$P\left(D \mid S_{i}\right)$ is the likelihood of the data given a particular structure, which is the integral over the likelihood function of the parameter values under the particular structure. $P\left(S_{i}\right)$ represents a structure's prior probability. The model initially assumes that both structures are equally likely, that is, $P\left(S_{i}\right)$ $=1 / 2$. When data become available, the posterior for each causal structure varies systematically with the observed contingency: the higher the contingency, the more likely $S_{1}$ becomes.

Next, the model estimates the parameters $b_{c}, w_{c}$, and $w_{a}$, for each causal structure. To express parameter uncertainty, distributions rather than point estimates are inferred. The posterior probability distributions for the parameters, $P(w \mid D)$, are proportional to the likelihood of the data given the set of parameters $w$, weighted by the prior probability distributions of the parameters:

$$
\begin{equation*}
P(w \mid D) \propto P(D \mid w) \cdot P(w) . \tag{5}
\end{equation*}
$$

$P(D \mid w)$ is the likelihood of the data given the parameter values for $b_{c}, w_{c}$, and $w_{a} . P(w)$ is the prior joint probability of the parameters. The prior distributions of the parameters are independently set to flat, uninformative $\operatorname{beta}(1,1)$ distributions. Since $C$ does not cause $E$ under $S_{0}, w_{c}$ is held fixed at 0 for this causal structure.

In the last step, SISC computes $P(c \xrightarrow{\text { sing. }} e \mid c, e)$ for each parameterized structure. The new discounting parameter alpha is set based on background assumptions about the target scenario. For the scenarios we used in the present experiments it is set to 1 because preemption seems to be highly probable. As all co-occurrences of $c$ and $e$ are coincidences under $S_{0}, P(c \xrightarrow{\text { sing. }} e \mid c, e)$ is set to 0 for $S_{0}$. For $S_{1}$, Equation 3 is applied. The final output of SISC is a single estimate for $P(c \xrightarrow{\text { sing. }} e \mid c, e)$, which is obtained through integrating out the two causal structures by summing over the derived values of $P(c \xrightarrow{\text { sing. }} e \mid c, e)$ for each structure weighted by its posterior probability:

$$
\begin{equation*}
P(c \xrightarrow{\text { sing. }} e \mid c, e ; D)=\sum_{i} P\left(c \xrightarrow{\text { sing. }} e \mid c, e ; S_{i}\right) \cdot P\left(S_{i} \mid D\right) . \tag{6}
\end{equation*}
$$

## Experiment 1a

The goal of Experiment 1a was to test SISC against the CN model of causal attribution for data sets with a sufficient cause, i.e., $P(e \mid c)=w_{c}=1$, but varying base rates of the effect. Whereas the CN model predicts maximal confidence in singular causation assessments for any observed co-occurrence of $C$ and $E$ in this case, SISC predicts an interaction with the base rate under the assumption that $A$ 's causal power generally preempts the effect of $C$. The goal of Experiment 1a was to demonstrate that this predicted deviation from the CN model is expected for the conceptual reasons discussed above. To rule out uncertainty as an explanation, we used sample sizes in our data sets for which the posterior probabilities of $S_{1}$ computed by SISC are close to 1 . The predictions of the models are shown in Figure 3. We set $\alpha$ in Equation 3 to 1, which represents complete preemption of $C$ by $A$. We also considered a Bayesian variant of the CN model that has been proposed by Holyoak et al. (2010). This model is sensitive to parameter uncertainty; it uses probability distributions over the parameters instead of point estimates. As Figure 3 shows, the predictions of both variants of the CN model converge for large sample sizes because the influence of parameter uncertainty decreases.

## Methods

Participants 90 participants $\left(M_{\text {age }}=33.24, S D_{\text {age }}=12.50\right.$, 35 female) were recruited via Prolific Academic (www .prolific.ac) and received a monetary compensation of £0.60.
Design, Materials, and Procedure Three contingencies (see Figure 3) were manipulated between subjects with each participant responding to two causal test queries (general causation vs. singular causation). We included the general causation query to establish that uncertainty cannot account for the predicted pattern of singular causation ratings. The task was a standard elemental causal induction task. As cover story we used the gene expression scenario (cf. Griffiths \& Tenenbaum, 2005) mentioned above: subjects were asked to assume that they were biologists who are interested in whether a particular chemical causes the expression of a particular gene in mice. Subjects read that they will be asked to conduct an experiment on the computer screen in which they will treat a random sample of mice with the substance while a control sample will remain untreated. It was mentioned that the control sample is important as some individuals may show the gene expression for other reasons.

