits. All had normal or corrected to normal vision and were naïve to the purpose of the study. The experiment was realized in accordance with the Code of Ethics of the World Medical Association (Declaration of Helsinki).

Apparatus and materials The experiment was performed using E-Prime 2 software (Schneider, Eschman, \&

Zuccolotto, 2002). The visual material consisted of pictures of a common mug disposed sideway on a white background and centered on the display. The mug dimensions were 340 x 320 pixels. All pictures were realized using the software Maya 16.0 (Palamar, 2014). The orientation of the initial picture was manipulated to produce two horizontal and two vertical orientations of the mug. Additionally, a second filler picture was presented in order to increase the difficulty of the task. The two stimuli are depicted in Figure 1.

Figure 1: The two visual stimuli used in all our experiments (in one orientation condition). The right panel object acted as a filler object.

As with the realistic mug, we reoriented the original picture of the filler object to produce four final pictures. The depicted objects were presented with an apparent size similar to their real size which is about 11 cm high and 7.5 cm wide and the participants performed the task at a distance of 45 cm from the screen and a visual angle of about $15^{\circ}$. All results associated with the filler object were not included into the analyses. Each of the eight pictures was presented ten times in the experiment so that a participant responded to an overall of 80 trials presented randomly. Trials wherein the object was presented with its handle oriented on the same side that the response effector were considered as compatible and incompatible when it was the reverse situation.

Procedure After filling out a consent form, participants sat in front of a computer and were asked to rest their hands on the table in front of them and their foots above the pedals. Then, they were asked to perform a forced choice categorization task on a computer by pressing a left or a right switch of a pedalboard. They had to determine as fast as possible if the displayed objects were disposed upright or inverted. Each pedal was attributed to a response category. This attribution was counterbalanced for the half of the sample. Each picture was displayed until the response and preceded by a fixation point which remained on the screen during 200 milliseconds.

## Results

First, we observed that participants have accurately performed the categorization task (less than $5 \%$ of error rate). Thus, we only considered latencies for analysis. We
excluded RTs above 1250 milliseconds (This cut-off led to the exclusion of $11.37 \%$ of trials). Thus, We performed a RT analysis between Compatible and Incompatible situations for responses exclusively related to the realistic mug pictures. Mean response times for the Compatible situations ( $M=713 \mathrm{~ms}, S D=76.77 \mathrm{~ms}$ ) were faster than mean response times for the Incompatible situations ( $M=$ $750 \mathrm{~ms}, S D=93 \mathrm{~ms}$ ). Using a bilateral paired t-test, we found that this difference was significant, $t(19)=2.55, p<$ $.05, d=.43$.

## Discussion

The results clearly demonstrated a SRC effect. Indeed the participants were faster to categorize objects when their graspable part was oriented on the same side as the response effector rather than the opposite side. With the same pattern of results, Phillips and Ward (2002) concluded that such facilitation effects had to be consecutive to an attentional shift and could not be associated with premotor activations. This conclusion is congruent with the fact that the graspable part of objects like the mug we used constitutes a visual protrusion that could capture the subject attention. Furthermore, a foot-press response seems to be not related to the perception of the affordance of the mug. However, to conclude that facilitation effects emerging from unsuited limb responses are not related to specific motor activations, this experimental design is insufficient. Indeed, contrary to the experimental context, the tool use in daily life implies a more global generation of movements and might involve that perception of graspable objects potentiate a higher range of muscles that the hand or even the arm. If the affordance theory is unclear to specify such implications, it is necessary to control the hand disposition during this kind of tasks for rejecting this motor hypothesis. If such of a hand constraint results in an alteration of facilitation effects as those observed in the experiment 1 , this would constitute evidence that such response facilitations are dependent on the subject action possibilities.

## Experiment 2a

In this experiment, we aimed at constraining subject hands to a certain position which is incompatible with the usual grasp of the object used in Experiment 1. The gloves used in this experiment were conceived to induce a large grasping position incompatible with the handle of the mug. If SRC effects such as the ones revealed by Tucker and Ellis (1998, 2001) or Phillips and Ward (2002) arise well from an abstract representational coding, this manipulation should not impact the effect. On the contrary, if the previous effect is a consequence of perceived affordances traduced by more general potentiations, wearing gloves inducing a particular grasp should invert the stimulus-response compatibility effect in the direction of the tank of the mug. This is precisely our hypothesis: considering that a large hand position is fitter with the manipulation of the tank of the mug and not anymore with its handle, the effects will be
inverted regarding Experiment 1 and the incompatible situation should be facilitating for the subjects.

## Method

Participants Twenty undergraduate students (19 women) from Paul Valéry Montpellier University aged from 18 to 41 years old $(M=22.45, S D=6.15)$ took part to this experiment and received course credits. All had normal or corrected to normal vision and were naïve to the purpose of the study. Among them, four left-handed were distributed into the two groups.

Apparatus and Materials The experimental setup and the materials remained the same as Experiment 1. The only change in the experimental design was that participants had this time to wear specific gloves. We constructed these gloves with Plaster bands in such a way that the participant's hands adopt the form of a large grasping position (i.e., a necessary position to grasp a mug by its tank).

Procedure The instructions were the same as Experiment 1. Nevertheless, participants were asked to wear the gloves and to place their hands on the table in front of them before beginning the experiment. Their hands were placed shoulder-width apart and with palms facing inward. Once the participants felt comfortable with the gloves and the pedalboard, they could begin the experiment.

## Results

Response errors accounted for $4.62 \%$ of the total of trials. There were no significant differences between error rates in compatible and incompatible situations. As in experiment 1, all response times exceeding 1250 milliseconds were removed from the analysis. Theses exclusions represented $17 \%$ of trials. The response time analysis between Compatible and Incompatible situations showed not statistically significant differences ( $p>.05$ ).

## Discussion

Apart from the fact that participants were wearing constraining gloves inducing a large grasp shape during the task, the second experiment was identical to experiment 1. This single difference has seemly altered the results in the way that there was no significant SRC effect anymore. However, contrary to our hypothesis, the hand constraint did not reverse the result's pattern but seemed to have interfered with the previous effect. This interference could represent an argument which is not in favor of the abstract coding. Indeed, if facilitation effects arise from an abstract spatial coding, there is no rational that a change applied to subject hands during foot-press responses impacts the facilitation effect. Nevertheless, this null result cannot be fully interpreted as it stands and there is a doubt as to whether the gloves acted on subjects. While the purpose of the gloves was to potentiate a large grasping position and thus promote
a facilitation effect directed toward the location of the mug tank, they may have been perceived by the subjects as a simple immobilization.

## Experiment 2b

Experiment 2a showed that a constraint applied to subject hands during a categorization task with foot-press responses seems to have significantly altered the facilitation effect previously observed in Experiment 1. It is unclear that this was due to a simple interference or to a conflict between a specific motor activation of the feet on one side and of another activation of hands on the other side. This could stem for an insufficient subject integration of the gloves possibilities. Indeed, in Experiment 2a, no rationales about the glove shaped were given to participants. Thus, in the present experiment, we proposed to new participants to perform a five minutes training in which they had to move a real mug along several drawn points on a sheet while wearing the gloves. The purpose of this training was to strengthen the potential disposition to grasp the mug tank with hands during the task. Our hypothesis is that a better integration of the grasping possibility of the gloves will produce a facilitation effect in favor of the side of the mug tank and thus, will facilitate incompatible responses regarding the handle location.

## Method

Participants A new sample of twenty undergraduate students (12 women) from Paul Valéry Montpellier University aged from 17 to 29 years old $(M=21.5, S D=$ 4.32) took part to this experiment and received course credits. All had normal or corrected to normal vision and were naïve to the purpose of the study. Among them, two left-handed were distributed into the two groups.

Apparatus and materials The experiment itself remained unchanged. The participants were preforming the same task while wearing the same gloves that in Experiment 2a. The difference was that they had to perform a training phase during which they had to move a real mug (with the same appearance that the one modelised for the experiment) on a sheet plotted course. The plotted course consisted in nine drawn circles. These circles were numbered from 1 to 9 . To ensure that participants remain focused during this phase, the mug was filled with water.

Procedure To perform the training phase, participants manipulated the mug while wearing the gloves (see Figure 2 ). They were told to move the filled mug circles by circles in the ascending and then in the descending order on the sheet with the left hand and after that, with the right hand. They had to put down the mug on each circle before moving on the next one. This course was repeated two times. Regarding the shape of the gloves, the participants were obliged to grasp the mug by its tank. No instructions were given concerning the better way to grasp the mug in this situation. The participants spontaneously grasped it by the
tank and performed the training without dropping the mug. After this training phase, they performed the same categorization task than the one proposed in the two previous experiments.

Figure 2: Plotted course for the training phase

## Results

Response errors accounted for $6.25 \%$ of the total of trials. There were no significant differences between error rates in compatible and incompatible situations. Response times exceeding 1250 milliseconds were excluded and represented also $6.25 \%$ of trials. Regarding the compatibility between response feet and handle locations, mean responses for the Incompatible situations ( $M=686 \mathrm{~ms} .14, S D=111.44 \mathrm{~ms}$ ) were faster than mean responses for the Compatible situations ( $M=713.66 \mathrm{~ms}, S D=126.76 \mathrm{~ms}$ ). A dependent t test revealed that the difference was statistically significant, $t(19)=2.64, p<.02, d=.23$. This pattern was therefore the reverse than the one observed in Experiment 1 (see Table 1).

Table 1: Summary of the chronometric results in milliseconds (with the standard deviations in parentheses) and associated $p$-values for the three experiments

|  | Compatible | Incompatible | $p$ |
| :--- | :--- | :--- | ---: |
| Experiment 1 | $713(76.77)$ | $749.96(93)$ | .02 |
| Experiment 2a | $766.41(105.80)$ | $786.73(127.22)$ | n.s. |
| Experiment 2b | $713.66(126.76)$ | $686.14(111.44)$ | .01 |

Complementary analysis We calculated the mean effect size differences between Compatible and Incompatible situations by subtracting the mean response times related to the Incompatible situation from the ones related to the Compatible situation for each subject and for each experiment. This allowed us to produce a value for each subject (i.e. positive if he was faster to respond in Compatible situations and negative if he was slower) and the size of this difference (see Figure 3). Regrouping those values for each experimental condition, we conducted a oneway between subjects ANOVA to compare the effect of

Experiments 1, 2 a and 2 b on mean effect size differences. There was a significant effect of the Experimental Conditions on subject Response times for the three conditions, $F(2,57)=7.42, p<.002, \eta_{\mathrm{p}}^{2}=.21$.

Post hoc comparisons using the Tukey HSD test indicated that the mean effect size for the Experiment 1 condition ( $M$ $=36.93, S D=64.62$ ) was significantly different than the one of the Experiment 2 b condition $(M=-27.51, S D=$ 46.54). The test indicated too that the mean effect size of the Experiment 2 a condition ( $M=20.32, S D=52.07$ ) was significantly different than the one of the Experiment 2b condition. However, the mean effect size of the Experiment 1 condition did not significantly differ from the one of the Experiment 2a.

Finally, considering that in the three experiments, our samples were quite inhomogeneous with respect to age, we performed the same analysis while excluding subjects older than 30 years. The results stayed unchanged.

Figure 3: Mean effect size differences (in milliseconds) as a function of the experimental conditions. Errors bars depict standard deviations.

## General Discussion

In Experiment 2b, subjects manipulated a real mug with constraining gloves before performing the categorization task. The only way to proceed was to grasp the mug by its tank and not by its handle which is in accordance with the purpose of the shape applied to the gloves. Results showed that a facilitation effect emerged from the incompatible situation regarding the classic stimulus-response compatibility paradigms. Thus, the training seems to have strengthened a potential reach to grasp gesture oriented to the mug tank and facilitated subsequent categorizations in situations wherein the responses and the mug tank were on the same side.

Taken together, the results suggest that facilitation effects observed in stimulus-response compatibility paradigms could well arise from specific motor activations instead of abstract coding like Philipps and Ward (2002) suggested it. Indeed, if the results observed in Experiment 1 were due to a representational abstract coding, no differences would be found applying a hand constraint during foot-press responses. Yet, in experiment 2 a , the effect was still in the
right direction but this time, it was not significant suggesting an interference in the subject disposition to respond. Furthermore, a real manipulation of a mug with a specific constraint inverted the location of the effect in Experiment 2b. This implies that the manipulation seems to have led to a sensorimotor integration changing the location of the potentiating part of the object. This result is also particularly interesting because it seems that no rationales can be found in the attentional shift hypothesis. Indeed, in all of our experiments, the stimulus stayed unchanged and hence, the perceptual asymmetry cannot be taken as the origin of these results.

Nevertheless, an alternative explanation could be as well proposed. Indeed, due to the manipulation phase, participants may have learnt to pay attention to the tank of the mug which could conduct to an attentional shift in the direction of this one. For further investigations, it would be interesting to expound on this by proposing a new experiment in which participants would realize the training but then, take off the gloves for the SRC experiment. This design should allow knowing if the results of the Experiment 2 a and 2 b are due to the wearing of the gloves or by sensorimotor integrations.

Regarding this possibility and considering that only a short training impacted the SRC effect directions. It is nevertheless possible that such attention-related effects be rooted in a sensorimotor process. For instance, a possible explanation could emerge if we replace our results within the framework of the premotor theory of attention (see Craighero, Fadiga, Rizzolatti \& Umiltà, 1999). According to this theory, orienting of attention implies an activation of basic circuits associated with the action goal. Therefore, the results of the Experiments 2 a and 2 b could arise from an attentional effect determined by the motor preparation induced by the training phase. This interpretation is in phase with both the specific motor activation account and the general ecological approach to perception. In this context, attentional shifts could be consecutive to premotor activations and be constitutive parts of the action-perception coupling.

In conclusion, the present study represents a further argument in favor of specific motor activations during perception of graspable objects. Nevertheless, it carries also some questions about its results and further works will be necessary to investigate such SRC modulation effects. More broadly, it underscores some imprecisions about the original propositions made by Gibson (1979). For instance, how a specific affordance can be perceived instead of another and how much the physical disposition to act in a given time impacts the subject's tendency to perceive them.

## Acknowledgments

Authors want to thank Jean-François Loisel for his help to design the visual stimuli used in this study.

# People toss coins with more vigor when the stakes are higher 

Gregory L. Dam (gdam@iue.edu)<br>Department of Psychology, Indiana University East<br>2325 Chester Blvd., Richmond, Indiana, 47374, USA.

#### Abstract

We trust that the uncertainty regarding the outcome of a coin toss makes it a fair procedure for making a decision. Small differences in the force used to toss a coin should not affect this uncertainty. However, the voluntary movement involved in tossing a coin is subject to motivational influences arising from the anticipation of the value of the outcome of the toss. Presented here are measurements of hand velocities during coin tossing when the outcomes entail monetary gains and losses. Finger position measurements show that hand velocities are proportional to the amount of money at stake. Coin toss movements are faster and larger for higher stakes than for smaller monetary stakes.

Keywords: motor control, decision-making, affect, behavioral economics

## Introduction

Animals move faster to acquire larger rewards than to acquire smaller rewards (Kawagoe, Takikawa and Hikosaka, 1998; Choi, Pavan and Shadmehr, 2014). Delays in acquiring a reward decrease the probability of being successful and, since future rewards are temporally discounted, they may also decrease the subjective value of the reward. It has been demonstrated that the vigor of a movement, which is overtly expressed as the reaction time and velocity of the movement, are influenced by motivation effects arising from the cost or value of the outcome (Turner and Desmurget, 2010). For example, people show faster eye saccades when they are in more rewarding environments (Haith, Reppert \& Shadmehr, 2012) and monkeys make faster arm movement to higher reward targets (Opris, Lebedev \& Nelson, 2011). It is hypothesized that the purpose of the larger vigor observed in movements for greater rewards is to increase the probability of success and decrease the time to acquire the reward (Choi, Pavan and Shadmehr, 2014; Turner and Desmurget, 2010; Guitart-Masip, Duzel, Dolan \& Dayan, 2014). An open question is whether this vigor effect would be observed even when it is independent of the movement outcome. Such as in situations where changes in movement vigor do not influence the probability or timing of reward acquisition. For example, when tossing a coin for a monetary wager.

Coin tosses are used in sporting events such as cricket and American football to determine which team goes first. They are even used to settle the results of tied mayoral races in accordance with the law of many US states. When a game of chance is used to make a decision, the assumption is that there is sufficient uncertainty about the outcome to make the procedure fair. Even though coin tosses are the textbook example of uncertainty, coin tosses are entirely deterministic
physical processes. The coin trajectory can be predicted from initial conditions with Newton's laws of motion and Euler's equation for rigid body dynamics. However, small differences in the initial velocity and spin of the coin result in different outcomes. Mahadevan and Yong (2011) performed a phase space analysis of the probability distributions of coin outcomes as function of initial spin and vertical speed. The analysis reveals a high sensitivity of the coin's outcome to its initial spin and vertical velocity. We can assume that most coin flippers have no knowledge of how initial toss conditions map onto outcomes. Stewart (2014) suggested that perhaps the precision of human hand control is not accurate enough to reliably affect the outcome given the thin alternating regions in the phase space between heads and tails. Perhaps the smallest possible motor error in voluntary movement to toss a coin is spread across two or more outcome distributions in the phase space. Considering this possibility, one might conclude that the coin toss procedure itself is deterministic, but the initial conditions are random. Therefore, coin tossing is a special case where the movement vigor is independent of the outcome.

The outcomes of bodily movements produce the substantive consequences of behavior. It is therefore not surprising that organisms have adapted to perform movements precisely and efficiently. The escape vectors of cockroaches (Domenici, Blagburn \& Bacon, 2008), the foraging paths of bees (Reynolds et al., 2007) and the reaching arm movements of humans (Flash \& Hogan, 1985) all demonstrate optimal or near optimal movement performance. Experimental measures of human movement performance are predicted well by mathematically optimal models of movement behavior (Körding and Wolpert, 2006; Todorov and Jordan, 2002; Dam and Körding, 2009).

The success of optimal models for understanding movement stands in contrast to the descriptive models used to understand human judgment and decision-making. People demonstrate a variety of persistent and systematic biases in many domains of decision-making. A large body of research has shown that people are particularly prone to error during economic decisions. For example, in many situations people are loss averse, where they are about twice as unhappy with a monetary loss than they are happy with an equal magnitude monetary gain (Kahneman and Tversky, 1979). This leads to errors in decision making, such as a greater willingness to take a risk when potential losses are looming than when there is an equal potential gain to be had. Deviations from normative models have been traditionally attributed to distortions of judgments of value and probability made by the decision maker. Interestingly, the irrational distortions
observed in economic decision tasks are only partially present in mathematically equivalent motor tasks and demonstrate qualitatively different judgements of probability (Wu, Delgado and Maloney, 2009). This suggests that decision makers use information about the outcome value and probability differently when making economic decisions than when making motor decisions.

Tossing a coin for a monetary stake combines a voluntary movement with a cognitive evaluation of the outcome. For a person that has learned the motor skill of coin tossing, the movement is simple and involves little effort or deliberate planning. The hypothesis here is that the vigor of coin tosses will be affected by both the amount and valence (loss or gain) of the outcome. Specifically, the prediction is that the velocity and size of the coin tossing movements would be larger when the monetary stakes where higher. Additionally, considering loss aversion, movement velocities should be roughly twice a high when tossing a coin for a potential loss than for a potential gain of equal value.

Figure 1: An illustration of the coin toss movement made by participants during the experiment. Tosses were made with the coin placed on the back of the hand in a palm down position. This procedure for coin tossing increased the accuracy of measurements of hand velocities by allowing the tracking of individual finger tips.

## Method

## Participants

The experimental protocol was approved in accordance with Indiana University's policy statement on the use of human participants. Informed consent was obtained from fifty righthanded participants ( 21 male, 29 female). Participants were compensated a $\$ 5$ stipend prior to beginning the experiment. In addition to this stipend, participants were compensated according to the outcomes of the coins tosses as described below.

## Design

Each participant tossed a standard US quarter dollar coin with their dominant hand. The hand movements of the toss were
performed above an instrument designed to measured finger and hand position. There were six conditions resulting from a 2 (valence of outcome: loss or gain) X 3 (amount: 10ф or $25 \phi$ or $\$ 1$ ) factorial within-subjects design. The dependent variable was the vertical velocity of the right hand during the coin tossing movement.

## Materials

A Leap Motion Controller was used to measure hand movements during the experiment. The controller uses three infrared LED emitters and two cameras to track finger and hand position, directions of movement and velocities. The device's resolution is below 0.78 mm of movement (Oliveira \& Andrade, 2015). The cameras capture more than 290 frames a second from which position, velocity and direction of movement are computed to provide a sampling rate of 145 Hz .