Participants were presented with an interactive animation showing the two samples arranged as in Figure 1, and a pipette containing a reddish chemical substance. All mice had gray color in this animation. Participants then dropped the substance into the test group area, whereupon the background color changed to a light red. On the next screen, subjects checked the results of the experimental manipulation by dragging a small magnifying glass over all the mice. Mice with the gene then became blue and those without became yellow. The final state of the animation looked like Figure 1.

Figure 3: Model predictions and results of Experiments 1a and b. The results show mean ratings and $95 \%$ bootstrapped CIs. Dark bars show general causation judgments; light bars singular judgments.

Subsequently, participants responded to two test questions. The general causation query referred to the causal structure. Participants were asked to indicate on a slider how confident they were that the chemical has an effect on the expression of the gene (from "very certain that the chemical has no effect" to "very certain that the chemical has an effect"). The singular causation query asked subjects about Mouse \# 25 from the test group. Participants were asked to indicate on a slider how confident they were that it was the chemical substance that caused the expression of the gene in this single case (from "very certain that it was not the chemical" to "very certain that it was the chemical").

## Results and Discussion

Figure 3 shows the results. The prediction for general causation responses corresponds to the posterior probability of $S_{1}$ computed by SISC. As predicted by the posterior probability of $S_{1}$, all general causation ratings were high, indicating very little uncertainty about the general causal structure. The singular causation ratings, by contrast, decreased with an increasing base rate of the effect, as predicted by SISC but not by the two CN models. The results of a multilevel model analysis revealed significant main effects for type of causal query, $\chi^{2}(1)=32.45, p<.001$, as well as contingency, $\chi^{2}(1)=12.63, p<.01$. General causation ratings were, on average, higher than singular causation ratings. Figure 3 shows that the main effect of contingency is driven by the decrease in singular causation ratings. Planned contrasts revealed that the general causation ratings neither differed between the first and second contingency, $t(80)=0.60$, nor between the second and third contingency, $t(80)=0.13$. Consequently, the interaction effect of query $\times$ contingency was also significant $\chi^{2}(1)=13.10$, $p<.01$. Planned contrasts breaking down this interaction effect showed that the difference between general and singular causation ratings was higher for the second than for the first contingency, $t(80)=2.10, p<.05, r=.23$, and also higher for the third compared to the second contingency, $t(80)=3.70$, $p<.001, r=.38$. In sum, both the trends for general as well as for singular causation ratings are captured well by SISC.

The observed trend for the singular causation judgments is, however, neither predicted by the CN model using point estimates nor by the Bayesian extension incorporating parameter uncertainty.

## Experiment 1b

The goal of Experiment 1 b was to assess how likely participants think it is that a particular individual from the test group already exhibited the effect caused by the background factors prior to the occurrence of the cause. Thus, instead of singular causation judgments for a particular individual, we asked subjects to provide a probability judgment. Crucially, responses to this query provide us with an estimate of the $\alpha$ value in Equation 3 that participants assumed.

## Methods

Participants 88 participants $\left(M_{\text {age }}=31.22, S D_{\text {age }}=10.84\right.$, 42 female) participated in this only study and received a monetary compensation of $£ 0.60$.
Design, Materials, and Procedure The study design and the materials were the same as in Experiment 1a. The only difference was that, instead of a singular causation judgment for Mouse \#25, we asked participants how likely they think it is that this individual already had the gene expressed prior to the experiment. The general causation query remained the same.

## Results and Discussion

Figure 3 shows that we replicated the pattern for general causation judgments found in Experiment 1a. Planned contrasts revealed that these ratings did not differ (all $t$ values $<1$ ). However, the probability judgments about the presence of the effect prior to the application of the chemical in the single case showed the opposite trend as the singular causation judgments in Experiment 1a. This finding supports our hypothesis that assumptions about preemption influence singular causation judgments, as predicted by Equation 3. Planned contrasts confirmed that ratings increased from the first to the second, $t(71)=2.67, p<.01, r=.30$, and also from the second to the third contingency, $t(71)=3.16, p<.01, r=.35$. Furthermore, the results indicate that participants indeed assumed high $\alpha$ values.