## Procedure

The experiment was designed to measure whether the stakes of a coin toss would influence how the coin is tossed. At the beginning of each trial participants placed a quarter on the back of their dominant hand near the fingernails while standing. Participants were instructed to position their dominant arm with their elbow bent at 90 degrees and with their hand extended in the pronated position (palm down). The device was attached to a tripod that was adjustable vertically in height and placed 5 cm below the hand so that the tossing movement would take place within its effective workspace. This was done to assure accurate measures of hand position.

Figure 1 illustrates how the coin tosses were performed. Participants tossed the coin by accelerating it vertically into the air and then allowing the coin to bounce on the floor. The result was read from the coin as it lay on the floor. Each participant performed 30 coin tosses. Altogether 1378 coin tosses were measured from 1500 trials. The missing trials are due to participants performing the movement outside the device's effective workspace. Although some participants had a higher tendency to perform the toss outside of the devices' effective range, the missing trials are randomly distributed across conditions with $23,24,31,16,24$ and 34 trials missing data from conditions $+10 \phi,-10 \phi,+25 \phi,-25 \phi$, $+\$ 1$, and -\$1 respectively

During each trial the outcome of a single coin flip determined a monetary gain or loss to the participant. Half of the trials were gain conditions, where the participant stood to make money contingent on the outcome of the coin toss. During the other 15 trials, participants faced a potential monetary loss. The outcomes of all coin tosses were added to determine the total stipend for participation with a mean stipend of $\$ 5.67$ ranging from $\$ 5$ to $\$ 9.20$. The presentation of trial condition was randomized and fully balanced with

Figure 2: Hand velocities during three coin tosses. The two graph panels labeled 'typical toss' were chosen to represent the most common coin toss velocity profiles. The third panel labeled 'atypical toss' includes a pre-toss preparatory movement. Such pre-movement artifacts were excluded from the statistical analysis by using the maximum velocity as a measure of coin toss velocity.
each condition appearing exactly 5 times during the experiment.
At the beginning of each trial, the participant was informed of the trial condition by text that appeared on a 21 ' computer screen at a distance of 32 cm from their face. For example, the text: "If you lose this coin flip, you will lose $\$ 1$ " would appear during the $-\$ 1$ trial conditions. Additionally, the text was read aloud by the experimenter prior to commencing the coin toss movement. Before each toss movement, the participant called the toss, choosing either 'heads' or 'tails' by pressing the corresponding key ' H ' or ' T ' on a computer keyboard. If the coin landed heads up and the participant called heads, then the toss was regarded as a win. If the coin result did not match the call, the coin toss was regarded a loss. During gain conditions $(+10 \phi,+25 \phi$ or $+\$ 1)$, if the coin toss was won, the monetary amount at stake was added to the total stipend. If the outcome didn't match the call, the stipend remained unchanged. During loss conditions ( $-10 \phi,-25 \phi$ and $-\$ 1$ ), participants stood to lose the monetary amount if the toss was lost, or leave the stipend unchanged in the case of a match in outcome and call.

The current total monetary stipend amount was displayed on the screen and updated after each coin toss. If the total stipend at the completion of 30 coin tosses was higher than $\$ 5$, then participants were paid the difference in cash before completing the experiment. On the other hand, if participants finished with a total amount less than $\$ 5$, they were allowed to keep the $\$ 5$ show-up stipend. This was done to ensure that participants were not penalized for the outcomes of their tosses. On average, participants received $\$ 5.42$ ( $\mathrm{SD}=1.51$ ).

Economic decision making is often studied by measuring preferences between two or more lottery choices (Kahneman and Tversky, 1979). A lottery is a probability of obtaining an outcome that has an explicit value and can be expressed with the notation: [probability(outcome); value(outcome)]. For example, consider which lottery you would prefer: (a) five dollars for sure, or (b) a $50 \%$ chance of winning ten dollars and nothing otherwise. This choice between lottery can be
expressed as a choice between $(1, \$ 5)$ or $(0.5, \$ 10 ; 0.5,0)$, and most people prefer the sure outcome although according to rational choice theory we should be indifferent to the choice. Physically flipping a coin to decide an outcome is analogous to having selected a single lottery choice. If we assume that the procedure used for the coin toss is fair, then the probability will approach 0.5 as the number of tosses increases. For example, if a person cares about the outcome of a coin toss during the beginning of a sporting event, the coin toss lottery can be expressed as ( 0.5 , my team gets the ball; 0.5 , the other team gets the ball). How people value different prospects can be estimated by their preferences in lottery selections. The assumption in the current experiment is that the utility assigned to the potential outcome of the coin toss is reflected in the manner in which the movement is made.

## Data collection and measures

Position and velocity measurements were collected for 10 seconds after the participant called the toss and indicated that they were going to make the movement. The average duration of the coin tossing movement for all participants across all conditions was 157.37 milliseconds ( $\mathrm{SD}=65.94$ ), providing an average of 22.81 position measurements per movement. Since the instrument's measurements of fingertip positions are more accurate than for palm position, participants performed tosses with their palm down which allowed for the independent tracking of an average of 3.87 fingertips ( $\mathrm{SD}=$ 1.23 ) on each toss. The vertical velocity of the hand was calculated as the mean vertical velocity of all fingertip positions captured by the cameras during the toss.

## Results

Figure 3 shows mean hand velocities as a function of time with $95 \%$ confidence intervals. The mean hand velocity profiles are similar in shape to typical toss movements. However, hand movements in preparation for the toss are

Figure 3: Mean hand velocities with $95 \%$ CIs across participants as a function of time. The six conditions are collapsed by amount into three groups: $\pm 10 \phi, \pm 25 \phi$ and $\pm \$ 1$.
included in the analysis. In order to quantify the velocity of individual coin tosses, the maximum vertical velocity of the hand was computed for each toss. Analyses using maximum acceleration and integrated velocity across the entire movement produced similar results to those described below.

Overall, the tossing movement is highly conserved across participants as is evident in the aligned and averaged coin tosses displayed in Figure 3. However, there is systematic variance in toss velocities evident in the tendency by some participants to consistently toss the coin with more or less vigor than the average participant.

Figure 4: Mean maximum hand velocities with $1 \pm$ SEM bars for all six toss conditions.

Maximum hand velocities were analyzed using linear mixed-effects regression (LMER) with the lme4 package in R (Bates, Maechler, Bolker \& Walker, 2013). LMER allows for the controlling of random factors, such as the systematic
variability in toss force between participants. The monetary amounts at stake for each toss were modeled as fixed effects. A main positive effect of monetary value on hand velocities was observed, $F(1,1297)=3.82, \mathrm{p}=0.022$. Figure 4 shows the mean maximum velocity $\pm 1$ SEM for all six conditions ordered so that an effect of loss aversion is visible. However, the effect of valence (gain or loss) on hand velocity was not significant, $F(1,1297)=2.15, \mathrm{p}=0.14$. The interaction effect was non-significant, $F(1,1297)=0.35, p>.55$.
The mean maximum hand velocities for the $\pm 10 \phi, \pm 25 \phi$ and $\pm \$ 1$ conditions were $1463.17,1482.23$ and $1603.01 \mathrm{~mm} / \mathrm{sec}$ with $95 \%$ CIs [1335.44, 1590.71], [1090.95, 1873.56] and [906.69, 2299.48] respectively. The Cohen's $d$ effect sizes for monetary amount on maximum movement velocity were $d=$ 0.022 , for the difference between $\pm 10 \phi$ and $\pm 25 \phi$ conditions, $d=0.13$, for the difference between $25 \phi$ and $\pm \$ 1$ conditions, and $d=0.15$ for the difference between the $\pm 10 \phi$ and $\pm \$ 1$ conditions. Overall, the money at stake explains less than $8 \%$ of the variance in the maximum velocity of hand movements.

## Discussion

This study was designed to investigate the effects of the anticipation of monetary outcomes on the movements for coin tossing a coin. As hypothesized, larger monetary stakes resulted in higher velocities of the hand during coin flipping. Prospect theory predicts that people are often twice as sensitive to monetary losses than to equal magnitude gains. In the context of coin tossing for a potential loss, prospect theory predicts twice as large an effect of outcome valence than outcome magnitude on movement velocity. This prediction was not observed. One possibility is that the current experiment may lack sufficient statistical power to demonstrate a loss aversion effect on coin tossing movements. However, the results suggest that the hypothesized effect is much smaller than predicted by the results from traditional behavioral economics experiments (Kahneman, Knetsch and Thaler, 1990). Previous studies
have demonstrated that voluntary movements are not subject to distortions of value to the same degree as financial decisions as predicted by prospect theory, but are instead more subject to distortions of judgments of probability ( Wu , Delgado and Maloney, 2009). Evidence from the current experiment provides further evidence that simple movements are not influenced by the same mechanisms that are involved in making explicit financial decisions.

An impressive analysis of over 2.5 million golf putts of professional golfers at PGA golfing championships demonstrated that golfers putt more accurately when they are behind than when they are leading (Pope and Schweitzer, 2011). The analysis of laser measured golf putts revealed that golfers are more likely to make a shot when they are in a loss frame (i.e. a par putt) than when they are in a gain frame (i.e. a birdie putt). Unlike coin flipping, golf putting is a complex skill that is made possible by a variety of cognitive functions such as attention to task, planning, and explicit decisions about the movement. Pope and Schweitzer (2011) suggested that golfers deliberately consider that hitting the ball too softly may decrease the probability of a success, but nearly guarantee good placement for the subsequent putt, a desired position if one is ahead putting for birdie, but not desired if one is behind putting for bogey. These explicit forecasts of potential outcomes are subject to influences from the current and predicted affective states of the golfer (Kermer, DriverLinn, Wilson \& Gilbert, 2006). However, it is reasonable to assume that no such deliberate movement planning occurs during coin tossing.

Russell (1980) proposed a two-dimensional circumplex model of emotion where emotions are classified according to arousal and valence. Applying this model to the current experiment, the monetary value of the outcome corresponds to the arousal associated with the outcome. Valence corresponds to whether the outcome is a loss or a gain. A large body of research on approach-avoidance motor behavior has shown an effect of emotional valence on the automatic activation of movements (Markman \& Brendl, 2005; Lavender and Hommel, 2007 Maxwell \& Davidson, 2007). Research has shown that reaction times are quickest for approach movements towards positive stimuli (i.e. high valence) and for avoidance movements away from negative stimuli (i.e. low valence). In these studies, images are most often used to elicit emotions rather than money.

Experimentally manipulating both valence and arousal with image stimuli is difficult, because images that are rated as low valence are typically, if not exclusively, also rated as high arousal. For example, there are no images or sounds rated as low valence and low arousal in the over 1200 stimuli available in International Affective Systems (IAPS and IADS). It remains a possibility that arousal ratings of emotional stimuli may have a larger effect on approachavoidance movement response times and force than do valence ratings.

The experiment presented here was designed to independently measure the effects of monetary amount and valence on the velocity of coin tossing movements. The
results show that the magnitude of the outcome has a small effect on movement vigor. However contrary to prospect theory's prediction, the valence of the outcome has little or no additional effect on the coin tossing movement. This provides further evidence that outcome value is assessed differently during movement planning than during financial decision-making.

# Perspective-Taking in Referential Communication: Does Stimulated Attention to Addressee's Perspective Influence Speakers' Reference Production? 

Debby Damen (d.j.damen@uvt.nl), Per van der Wijst (per.vanderwijst @uvt.nl), Marije van Amelsvoort (m.a.a.vanamelsvoort@uvt.nl), Emiel Krahmer (e.j.krahmer@uvt.nl)

#### Abstract

We investigated whether speakers' referential communication benefits from an explicit focus on addressees' perspective. Dyads took part in a referential communication game and were allocated to one of three experimental settings. Each of these settings elicited a different perspective mindset (none, selffocus, other-focus). In the two perspective settings, speakers were explicitly instructed to regard their addressee's (otherfocus) or their own (self-focus) perspective before construing their referential message. Results indicated that eliciting speakers' self- versus other-focus did not influence their reference production. We did find that speakers with an elicited egocentric perspective reported a higher perspective-taking tendency than speakers in the other two settings. This tendency correlated with actual referring behavior during the game, indicating that speakers who reported a high perspective-taking tendency were less likely to make egocentric errors such as leaking information privileged to speakers themselves. These findings are explained using the objective self-awareness theory.

Keywords: perspective-taking; referential communication; egocentricity bias; privileged information.

## Introduction

Engaging in successful referential communication implies that addressees are able to select the intended referent on the basis of speakers' descriptions. For this, speakers are expected to design their message optimally (i.e., audience design in Clark \& Murphy, 1982), adhering to addressees’ informational need (Clark, 1992). Speakers are supposed to exchange just the right amount of information, neither too little nor too much (Grice, 1975), and base their contributions on the knowledge, beliefs and assumptions that are shared or salient between themselves and their addressee (i.e., common-ground information). This is necessary, because addressees will rely on this shared, salient knowledge when interpreting the referential message (Arnold, Kaiser, Kahn, \& Kim, 2013). Referential communication thus relies a great deal on interlocutors' ability to accurately engage in the process of perspective-taking; the ability to take into account the knowledge and attentional state of their interaction partner at each step in the conversation. The questions that arise here are whether interlocutors are inclined to regard the other's perspective accurately during interaction, and if this is not the case, whether a stimulated attention to another's perspective would be beneficial for the referential communication process.

The literature shows a puzzling picture with regard to speakers' ability and propensity to accurately regard addressee's perspective and, thus, to engage in an accurate
audience design. On the one hand, studies evidenced that speakers succeed at assessing and adapting their communication to their addressees' knowledge (needs) (Heller, Gorman, \& Tanenhaus, 2012; Nadig \& Sedivy, 2002), whereas others have indicated that these adjustments are not always accurate (Horton \& Keysar, 1996; Keysar, Barr, Balin, \& Brauner, 2000). According to these latter studies, language production is not necessarily anchored to addressees' needs, but more to speakers' own knowledge and attentional state, resulting in utterances that are based on information immediately accessible to speakers themselves. Following this approach, addressee's knowledge is only considered in a later, optional stage in which speakers can consciously choose whether to adjust their language production to the common ground status (Horton \& Keysar, 1996). Scholars defending the latter view argue for speakers’ egocentricity bias (Keysar, Barr, \& Horton, 1998), entailing that speakers use their own mental state as a representational default to infer the one of their addressee (Epley, Keysar, Van Boven, \& Gilovich, 2004). Engaging in perspective-taking is then considered to be a cognitive effortful process that can result in egocentric anchor mistakes when speakers do not correct their automatic response. Research indicated that these errors are likely to occur in social interactions, as speakers sometimes refer to information not known to their addressee (Horton \& Keysar, 1996), or even leak privileged information that should have stayed confidential (Kaland, Krahmer, \& Swerts, 2014; Wardlow Lane, Groisman, \& Ferreira, 2006).

In a referential communication task, Wardlow Lane et al. (2006) evidenced speakers' informational leakage even when it bore negative consequences. During the task, speakers described geometrical objects to their addressees, with the goal of earning both of them points if the addressee correctly identified the referent. Before every description, speakers hid one object from their addressee's view. This object always differed in size from the target object speakers had to describe. Addressees could earn additional points by correctly guessing the identity of the hidden object. Although speakers were instructed not to let their addressee gain additional points, results showed that speakers were likely to cue the identity of their privileged object by referring to the size contrast they themselves were seeing. This was especially the case when the target object and speakers' privileged object were similarly rather than differently shaped, as the size contrast presented to speakers was then most relevant (i.e., salient) for speakers to discern.

Subsequent studies replicated findings of Wardlow Lane et al. (2006) by showing that speakers also leak information
non-verbally (Kaland et al., 2014), and especially when they do not have enough cognitive resources left to correct perspective mistakes (Wardlow Lane \& Ferreira, 2008). Intriguingly, speakers are even more likely to refer to privileged information when they are motivated to keep it confidential. The motivation to keep private information privileged further enhances its salience which, as a consequence, can result in it being revealed (Wardlow Lane \& Liersch, 2012).

It seems that despite their efforts speakers are not always able to monitor for perspective mistakes or to adjust their egocentric errors to addressees’ informational need. The question raised here is whether speakers' audience design would benefit from a constant reminder of interlocutor's informational need (i.e., perspective). Research has suggested that audience design is more likely to occur when speakers are made aware that such design is needed (Horton \& Gerrig, 2002). We therefore suggest that guiding speakers through a perspective-taking process might inhibit egocentric anchoring, and might boost their monitoring for perspective mistakes. This might incite speakers to correct for egocentric errors such as the leakage of privileged information (Horton \& Keysar, 1996), resulting in a references that are more accurately based on addressee's perspective, and less on speakers' own knowledge and attentional state.

## Current Study

This study examines whether speakers' elicited attention to addressee's perspective influences their reference production. Following the assumptions of the egocentricity hypothesis (Keysar et al., 1998), we expect speakers in a baseline setting (i.e., in which perspectives are not induced) to automatically anchor their referential expressions to their private knowledge, increasing the likelihood they will refer to this information, compared to other-focused speakers whose attention is focused on their interlocutor's perspective. We further hypothesize that self-focused speakers who are made explicitly aware of their own perspective will be more likely to leak privileged information than speakers referring in the baseline setting.

Based on the findings of Wardlow Lane et al. (2006), we additionally expect that speakers will be more likely to leak privileged information when this information is salient versus non-salient to them. That is, if speakers refer to a commonground figure (e.g., a circle) that has a size-contrasting match (e.g., a bigger circle) in their privileged ground, the size difference is relevant and, thus, salient to speakers themselves to discern. This in contrast to situations in which speakers are presented with a size-contrasting mismatch (e.g., a bigger triangle) in their privileged ground. The salience of the size contrast presented by matching rather than mismatching figures makes speakers more likely to add contrasting adjectives in their description of the target figure (e.g., "the small circle"), by which they leak privileged information. Finally, we expect that the salience of privileged information will interact with the induced perspective. Self-focused speakers are expected to be more likely to leak information
when it is salient versus non-salient, compared to the baseline setting. Since other-focused speakers explicitly focus on addressee's perspective, we expect these speakers to be less influenced by the salience of their private information, compared to the baseline setting.

## Method

## Participants

In total, 93 student-dyads $(N=186)$ participated in this study. The data of three dyads were excluded from analyses, due to an error in the experimental procedure $(N=2)$, or due to a low proficiency in the language of the experiment (Dutch) ( $N$ $=4)$. The analyses were based on 90 dyads in which the participants were randomly assigned either the role of the speaker ( 55 women, 35 men, $M_{\text {age }}=22.0$ years; age range 1834 years) or the role of the addressee ( 59 women, 31 men, $M_{\text {age }}=21.3$ years; age range 17-27). All participants were fluent in Dutch, did not experience problems at discerning the colors used in the study, and received a small remuneration for their participation.

## Design

The experimental design and procedure were replicated from Kaland et al. (2014), which in turn were inspired by Wardlow Lane et al. (2006). The experiment consisted of a referential communication task in which speakers were asked to describe mutually visible geometrical figures in such a way that the addressee could indicate the intended one out of a set of four. These four figures were physically presented on the table in between both interlocutors, and depicted on speakers' private computer screen. From their private computer screen, speakers were instructed to block one figure and, subsequently, to identify another figure on the table in front of them (figure 1). The occluded figure differed either in size or color from the three mutually visible figures. In our experiment, we replicated Kaland et al. (2014) privileged situation and added a perspective-taking manipulation. In this privileged setting, one object was always blocked from addressee's view and thus belonged to speaker's privileged ground.

Figure 1: The experimental setting in which the speaker (on the bottom) identified figures to the addressee (on the top).

## Materials

Eliciting Self- Versus Other-Focus Speakers' self- versus other-focus was manipulated by asking them explicitly to either regard their own (self-focus) or their addressee's (other-focus) perspective before they identified the target object. Participants were randomly assigned to one of the three communication settings (self-focus, other-focus, baseline), resulting in 30 speakers per setting. The selfversus other-focus was operationalized by asking speakers to answer a perspective question portrayed on the computer screen next to them. In the self-focus setting, speakers answered the question reinforcing their egocentric perspective: "Which four figures are visible to you?". This in contrast to the speakers in the other-focus setting who were asked to regard the perspective of their addressee: "Which three figures are visible to your addressee?". Speakers answered the question by selecting the figures on their private computer screen. To eliminate the possibility that the selffocused speakers would simply select all figures as a response to the question, a fifth figure was added to the figures presented on the computer screen.

To investigate the influence of our perspective manipulation, we allocated one third of the speakers to a baseline setting. In this setting, we did not reinforce speakers' self- versus other-focus. In this way, we were able to examine how speakers' reference production in the self- versus otherfocused settings would diverge from a baseline situation.

Salience of Privileged Information The salience of speakers' privileged knowledge was manipulated within communicative settings. Participants were confronted with 40 experimental trials, consisting of 20 salient and 20 nonsalient trials. In the salient trials, speakers' privileged figure was identically shaped to the target figure (e.g., both were circles) whereas in the non-salient trials both figures were differently shaped (e.g., a circle and a triangle). The salient trials were designed to elicit utterances that contrasted the target figure with the privileged one, whereas the non-salient trials assessed how often speakers included adjectives irrespective of the contrast presented. Figures in successive trials were never identically shaped, and half of the figures contrasted in size (big, small) and the other half in color (red, blue, green, black, grey, yellow) (Kaland et al., 2014). The figures' shape, color, and position were balanced across all trials. This resulted in $3 \times 2 \times 2$ design, with communication setting (self-focus, other-focus, baseline) as a between subjects' factor, and trial type (salient, non-salient), and contrast type (color, size) as within subject factors.

## Procedure

A throw of a dice decided which participant took the role of the speaker. Participants were told that, when the addressee was able to correctly identify the target figure, both the speaker and the addressee would obtain one point. Participants were told that failing to identify the target figure would result in zero points obtained, and the goal of the game was to obtain the maximum number of points.

Speakers and addressees sat down on opposite sides of a table. Speakers were seated next to a computer screen on which the experimental trails were presented using E-Prime version 2. At the beginning of each trial, addressees closed their eyes while the experimenter placed four cards on the table. When the four cards were put in place, speakers (a) hid one figure from their addressee's view by placing an occluder between the figure and their addressee. Subsequently in the other- and self-focused setting, speakers (b) answered a perspective question by selected either the three figures visible to their addressee (other-focus) or the four figures visible to them (self-focus). Hereafter, speakers (c) described the target object with just enough information so that their addressee was able to identify the intended figure. Speakers were instructed to look at the four cards on the table when referring to the target object. While hearing speakers refer to a figure, addressees opened their eyes and pointed at the intended figure on the table in front of them. Speakers subsequently (d) informed their addressee whether their selection was correct. Since speakers in the baseline setting were not confronted with a perspective-taking manipulation, these speakers only performed actions (a), (c), and (d). To ensure all steps of the procedure were executed correctly, the experimenter was present during the entire game.

The experimental game ended after 40 rounds. After the final round, speakers indicated on a ten-point scale to what extent they took into account their addressee's perspective during the game $(1=$ not at all, $10=$ very much $)$. Since audio recordings were made of all sessions, participants' consent to making these recordings and using them for scientific purposes were collected. Afterwards, all participants were debriefed.

## Coding

To measure speakers' reference to privileged information (RPI), we counted the adjectives that matched the contrast between the target and privileged figure. Adjectives that did not contrast the target figure to the privileged one were not taken into account. Speakers' RPI was calculated as a proportion ( $1=$ contrasting adjective uttered; $0=$ no contrasting adjective uttered).

## Results

All dyads obtained the maximum of 40 points, indicating that they were able to correctly identify all targets. In figure 2, the mean proportions of speakers' informational leakage (RPI) as a function of the perspective manipulation (baseline, otherfocus, self-focus), whether the target and speakers' privileged figure were similarly (salient trials) or differently (nonsalient trials) shaped, and whether these contrasts were presented in either color or size are shown. Overall, speakers in the baseline setting referred to privileged information in half of the produced references ( $50 \%$ ), followed by the otherfocused ( $45 \%$ ), and self-focused speakers ( $29 \%$ ). Across the three communicative settings, speakers seem to have referred to privileged information to the same degree for salient (43\%) and non-salient (40\%) trials.

Figure 2: Mean proportions of speakers' RPI. Error bars represent $95 \%$ confidence intervals.

The influence of the perspective manipulation and the interplay with the salience of speakers' privileged information on the probability of privileged information to be mentioned was analyzed using a generalized linear mixed model analysis with a binomial distribution. For this we used the GLMER function from the lme4 package (Bates, Maechler, \& Bolker, 2011) in R (version 3.3.0; www.rproject.org). We constructed a maximal model that included a full random effect structure (Barr, Levy, Scheepers, \& Tily, 2013). This maximal model included the perspective manipulation (self-focus, other-focus, baseline), the salience of the trials (salient, non-salient), and the contrast (color, size) presented in the trials as fixed factors. We included random intercepts and slopes for both speakers and experimental trials. The probability distribution was set on binomial with a logit link function and we used parametric bootstrapping over 100 iterations to estimate the confidence intervals and $p$-values. When the maximal model did not converge, we excluded random slopes with the lowest variance until convergence was reached. We report the results of the models that were the first to converge (Barr et al., 2013). An alpha level of .05 was used for all statistical tests. The models treated the baseline setting as the reference category, to which speakers' RPI in the other- and selffocused settings were contrasted.

Influence of Perspective on Speakers' RPI Speakers' RPI in the self- and other-focused setting did not significantly differ from speakers' RPI in the baseline setting. For nonsalient size trials, speakers in the other-focused ( $M=.33, S D$ $=.45, b=0.80, S E=2.07$, CI: [-3.02, 5.11]), and self-focused setting ( $M=.24, S D=.41, b=1.28, S E=1.66, \mathrm{CI}:[-1.98$, 4.52]), were just as likely as the baseline speakers ( $M=.44$, $S D=.50$ ) to refer to privileged information. The same held for non-salient color trials: other-focused ( $M=.55, S D=.47$, $b=1.24, S E=1.90, \mathrm{CI}:[-1.67,5.76])$, and self-focused speakers' $\operatorname{RPI}(M=.31, S D=.43, b=-3.31, S E=4.41$, CI: [$12.06,5.21]$ ) did not significantly differ from the baseline ( $M$
$=.54, S D=.50$ ). This pattern also held for salient size trials: speakers' RPI in the other- $(M=.34, S D=.44, b=-0.07, S E$ $=1.61$, CI: $[-2.92,3.38]$ ), and self-focused setting ( $M=.24$, $S D=.41, b=0.98, S E=1.56, \mathrm{CI}:[-1.86,4.25])$ did not significantly differ from the baseline ( $M=.46, S D=.50$ ). Finally, speakers' RPI on salient color trials in the other- ( $M$ $=.58, S D=.46, b=0.57, S E=2.36, \mathrm{CI}:[-3.38,5.88]$ ), and self-focused setting ( $M=.35, S D=.42, b=-3.26, S E=4.41$, CI: [-12.64, 4.67]) did also not significantly differ from the baseline ( $M=.55, S D=.49$ ).

Influence of Salience on Speakers' RPI In the baseline setting, the salience of privileged information did not influence speakers' RPI. Baseline speakers were just as likely to refer to privileged information on non-salient ( $M=.44, S D$ $=.50)$ and salient $(M=.46, S D=.50)$ size trials $(b=1.53, S E$ $=0.81$, CI: $[-0.33,2.86])$, and on non-salient $(M=.54, S D=$ $.50)$ and salient $(M=.55, S D=.49)$ color trails $(b=0.46, S E$ $=2.04$, CI: [-3.05, 4.93]).

Baseline speakers' RPI was also not influenced by the contrast presented in the trials. Speakers were just as likely to refer to privileged information on non-salient size ( $M=.44$, $S D=.50$ ) and non-salient color ( $M=.54, S D=.50$ ) trials ( $b$ $=-1.91, S E=1.93$, CI: $[-6.59,0.97])$, as on salient size $(M=$ $.46, S D=.50)$ and salient color $(M=.55, S D=.49)$ trials $(b$ $=-1.91, S E=2.23$, CI: $[-6.81,1.95])$.

When the two perspective settings were contrasted to the baseline setting, no significant differences were found. Like the speakers in the baseline setting, other-focused speakers' RPI did not differ between salient ( $M=.34, S D=.44$ ) and non-salient $(M=.33, S D=.45)$ size trials $(b=-0.88, S E=$ 0.90 , CI: [-2.61, 0.93]), nor between salient ( $M=.58, S D=$ .46) and non-salient ( $M=.55, S D=.47$ ) color trials ( $b=-$ $0.79, S E=1.13, \mathrm{CI}:[-3.10,1.32])$. The same held for the selffocused speakers. Their RPI did not differ significantly between salient ( $M=.24, S D=.41$ ) and non-salient $(M=.24$, $S D=.41$ ) size trials $(b=-0.30, S E=0.90, \mathrm{CI}:[-2.03,1.51])$, nor between salient ( $M=.35, S D=.42$ ) and non-salient ( $M=$ $.31, S D=.43$ ) color trials $(b=-0.24, S E=1.16, \mathrm{CI}:[-2.58$, 1.97]).

Like the baseline speakers, other- and self-focused speakers' RPI did not depend on the contrast presented in the trials. Other-focused speakers' RPI did not significantly differ between salient size ( $M=.34, S D=.44$ ) and salient color $(M=.58, S D=.46)$ trials $(b=0.64, S E=2.71, \mathrm{CI}$ : $[-$ 4.33, 6.27]), nor between non-salient size ( $M=.33, S D=.45$ ) and non-salient color $(M=.55, S D=.46)$ trials $(b=0.64, S E$ $=3.45$, CI: $[-5.32,8.20])$. Further, self-focused speakers' RPI did not significantly differ between salient size ( $M=.24, S D$ $=.41)$ and salient color $(M=.35, S D=.42)$ trials $(b=-4.24$, $S E=4.43$, CI: [-13.71, 3.64]), nor between non-salient size ( $M=.24, S D=.41$ ) and non-salient color trials $(M=.31, S D$ $=.43)(b=-4.24, S E=5.11, \mathrm{CI}:[-14.67,5.37])$.

Speakers' Self-Reported Perspective-Taking A one-way between-subjects ANOVA revealed that speakers' selfreported perspective-taking tendency significantly differed
between settings, Welch's $F(2,57)=4.43, p<.05$. Tukey HSD post-hoc comparisons revealed that self-focused speakers ( $M=7.73, S D=2.94$ ) reported a significant higher perspective-taking tendency than both other-focused ( $M=$ 5.62, $S D=3.63$ ) and baseline speakers $(M=5.60, S D=3.51)$ (both $p<.05$ ). Perspective-taking tendencies did not significantly differ between the other-focused and the baseline setting ( $p>.05$ ). To investigate whether speakers' self-reported perspective-taking tendency corresponded with their actual behavior during the game, a follow-up logit mixed model analysis was conducted. This model included speakers' SELF-REPORT as fixed effect, a random intercept for subjects, and a by-subject random slope for the effect of SELFREPORT. $P$-values were obtained using the Likelihood Ratio Test (LRT). The LRT revealed that speakers' SELF-REPORT was a significant predictor of their actual RPI, $\chi^{2}(2)=9.90$, $p<.001$. As speakers' perspective-taking tendency increased, they were less likely to have leaked privileged information during the game, $b=-2.75, S E=0.45, p<.001$.

## Discussion

In this paper we studied whether eliciting speakers' selfversus other-focus would influence their subsequent reference production. We found that speakers in the otherand self-focused settings were just as likely to refer to privileged information as the speakers whose perspectivetaking was not manipulated (i.e., in the baseline setting). Further, we did not replicate the results of (Kaland et al., 2014; Wardlow Lane \& Ferreira, 2008; Wardlow Lane et al., 2006; Wardlow Lane \& Liersch, 2012) who found that the salience of privileged information can boost the probability of it being leaked. In our study, speakers were just as likely to refer to private information, regardless of its salience. Perhaps speakers' tendency to retain a certain reference strategy throughout the game could have interfered with their audience design (Horton \& Gerrig, 2002), and the extent to which they were influenced by the elicited perspective and the salience of their privileged knowledge.

In our study, $66 \%$ of speakers $(N=59)$ either referred to color and size contrasts on all trials, or they refrained from including any adjectives throughout the game. Speakers' consistent referring behavior has been supported by previous research (Brennan \& Clark, 1996), and is strengthened by addressees' ability to identify the referent on the basis of speakers' descriptions (Clark \& Krych, 2004). Addressees partaking in our study were always able to correctly identify the intended object, regardless of the presence or absence of speakers' informational leakage. Each time addressees correctly identified the target object, they signaled to speakers that the reference had been successful. This could have inspired speakers to keep hold of their referential tactic and to base their references on previous formulated descriptions. This tendency to be consistent could have interfered with our perspective-taking manipulation and the extent to which speakers were influenced by (the salience of) their privileged knowledge. Furthermore, in our study speakers' leakage did not bear negative consequences. As a
result, egocentric errors were not detected and speakers were not encouraged to adjust their reference production. This implies that increasing speakers' awareness of the negative consequences associated with their leakage could reduce the extent to which they would leak such information. However, as previous research has shown (e.g., Kaland et al., 2014; Wardlow Lane et al., 2006) incentives to keep privileged information confidential might increase speakers' attention to this information, thereby ironically boosting the likeliness of it being mentioned. Enhancing speakers' awareness of the negative consequences of their leakage thus might not be the right solution. There are, however, other factors that should be considered with regard to addressing speakers' consistency in reference production.
One of these factors is the self-paced method by which speakers were confronted to the instructions and perspective manipulation. The self-paced method could have induced the routineness by which speakers performed the instructions and completed the trials. Moreover, the fact that the perspectivetaking manipulation was posed on speakers' private computer screen in which perspectives were not visibly marked could have reduced the intrusiveness of the elicited mindsets. Although speakers were explicitly trained to return their attention from their private screen to the physical context shared between them and their addressee before they identified the target figure, the possibility exists that speakers were still regarding their private screen (in which perspectives were not marked) while formulating their reference. These issues could be addressed in a future study by allowing the experimental leader to pace the experiment and to expose speakers in the shared physical context to the perspective-taking manipulation. For example, speakers could be explicitly asked to indicate which figures are visible to their addressee (i.e., eliciting an other-focus) or visible to themselves (i.e., eliciting a self-focus) by using the figures lying between them and their interlocutor.

Moreover, following the design of Kaland et al. (2014), speakers were confronted with six color manipulations compared to the two size manipulations. The obtrusive use of color could have induced speakers to refer to color contrasts on all of the experimental trials (Koolen, Goudbeek, \& Krahmer, 2013), irrespective of the elicited perspective or the salience of privileged information. A future study could explore this possibility by equalizing the number of colors used to the number of size contrasts employed in the game.

An interesting finding of this study that merits further attention is the result of speakers' self-reported perspectivetaking tendency and its relation to their reference production. Ironically, speakers with an elicited self-focus reported to have regarded their addressee's perspective more than the speakers in the other two settings. This self-reported tendency correlated negatively with speakers' previous leakage behavior, indicating that speakers with a high perspectivetaking tendency were less likely to have leaked private information during the game. It thus seems that not an elicited other- but instead a self-focus activated speakers' awareness
of their interlocutor's informational need, reducing the likelihood of egocentric perspective errors to occur.

Differences in speakers' self-report and leakage between the self-focused and baseline setting can be explained by the presence or absence of the perspective manipulation. In the self-focused setting, speakers answered a question that enhanced their own mental representation of the scene, whereas in the baseline setting, perspective enhancements were absent. A more intriguing finding, however, is the occurrence of a stronger perspective-taking tendency by the self-focused speakers than by the other-focused speakers. This tendency can be explained using the objective selfawareness theory (Wicklund, 1975). According to this theory, self-aware persons reflect on themselves as if they are an object under scrutinization. Under this scrutinization, the difference between their actual and required behavior, derived from the standards that apply to the interaction, becomes salient. Our self-focused speakers could have found themselves in such a reflective state, especially since a cue of their addressee's different perspective was present (Gendolla \& Wicklund, 2009). Speakers were able to see which figures were available for addressee's selection process (and which one was not). As a consequence, self-focused speakers could have been more aware of addressees' informational need than other-focused speakers, reducing the extent to which they were influenced by privileged information. This possible explanation needs further examination by exploring how much the self- versus other-focus perspective questions used in this study elicited speakers' self-awareness. For this, the validated Situational Self-Awareness Scale can be employed (Govern \& Marsch, 2001).

#### Abstract

How do covert emotional stimuli affect decisionmaking? We investigated this question by exposing participants to subliminal visual stimuli during a computerized version of the Iowa Gambling Task (IGT) to assess whether different categories of images (negative, neutral, or positive emotional evaluations) would influence deci-sion-making behavior. Results did show sex-group interactions for IGT scores. In decision learning model simulations, it was found that different models were more appropriate to explain the task performance for different sex-group pairs. Overall, women showed more of an ability to integrate the additive negative signals from the stimuli to make more advantageous decisions than the men; consequently, this made the men more resilient to the negative effects of the positive stimuli on taskperformance. When taken with existing research, the results indicate that subliminal emotional stimuli can have subtle, potentially sex-dependent, effects on behavior during the decision-making process.

## Keywords: Decision-Making, IGT, Emotion, Simulation

## Introduction

How do covert emotional stimuli affect decisionmaking and choice behavior? There have been several studies that have explored the processes involved in, and the outcomes of, decision-making behavior (e.g., see Lerner et al., 2015; Weber \& Johnson, 2008), but relatively few studies that explore decision-making have also explicitly introduced emotional stimuli (Phelps \& Sokol-Hessner, 2012) and even fewer have sought to understand the interaction between unconsciously presented emotional stimuli and decisionmaking. One decision-making study by Winkielman et al. (2005) found that subliminally presented images (emotional faces) influenced judgment and choice during a series of decisions directly following the masked image exposure (with happy faces increasing the
amount of a beverage poured and consumed, and the purchase price a participant would be willing to pay). These images affected the decision despite not being consciously perceived or semantically related to the series of decisions made after the exposure. Subliminal image presentation can also cause changes in peripheral physiology that may not be perceived, particularly measures related to activation of the LC-Noradrenergic system and amygdala, for example heart-rate and eyeblink response (e.g., Ruiz-Padial et al., 2011). These effects on peripheral physiology are important, as the areas of the brain that are shown to respond to these subliminal stimuli are likely causing these cascades of changes (Öhman \& Mineka, 2001; Tamietto \& de Gelder, 2010).

The Iowa Gambling task (IGT) has been used to better explain links between changes in peripheral physiology and choice behavior, as well as to better understand some of the brain areas key to decision-making and related physiological behavior during the decisionmaking process (Bechara et al., 1999).

IGT subjects repeatedly chooses cards from 4 decks of cards. The payoff per card varies, and the subject is asked to maximize their payoff. The decks differ in the payoff they give for each card; some decks give better average payoffs than others, although all have variability. The task is used to study how subjects learn to use the payoffs in their decision-making. For some cognitive deficits the choices are not learned very quickly.

An important finding from Bechara et al. (1999) is that normal participants exhibited different skin conductance response (SCR) behavior than clinical patients with amygdala lesions and those with lesions in the ventromedial prefrontal cortex (VMPFC). These distinct clinical groups exhibited different SCRs both prior to selecting a card from a deck and in response to receiving a net gain or loss after selecting a card; this difference is especially apparent in the disadvantageous
decks (those decks that had a negative average payoff). The group with amygdala lesions exhibited both a reduced SCR prior to selecting a card from a deck and a reduced SCR after receiving a reward or loss, while the VMPFC group showed a more attenuated SCR prior to the selection of a card from a deck, indicating that amygdala nuclei may play an important role in giving affective value to representations in decision-making. SCR response patterns by those with amygdala lesions indicated a difficulty with coupling an affective value with the different decks and the cards from those decks.

We sought to better understand behavioral effects of this unconscious emotion perception and decisionmaking interaction by exposing study participants to subliminal emotional stimuli while they completed the IGT. Behavioral responses to the affective value of objects are mediated by cognitive processes that are modulated by neural processing in the amygdala (Moscarello \& LeDoux, 2013; Panksepp et al., 2011; Phelps, 2006). Given that the amygdala is also important for the processing of unconsciously presented emotional stimuli (Tamietto \& de Gelder, 2010), the unconscious perception of emotional stimuli may have behavioral effects on decision-making even if the stimuli are not integral to the decisions being made (e.g., Winkielman et al., 2005).

We expected that decision-making would differ depending on whether the subliminal image presented had negative, neutral, or positive evaluations. We present a study to test this hypothesis. Normally, in nonpathological populations, IGT performance is largely dependent upon learning deck contingencies over-time. This can be represented somewhat as a reinforcement learning process (e.g., with the expectance-valence model or the prospective-valence model; Ahn et al., 2008). To further explore the potential differences between groups (and, later, participant sex), we developed decision learning models (e.g., Ahn et al., 2008) that were run in simulations ${ }^{1}$; this gave us the opportunity to understand potential computational processes affected by the treatment.