## Experiment 2

Experiment 1a showed that singular causation ratings for sufficient causes deviate systematically from the predictions of the CN models. This deviation is predicted as a consequence of assumptions about preemption relations between $C$ and $A$. Experiment 2 pursued two main goals: first, we aimed to test SISC using a larger set of contingencies with a combination of different levels of $P(e \mid c)$ and $P(e \mid \neg c)$. Second, we wanted to demonstrate that parameter and structure uncertainty indeed influence general and singular cause judgments. We used the set of contingencies studied in Buehner, Cheng, and Clifford (2003) but excluded the one contingency from the set in which the effect never occurs. It does not make sense to ask for singular causation if the effect is absent. The data sets and model predictions are shown in Figure 4. We set

Figure 4: Predictions of different models and results (means and within-subjects adjusted $95 \%$ CIs) of Experiment 2. Graphs (a) and (b) refer to general causation assessments. All other graphs refer to singular causation assessments.
the discount parameter $\alpha$ to 1 again.

## Methods

Participants 82 participants $\left(M_{\text {age }}=34.41, S D_{\text {age }}=10.42\right.$, 31 female) participated in this online study and were paid $£ 1.00$ for their participation.
Design, Materials, and Procedure The causal query (general causation vs. singular causation) was manipulated between subjects, whereas contingency was varied within subject. The fourteen contingency data sets were presented in random order. We used the same cover story as in Experiment 1 , except that subjects read that they will investigate the effects of fourteen different chemicals on fourteen different genes in fourteen different samples. We pointed out that the results of the studies are independent of each other. The assignment of mice to the cells of the contingency tables was randomly determined. Also the test mouse for the singular query showing both $c$ and $e$ was randomly chosen prior to the experiment.

## Results and Discussion

Figure 4 shows the results and the predictions of the different models: (a) and (b) display the predictions of SISC for general causation and the mean general causation responses. Panels (c) and (d) show the predictions of SISC and the results regarding the singular causation queries. Predictions of the standard CN model and its Bayesian variant are displayed in (e) and (f). Graph (g) shows predictions of SISC when $\alpha$ is set to zero but both structure and parameter uncertainty are incorporated. Finally, (h) shows point estimates of Equation 3 while neglecting statistical uncertainty.

Table 1: Model comparisons for singular causation judgments in Experiment 2. $\Delta P$ refers to the different contingency levels (.00, $.25, .75,1.00$ ) within the whole data set; $r_{\Delta P}$ expresses the model fits for these levels. $N / A$ represents undefined values.

| Fit measure | SISC | CN Model | Bayesian CN Model | SISC CN Model | Point Est. Eq. 3 |
| :---: | :---: | :---: | :---: | :---: | :---: |
| $r_{\Delta P=.00}$ | $\mathbf{. 7 2}$ | N/A | -.78 | -.68 | N/A |
| $r_{\Delta P=.25}$ | $\mathbf{1 . 0 0}$ | .21 | .38 | -.61 | .98 |
| $r_{\Delta P=.50}$ | $\mathbf{8 8}$ | .68 | .79 | .44 | .85 |
| $r_{\Delta P=.75}$ | 1.00 | N/A | 1.00 | -1.00 | 1.00 |
| $M_{r \Delta P}$ | .90 | .44 | .35 | -.46 | .94 |
| $r_{\text {overall }}$ | $\mathbf{. 9 4}$ | .88 | .93 | .90 | .90 |
| $R^{2}$ | $\mathbf{. 8 8}$ | .77 | .87 | .82 | .82 |
| $R M S E$ | .11 | .27 | $\mathbf{. 0 9}$ | .14 | .22 |

The overall pattern for both general and singular causation ratings was captured best by the revised version of SISC. As in our previous research, the results show that participants differentiated between general and singular queries. Moreover, the responses to the general causation query replicate those found in Griffiths and Tenenbaum (2005). Most importantly, the singular causation assessments were captured best by the revised SISC. The other models, by contrast, struggled to account for the local trends observed within the subsections of the contingency set in which $\Delta P$ is constant. The difference between the singular causation ratings and the point estimates for the revised causal attribution measure (Equation 3) implies that participants were sensitive to structure and parameter uncertainty.