## Method

97 undergraduate students were recruited as participants for this study ( 52 males; 45 females). The average ages of males and females were similar at 20.7 and 19.8 (respectively). Electrodermal Activity (EDA) data were collected for the final 66 ( 37 males and 29 females) participants (data not reported here). All participants were given college course extra credit.

A filter process that removed participants who completed less than $20 \%$ of their trials due to time re-

[^311]strictions (max 3.5 s per trial) resulted in the removal of 4 participants' data from further analysis; data from 93 total participants were analyzed. The negative, neutral, and positive (image) groups each had 31 participants. We ceased participant enrollment in the study after we crossed a 31 per-group threshold for task-related behavioral analysis and all volunteers had the opportunity to participate.

Participants used a version of the IGT that included a fixed reward and punishment schedule for each deck that was the same as the schedule used for the original IGT by Bechara et al. (2000). A modified computerized version of the IGT was used that runs in Matlab and uses the Psychtoolbox Matlab extensions (Brainard, 1997), which were used due to their high timing accuracy, community support, and cross-platform availability. The specific software used has had IGT-specific timing tests done to confirm timing accuracy (Dancy \& Ritter, 2017).

The visual stimuli presented during the IGT were obtained from the International Affective Picture System (IAPS; Lang et al., 1997). Table 1 lists the images used in the image sets used by the groups. Male and female pictures were matched so that, for each group, they had similar valence/arousal/dominance ratings and had a similar content subject; for example, some snake pictures had different ratings between sexes within the IAPS manual, so those images with lower valence/higher arousal ratings among the same category were chosen. Given that picture ratings in all categories differed between sexes, this method allowed more consistency in mean measured quantitative ratings among participant sexes.

Table 1. The IAPS images used in the experiment.

| Picture-Set | Picture Numbers |
| :---: | :---: |
| Negative $_{\text {Male }}$ | $1050,1202,1220,1304,1525$ |

## Procedure

Before participating in the study, all participants read and signed a consent form approved by the Office of Research Protections (ORP) at Penn State. After consenting to the form, all participants filled out a Positive and Negative Affect Schedule (PANAS) questionnaire. All participants who had their EDA recorded were then fitted with a Q sensor EDA device (Ming-Zher et al., 2010).

Each participant was assigned to one of three groups that determined which set of images they were shown: (a) a negative image group that consisted of images
with a low rated valence, and a high arousal; (b) a neutral image group that consisted of images with a medium rated valence and a low arousal (c) a positive image group that consisted of images with a high rated valence and a high arousal.

In this version of the IGT, participants had a maximum of 3.5 seconds to select a card from one of the four decks and if they failed to make a selection in the allotted time on any trial, a random deck was selected for them. After a card was selected from a deck, a red or black card was shown for 4 seconds. A (groupdependent) image was shown in place of the background image of the box where the reward and losses were shown for 17 ms when the participant selected from deck A or B. If the participant made a selection from deck C or D , a plain gray background image was shown for 17 ms . Directly after this 17 ms , the reward and loss that the participant received in response to their deck selection was presented in the same box for 3.5 seconds. All images used from the image set, as well as the background image used throughout the task, were converted to gray scale. Each intertrial break lasted 3.5 seconds, except every $20^{\text {th }}$ trial, after each of which the participant was asked two questions to assess their awareness of the task itself.

After the IGT was completed, participants filled out a second PANAS questionnaire and then (as needed) had the EDA device removed. Participants were then asked "Did you discover anything new by the end of the game?" and were partially debriefed on the task itself. Participants then completed the Affective Neuroscience Personality Scales (ANPS) questionnaire and were fully debriefed before ending the study session.

## Results

To understand the results, we used both traditional statistical techniques (e.g., one-way and repeated measure ANOVAs), as well as results from decision learning models. While the ANOVAs were useful for understanding general differences between participant groups, the decision-learning models allowed us to explore potential differences in the computational processes that may govern group differences.

## Analysis of Initial Hypotheses

We hypothesized that the score would be different between the negative, neutral, and positive image groups, and that performance would be highest in the negative image group and lowest in the positive image group. A one-way ANOVA for cumulative score (total score at the end of the IGT) did not show a statistically significant difference between groups $(F(2,90)=$ $0.81, \eta^{2}=.02$ ). We also hypothesized that score would improve over the course of the task (indicating a learning of the advantageous decks) and that this im-
provement would also differ between groups. A 3 (image group) x 5 (block) mixed-model ANOVA for score revealed a statistically significant block factor, showing that learning occurred $(F(4,360)=13.22, p<$ $.0001, \eta_{p}^{2}=.13$ ), but did not show a statistically significant block:group interaction $\left(F(8,360)=0.40, \eta_{p}^{2}=\right.$ .01).

## Post-hoc Analysis

Additional analysis of the data indicated that participant sex was a behavioral factor. Figure 1 shows mean cumulative scores by group for both males and females. The distribution of mean scores on the task among groups is mirrored between males and females; the mean cumulative score for the positive group among females ( -2.4 ) is closer to the negative group mean cumulative score in male participants ( -3.4 ) than the positive group mean score in male participants (11.6).

Figure 1 Cumulative score for male (left) and female (right) participants at the end of the task. (The error bars represent the standard error means)

A 2 (sex) x 3 (group) ANOVA for cumulative score showed a marginally statistically significant sex:group interaction $\left(F(2,87)=2.77, p=.07, \eta_{p}^{2}=.06\right)$. A $2 \times 3 \times 5$ mixed-model ANOVA for score showed a statistically significant block factor $(F(4,348)=$ $\left.13.55, \eta_{p}^{2}=.13\right)$ and a statistically significant block:sex:group interaction $(F(8,348)=2.12, p=$ $.034, \eta_{p}^{2}=.05$ ) indicating a difference in trends between sex:group pairs.

Thus, we see that the effect of stimuli valence had an effect on the cumulative score on this task, but that the positive and negative valence images appear to have different effects on men and women.

## Using Decision-Learning Models

Though using methods such as those used above are useful for finding differences between groups, simulations of decision-learning models can also be useful as they allow one to explore theoretical aspects of the computation leading to learning and decision-making performance. We ran simulations of decision-learning models to explore how different groups may have evaluated positive and negative payoffs (utility), how they learned these utilities after experiencing them (learning rule), and how these learned expectations may have influenced participants' actual choice (choice probability rule). This resulted in simulation parameter sweeps on 8 total models ( 2 per category); each model was run 100 times during the parameter sweep using the MindModeling@Home cognitive research system.

Functions Used to Construct the Models The two utility functions used were the expectancy utility function (hereinafter referred to as EU ) and the prospect utility function (hereinafter referred to as PU). EU contains a parameter meant to specify a model's attention to loss ( $w$ in eq. 1). Instead of assuming a subjective utility that is linearly proportional to the payoff amount, PU uses a non-linear function (e.g., Tversky \& Kahneman, 1992) to better account for the gain-loss frequency effect (whereby multiple small losses have a larger effect on choice behavior than a single loss equal to the sum of the smaller losses. In (eq. 2) net ( $t$ ) represents the net amount gained (or lost) on trial $t, w$ is a loss-aversion parameter, and $\gamma$ governs the shape of the equation.

$$
\begin{align*}
& u(t)=(1-w) * \operatorname{rew}(t)-w * \operatorname{loss}(t)  \tag{1}\\
& u(t)= \begin{cases}\operatorname{net}(t)^{\gamma} & \forall \operatorname{net}(t) \geq 0 \\
-w *|\operatorname{net}(t)|^{\gamma} & \forall \operatorname{net}(t) \geq 0\end{cases} \tag{2}
\end{align*}
$$

For learning, the Rescorla-Wagner, or delta, rule (Rescorla \& Wagner, 1972) and the decay reinforcement rule (Erev \& Roth, 1998) were used in separate decision models. In the Rescorla-Wagner rule (eq. 3) $\alpha$ represents a learning rate that determines the effect of the the prediction error (the utility minus the current expectancy). The same parameter provides a slightly different representation for the decay reinforcement rule (shown in e. 4). Here, the rule represents a recency parameter, which determines discount of past expectancy when updating with the new utility. Both the delta and decay rules are represented in Table 2 as Del and Dec, respectively.

$$
\begin{align*}
& E_{i}(t)=E_{i}(t-1)+\alpha *\left(u(t)-E_{i}(t-1)\right)  \tag{3}\\
& E_{i}(t)=\alpha * E_{i}(t-1)+u(t) \tag{4}
\end{align*}
$$

Finally, every model had one of two choice rules: tri-al-dependent and trial-independent. These rules define a parameter that affects the probability of selecting a card from each deck $\theta$ in equation 5 . In this case, $\theta$ affects the propensity to explore or exploit the problem space. When the parameter is low, the model is more likely to explore and select a random deck, and when it is higher it will exploit its knowledge and be more likely to select the decks that have a higher utility. The trial-dependent rule (eq. 6) is affected by the number of trials which the model has completed and the consistency parameter c, while the trial independent rule (eq. 7) is only affected by the parameter c (and thus static during the task).

$$
\begin{align*}
& P\left(D_{i}(t+1)\right)=e^{\theta(t) * E_{i}(t)} / \sum_{j=1}^{4} e^{\theta(t) * E_{j}(t)}  \tag{5}\\
& \theta(t)=(t / 10)^{c}  \tag{6}\\
& \theta(t)=3^{c}-1 \tag{7}
\end{align*}
$$

Model Results As one may predict from the human results reported above, the models that best matched human behavior differed between sex-group pairs. To find the best matching models we calculated the $R^{2}$ for each model-parameter-set combination using the proportions of cards selected from each deck during that particular block (i.e., four proportions adding to 1.0 in each of the five blocks). This measure was chosen because it allowed us to further specify how different processes (i.e., models) may explain not only the overall performance (i.e., score), but the proportions of cards selected from decks in each block that define the overall performance. Table 2 lists the top model (and related parameters) for each sex-group combination.

Table 2. Models and corresponding parameters that best matched each sex:group pair. Dec = Decay; Del = Delta; TI = Trial Independent; TD = Trial Dependent. All $\mathrm{R}^{2}(19) \mathrm{p}<.01$

| Sex:Group | Model | $\mathbf{c}$ | $\boldsymbol{w}$ | $\boldsymbol{\gamma}$ | $\boldsymbol{\alpha}$ | $\mathbf{R}^{\mathbf{2}}$ |
| :--- | :--- | :--- | :--- | :--- | :--- | :--- |
| Male:Neg | PU-Dec-TI | -9.25 | 5.2 | .35 | .15 | .87 |
| Male:Neu | PU-Dec-TD | -8.25 | 4.1 | .20 | .93 | .89 |
| Male:Pos | PU-Del-TI | -1.50 | .13 | .00 | .75 | .88 |
| Female:Neg | PU-Del-TI | -5.50 | 2.5 | .65 | .43 | .87 |
| Female:Neu | PU-De1-TI | -6.75 | 6.8 | .15 | .30 | .92 |
| Female:Pos | PU-Dec-TI | -2.50 | 0.5 | .25 | .25 | .89 |

While there were varying parameters for all models a variant of the prospect utility (PU) model showed the greatest match to all of the sex:group pairs. The same model had the highest $\mathrm{R}^{2}$ for the negative scoring per-
formance group for each sex (females in the positive group and males in the negative group). The male:neutral group was the lone group pair to show the highest R2 with a trial dependent model.

## Discussion and Conclusion

These data indicate that the subliminal emotional stimuli had an effect on decision-making. There appears to be an important interaction between sex and emotional decision-making. Even though the stimuli were presented subliminally and were non-integral to the choices made, participants exposed to affectively charged stimuli responded differently to the outcomes of deck selections and performed better or worse on the task, depending on sex and the valence of the stimuli.

We did not find statistically significant evidence for a between group (negative, neutral, or positive) difference in IGT scores. However, we did find that there were significant differences between groups for IGT scores when factoring in participants' sex. What's more, mean scores among males showed a trend opposite of females across groups. These results seem to indicate that the stimuli had opposite effects on males and females.

This may be due to these stimuli affecting portions of the affect-memory coupling portion of the decisionmaking process that can go unnoticed without conscious reflection by the decision-maker. This seems likely given the mirrored distributions, but with similar performance between men and women in the neutral group. Indeed, the simulation model results showed that males in the negative group and females in the positive group were similar to the same class of model.

Similar to the results from a previous study by Aïte et al. (2013), the image-deck congruency also affected the participant's decision-making behavior, albeit differently in men and women. Though females exhibited a pattern similar to Aïte et al. (2013) with the cumulative score for the negative image group being the highest and the cumulative score for the positive group being the lowest, males exhibited the opposite behavior and the image effect was intensified. Indeed, a more recent review points to a difference between men and women in decision-making behavior during the IGT (van den Bos et al., 2013). In the study presented here, women perhaps showed more of an ability to integrate the additive negative signals from the stimuli to make more advantageous decisions than the men; this explanation, would also apply to men, making them more resilient to the negative effects of the positive stimuli on taskperformance. The difference in this affective signal integration may be partially due to the differences in amygdala activity found in men and women (e.g., Cahill, 2006; Hamann et al., 2004). These differences may have also led to a difference in memory processes
predominantly used to make decisions, as the differences in models (particularly learning processes) may suggest. A decay-based learning rule would better lend itself to a more hippocampal/declarative memory, timedependent (e.g., Anderson et al., 1999) emphasized decision-making process.

While this study yields interesting and worthwhile results, there were limitations in the study that restricted the scope of analysis and discussion. Our study is somewhat limited in that we were unable to compliment the results with neuroimaging data (e.g., fMRI). Neuroimaging data could allow more comment on the neural process mediated reasons that we found a difference in decision-making performance between groups that was dependent on participant sex.

Furthermore, the model analysis could be expanded in the future. Indeed, it may also be interesting to integrate an affective component into the simulations to more directly account for the stimuli. This would allow a finer analysis of the computational processes at work, albeit with a more complex model.

The aim of this study was to better understand how non-integral, subliminal stimuli may affect decisionmaking behavior and physiological responses during decision-making. Though we found some expected image-deck congruency effects, these were not as prevalent as originally hypothesized and participant sex also played a role in how decision behavior was unconsciously moderated by the stimuli. More study is necessary to better understand how these unconsciously perceived stimuli are affecting the process of decisionmaking.

Nonetheless, this work provides evidence that nonintegral subliminal stimuli may affect decision-making behavior at several points in the process depending on stimuli characteristics relative to the decision-maker, and reward and punishment contingencies present in the series of decisions. The work also provides evidence that methods of affective intervention during decisionmaking (e.g., presentation of an emotionally charged image to an individual as a part of a decision to purchase an item) should take into consideration the potential effects of the stimulus on males and females. The stimulus will likely have dissimilar effects and may have completely contrasting effects on individual choices based upon the sex of the decision-maker; this could lead to unintended behavioral consequences.

## Acknowledgements

# Novice to Expert continuum may affect System Response Time 

Arindam Das ${ }^{1}$, Olivia Das ${ }^{2}$<br>York University (Alumni) ${ }^{1}$, Toronto, Canada; Ryerson University ${ }^{2}$, Toronto, Canada.

#### Abstract

To familiarize herself with a user-interface of a software system, a user needs practice. With practice, a user's think time gradually decreases-the novice to expert transition. We propose a queueing model that accounts for this transition in analyzing the performance of a distributed software system. We solve the model using deterministic simulation. Our model captures system performance in terms of system response time. We use the model to demonstrate how userswho are at various experience levels in the novice to expert continuum-may affect the system response time.

Keywords: User Think Time; System Response Time; Queueing Network, Novice to Expert Transition.

## Introduction

Nowadays, distributed systems are getting deployed in cloud since cloud computing allows for dynamic scaling of computational resources as required on a pay-per-use basis. This relieves the providers of cloud system services from buying and maintaining data centers thereby reducing the operational cost.

The performance of a cloud system can get affected due to novice to expert transition as the end users of the system learn to use the system through its user interface. When a user learns, gradual decrease in her think time occurs. Once a software system has responded to a request that was submitted by an end user (through a user interface), the user think time (UTT) refers to the number of seconds the user takes to plan before submitting the next request to the system. The request submission is usually accomplished by clicking an icon on a computer screen. This think time is negatively correlated to the user's expertise level-lower expertise level leads to larger think time and higher expertise level leads to smaller think time. The system workload is affected as a user continues to learn using a system. A novice (one having lower expertise level) requires larger UTT and therefore submits less number of requests per unit time (to the system) compared to an expert (one having higher expertise level). Consequently, as UTT of a user gradually decreases with practice (i.e. repeatedly using the system), the number of requests submitted to the system gradually increases, thereby impacting the system response time (SRT).

Performance evaluation of distributed systems has always considered the UTT as a random variable with a constant mean that does not change with practice (Trivedi, 2005). It never considered novice to expert transition during evaluation.

In this work, we focus on cloud-based systems where the number of computer terminals is fixed at any given point of time. Examples abound-ATMs for a banking system, check-in terminals for an airline at an airport, navigation
training simulators for aircraft pilots-that are deployed in cloud. For our modeling purpose, we assume a hypothetical scenario of a tutorial that is run from inside a classroom. The tutorial consists of learning the fixed locations of buttons on a graphical user interface (GUI) of a cloud system. The classroom has a fixed number of computer terminals, one per student, for the tutorial. No sooner a student finishes the requirements of the tutorial, she is replaced by a new one who is assumed to be at the lowest expertise level.

To realize the above tutorial scenario, we choose a closed queuing network as our system performance model. Choice of a closed queuing network helps us in two ways-one, it allows us to conform to the number of terminals being constant at any given point of time during the tutorial. Secondly, it enables us to account for the decreasing UTT of a user that could occur with repeated use of the interface.

The key contribution of our work is as follows: We demonstrate the effect of novice to expert transition on SRT of distributed systems. We accomplish this through a queueing model. The model accounts for novice to expert transition. Through our model, we show how users-who are at various experience levels in using a system-may affect the system response time.

## Novice to Expert Continuum: In the Context of Human Computer Interaction

We briefly explain what a learning curve is in the traditional context of human computer interaction (HCI).

Any new skill takes time to learn. End users take a while to ramp up on a new user interface; software designers take a while to ramp up on a new project. Learning refers to the acquisition of skill in performing a task through repeatedly executing the same task over time. People get faster and make fewer errors with practice-i.e. with repeated task execution.

In the domain of user interface, the core focus is always a human-centered approach to design-be it the design of a smartphone interface or the interface of a desktop screen. By doing so, we concede that the target of our user interfaces is a population of users with a wide span of skills. We must be aware that these skills change over time as a result of learning. If there are multiple users, they may operate at different expertise levels at the same time due to differences in their experience (Ritter, Baxter, Kim, and Srinivasmurthy, 2013). Such variation in user expertise often calls for a planning of computational resources that would ensure usability satisfaction with respect to SRT for users across all expertise levels.

To take learning into account, what we need is a graph that plots UTTs at different practice sessions for a given
task. A graph like this is popularly referred to as the learning curve-the novice to expert continuum. Figure 1 elucidates the three level hypothesis of learning postulated by Fitts (1964), Anderson (1982), and Kim and Ritter (2015). The hypothesis posits that a learning curve is roughly divided into three levels of user expertise. The first level is where a user is a novice trying to acquire the knowledge to execute a trial. The UTT is usually high at this level. The next level is the intermediate level. At this level, the user tries to consolidate the knowledge acquired in the novice stage. The final level is the expert level. At this third level, the user fine tunes the existing knowledge-users still get faster at the trial, although the improvements get diminishingly smaller (Ritter, Baxter, Kim, and Srinivasmurthy, 2013).

Figure 1. Three Level Hypothesis-Change in user think time across three levels of learning. The thick continuous line indicates continuous practice. (Figure adapted from Kim and Ritter (2015)).

In HCI, a learning curve for a user interface task is often obtained through empirical studies. Here, an interface under study is evaluated in a standalone mode of the client device such that the client software does not have to depend on anything other than the device it is hosted on. As a result, the delay between the submission of a user request (in form of a finger-press or mouse-click on the interface) and the corresponding response is assumed 0 . The interface is evaluated through an interactive task. Multiple human subjects are sampled from a population of novice users of the task. The task involves completing a set of trials-let a trial be the submission of a user request to the software system (in the context of this paper). Each of the users is given equal number of practice sessions to perform the task. The time to complete every trial of the task is measured at each practice session. This measurement is taken for every subject over all the practice sessions. The mean time to complete a trial at a given practice session-mean trial completion time-is then obtained by averaging over the trial completion times measured across all the subjects at that session. Since the delay between every user request and
its response is assumed 0 , the mean trial completion time at a given practice session (which normally would have been the sum of mean user think time and mean system response time at the session) reduces to the mean user think time at that session.

## Closed Queueing Network

A queueing network can be thought of as a network of servers with a queue of jobs (e.g. requests submitted due to mouse-click actions) at each server (Trivedi, 2001). We think of a server as being a world-wide-web server (web server), an application server (app server) or a database server (DB server).

In this work, we exploit a type of queueing network known as closed queueing network. An interactive terminal driven system is often modeled as a closed queueing network with a fixed set of terminals assumed to be part of the network. Each terminal models a delay center in the network. A terminal submits a request and waits for the response. It cannot submit another request until the response of the previous request returns. At any given point of time, the number of terminals in the network remains fixed.

A notion of think time exists in a closed queueing network. It is the time at each terminal between receiving the response of a request and sending out the next request. The idea of think time in a closed queueing network makes it a natural candidate for modeling an interactive system where a user ponders between the completion of a service request and the initiation of a new service request-the time to ponder thus being the UTT.

## A hypothetical Scenario to predict the Learning Effect on System Performance

Our hypothetical scenario consists of the followings: a tutorial that enables a student to learn the fixed locations of buttons on a GUI; a location learning task that is repeatedly executed by a student in the tutorial; and a software system that is used to conduct the tutorial. The tutorial involves the learning of button locations on the GUI only. It does not involve learning of any other type of content.

Note that the task of learning stable layouts of GUI items is not uncommon in real life. While such tasks are routinely executed on banking ATMs and interactive kiosks on a daily basis, they are also prevalent in aviation training, command and control scenarios, and process control plants (Waldron et al., 2005).

## Tutorial scenario

The focus of this paper is to demonstrate the effect of a learning curve on the performance of a 3-tier cloud system. To do so we imagine a tutorial scenario. We assume that a student attending the tutorial interacts with the system through a web-based user interface at a dedicated computer terminal.

The aim of the tutorial is to learn the location of buttons on a stable GUI of the system. The tutorial involves a given
number of practice sessions. The practice sessions are assumed to be separated from one another by a constant period of inactivity. Each student is required to complete all the practice sessions.

The tutorial is conducted inside a classroom having a fixed number of computer terminals. We assume that one student uses one terminal only for her practice sessions. The tutorial begins with one student at every terminal.

Different students may complete their practice sessions at different points of time. It is assumed that when a student completes all her practice sessions, she is replaced by a new student joining the tutorial at the lowest expertise level-the first practice session.

## Location learning task

We assume a simple location learning task that a student will repeatedly perform across multiple practice sessions in the aforementioned tutorial scenario. A location learning task is one where a student learns the locations of graphical items present on a user interface, given that the position (i.e. location) of the items on the interface do not change. We adopt such a task from Ehret's empirical study (Ehret, 2002). The interface on which the task is performed is a graphical layout that consists of 12 unlabelled square buttons arranged along the periphery of a circle. The locations of these square buttons are to be learned through practice. We refer to this interface as Unlabelled Interface. The twelve square buttons are mapped to twelve distinct colors. The colors are not visible; they stay hidden. The circle of square buttons surrounds a centrally located rectangular button. While every square button in the periphery acts as a potential target, the rectangular button at the centre of the circle acts as a cue color.

We refer to the task performed in learning the Unlabelled Interface as "Ehret's task". One practice session of Ehret's task consists of twelve trials. Each trial involves first locating and then clicking a square button that corresponds to a color displayed on the rectangular cue button. In a given practice session, the cue color is different for each of the twelve trials-every trial in a practice thus involves finding a target that is different from the rest eleven targets. In a trial, if the cue color is the color that is associated with the clicked square button, the user has found the target-the trial is therefore considered complete; otherwise the trial is to be repeated. For example, in a trial when the color in the rectangular cue button is green, the trial would be deemed complete only if the square button mapped to green is clicked by the user, not otherwise.

When Ehret conducted this task, he considered only the completed trials. We do the same while considering human learning in our model-we assume that every trial ends up finding the desired target. This helps us keep our model simple.

In Ehret's study, several human subjects had performed multiple practice sessions of Ehret's task on a standalone desktop computer with no internet connection. As a result the delay between the submission of a user request (in form
of a mouse-click) and the corresponding response was assumed 0 . We therefore consider a trial completion time in Ehret's study to be essentially a user think time (UTT) for the modeling purposes in this paper.

In our model, we utilize the mean trial completion time corresponding to each practice session of Ehret's task as the mean user think time for that session. We incorporate a 3tier, cloud-based distributed system that is responsible for processing a submitted user request (mouse-click on a square button). We assume that this system processes the mouse-click and returns the response-the cue color for the next trial-after a non-zero delay (the delay being the system response time, SRT).

## Software System

Figure 2 shows the software architecture of our hypothetical cloud-based distributed system that is used for conducting the aforementioned tutorial. We analyze this system in this work.

Figure 2. Our hypothetical 3-tier, cloud-based distributed system that is used to accomplish our tutorial scenario.

The system consists of 3 tiers. One or more Web servers run in the first tier (tier-1), one or more application servers (App servers) run in the second tier (tier-2) and one or more database servers (DB servers) run in the third tier (tier-3). The servers run of virtual machines (VMs). VM is a term used in cloud computing. It refers to a virtual (i.e. emulated) host. Similar to a physical host (computer), a VM can run an operating system as well as other processes. A VM can be acquired, networked, or released on demand through software based mechanisms. We assume that at any given tier, one or more VMs can be provisioned, each running a single instance of a server relevant to that tier.

We assume that the workload is equally distributed among the servers at any given tier. We indicate this in Figure 2 using the phrase "balanced load".

The student users access the application at the web servers through their web-based user interfaces.

## Control flow of a trial

A trial refers to first locating and then clicking a target square button on Ehret's Unlabelled Interface. In a trial, first a user spends time in reasoning and planning where the target square button would be. Then she submits a request to the system by clicking the potential target. Here, a request refers to a job that is generated due to a button-click and that is to be subsequently processed by the software system (Figure 2) starting from tier-1 and until tier-3. We assume that a request will be processed exactly once (in a server) at each tier. After completion of processing at the third tier, a response corresponding to the processed request is returned to the user. We assume that a request incurs a waiting time in the server's queue before being processed, if the server is busy. The request then incurs a service time for getting processed in the server.
The request is first sent to a Web server in tier-1 for processing. If the Web server is busy then the request needs to wait in the server's queue before getting processed.
Once the processing of the request at tier- 1 is finished, the request is redirected to an App server in tier-2. If the App server is busy then the request needs to wait in the server's queue before getting processed.
Once the processing of the request at tier-2 is finished, the request is redirected to a DB server in tier-3. If the DB server is busy then the request needs to wait in the server's queue before getting processed.

Once the processing of the request is finished at the DB server, the response corresponding to the request is sent back to the user. At this point, the trial is complete. We assume that the response returned to the user contains the information about a new cue color whose associated button is to be located (on the interface) in the next trial.

A trial thus incurs two delays. One is the time spent by a user in reasoning and planning where the target square button is located, given a cue color. This delay period is the user think time (UTT). The other is the system delay due to waiting times and service times incurred by the request between the click of a target button on the user interface and the return of the response. This second delay is the system response time (SRT).

Once all the trials of a practice session are complete, there is period of inactivity before the first trial of the next practice session begins-this period of inactivity is the inter practice time.

## A Queueing Model Considering the Effect of Novice to Expert Continuum

A user with lower expertise level requires larger UTT and therefore submits less number of requests per unit time to the system. In contrast, a user with higher expertise level
requires smaller UTT and therefore submits more number of requests to the system. Thus, as UTT of a user gradually decreases with practice, the number of requests submitted to the system gradually increases. The decreasing UTT thus influences the system workload which in turn affects the waiting times of the requests and consequently, the SRT. Keeping this in mind, we model our hypothetical distributed system as a closed queuing network.

The queuing model parameters, their meaning and their values are summarized in Table 1. The parameter values are specified inside bold parenthesis in the right column of the table. Each parameter is explained in due context as our work unfolds. Since the queueing network is a closed one, the total number of terminals (concurrent users) $\boldsymbol{N}$ in the system is constant at any point of time. An individual terminal user initiates a practice session $p$ by first thinking for a certain amount of time with mean $u_{p}$ (mean user think time per trial of practice session $p$ ) and then submitting the first request of that session to the system. After the completion of the request, the user thinks again for a time with mean $u_{p}$ and then submits the subsequent request of the practice session $p$.

Once a user finishes $\boldsymbol{T}$ number of trials needed to complete a practice session, she takes a break for some time with mean $\alpha$ (mean inter practice time). The user then proceeds with the next practice session. The user completes $\boldsymbol{P}$ practice sessions in total before leaving the system. A departing user is replaced by a new novice user who begins her practice at practice session 1 .
We assume that $\mu_{1}$ is the mean service time of each Web server replica at tier-1, $\mu_{2}$ is the the mean service time of each App server replica at tier-2, and $\mu_{3}$ is the mean service time of each DB Server replica at tier-3.

Table 1. Model Parameters

| Parameter | Meaning |
| :---: | :---: |
| P | Total number of practice sessions assumed to be completed by a user before leaving the system $(1 \leq p \leq P)$. ( $P=15$ sessions) |
| $N$ | Number of computer terminals (concurrent users). Once a user completes $\boldsymbol{P}$ practice sessions, she leaves the system and a new novice user occupies the terminal. The new user begins her practice at practice session $1 . N$ thus stays fixed during a simulation run, thereby abiding by the "constant number of customers" requirement for a closed queueing network. $(1 \leq i \leq N)$. (Simulation data collected at $N=120$ simulated concurrent users) |
| $N_{p}$ | Number of concurrent users at practice session $p$ at the start of a simulation run ( $1 \leq p \leq P$ ) where $N_{1}+N_{2}+\ldots+N_{P}=N$. This is applicable when human learning is considered. |
| $T$ | Number of trials to be completed in a practice session. This is assumed to be equal for all practice sessions. ( $\boldsymbol{T}=\mathbf{1 2}$ trials per session) |
| $r_{i, p}$ | Actual number of completed trials in practice session $p$ at terminal $i$ during the simulation. |

| $\alpha$ | Mean inter practice time (1 sec) |
| :--- | :--- |
| $\mu_{1}$ | Mean service time at tier-1 (0.5 sec) |
| $\mu_{2}$ | Mean service time at tier-2 $(\mathbf{0 . 5} \mathbf{~ s e c})$ |
| $\mu_{3}$ | Mean service time at tier-3 (0.5 sec) |
|  | Mean User Think Time per trial of <br> practice session $p \quad\left(u_{1}=\mathbf{1 2 . 5}, u_{2}=\mathbf{1 0 . 6}, u_{3}=\right.$ <br> $u_{p}$ |
| $\mathbf{8 . 9}, u_{4}=\mathbf{6 . 8}, u_{5}=\mathbf{6 . 5}, u_{6}=\mathbf{6 . 1}, u_{7}=\mathbf{5 . 1}, \quad u_{8}$ <br> $=\mathbf{4 . 2}, u_{9}=\mathbf{4 . 3}, u_{10}=\mathbf{4 . 3}, u_{11}=\mathbf{3 . 1}, u_{12}=\mathbf{2 . 7}$, <br> $u_{13}=\mathbf{2 . 9}, u_{14}=\mathbf{2 . 5}, u_{15}=\mathbf{2 . 2}$. The values are in <br> $\mathbf{s e c o n d s . ~ T h e y ~ a r e ~ o b t a i n e d ~ f r o m ~ F i g u r e ~ 3 ) ~}$ |  |

The system response time of a request is the time between the arrival of the request at a tier-1 server to the completion of the request at a tier-3 server. This time includes the waiting times at the queues of the relevant servers at different tiers and the service times of those servers. This implies that the SRT of a request is affected by the rate of request submissions (i.e. the number of requests submitted to the system per unit time) in addition to the service times of the servers.

User Think Time when human learning is not considered: When human learning is not considered, the think times of a user across all practice sessions will be identically distributed random variables with same mean $u_{1}$ $=u_{2} \ldots=u_{P}$.

User Think Time when human learning is considered: When human learning is taken into account, the think times of a user across all practice sessions will be identically distributed random variables with unequal means $u_{1} \neq u_{2} \ldots$ $\neq u_{P}$. Here, we take unequal means instead of purely decreasing means because of the following reason: Although a learning curve obtained through empirical studies show an overall decreasing trend in user think time with practice, sometimes it may exhibit exceptions in form of increased user think times at some practice sessions possibly owing to user fatigue.

We accomplish the analysis of our queuing model through deterministic discrete-event simulation. For simplicity, we assume that the user think times, the service times of the servers, and the inter practice time are deterministically distributed.

Let $s_{i, j, p}$ denote the system response time for a trial $j$ of practice session $p$ by a user at terminal $i$. During every simulation run, we record the response times $s_{i, j, p}$. Let $r_{i, p}$ denote the number of completed trials of practice session $p$ at terminal $i$.

The Mean System Response Time (Mean SRT) per trial $\overline{S_{p}}$ of practice session $p$, where $p=1,2, \ldots, P$ can be estimated as:

$$
\overline{s_{p}}=\frac{\sum_{i=1}^{N} \sum_{j=1}^{r_{i, p}} s_{i, j, p}}{\sum_{i=1}^{N} r_{i, p}}
$$

The numerator of the above equation denotes the total system response time of all the trials of practice session $p$
completed from all the terminals. The denominator represents the number of those trials.

## Model Results

We use the human learning curve observed by Ehret (2002) as an input to our model. This empirical curve of human learning was measured when human subjects executed Ehret's task-the task to learn the locations of square buttons on an Unlabelled Interface explained earlier. Figure 3 shows the learning curve. The curve is in terms of the mean user think times across the first 15 practice sessions completed by the sixteen human subjects. Subjects' point of regard was measured as they performed the task. The eye data was collected via an ASL 5000 eye-tracker.

Our simulated users are assumed to execute the aforementioned Ehret's task. The simulation emulates the hypothetical tutorial scenario explained earlier.

The simulated tutorial is assumed to start with a fixed number of computer terminals-one student using one terminal only. Once a user completes all the 15 practice sessions she leaves the system. A departed user is then replaced by a new novice user who begins her practice at practice session 1.

Figure 3. Human learning curve for Ehret's task (Ehret, 2002).

We show how users-who are at various experience levels in using a system-may affect the system response time. To do so, we run our simulation model with an initial proportion of users who are at various expertise levels.

We refer to the learning curve of Ehret's task (Figure 3). Let $\left[N_{1} / N_{6} / N_{11}\right]$ denote the initial proportion of users where $N_{1}$ users begin their practice at session $1, N_{6}$ users begin their practice at session 6 , and $N_{11}$ users begin their practice at session 11 at the start of a simulation run. We assume that there are no users at other expertise levels at the start of the simulation run, i.e. $N_{1}+N_{6}+N_{11}=N$. Here, we choose the practice sessions 1,6 and 11 assuming that novice-level experience starts at session 1, intermediatelevel experience starts at session 6 and expert-level experience starts at session 11 . Our choice is dictated by the
three level hypothesis of learning (discussed earlier; see Figure 1) applied on the learning curve of Figure 3.

We consider 120 concurrent users in the system, i.e. $N_{1}+$ $N_{6}+N_{11}$ is 120 . We perform one logical-hour analysis for a VM configuration where every tier of our three-tiered system has 6 VM replicas.

Table 2 shows mean SRTs $\overline{s_{\text {novice }}}, \overline{S_{\text {intermedıate }}}$ and $\overline{S_{\text {expert }}}$ for two initial proportions of users [120/0/0] and [40/40/40]. Here $\overline{s_{\text {novice }}}$ refers to $\overline{s_{1}}$, the Mean SRT at practice session $1 ; \overline{s_{\text {intermediate }}}$ refers to $\overline{s_{7}}$, the Mean SRT at practice session 7 ; and $\overline{S_{\text {expert }}}$ refers to $\overline{s_{15}}$, the Mean SRT at practice session 15 .

With respect to analyzing the initial user proportion [120/0/0] for one logical-hour, the reason for low mean SRT per novice trial $(2.25 \mathrm{sec})$ but high mean SRT per expert trial ( 7.22 sec ) is as follows: In this case, the system is transiting from all-novices to all-experts. The user think times (UTTs) at the novice level are substantially higher than those at the expert level. Therefore when all the users are at novice level, the rate of request submissions (to the system) is lower compared to all-experts. This leads to less waiting times during novice request executions and higher waiting times for expert request executions.

Table 2. Mean SRTs $\overline{\boldsymbol{s}_{\text {novıce }}}$ (i.e. $\overline{\boldsymbol{s}_{1}}$ ), $\overline{\boldsymbol{s}_{\text {intermedıate }}}$ (i.e. $\overline{\boldsymbol{s}_{7}}$ ) and $\overline{\boldsymbol{s}_{\text {expert }}}\left(\right.$ i.e. $\overline{\boldsymbol{s}_{15}}$ ) for different initial proportions of users. One logical-hour analysis. VM configuration consists of 6 VM replicas per tier. $N=120$ users.

| Initial User <br> Proportion <br> $\left[\mathbf{N}_{\mathbf{1}} / \mathbf{N}_{\mathbf{6}} / \mathbf{N}_{\mathbf{1 1}}\right]$ | $\overline{\boldsymbol{S}_{\text {novice }}}$ <br> (sec) | $\overline{S_{\text {Intermedıate }}}$ <br> (sec) | $\overline{\boldsymbol{s}_{\text {expert }}}$ <br> $(\mathrm{sec})$ |
| :---: | :---: | :---: | :---: |
| $[120 / 0 / 0]$ | 2.25 | 5.12 | 7.22 |
| $[40 / 40 / 40]$ | 4.36 | 4.5 | 5.03 |

On the contrary, the mean SRT of 5.03 sec per expert trial is less in case of [40/40/40] in comparison to 7.22 sec for the proportion [120/0/0]. This is found from a one logicalhour analysis. The reason is as follows: In case of [120/0/0], all the users start at the novice level. They then transition to the intermediate level almost at the similar time. Finally, all the users transition from the intermediate to the expert level-again, almost at the similar time. Once at the expert level, the rate of request submissions by a user is higher in comparison to her rate of submissions either at the intermediate or at the novice level. On top of that, since almost all the users have transitioned to the expert level, an expert trial has no choice but to compete for resources against majority of the trials which are also occurring at the expert level. In contrast, for the case [40/40/40], an expert trial competes for resources against a mixture of novice, intermediate and expert trials. Consequently, the mean SRT for an expert trial is higher in case of [120/0/0] than the proportion [40/40/40].

Let an example SRT requirement be as follows: "The mean SRT should be less than or equal to 5.5 sec ". Table 2 suggests that the VM configuration ( 6 VM replicas per tier) will satisfy the threshold of 5.5 sec for only the proportion
[40/40/40] in one logical-hour analysis since all of $\overline{s_{\text {novice }}}$, $\overline{S_{\text {Intermedıate }}}$ and $\overline{S_{\text {expert }}}$ are below the threshold for that proportion. The other proportion [120/0/0] will not satisfy the threshold since $\overline{S_{\text {expert }}}=7.22 \mathrm{sec}$ being more than 5.5 sec , the proportion will not be able to meet the SRT threshold for the expert trials.

This analysis of the effect of user proportion on SRT can be used by the system analysts when the workload trend for the system under analysis is known. An example workload trend could be a plot of initial user proportions of 120 concurrent users of the system against different times of the day obtained from the historical data of the system's usage. Suppose the plot shows an initial user proportion [120/0/0] at 8 am and $[40 / 40 / 40]$ at 3 pm . Our aforementioned one logical-hour analysis predicts that from 8am to 9am, the configuration of 6 VM replicas per tier would not satisfy the threshold SRT of 5.5 sec . But, the same configuration would ensure usability satisfaction (with respect to SRT) across all expertise levels from 3 pm to 4 pm .

## Conclusions

We propose a queueing model that accounts for novice to expert transition in analyzing the performance of a distributed software system. Our model captures system performance in terms of system response time. We use the model to demonstrate how users-who are at various experience levels in the novice to expert continuum-may affect the system response time.