A multilevel model analysis confirmed the main effect of contingency, $\chi^{2}(13)=1010.04, p<.001$, as well as the interaction between contingency $\times$ query, $\chi^{2}(13)=49.39$, $p<.001$, that is shown in Figure 4. To test the different models, we computed different fit measures shown in Table 1. As can be seen there, SISC achieved a good fit in the overall fit measures (bottom part of the table). It explained most variance, with $R^{2}=.88$, and yielded the second smallest $R M S E$ of .11 . Yet, all models obtained relatively high values on the global measures. Even the CN model with the lowest overall fit accounted for 77 percent of the variance. The similarity between the models is not unexpected, however, as all models are sensitive to $\Delta P$. More interesting are the fit measures for the subsections of the contingency set in which $\Delta P$ is kept constant. The upper part of Table 1 shows that SISC yielded high fit values there, too, and hence accounted well for these local trends, whereas the Bayesian CN model, which yielded the smallest RSME, even showed negative correlations here.

## General Discussion

We addressed two different problems that the power PC framework of causal attribution (Cheng \& Novick, 2005) faces: first, the CN model attributes causal responsibility for the occurrence of a particular effect $e$ to a present singular event $c$ whenever its causal power is sufficient to bring about the effect. We have argued that this conceptualization fails to take into account that people make assumptions about the point in time at which different causal powers exert their influences. Not every manifestation of a sufficient cause $c$ needs to be causally responsible for an observed outcome; it might be the case that a competing cause (e.g., a) preempts it. This problem of redundant causation, which occurs whenever two causes are individually sufficient for the effect, is widely acknowledged in the philosophical literature as a challenge for models of causation (see, e.g., Paul \& Hall, 2013). To account for the possibility of preemption we have modified the equation developed by Cheng and Novick (2005) as an account of causal attribution. The revised equation includes the discount parameter $\alpha$ that can be set to express domain-related assumptions about the temporal relations between the alternative causal factors. A second shortcoming of the standard causal attribution model (Cheng \& Novick, 2005) is that it
does not take into account statistical uncertainty about structure and causal parameters (cf. Griffiths \& Tenenbaum, 2005; Meder et al., 2014). Our model SISC remedies both shortcomings. It is sensitive to both the temporal relations between the alternative causes and to statistical uncertainty. Our experiments showed that both aspects are important to account for subjects' judgments about singular causation.

We have set the discount parameter $\alpha$ to 1 in Equation 3 which implies a complete preemption relation between $A$ and $C$ whenever A's causal power is sufficient in a situation. Better fits might be possible by estimating the size of $\alpha$ for each individual subject separately. We avoided this strategy to demonstrate that model improvements can already be achieved with very general assumptions. The goal of future experiments will be to manipulate the size of $\alpha$ by manipulating domain assumptions about the temporal relations between $C$ and $A$. Cases in which $\alpha$ is 1 are situations in which $A$ always preempts $C$. The cover stories used in the present experiments are an example in which it is plausible to assume that $A$ represents a temporally stable factor that has already been efficacious prior to the manipulation of $C$. Although preemption seems to be the default situation in most singular causation scenarios, there might be rare cases in which other assumptions need to be made. Consider cases of symmetric overdetermination that have also been discussed in the literature (see Paul \& Hall, 2013): in the famous firing squad scenario, for example, in which each shooter is a sufficient cause for the death of the target, a possible intuition is that each shooter should be counted as a singular cause of the death of the victim. In this case, alpha would have to be set to zero. Similarly, alpha would have to be set to zero if $C$ preempts $A$ so that $A$ cannot manifest its potential causal power. Cases of temporal variability between $C$ and $A$ might also be an interesting topic for future studies.
Acknowledgments We thank Jonas Nagel and Ralf Mayrhofer for helpful discussions.

#### Abstract

Consider the following causal explanation: The ball went through the goal because the defender didn't block it. There are at least two problems with citing omissions as causal explanations. First, how do we choose the relevant candidate omission (e.g. why the defender and not the goalkeeper). Second, how do we determine what would have happened in the relevant counterfactual situation (i.e. maybe the shot would still have gone through the goal even if it had been blocked). In this paper, we extend the counterfactual simulation model (CSM) of causal judgment (Gerstenberg, Goodman, Lagnado, \& Tenenbaum, 2014) to handle the second problem. In two experiments, we show how people's causal model of the situation affects their causal judgments via influencing what counterfactuals they consider. Omissions are considered causes to the extent that the outcome in the relevant counterfactual situation would have been different from what it actually was.