#### Abstract

Dialogism provides the grounds for building a comprehensive model of discourse and it is focused on the multiplicity of perspectives (i.e., voices). Dialogism can be present in any type of text, while voices become themes or recurrent topics emerging from the discourse. In this study, we examine the extent that differences between self-explanations and thinkalouds can be detected using computational textual indices derived from dialogism. Students $(n=68)$ read a text about natural selection and were instructed to generate selfexplanations or think-alouds. The linguistic features of these text responses were analyzed using ReaderBench, an automated text analysis tool. A discriminant function analysis using these features correctly classified $80.9 \%$ of the students' assigned experimental conditions (self-explanation vs. think aloud). Our results indicate that self-explanation promotes text processing that focuses on connected ideas, rather than separate voices or points of view covering multiple topics.

Keywords: comprehension; discourse analysis; dialogism; polyphonic model; self-explanation; think-aloud

## Introduction

Research on text comprehension suggests that skilled and less skilled readers differ in the frequency and type of strategies they employ while processing texts (Millis, Magliano, \& Todaro, 2006; Oakhill \& Yuill, 1996). Skilled readers, for instance, generate more inferences while reading, which allows them to establish connections between information in the text and their prior knowledge (Kintsch, 1998). Although not all readers naturally make these connections while reading, students can be prompted to generate inferences through instructions to self-explain (McNamara, 2004). Self-explanation is a response to text or discourse that is directed toward oneself, with an explicit purpose to construct meaning from the text. Explanations are statements generated aloud, through text, or silently to oneself, that go beyond the information provided explicitly
in the text to explain the ideas, their relations, and their underlying meaning.

In the context of text comprehension, self-explanation can improve readers' understanding of complex topics (McNamara, 2004, in press). From the point of view of theories within the field of text and discourse comprehension, the benefits of self-explanation have been attributed to increased bridging and elaborative inferences (i.e., making connections to prior ideas in the text or to prior knowledge) and to increased causal inferences (e.g., making connections to causal events; (Allen, McNamara, \& McCrudden, 2015)

Instructions to self-explain can be contrasted with those to think-aloud, which ask readers to report whatever thoughts are available to them while reading a text (e.g., readers report these thoughts after reading each sentence). Asking a reader to think-aloud reveals their use of comprehension strategies, including any inferences they generate while reading, but does not alter a reader's natural comprehension processes (McNamara \& Magliano, 2009).

In this study, we compare the comprehension processes associated with self-explanation and think-aloud from the lens of dialogism. Dialogism refers to a wider perspective of dialogue which is assumed to be present within any verbal or non-verbal language activity. Dialogism originates from the Russian philosopher and philologist Mikhail Bakhtin ( 1981,1984 ) who proposed that there is an implicit and multi-voiced dialogue underlying sense-making, communication, actions, and interactions (Linell, 2009). Accordingly, voices represent distinct positions, points of view, or ideas, that impact the nature and outcome of a discourse. Multi-voicedness, may drive to polyphony, which is a central concept within dialogism, and a focus of the polyphonic model, which is essential to this study (TrausanMatu \& Rebedea, 2009).

Dialogue traditionally refers to communication between two or more individuals. Indeed, within the context of

Computer Supported Collaborative Learning, dialogism has been considered better suited as a theoretical framework for multi-party conversations than classic Natural Language Processing theories that focus on phone-like interactions between two interlocutors (Trausan-Matu \& Rebedea, 2009).

Bakhtin, however, stressed the point that all text is multivocal, wherein our speech (all of our utterances) is filled with others' words (Bakhtin, 1986, p. 89). In this view, the concept of dialogue can be extended to include a wider variety of language activities. For instance, it may also refer to an internal dialogue within oneself or a dialogue amongst inner voices contrasting and debating ideas (Marková, Linell, Grossen, \& Salazar Orvig, 2007, ch. 6).

The polyphonic model is a generalization of Bakhtin's ideas in the sense that voices may not be only associated to an individual person. Voices may also be themes, or recurrent topics emerging from the discourse. They enter in inter-animation patterns which generate a polyphonic weaving characterized by a multitude of voices, each with its individuality, but which give birth to a coherent whole (Trausan-Matu \& Rebedea, 2009).

In this study, we apply the polyphonic model to analyze the presence of voices and their interactions within students' think-alouds and self-explanations. Think-aloud, by definition, is the externalization of the inner voice of the student, including voices that correspond to ideas, justifications, and assumed positions. Expressions of the text comprehension process by a student, in the form of think aloud or self-explanation, can be expected to include positions, reasons, ideas, all which may be viewed as voices.

We have operationalized the polyphonic model within the ReaderBench framework, which provides automated text and conversational analysis (Dascalu, 2014; Dascalu, Dessus, Bianco, Trausan-Matu, \& Nardy, 2014; Dascalu, Trausan-Matu, McNamara, \& Dessus, 2015). In ReaderBench, voices are identified using Natural Language Processing (NLP). Lexical chains (Galley \& McKeown, 2003), or sequences of repeated or related words, are merged into semantic chains by using relatedness calculated using Latent Semantic Analysis (Landauer \& Dumais, 1997) and Latent Dirichlet Allocation (Blei, Ng, \& Jordan, 2003). The previous semantic models play an important role in our polyphonic model as they are used to identify voices through semantic relatedness, thus highlighting cohesive contexts.

In addition, polyphonic inter-animation considers relations between voices, or points of view, along two dimensions: longitudinal along time, and transversal across time, using voices' co-occurrences within and across text segments (Trausan-Matu, Stahl, \& Sarmiento, 2007). The longitudinal dimension follows the continuation of ideas throughout the discourse, similar to a voice's individual melodic line in music. Simultaneously, voices co-occur in a vertical manner and, as in polyphonic music, this generates specific discourse contexts consisting of potential dissonances that need to be solved toward consonances.

This transversal effect, or voice overlap, supports the integration process that can create both unity across various themes, as well as differences or variations in points of view.

Specifically, we examine the extent to which differences between participants' expressions of self-explanation and think-aloud can be detected using the computational text analyses provided by ReaderBench, and in turn, how this theoretical perspective informs our understanding of text and discourse comprehension.

## Discourse Analysis within the Polyphonic Model

The polyphonic model can be used to analyze discourse in both conversations and plain texts (Trausan-Matu \& Rebedea, 2009). Bakhtin (1984) stated that polyphony occurs in any text, similarly to polyphonic music, composed under counterpoint rules. That means that there is a multitude of voices, each with its own individuality, whose sum comprises a coherent whole: "the voices of others become woven into what we say, write, and think" (Koschmann, 1999, p. 308). Meanwhile, the polyphonic discourse should also bring novelty, voices should interanimate in order to foster creativity. Following this perspective, the polyphonic approach to discourse analysis identifies voices in text and then investigates how voices are woven and how they inter-animate (Trausan-Matu, Stahl, et al., 2007).

Our automated process of voice identification starts by building lexical chains that are merged into semantic chains through semantic relatedness (Dascalu et al., 2015). Lexical chains can be identified using a disambiguation graph in which nodes are word instances having assigned their most probable sense, while weighted edges are semantic distances from WordNet (Galley \& McKeown, 2003). However, this approach is inherently limited because it only includes words from the same part of speech. Thus, we have used an iterative agglomerative hierarchical clustering algorithm that begins with the identified lexical chains as groups of clustered words and uses the semantic similarity between lexical chains as a distance function (Dascalu et al., 2015). If the semantic relatedness value is greater than an imposed threshold or if identical lemmas are identified in two word clusters, the latter are automatically merged.

Voices emerge as central topics of each text and rely on the occurrences of the underlying cohesive and semantically related words. The longitudinal dimension of voices becomes the context in which the voices span throughout the entire discourse. In contrast, the transversal dimension highlights different co-occurrence and inter-animation patterns of voices present within the same textual element, i.e., sentence or paragraph.

After voices are identified, a cohesion (or utterance) graph is constructed from the links between utterances (Dascalu, 2014; Dascalu, Dessus, Trausan-Matu, Bianco, \& Nardy, 2013; Trausan-Matu, Dascalu, \& Dessus, 2012; Trausan-Matu, Rebedea, Dragan, \& Alexandru, 2007) Within the cohesion graph, utterances are the nodes and
links consist of adjacency pairs, repetitions, or lexical and semantic chains, which are detected using NLP.

As such, voices can be identified as threads in the graphs (Trausan-Matu, Dascalu, \& Rebedea, 2014). Each utterance has an inner voice that inter-twines with other voices from the same thread or from different ones, but with less strength. Any new utterance in a dialogue is expressed as a voice, including its degree of interconnection with other utterances, relevance within the discourse, and potential impact within the overall discussion. Examining different semantic chains within the same textual fragment (sentences or paragraphs) reveals the transversal dimension of voice inter-animation.

## Current Study

This study comprises an analysis of a corpus of selfexplanations and think-alouds previously described in Allen et al. (2015). University students $(n=68)$ read a text about natural selection and were randomly assigned to one of two conditions related to their reading instructions: selfexplanation $(n=33)$ and think-aloud ( $n=35$ ). Students in the self-explanation and think-aloud conditions were prompted to generate typed responses on 16 occasions (i.e., on 16 of the 41 sentences). The self-explanation instructions asked students to explain the information they had just read to themselves, whereas the think-aloud instructions asked students to state whatever they were thinking. We aggregated students' 16 text responses (their self-
explanations or think-alouds) following the procedure described in Allen et al. (2015).

The individual files were then analyzed using ReaderBench. We calculated 29 voice indices related to:
a) span (distances between word occurrences within the same semantic chain),
b) recurrence (average and standard deviation in terms of distance between two consecutive words pertaining to the same voice, measured in number of in-between words from the initial text),
c) coverage of these semantic chains (average number of contained concepts per sentence or paragraph), and
d) information theory entropy (Shannon, 1948) based on the probability that a voice appears in a given text segment.

The previous indices relate to the longitudinal dimension of our analysis, while voice inter-animation relates to the transversal effect, which is computed in terms of cooccurrence patterns. As operationalization of the transversal dimension, we rely on: a) counting the number of concepts pertaining to different voices, but present in the same text segment, and b) pointwise mutual information (PMI) that measures the degree of association between voice distributions (Dascalu et al., 2015). These dialogic indices provide insights in terms of a text's overall cohesion, as voices help build a higher cohesion through lexical and semantic relatedness.

| Self-explanation (SE) | Think-aloud (TA) |
| :---: | :---: |
| In our lives, there are so many types of people around us to our lives colorful. also, in our daily lives, we meet different people who have different story to tell. some of them are happy, wealthy. Some of them have to worry about how to survive in this society. they are components to make our lives fascinates. <br> Life around us is fascinating because of the force of nature. those creatures around us are differently designed. Some of them are capable of seeing stuffs because they are given an unique thing-eye. that's one of the things to make them special, to make their lives fancy. <br> Life fascinates us because we have eyes. And eyes have precise arrangement so that eyes make us see things. This is also true for other organs, they are complexly design to make our body function. <br> Organs are not designed in advance for a specific purpose. organs are formed by the activities people do in their everyday-lives. organs are formed for the destination to make people survive, to make people's body function well. the two animals with cloudy lenses must give their next generation cloudy lens. and the generation of cloudy lens animal and clear lens animal will be hard to tell. because the offspring are given clear lens due to those who gave birth to it. Because a replicator is something that can make a copy of itself, with most of its traits duplicated in the copy, including the ability to replicate. The offspring's parents survived and pass this replicator to it, so that the offspring's eyes are the same as its parent's. | The surroundings we cannot to change, but we can our heart to adopt. <br> In my mind, the human also as one of the animals in the world, we have only different from the other animals because we have a thought. <br> The eyes is difference with the other organs. The animals eyes may be less important than other organs. <br> The author cannot to believe that the organs must have been designed in advance for a specific purpose is right. Used an example to support his ideal. According to the example, I feel that the offspring has clear lenses and can see well which is incorrect. in some way, their eyes has different with their parents' eyes. <br> That's mean the their another eyes is usedness. the better vision can help these animals to reproduce and get better generation. It's to point out the ideal which is the author want to explain. <br> The living surrounding makes natural selection in order to get better next generation. that's mean we can change or direct the selection to product. replicators try to use-up material to find their the great copies and energy to power replication. the most of the copying is worse that causing less efficient just the less of the copying is better and useful, back to the viewpoint. the apparent well engineered body is result by the replicator to make the natural selection. <br> Organisms is the standard by the natural selection. |

| Percentage of words that are included in <br> lexical chains | $\mathbf{0 . 5 8}(0.07)$ | $\mathbf{0 . 6 5}(0.13)$ | 5.755 | $<.05$ | .080 |
| Standard deviation of distributions per <br> paragraph | $\mathbf{0 . 7 5}(0.04)$ | $0.09(0.03)$ | 5.291 | $<.05$ | .074 |
| Standard deviation of sentence voice co- <br> occurrences | $\mathbf{1 . 5 1}(0.35)$ | $0.72(0.06)$ | 4.994 | $<.05$ | .070 |

Figure 1 presents an example of inter-animation of voices within a self-explanation and a think-aloud verbal protocol. Several threads that can be considered as voices, ranging from simple word repetitions (i.e., "organs") to semantically related concepts (i.e., "eye - lens", "generation - parent offspring", "copy - replication - duplicate - replication"), co-appear and inter-animate. Additional voices can be identified in both texts, but it is important to observe differences in terms of distributions: denser, more cluttered and more elaborated voices are present in self-explanations versus more varied and more spread-out voices in thinkalouds.

In addition, the texts exhibit different discourse structures: longer, more elaborated and more cohesive paragraphs in self-explanations versus shorter, more condensed phrases introducing multiple ideas in think-alouds. These latter discourse specific traits also directly influence the distribution of voices within the underlying analysis element (paragraph or sentence) as the chance of voice cooccurrence inherently increases in longer texts (e.g., selfexplanations).

## Results

Statistical analyses were conducted to assess the extent to which the dialogic indices related to voices and in turn, accurately classified students based on their experimental condition. Because ReaderBench reports raw voice counts, indices were also checked for multicollinearity with text length. Any index that was highly collinear ( $r>.90$ ) with text length was removed. We then conducted a MANOVA to identify which indices exhibited significant differences between the self-explanation and think-aloud conditions. Indices that were highly collinear ( $r>.90$ ) were flagged, and the index with the strongest effect size in the MANOVA was retained while the other indices were removed (see Table 1).

Longer spans of both lexical chains and voices, as well as higher paragraph and sentence voice co-occurrences, are indicative of longer, more elaborated texts (i.e. selfexplanations). Self-explanations also have higher standard deviations of co-occurrence patterns at both sentence and paragraph levels which reflect a greater variety of voices, as well as a more diverse and unequal overlap of voices. Higher voice entropy at sentence level and higher standard deviation of voice distributions at paragraph level also support the latter finding. Moreover, self-explanations have a slightly higher coverage of words that are integrated in longer semantic chains, thus denoting a more connected discourse. In contrast, think-alouds exhibited a higher standard deviation of paragraph voice pointwise mutual information. This was specific to the generation of new ideas which may or may not be intertwined with other voices. This result is indicative of a wider spread of synergic effects - either new, more isolated voices, or ones that interanimate more with the previous voices.

Based on the MANOVA, we selected the four indices with the strongest effect sizes to enter into a stepwise discriminant function analysis (DFA): Average span of lexical chains $(S E>T A)$, Average paragraph voice cooccurrence $(S E>T A)$, Average sentence voice cooccurrence ( $S E>T A$ ), and Standard deviation of paragraph voice co-occurrences ( $S E>T A$ ).

Table 2: DFA results.

|  | Type | Predicted Group <br> Membership |  | Total |
| :--- | :--- | :---: | :---: | :---: |
|  |  | SE | TA |  |
| Original | SE | 25 | 8 | 33 |
|  | TA | 5 | 30 | 35 |
| Cross- | SE | 25 | 8 | 33 |
| validated | TA | 6 | 29 | 35 |

Note: $\mathrm{SE}=$ self-explanation; $\mathrm{TA}=$ think-aloud

The DFA yielded a significant model, $\chi 2(d f=1$, $n=68)=34.243, p<.001$, correctly allocating $55(25+30)$ of the 68 students (accuracy $=80.9 \%$, see Table 2). To test the stability of our model, we conducted a leave-one-out cross-validation analysis, which also yielded an accuracy of $79.4 \%$. The measure of agreement between the actual instructional group and that assigned by our model produced a weighted Cohen's Kappa of .616, demonstrating substantial agreement.

## Discussion and Conclusions

In the current study, we examined the differences from a dialogism perspective between self-explanations and thinkalouds generated in response to a text. In previous research on this dataset (Allen et al, 2015), we examined the causal and referential cohesion differences between selfexplanation and think-aloud. The results of the latter study indicated that causal cohesion, but not referential cohesion differentiated students who were in the self-explanation and think-aloud conditions. In the current study, we build on this prior research by examining how textual indices related to dialogism relate to students' processing of text based on their text reading instructions.

Our results indicate that students who self-explained the text generated longer voices (lexical or semantic chains with a higher span) that inter-animate more (higher voice cooccurrences at sentence and paragraph levels). This suggests that students who were prompted to self-explain responded to the text by maintaining semantic connections of the concepts within the text.

We interpret these results to indicate that self-explanation promotes specific comprehension processes that are fundamentally different from responses generated during think-aloud protocols, evidenced by students' generation of more conceptually related and cohesive text responses, rather than multiple, separate "voices" or points of view covering multiple topics. Previous research indicates that self-explanation can enhance students' understanding of complex concepts; however, it is less clear how these instructional differences manifest in the linguistic properties of students' text responses.

By adopting a Natural Language Processing approach, this study examines on-line comprehension processes at a more fine-grained level and also contributes to a better understanding of how these processes may be automatically detected via computational linguistic analyses. The polyphonic model, built on dialogism and integrating advanced NLP techniques, represented a viable alternative to analyze students' discourse and differentiate among instructional settings.

As a limitation of our approach, voices need to account for more than word clustering based on distance, lexical and semantic overlaps which are currently used to operationalize our polyphonic model. In addition, many voice indices are multicollinear with text length. We need to develop methods to normalize raw voice score to help control for text length constraints. Voices represent a generalization of emerging
topics and should consider the corresponding sentiment valences in order to create a clearer perspective whether convergence or dissonances are encountered in the discourse. In order to address this issue, opinion mining techniques will be integrated in a follow-up iteration of our implemented model.

The dialogical framework offers new perspectives in the context of this study because both self-explanation and think-aloud be perceived as different kinds of dialogues. Self-explanations on the one hand include positions, reasons, ideas, all of which may be viewed as voices while the overall discourse can be regarded as an 'internal dialogue within the self' (Linell, 2009, ch. 6). On the other hand, think-alouds are more condensed, centered on generating new ideas and can also be perceived a 'dialogue between ideas' (Marková et al., 2007, ch. 6), a dialogue in which the debating voices are ideas. However, in both cases reflexive and cognitive processes are needed in order for students to express themselves.

As Linell (2009) stated, dialogues occur 'in and through words.' Certainly, there is more to dialogue and communication - for example, gestures, facial expressions, emotions, movement, all play crucial roles in dialogue; but here, because it is printed text, we can only examine words. Nonetheless, dialogism is tightly connected to the notion of sense-making as meaning is constructed by interacting with others and with the world, as well as with oneself via internal dialogue. As such, dialogism has a strong connection to cognition, which is sometimes ignored. Figure 2 represents this viewpoint. Cognition reflects prior and intrapersonal (individual) information and knowledge about the world, while meaning is constructed through social interactions and language within the dialogical context. Communication, both explicit interpersonal dialogue and implicit to oneself (i.e., internal dialogue), becomes a facilitator in terms of interaction, therein generating meaning in discourse.

Figure 2. Dialogical framing and interdependencies with core concepts.

#### Abstract

Bayesian models of cognition posit that people compute probability distributions over hypotheses, possibly by constructing a sample-based approximation. Since people encounter many closely related distributions, a computationally efficient strategy is to selectively reuse computations - either the samples themselves or some summary statistic. We refer to these reuse strategies as amortized inference. In two experiments, we present evidence consistent with amortization. When sequentially answering two related queries about natural scenes, we show that answers to the second query vary systematically depending on the structure of the first query. Using a cognitive load manipulation, we find evidence that people cache summary statistics rather than raw sample sets. These results enrich our notions of how the brain approximates probabilistic inference.

Keywords: Amortization; hypothesis generation; Bayesian inference; Monte Carlo methods

## Introduction

Many theories of probabilistic reasoning assume that people are equipped with a general-purpose inference engine that can be used to answer arbitrary queries for a wide variety of probabilistic models (Griffiths et al., 2012). The flexibility and power of a general-purpose inference engine trades off against its computational efficiency: by avoiding any assumptions about the query distribution, the inference engine relinquishes the opportunity to reuse computations across queries. Conversely, an inference engine may gain efficiency by incurring some amount of bias due to reuse-a strategy we refer to as amortized inference (Stuhlmüller et al., 2013; Gershman \& Goodman, 2014). We propose that people employ some form of this strategy, flexibly reusing past inferences in order to efficiently answer new but related queries.

The experiments reported in this paper explore amortization in sets of related queries that involve probabilistic inference over a very large space of possibilities. These possibilities are not all explicitly provided and have to be generated by the participant in order to carry out the inference. We frame amortization as the reuse of hypotheses that have already been generated in response to previous queries. We model the process of hypothesis generation with a stochastic sampling mechanism (Lieder et al., 2012; Dasgupta et al., 2016). One way to implement amortization in this framework is to directly reuse samples across different queries. Alternatively, amortization could be implemented by reusing some summary statistic compiled from previous samples. One goal of our experiments is to tease apart these different mechanistic assumptions. The basic logic of our experiments is to hold
one query fixed while manipulating an earlier query, allowing us to interrogate reuse of computations across queries.

## Stochastic hypothesis generation

For complex hypothesis spaces, exact probabilistic inference is typically intractable. Several lines of evidence point to the idea that humans approximate inference by constructing a Monte Carlo approximation of the posterior distribution (see Griffiths et al., 2012; Sanborn \& Chater, 2016, for a review). This "sampling hypothesis" can be realized algorithmically in a number of ways. Recent studies have shown how a number of apparent probabilistic fallacies can be understood as a consequence of resource-bounded sampling using a Markov chain Monte Carlo (MCMC) algorithm (Lieder et al., 2012; Dasgupta et al., 2016). Because we build on those studies in this paper, we briefly describe the theoretical framework.

A Monte Carlo approximation uses a set of $N$ samples $\left\{h_{1}, \ldots, h_{N}\right\}$, drawn from a hypothesis space $\mathcal{H}$, to approximate a target distribution. In our case, the target is the posterior distribution over hypotheses given data $d, P(h \mid d) \propto$ $P(d \mid h) P(h)$. The Monte Carlo approximation is defined by:

$$
\begin{equation*}
P(h \mid d) \approx \frac{1}{N} \sum_{n=1}^{N} \mathbb{I}\left[h_{n}=h\right], \tag{1}
\end{equation*}
$$

where $\mathbb{I}[\cdot]=1$ if its argument is true ( 0 otherwise). MCMC algorithms generate samples by simulating a Markov chain whose stationary distribution is the posterior (MacKay, 2003). This approach is asymptotically exact (the approximation converges to the posterior as the number of samples approaches infinity) but under time or resource constraints only a small number of samples may be generated. Although this gives rise to systematic deviations from exact inference, it may in fact be the computationally rational sampling policy (Lieder et al., 2012; Vul et al., 2014; Gershman et al., 2015).

In our prior research (Dasgupta et al., 2016), we applied this model to a scene inference domain, using a database of natural object co-occurrence statistics compiled by Greene (2013). The task facing subjects in our experiments was to judge the probability of a particular set of latent objects in a scene conditional on observing another object (the cue). By manipulating the framing of the query, we showed that subjects gave different answers to formally equivalent queries. Specifically, by partially unpacking the queried object set (where fully unpacking an object set means to present it explicitly as a union of each of its member objects) into a small set of exemplars and a 'catch-all' hypothesis (e.g., "what is the probability that there is a book, a box, or any other object
beginning with B ?"), we found that subjects judged the probability to be higher when the unpacked exemplars were typical (a "subadditivity" effect; cf. Tversky \& Koehler, 1994) and lower when the unpacked exemplars were atypical (a "superadditivity" effect; cf. Sloman et al., 2004) compared to when the query is presented without any unpacking. To give a concrete example, in the presence of say a 'table', the typically unpacked query "what is the probability that there is also a chair, a curtain, or any other object beginning with C?" generates higher probability estimates, and the atypically unpacked query "what is the probability that there is also a cow, a canoe, or any other object beginning with C?" generates lower probability estimates, when compared to the packed query "what is the probability that there is also another object beginning with C ?".

These effects could be accounted for by the MCMC model under the assumption that the unpacked exemplar(s) initialize the Markov chain(s) that form the sample set. Because the initialization of the Markov chain transiently determines its future trajectory, initializing with typical examples causes the chain to tarry in the high probability region of the queried object set, thereby increasing its judged probability (subadditivity). However, initializing with atypical examples causes the chain to get easily derailed into regions outside the queried object set and thus generate more hypotheses that are not in the queried object set. This decreases the judged probability of the queried object set (superadditivity). The strength of these effects diminishes with the number of samples, as the chain approaches its stationary distribution (which is the same for all conditions). Accordingly, response time and cognitive resource availability modulate the effect size (Dasgupta et al., 2016).

## Amortized inference in hypothesis generation

We will consider two simple amortization schemes within the MCMC framework described above. ${ }^{1}$ In sample reuse, people may simply add samples generated in response to one query ( $Q 1$ ) to the sample set for another query ( $Q 2$ ). So if $N_{1}$ samples were generated in response to $Q 1$, and $N_{2}$ new samples are generated in response to $Q 2$, the response to $Q 2$ is given by a calculation carried out over all $N_{1}+N_{2}$ equally weighted samples. Under this scheme, all the computations carried out for $Q 1$ are available for flexible reuse in the computation for $Q 2$. In summary reuse, people may reuse a summary statistic computed from $Q 1$. This strategy is only applicable to problems where the answer to $Q 2$ can be expressed as the composition of the answer to $Q 1$, and an additional simpler computation. To make this viable in our experiments, $Q 2$ queries a hypothesis space that is the union between the hypothesis space queried in $Q 1$ and a disjoint hypothesis space. For example if $Q 1$ is "What is the probability that there is an object starting with a C in the scene?",

[^312]Q2 could be "What is the probability that there is an object starting with a C or an R in the scene?". In this case, the $N_{1}$ samples generated in response to $Q 1$ are summarized into one probability ("the probability of an object starting with C"), $N_{2}$ new samples are generated in response to a simpler query ("the probability of an object starting with R"), and these two numbers are then composed (in this case simply added) to give the final estimate for $Q 2$ ("the probability of an object starting with $C$ or R"). Under this scheme, only the final product of the computation carried out for $Q 1$ is reused in the calculations for $Q 2$. These two models are the two extremes between very flexible and very rigid reuse; intermediates are of course possible.

Figure 1: Simulation of subadditivity and superadditivity effects under sample-based (top) and summary-based (bottom) amortization schemes. In all panels, the y-axis represents the effect size for $Q 2$. Left panels show the effects of changing the sample size for $Q 1$; right panels show the effects of changing the sample size for $Q 2$. When, sample size for $Q 2$ is changed, sample size for $Q 1$ is held fixed at 230 , and vice versa.

Sample-based and summary-based amortization schemes make different predictions about how subadditivity and superadditivity change as a function of the sample size (Figure 1). Increasing the sample size for $Q 1$ amplifies the effects for $Q 2$ under a sample-based scheme, because this leads to more $Q 1$ samples being reused for $Q 2$. This effect can be counteracted by increasing the sample size for $Q 2$, which pushes the effects down (the effects go to 0 as the sample size for Q2 tends to infinity, since the Markov chain will converge to the same posterior for all conditions). Under a summarybased scheme, increasing the sample size for $Q 1$ will actually diminish the effects for $Q 2$, because the bias from $Q 1$ is strongest when the chain is close to its starting point. In other words, the subadditivity and superadditivity effects for Q2 derive from the same effects in $Q 1$, which themselves are primarily driven by the initialization (see Dasgupta et al., 2016). In Experiment 2, we test these different predictions by placing people under cognitive load during either $Q 1$ or

Table 1: Experimental stimuli and queries.

Q2, a manipulation that is thought to reduce the number of samples (Dasgupta et al., 2016; Thaker et al., 2017).

## Experiment 1

Our first experiment pursued a basic carryover effect from one query $(Q 1)$ to the next ( $Q 2$ ). We assessed two putative signatures of sampling-subadditivity and superadditivityfor a fixed $Q 2$ while changing the structure of $Q 1$. Specifically, we compared three conditions that differed only in how $Q 1$ was framed: packed, unpacked-typical, and unpackedatypical. In order to encourage amortization, we specified $Q 2$ as a union of the hypothesis space queried by $Q 1$ and another hypothesis space-i.e., a disjunctive query. The design is summarized in Table 1.

## Participants

84 participants ( 53 males, mean age $=32.61, \mathrm{SD}=8.79$ ) were recruited via Amazon's Mechanical Turk and received \$0.5 for their participation plus an additional bonus of $\$ 0.1$ for every on-time response.

## Procedure

Participants were asked to imagine playing a game in which their friend sees a photo and then mentions one particular object present in the photo (the cued object). The participant is then queried about the probability that another class of objects (e.g., "objects beginning with the letter B") is also present in the photo.

Each participant completed 6 trials, where the stimuli on every trial corresponded to the rows in Table 1. On each trial, participants first answered $Q 1$ given the cued object, using a slider bar to report the conditional probability (Figure 2). The Q1 framing (typical-unpacked, atypical-unpacked or packed) was chosen randomly. Participants then completed the same

Figure 2: Experimental setup. Participants were asked to estimate the conditional probability using a slider bar within a 20 -second time limit.
procedure for $Q 2$, conditional on the same cued object. The framing for $Q 2$ was always packed.

## Results

Consistent with our prior studies (Dasgupta et al., 2016), we find both subadditivity and superadditivity effects for $Q 1$, depending on the unpacking (Figure 3): probability judgments were higher for unpacked-typical queries than for packed queries (a subadditivity effect; $t(77)=4.029, p<0.001$ ) and lower for unpacked-atypical than for packed queries (a superadditivity effect; $t(77)=-6.4419, p<0.001$ )

Figure 3: Experiment 1 results. Mean probability estimates by condition. Error bars represent the standard error of the mean.

Crucially, we also saw effects of $Q 1$ unpacking on response to $Q 2$, even though these queries were all presented as packed hypotheses. In particular, estimates for $Q 2$ were lower when $Q 1$ was unpacked to atypical exemplars $(t(77)=$ $-5.0789, p<0.001)$, demonstrating a superadditivity effect
that carried over from one query to another. We did not find an analogous carry-over effect for subadditivity $(t(77)=$ $0.72, p>0.4$ ), possibly due to the subadditivity effect "washing out" more quickly (i.e. with fewer samples) than superadditivity, at least within this domain (see Dasgupta et al., 2016).

Next, we explored whether responses to $Q 1$ predicted trial-by-trial variation in responses to Q2. As shown in Figure 4, we found significant positive correlations between the two queries in all conditions when aggregating across participants ( $p<0.01$ ). The same conclusion can be drawn from analyzing correlations within participants and then testing the average correlation against 0 (average correlation: $r=0.55$, $p<0.01$ ). Moreover, the within-participant effect size (the response difference between the unpacked conditions and the packed conditions) for $Q 1$ was correlated with responses to $Q 2$ for both atypical ( $r=0.35, p<0.01$ ) and typical ( $r=0.21, p<0.05$ ) unpacking conditions. This means that even though the subadditive condition did not significantly differ from the unpacked condition for $Q 2$ overall, participants who showed greater subadditivity or superadditivity for Q1 also showed correspondingly greater effects for $Q 2$.

Figure 4: Experiment 1 trial-by-trial analyses: Relationship between aggregated $Q 1$ and $Q 2$ responses. Lines show the leastsquares fit with standard error bands.

## Experiment 2

Experiment 1 showed strong evidence for reuse of inferential computations across queries when the evidence is fixed. Two questions naturally arise from this finding. First, how adaptive is amortization? Are samples reused promiscuously across queries (potentially leading to rampant memory-based biases), or is reuse sensitive to conditions where it is likely to be accurate? This is a delicate point, since it is impossible to know with certainty whether amortization is useful without knowing some properties of the problem (e.g., decomposability of the conditional distribution). Nonetheless, humans
may be able to utilize heuristics for constructing amortization strategies whose errors can be corrected by additional experience or computation (Stuhlmüller et al., 2013). We address this question by manipulating the "amortizability" of $Q 1$, in order to test the hypothesis that carry-over effects across queries will only occur under high amortizability conditions. We operationalize amortizability in terms of whether or not the hypothesis space queried by $Q 1$ is a subset of the hypothesis space queried by $Q 2$.

The second question concerns resource allocation. Theories of computational rationality argue that computations are selected to balance accuracy and cost (Lieder et al., 2012; Gershman et al., 2015). In the context of sampling, this means that fewer samples will be generated when cognitive resources are scarce. This hypothesis is consistent with the observation that subadditivity (Sprenger et al., 2011) and order effects (Thaker et al., 2017) are amplified under cognitive load. We pursue this question by manipulating cognitive load at both $Q 1$ and $Q_{2}$. As discussed in the Introduction, the different amortization schemes make different predictions for these manipulations (see Figure 1).

## Participants

80 participants ( 53 males, mean age $=32.96, \mathrm{SD}=11.56$ ) were recruited from Amazon Mechanical Turk and received \$0.5 as a basic participation fee and an additional bonus of $\$ 0.1$ for every on time response as well as $\$ 0.1$ for every correctly classified digit during cognitive load trials.

## Procedure

The procedure in Experiment 2 was largely the same as in Experiment 1, with the main difference being that participants had to remember a sequence of digits. On half of the trials the cognitive load manipulation occurred at $Q 1$ and on half at $Q 2$. The digit sequence was presented prior to the query, and then following their response to the query they were asked to make a same/different judgment about a probe sequence. Half of the probes were old and half were new.

To probe adaptive amortization, we added several $Q 2$ queries to the list shown in Table 1. These queries were deemed less amortizable because they lack any of the letters queried in Q1 (for example, ' T or R ' instead of ' C or R ' in the trial shown in the first row in Table1). In other words, these queries could not be decomposed and hence could not benefit from reuse. Half of the Q2 trials were randomly chosen to provide hypotheses with low amortizability.

## Results

As shown in Figure 5, we replicated and extended the results from Experiment 1, showing both subadditivity and superadditivity effects for $Q 1$ that carried over to $Q 2$. Analyzing only amortizable queries (averaging across load conditions), we found that probability judgments for Q1 were higher for unpacked-typical compared to packed (subadditivity; $t(79)=4.38, p<0.001)$ and lower for unpackedatypical compared to packed (superadditivity $t(79)=-4.94$,
$p<0.001$ ). These same effects occurred for $Q 2$ (unpackedtypical vs. packed: $t(79)=2.44, p<0.01$; unpackedatypical vs. packed: $t(79)=-1.93, p<0.05)$.

Figure 5: Experiment 2 results. Mean probability estimates for Q2 by condition. Error bars represent the standard error of the mean.

As in Experiment 1, there was strong correlation between responses to $Q 1$ and $Q 2$ overall conditions ( $r=0.44, p<$ 0.001 ), for the packed ( $r=0.44, p<0.001$ ), the typically unpacked ( $r=0.45, p<0.001$ ), as well as the atypically unpacked condition ( $r=0.35, p<0.01$ ); see Figure 6. Moreover, $Q 1$ and $Q 2$ were also highly correlated within participants (mean $r=0.31, p<0.01$ ) and participants who showed higher subadditivity or superadditivty effects for $Q 1$ also showed higher effects for $Q 2$ overall ( $r=0.31, p<0.001$ ), for the superadditive ( $r=0.3, p<0.001$ ), and for the subadditive condition ( $r=0.29, p<0.001$ ). This replicates the effects of amortization found in Experiment 1.

Figure 6: Experiment 2 trial-by-trial analyses: Relationship between aggregated $Q 1$ and $Q 2$ responses. Lines show the leastsquares fit with standard error bands.

Finally, we assessed how the carryover effects were mod-

Figure 7: Experiment 2: differences between responses for each condition and an average packed baseline. Bars represent a mean within-participant absolute effect. Error bars represent the standard error of the mean.
ulated by cognitive load and amortizability. To highlight the effects more clearly, we calculated each participant's mean response to all packed hypotheses for $Q 2$ over all trials as a baseline measure. We then calculated the difference between each condition's mean response and this mean packed response. This provides us with a measure of an average effect size within $Q 2$-responses (how much each participant underor overestimates different hypotheses as compared to an average packed hypothesis). Results are shown in Figure 7.

If cognitive load occurred during $Q 2$ and amortizability was low, none of the conditions produced an effect significantly different from 0 (all $p>0.5$ ). If cognitive load occurred during $Q 2$ and amortizability was high, only typically unpacked hypotheses produced an effect significantly higher than $0(t(38)=2.14, p<0.05)$. If cognitive load occurred during $Q 1$ and amortizability was low, again none of the conditions significantly differed from 0 (all $p>0.05$ ). Crucially, if cognitive load occurred during $Q 1$ and amortizability was high, both conditions showed the expected subadditive $(t(38)=4.18, p<0.05)$ and superadditive $(t(46)=$ $-1.89, p<0.05)$ effects. Moreover, calculating the average effect size for the different quadrants of Figure 7, the high amortizability-cognitive load at $Q 1$-condition produced the highest overall effect ( $d=0.8$ ), followed by the high amortizability-cognitive load at $Q 2$-condition $(d=0.56)$ and the low amortizability-cognitive load at $Q 1$-condition ( $d=0.42$ ). The low amortizability-cognitive load at $Q 2$ condition did not produce an effect higher than 0 . Moreover, highly amortizable trials were more strongly correlated with responses during $Q 1$ than trials with low amortizability ( 0.15 vs $0.41, t(157)=-2.28, p<0.05)$.

Intriguingly, on trials with cognitive load at $Q 2$, participants were on average more likely to answer the probe correctly for high amortizability trials compared to low amortizability trials $(t(36)=3.16, p<0.05)$. This is another signature of amortization: participants are expected to have more resources to spare for the memory task at $Q 2$ if the computations they did for $Q 1$ are re-usable in answering $Q 2$. This also indicates that these results cannot be explained by simply initializing the chain for $Q 2$ where the chain for $Q 1$ ended, which would not have affected computation time. Our results suggest that the transfer actually makes the second computation easier by re-using previous computations.

In summary, Experiment 2 replicates the effects found in Experiment 1 and the increased effect for the high amortizability condition provides further evidence that this effect is actually driven by amortization. These experiments also give us some insight into how amortization is implemented. Based on our simulations (Figure 1), we argue that the effect of cognitive load at $Q 1$ on $Q 2$ responses is more consistent with summary amortization than with sample amortization. These results suggest an active process of $Q 2$ being expressed in terms of the results to $Q 1$, when possible. This approach is more structured and less flexible than sample amortization but trades in this inference limitation for an increase in memory-efficiency and is thus consistent with beliefs about cost-efficient resource-rational inference strategies in humans.

## Discussion

In two experiments, we provided empirical support for amortized hypothesis generation. Participants not only exhibited subadditive and superadditive probability judgments in the same paradigm (replicating Dasgupta et al., 2016), but also carried over these effects to subsequent queries. Importantly, Experiment 2 demonstrated that such carry-over effects only occur when amortization can exploit shared structure across queries. Experiment 2 also demonstrated that cognitive load exerts its strongest effect when applied to the first query, suggesting (based on our simulations) that the carry-over effects are driven by some kind of summary-based amortization, whereby a summary statistic is computed from the samples and then reused to answer subsequent queries that can be expressed in terms of already completed calculations. This implies a structured amortization strategy, over one that reuses all old samples, and thus gives up some flexibility for memory-efficiency. Building on earlier results (Gershman \& Goodman, 2014), our results support the existence of a sophisticated inference engine that adaptively exploits past computations. While reuse can introduce error, this error may be a natural consequence of a resource-bounded system that optimally balances accuracy and efficiency (Lieder et al., 2012; Vul et al., 2014; Griffiths et al., 2015; Gershman et al., 2015). The incorporation of reuse into a Monte Carlo sampling framework allows the inference engine to preserve asymptotic exactness while improving efficiency in the finite-
sample regime
Future studies could use similar methods to study amortization in other domains, such as in concept learning (Goodman et al., 2008) or reinforcement learning tasks (Daw et al., 2011). There is also a much larger space of more sophisticated amortization schemes (e.g., Stuhlmüller et al., 2013; Rezende et al., 2014; Paige \& Wood, 2016) that we have not yet tried to test. Pinning down the computational details of amortization will be an important task for future work.