Keywords: causality; counterfactuals; causation by omission; causal attribution; mental simulation.

## Introduction

Billy is on his way home. He is driving on a lonely country road, when he notices a damaged car next to the road. The car seems to have collided with a tree, and the driver appears unconscious. Billy decides not to stop and keeps driving. A few days later, Billy reads in the newspaper that the driver died because he had not received any medical attention.

Many people would concur that Billy's not having stopped was causally relevant for the driver's death. However, there are two fundamental problems with citing omissions (i.e., events that did not happen) as causes. First, there is the problem of causal selection. Why cite Billy's not stopping as causally relevant for the driver's death? Why not cite the Queen of England? Second, there is the problem of underspecification. Assuming that Billy would have stopped to check on the driver, what would he have done? Would Billy's acting have prevented the driver's death, or would she have died anyway?

In this paper, we show how the counterfactual simulation model (CSM) of causal judgment developed in Gerstenberg, Goodman, Lagnado, and Tenenbaum (2012) (see also Gerstenberg et al., 2014; Gerstenberg, Goodman, Lagnado, \& Tenenbaum, 2015) provides a natural solution to the underspecification problem. The CSM predicts that an omission is a cause when the positive event that is chosen as its replacement would have changed the outcome of interest. More specifically, we show how people's causal model of a situation guides their selection of the relevant counterfactual which subsequently determines their judgment about whether the omission made a difference to the outcome.

The paper is organized as follows: We first describe the causal selection and the underspecification problem in more detail. We then propose an extension to the CSM as a solution to the underspecification problem. Thereafter, we present and discuss the results of two experiments which test the CSM.

## The Causal Selection Problem

Many philosophers argue that counterfactual approaches to causation are too inclusive when it comes to omissions (e.g. McGrath, 2005). If Billy had stopped and checked on the unconscious driver, the driver would not have died. Consequently, the driver died because Billy did not stop. However, following this logic, the same counterfactual seems to be true for the Queen of England. If the Queen of England had stopped, the driver would not have died either. However, intuitively, it is Billy's omission that was causally relevant, and not the Queen's. The problem of causal selection has been intensively discussed in both philosophy and empirical studies (e.g. Hesslow, 1988). Interestingly, while the causal selection problem presents a challenge to certain philosophical theories of causation, laypeople do not have any difficulty in selecting the cause of the driver's death. Based on evidence from research on causal cognition, it has been suggested that the concept of causation is not a purely descriptive one, but that it depends on reasoners' expectations (Willemsen, 2016). While we would have expected Billy to stop and help, we didn't entertain any such expectation for the Queen.

## The Underspecification Problem

When it comes to omissive causation a fundamental problem is how to define the relevant counterfactual contrast (cf. Schaffer, 2005). For positive events ("something happened"), the counterfactual contrast ("it didn't happen") is often welldefined. However, replacing a negative event with a positive event seems more problematic because there are a infinitely many ways in which events can come about. If Billy actually helped the driver, it seems to be pretty clear what would have happened if he had not helped (he would just have continued to drive on). However, if Billy did not help, it is unclear what would have happened if he had helped (would he have helped in a competent manner to prevent the driver's death, or would he have been too nervous and screwed things up?).

While the causal selection problem has received much attention in the literature (e.g., Henne, Pinillos, \& De Brigard, 2015; Livengood \& Machery, 2007), the underspecification problem has not. One exception is the account by Wolff, Barbey, and Hausknecht (2010) that addresses both problems. The general idea proposed by Wolff et al. (2010) is that cau-
sation by omission is linked to the removal of an actual (or anticipated) force that previously prevented a certain outcome from occurring. One problem of this account, however, is that it appears too restrictive in that it cannot account for cases in which no (apparent) force is removed. Imagine, for instance, sentences like "The lack of rain caused the drought in Somalia". Here, it would be a stretch to think of a the lack of rain as the removal of a force.

The extension of the CSM that we propose in this paper provides a different solution to the underspecification problem. Previous research has suggested that the extent to which a certain counterfactual is relevant is a function of both how likely we are to consider it, and how likely it would have changed the outcome of interest (Petrocelli, Percy, Sherman, \& Tormala, 2011). However, while this research has shown that these counterfactual probabilities affect people's causal judgments, it doesn't explain how we come up with the relevant probabilities in the first place. Here, we will show how the CSM provides a natural solution to determine whether an omission made a difference to the outcome.