# The Causal Sampler: A Sampling Approach to Causal Representation, Reasoning and Learning 

Zachary J. Davis (zach.davis@nyu.edu)<br>Bob Rehder (bob.rehder@nyu.edu)<br>Department of Psychology, New York University<br>6 Washington Place, New York, NY, USA 10003 USA

#### Abstract

Although the causal graphical model framework has achieved success accounting for numerous causal-based judgments, a key property of these models, the Markov condition, is consistently violated (Rehder, 2014; Rehder \& Davis, 2016). A new process model-the causal sampler-accounts for these effects in a psychologically plausible manner by assuming that people construct their causal representations using the Metropolis-Hastings sampling algorithm constrained to only a small number of samples (e.g., $<20$ ). Because it assumes that Markov violations are built into people's causal representations, the causal sampler accounts for the fact that those violations manifest themselves in multiple tasks (both causal reasoning and learning). This prediction was corroborated by a new experiment that directly measured people's causal representations.

Keywords: causal learning, causal reasoning, sampling

## Introduction

The representation and use of causal knowledge is a central object of investigation in the cognitive sciences. Causal models have been found to affect cognition in a wide variety of inference problems, from reasoning and learning to decisionmaking and categorization (for a summary, see Rottman \& Hastie, 2014; Waldmann \& Hagmayer, 2013). One formal model of the representation of causal information - causal graphical models - has achieved success in modeling behavior across these tasks.

A foundational feature of causal graphical models is the Markov condition, which stipulates that the value of a node is independent of its non-descendants, conditional on its parents. This principle is crucial for statistical inference from causal graphical models (Pearl, 1988; Koller \& Friedman, 2009), and has been argued to be necessary for a rigorous account of interventions (Hausman \& Woodward, 1999).

Given the success of the causal graphical model formalism, one might expect to find the Markov condition satisfied in human behavior. In contrast, the causal inferences that people draw consistently violate the independence relationships implied by the Markov condition (Rehder, 2014; Rehder \& Burnett, 2005; Rehder \& Waldmann, 2016).

One explanation for Markov violations is that they represent a flaw in people's causal reasoning process. On this account, Markov violations would not necessarily manifest themselves on other causal-based tasks (e.g., causal learning). Rehder and Davis (2016) investigated this possibility by testing whether people honor the Markov condition during a causal hypothesis testing task. In fact, the hypothesis they favored reflected the same independence violations that characterize causal reasoning (details below).

Together, these findings pose a problem for current theories of causal cognition. We propose that the generality of these errors suggests that a reorientation is needed in our understanding of how people represent causal relationships. To this end, we propose a process model that conceives of causal cognition as based on simulation, rather than analytic calculation. The model outperforms traditional Bayes nets across tasks, and we test its predictions in a novel task.

## Process Model

Building on recent work in cognitive science that investigates the role of sampling methods in accounting for judgments in a variety of domains (Hertwig \& Pleskac, 2010; Lieder, Griffiths, \& Goodman, 2012; Vul et al., 2014), we propose a model for resource-constrained inference using causal models. In particular, we propose that, when reasoning about causal systems, people attend to concrete cases and shift attention between those cases systematically. This process yields a joint distribution as a representation of the causal system, which can be used for inference in any task that can be modeled with causal graphical models.

## Formalization

The proposed model is a variant of Metropolis-Hastings (MH) Markov Chain Monte Carlo, a computationally efficient rejection sampling method (Hastings, 1970). MH is defined by two components: a proposal distribution $\mathbb{Q}\left(q^{\prime} \mid q\right)$ and a transition probability $a\left(q^{\prime} \mid q\right)$, where $q$ is the current state and $q^{\prime}$ is the proposal state in the random walk. Whereas MH models often deal with a continuous state space, the proposed model samples over the discrete states of a causal model. Figure 1B presents the eight states for the three variable graph shown in Figure 1A.

The sampling process uses the standard MH transition probability:

$$
a\left(q^{\prime} \mid q\right)=\min \left(1, \frac{\pi\left(q^{\prime}\right)}{\pi(q)}\right)
$$

where $\pi(q)$ is the joint probability of the graph being in state $q$ given the graph's parameters (see the Appendix for an example of how $\pi(q)$ is calculated). The parameters reflect the particular beliefs of the participant (e.g. the causal strength between cause and effect).

We assume a proposal distribution $\mathbb{Q}\left(q^{\prime} \mid q\right)$ that restricts reachable states $q^{\prime}$ to those that differ from the current state $q$ by one binary variable. Each reachable state has an equal
probability of being selected. Edges in Figure 1B denote reachable states for a node.

Note that this proposal distribution confers additional efficiency benefits. Because only one variable is changed, the ratio $\frac{\pi\left(q^{\prime}\right)}{\pi(q)}$ simplifies to

$$
\frac{\pi\left(v_{i}^{\prime}, v_{-i}\right)}{\pi\left(v_{i}, v_{-i}\right)}=\frac{\pi\left(v_{i}^{\prime} \mid v_{-i}\right) \pi\left(v_{-i}\right)}{\pi\left(v_{i} \mid v_{-i}\right) \pi\left(v_{-i}\right)}=\frac{\pi\left(v_{i}^{\prime} \mid v_{-i}\right)}{\pi\left(v_{i} \mid v_{-i}\right)}
$$

where $v_{i}$ is the value of node $i$ in $q$, and $v_{i}^{\prime}$ is the value in $q^{\prime}$. This reduces the problem to calculating the relative conditional probabilities of two states, rather than representing the entire joint distribution. That calculating conditional probabilities only requires consideration of the node's Markov blanket further aids efficiency (Koller \& Friedman, 2009).

The model thus far is simply an efficient MH model for estimating a causal graph's joint distribution. Importantly, however, we introduce a bias in the starting point for sampling: It always starts sampling from 'prototype' states, those in which nodes are either all 0 or all 1 (bottom left and top right corners of Figure 1B). This assumption is inspired by JohnsonLaird's influential Mental Models theory, in which the most easily represented state is the one where antecedent and consequent are both true (Johnson-Laird \& Byrne, 2002). We propose that prototype states are the most easily represented states of a causal graph.

Regardless of our proposal distribution and biased initial samples, with many samples (e.g., $10^{6}$ ), the causal sampler will converge to the normative distribution. However, we assume that people are resource-constrained and thus can only take a few samples (on the order of less than twenty). In this range, an MH model will overestimate the probability of states near the starting point (as it did not have time to fully explore the state space) and underestimate the remaining states. This effect is shown in Figure 2.

Figure 1: (A) Common effect network. (B) Possible concrete states of a common effect network. Filled in circles indicate a value of 1 , empty circles indicate a value of 0 .

Figure 2: Joint distributions with causal strength $=.5$, causal prevalence $=.5$, strength of background causes $=.33$. The blue line (solid points) represents the joint distribution entailed by the normative model. Red lines (open points) represent the joint distributions simulated by the causal sampler, with thicker lines meaning fewer samples (thick $=4$ samples, medium $=8$, thin $=32$ ).

An important prediction of the causal sampler model is that Markov violations are not resultant from a particular reasoning or learning process. Instead, these violations are built into the representations of causal graphs and so will propagate to any task that used the representation. To test this prediction, we compared our model to standard Bayes nets on existing data sets in causal learning and reasoning, as well as a new task introduced at the end of this paper.

## Task 1: Causal Reasoning

The causal sampler model accounts for the independence violations found in human causal reasoning. For example, Rehder and Waldmann (2016) assessed the inferences people draw with the simple common effect graph in Figure 1A. Subjects were first instructed on two causal relationships that formed a common effect graph in the domains of economics, sociology, or meteorology (see the new experiment below for examples of these materials). The causal relationships were described as generative (a cause makes the effect more likely) and independent (each cause can bring about the effect on its own). Subjects were then asked to draw a number of causal inferences. For example, they were asked to estimate both $p\left(Y_{A}=1 \mid Y_{B}=1\right)$ and $p\left(Y_{A}=1 \mid Y_{B}=0\right)$ and also the same questions with the role of $Y_{A}$ and $Y_{B}$ reversed; thus, these inferences will be referred to as $p\left(Y_{i}=1 \mid Y_{j}=1\right)$ and $p\left(Y_{i}=1 \mid Y_{j}=0\right)$. The Markov condition stipulates that the two $Y \mathrm{~s}$ should be conditionally independent, that is, that $p\left(Y_{i}=1 \mid Y_{j}=1\right)$ should equal $p\left(Y_{i}=1 \mid Y_{j}=0\right)$. The empirical results shown in the left hand side of Figure 3 (gray bars)
reveal that subjects judged that $p\left(Y_{i}=1 \mid Y_{j}=1\right)>p\left(Y_{i}=\right.$ $\left.1 \mid Y_{j}=0\right)$ instead. This violation of independence is also illustrated by the normative fit of the common effect graphical model in Figure 1A (blue solid line) to the ratings of Rehder and Waldmann's subjects (which included conditional probability queries other than those shown in Figure 3) ${ }^{1}$. As expected, the normative model is constrained to predict that $p\left(Y_{i}=1 \mid Y_{j}=1\right)=p\left(Y_{i}=1 \mid Y_{j}=0\right)$. This apparent expectation that the causes of a common effect graph are positively correlated has been observed in other studies (e.g. Rehder \& Burnett, 2005; Rehder, 2014; Rottman \& Hastie, 2016) and violations of the Markov condition have been observed with other graph topologies (see Hagmayer, 2016, and Rottman \& Hastie, 2014, for reviews).

Figure 3: Data from Rehder \& Waldmann (2014), Experiment 1. Sampler (red lines) and normative (blue lines, solid points) fits to conditional probability judgments. Error bars denote $95 \%$ confidence intervals.

Figure 3 also presents the best fit of the causal sampler to these data (red solid line) and shows that an average of 17.9 samples in fact reproduces subjects' belief that $p\left(Y_{i}=1 \mid Y_{j}=\right.$ 1) $>p\left(Y_{i}=1 \mid Y_{j}=0\right)^{2}$. It does so because the two prototype

[^313]states are such that the causes are congruent $\left(Y_{i}=1 \& Y_{j}=1\right)$ or $\left(Y_{i}=0 \& Y_{j}=0\right)$. As was shown in Figure 2, the causal sampler overestimates these states, resulting in an inflated probability for states where the causes are congruent (e.g. $p\left(Y_{i}=1 \mid Y_{j}=1\right)$ ), and underestimates states where the causes are incongruent (e.g. $p\left(Y_{i}=1 \mid Y_{j}=0\right)$ ).

Note that the sampler also accounts for another reasoning error that subjects commit with the graph in Figure 1A. Explaining away is a signature property of common effect graphs. If $X$ is observed to occur then the probability that $Y_{A}$ is present of course increases. But if it is then further observed that the second cause $Y_{B}$ is present then the probability that $Y_{A}$ is present should decrease. (Conversely, if $Y_{B}$ is observed to be absent then the probability of $Y_{A}$ should increase.) In fact however, research finds that subjects often explain away too little or not at all (Morris \& Larrick, 1995; Rehder, 2014; see Rottman \& Hastie, 2014, for a review). The right three bars in Figure 3 illustrate the three conditional probability judgments relevant to explaining away: $p\left(Y_{i}=1 \mid X=1, Y_{j}=0\right)$, $p\left(Y_{i}=1 \mid X=1\right)$, and $p\left(Y_{i}=1 \mid X=1, Y_{j}=1\right)$. The fits of the normative model to these data points reveal that explaining away with Rehder and Waldmanns subjects was indeed too weak (the slope of the blue line is steeper than the empirical ratings). In contrast, the fit of the sampler predicts this too-weak explaining away (the slope of the red line is shallower). Because it predicts both independence violations and weak explaining away, the sampler achieves a better fit to these data according to a measure (AIC) that corrects for its extra parameter ( 30.3 vs. 33.6 ).

## Task 2: Causal Learning

The causal sampler also outperforms the normative model in a causal learning experiment. Rehder and Davis (2016) tested for the presence of independence violations in a hypothesis testing task by presenting subjects with a candidate theory that took the form of the graph in Figure 1A (again, in either the domain of economics, meteorology, or sociology). Subjects were then presented with hypothetical data and asked to rate the likelihood of observing the data if the theory was true. The correlation between $Y_{A}$ and $Y_{B}$ that obtained in the data was manipulated to be either negative, zero, or positive (all other aspects of the data, e.g., causal strengths, were held constant). The empirical results shown in Figure 4 (gray bars) revealed that subjects' ratings were largest when the inter-Y correlation was positive and smallest when it was negative.

The normative model's predictions for this task were derived by, for each of the three data sets, identifying the maximum likelihood parameters for the graph in Figure 1A to that data set. Using simple linear regression, the three maximum log-likelihoods were then scaled and translated onto the subjects' $0-100$ ratings. The fitted predictions averaged over subjects (blue line in Figure 4) show the expected result that the data set with a zero inter-Y correlation is more likely than

[^314]those with non-zero correlations, reflecting the independence between the causes stipulated by the normative model. ${ }^{3}$

The same process was followed for the causal sampler with the elaboration that we performed a grid search on the number of samples from 1 to 32. The fitted predictions (red line in Figure 4) reveal that the model, like the subjects, judged that the data set with the positive $Y_{A}-Y_{B}$ correlation is most likely to be generated by the candidate theory (chain length averaged over subjects was 2.3). As in conditional probability judgments, it makes this prediction because biased sampling (starting at the prototypes) combined with a limited number of samples naturally generates the expectation that $Y_{A}$ and $Y_{B}$ will be positively correlated.

## Task 3: Expected Distributions

Recall that when the causal sampler's number of samples is limited, it warps a causal graph's joint distribution, overestimating prototype states and underestimating others (Figure 2). The following experiment tests this account using a novel methodology, one that directly asks participants to generate a distribution for a causal graph.

## Method

Materials. Participants were presented with causal hypotheses in one of three domains: meteorology, sociology, or economics. Each domain had three variables (in economics: interest rates, trade deficits, and retirement savings; in meteorology: ozone levels, air pressure, and humidity; in sociology:

[^315]urbanization, interest in religion, and socioeconomic mobility). Each variable could take on two possible values. One of these values was described as "Normal" and the other was either "High" or "Low". The values of the variables were mixed to prevent domain-specific beliefs from affecting the results (alternate values were either all "High", all "Low", or a mixture of "High" and "Low"). All hypotheses were of the form shown in Figure 1A, with two causes of one effect.
Procedure. Participants first studied screens of information that defined the variables, provided a mechanism describing how each cause could independently generate the effect, and a diagram of the causal relationships. They were then required to pass a multiple-choice test of this knowledge.

Next, participants were asked to generate a data set that they would expect to result from the causal graph. The causal relationship between smoking and lung cancer was used as an example. Subjects were shown the four cells formed by crossing smoker/non-smoker with lung cancer/no-lung cancer and how (in terms of how hypothetical people were allocated to the four cells) a greater proportion of smokers had lung cancer as compared to non-smokers. Subjects were asked to generate an analogous distribution in their assigned domain (economics, etc.). Specifically, they were given 50 pennies and asked to distribute them among the cells formed by crossing the three binary variables. They did so by placing the coins on a large sheet that contained the eight possible states (the position of the states on the sheet was randomized).
Design and Participants. The experiment consisted of a 3 (domain) by 4 (variable senses, e.g., all "High") betweensubjects design. 60 New York University undergraduates received course credit for participation.

## Results

Figure 5 presents how subjects allocated the 50 pennies to the eight states of the graph in Figure 1A (gray bars). Because these raw data are difficult to interpret, we computed measures that reflect the statistical relationships among the three binary variables implied by the pennies. In particular, we first normalized a subject's distribution and then computed the phi coefficients between a $Y$ and an $X\left(\phi\left(Y_{i}, X\right)\right.$; the pennies were aggregated so that the two $Y$ s are interchangeable), between the $Y$ s themselves $\left(\phi\left(Y_{A}, Y_{B}\right)\right)$, and between the $Y \mathrm{~s}$ conditioned on the presence of $X\left(\phi\left(Y_{A}, Y_{B} \mid X=1\right)\right)$. These measures averaged over subjects are presented in Figure 6. First, the fact that $\phi\left(Y_{i}, X\right) \gg 0$ indicates that subjects understood that the $Y$ s were generative causes of $X$. Of greater theoretical importance is the fact that $\phi\left(Y_{A}, Y_{B}\right)$ was also significantly greater than $0, t(59)=3.62, p<.001$. This corroborates our claim that the violations of independence that obtain during causal reasoning (Figure 3) and hypothesis testing (Figure 4) are also manifested in peoples' causal representations (Figure 5).

The best fit of the normative model is shown superimposed

on the empirical data in Figure 5 (blue line) ${ }^{4}$. The figure indicates that the normative model tends to underpredict subjects' judgments for the two prototype states (111 and 000) and overpredict the remaining states. Phi coefficients computed for these fits (blue line in Figure 6) show the expected result that the normative model requires that $\phi\left(Y_{A}, Y_{B}\right)=0$, at odds with subjects' distributions. Moreover, it sharply underpredicts $\phi\left(Y_{A}, Y_{B} \mid X=1\right)$. Because of the explaining away phenomenon described above, the normative model requires that $\phi\left(Y_{A}, Y_{B} \mid X=1\right)$ is negative (one cause is less likely when the other is present). Figure 6 shows that subjects' distributions implied a value of $\phi\left(Y_{A}, Y_{B} \mid X=1\right)$ that is less negative (i.e., explaining away was again too weak).

The best fit of the causal sampler (red lines in Figs. 5 and 6) shows that it accounts for the fact that, relative to the normative model, the number of pennies is generally too large for the prototype states and too small for other states ${ }^{5}$. Of course, this pattern was expected on the basis of the theoretical predictions in Figure 2. Like the subjects, the causal sampler predicts that $\phi\left(Y_{A}, Y_{B}\right)>0$ and that explaining away (as represented by $\phi\left(Y_{A}, Y_{B} \mid X=1\right)$ is too weak relative to the normative model. As a result, it achieved a better fit to these data than the normative model (AIC of 3.2 vs. 10.8).

## Discussion

Although causal graphical models have enjoyed success in explaining causal cognition, people consistently violate key predictions of these models. That independence violations manifest themselves in multiple tasks suggests that they arise from the causal representations that people construct. This

[^316]

conjecture was confirmed in an experiment using a new methodology that assessed, in a relatively direct way, people's causal representations. This result suggests that the fault lies not in how we reason or learn but how we represent.

This paper has proposed a process model that naturally constructs faulty causal representations. Importantly, it does so in a manner that is computationally efficient and psychologically plausible. The Metropolis-Hasting rule combined with the proposal distribution we advocate implies that at any one time reasoners only need to consider the relative likelihood of two graph states that differ by one variable, a computation that can be carried out very efficiently (because it involves only those nodes in the variable's Markov blanket; Koller \& Friendman, 2009). Yet further efficiencies can be achieved for conditional probability queries (because sampling can be limited to those graph states that instantiate a query's antecedent). Note that this view suggests that humans could construct veridical causal representations-if only they had the cognitive resources to do so. The fault thus lies not in our causal representations per se but rather in the fact that causal judgments must be computed in finite time and with limited resources. Independence violations are thus an unavoidable consequence of the tradeoff between accuracy, speed, and effort.

The causal sampler perhaps gains some credence given the property it shares with the well-known Mental Model theory, namely, that reasoning is based on concrete states of the world (Goldvarg \& Johnson-Laird, 2001; JohnsonLaird \& Byrne, 2002). There are, however, some differences. Whereas the model theory never represents cause-present/effect-absent situations, the causal sampler, as a probabilistic model, merely asserts that such situations are un-
likely (depending on the causal graph's parameters) and thus rarely sampled (cf. Khemlani, Barbey, \& Johnson-Laird, 2014). There are also differences regarding which states reasoners initially consider (initial mental models are similar but not identical to the causal sampler's starting samples).

The causal sampler accounts for independence violations with other graph topologies. For example, suppose the direction of causality in Figure 1A is reversed, yielding a common cause graph. Independence is then captured by the screening off principle whereby the effects ( $Y_{A}$ and $Y_{B}$ ) are independent conditioned on the cause $X$. In fact, people judge that $p\left(Y_{i}=1 \mid X=1, Y_{j}=1\right)>p\left(Y_{i}=1 \mid X=1, Y_{j}=0\right)$ instead (Rehder, 2014; Rehder \& Waldmann, 2016; Rehder \& Burnett, 2005). The causal sampler predicts this result as well (because biased sampling induces a positive correlation between the $Y$ s conditioned on $X$ ).

There are many possible directions for future research. For one, current models do not attempt to model the substantial variability in peoples causal inferences (Rehder, 2014; Rottman \& Hastie, 2016). The stochastic nature of sampling may shed light on this important aspect of behavior. The causal sampler also makes predictions about reaction times. For example, it would predict that longer reaction times implies a less warped joint distribution (because more samples were taken).