## Counterfactual Simulation and Omission

The CSM predicts that people make causal judgments by comparing what actually happened with the outcome of a counterfactual simulation. So far, the model has been applied to capturing participants' judgments about events that actually happened (Gerstenberg et al., 2012, 2014, 2015). Consider the situation shown in Figure 1b (bottom) illustrated as the ideal path. Here, A collides with B and B subsequently goes through the gate. The CSM says that ball A's colliding with ball B caused ball B to go through the gate in this case, because it is obvious that ball B would have missed the gate but for the collision with A. More generally, the CSM predicts that causal judgments are a function of the reasoner's subjective degree of belief that the candidate cause made a difference to the outcome. More formally, we can express the degree of belief that $x$ caused $y$ as

$$
\begin{equation*}
P(x \triangleright y)=P\left(y^{\prime} \neq y \mid S, \operatorname{do}\left(x^{\prime}\right)\right), \tag{1}
\end{equation*}
$$

in which $x$ denotes the event of ball A hitting ball B , and the outcome $y$ captures the event of ball B going through the gate. We first condition on what actually happened $\mathcal{S}$ (i.e., the motion paths of each ball, the position of the walls, etc.). We then intervene to set the candidate cause event $x$ to be different from what it was in the actual situation, do $\left(x^{\prime}\right)$. Finally, we evaluate the probability that the outcome in this counterfactual situation $y^{\prime}$ would have been different from the outcome $y$ that actually happened. The results of several experiments (cf. Gerstenberg et al., 2012, 2014, 2015) have revealed that there exists a tight relationship between the counterfactual judgments of one group of participants (about what would have happened if the candidate cause had been absent), and the causal judgments of another group of participants.

To model causal judgments about positive events, the CSM considers counterfactuals in which the positive event (ball A colliding with $B$ ) is simply removed from the scene (indicated

Figure 1: Illustration of what actually happened (top) and the counterfactual simulation model (bottom). The diagrams illustrate the actual path that ball B took, as well as an ideal path for (a) A preventing $B$ from going through the gate, or (b) A causing $B$ to go through the gate. The sampled paths show example simulations that result from applying implementation noise to the ideal path. Note: In (a), A would have prevented B from going through the gate for both sampled paths. In (b), A would have caused B go through the gate in one sample but not so in the other in which $B$ would still have missed even though A hit B.
by $\operatorname{do}\left(x^{\prime}\right)$ in Equation1). Things become more intricate, however, when we want to model omissions as causes. As discussed above, it is often straightforward to replace an event with a non-event (e.g., a collision with no collision), but it is less clear how to replace a non-event with an event. Consider the situation shown in Figure 1a. Did ball B go through the gate because ball A did not hit it? The problem is that there are infinitely many ways for ball A to collide with ball B. Which of these events are we to consider? The collision event is severely underspecified. We will now show how the CSM can be extended to yield predictions about omissions as causes, and thereby provide a solution to the underspecification problem.

## Modeling Omissions

We assume that people solve the underspecification problem by sampling counterfactual possibilities based on their intuitive understanding of the situation (cf. Kahneman \& Tversky, 1982). The extent to which the omission is viewed as a cause of the outcome is assumed to be a function of the proportion of samples in which the outcome would have been different from what actually happened, assuming that the type of counterfactual event of interest was realized. Let us illustrate how the model works by example of the situation depicted in Figure 1a. In the actual situation, ball A did not move and ball B went right through the middle of the gate. We want to determine to what extent A's not hitting ball B was a cause of B's going through the gate. To do so, we simulate what would have happened if ball A had collided with B. More specifically, we need to determine the time $t$ at which A would have started to move, the direction $d$ in which ball

A would have moved, and the velocity $v$. Once we have determined these quantities, we can simulate what would have happened. For many combinations of values for $t, d$, and $v$ ball A would not have collided with ball B. We can discard all such situations since we are interested in evaluating what would have happened if ball A had hit ball B. For each situation in which the two balls collide, we record what the outcome would have been - would B have missed the gate, or would it still have gone through the gate? We can now obtain the probability that ball A's not hitting ball B was a cause of ball B's going through the gate (cf. Equation 1) by looking at the proportion of samples in which B would have missed the gate instead of going through.

But how do we determine what values to take for $t, d$, and $v$ which jointly determine what counterfactual situation we consider? We predict that prior expectations guide the counterfactuals we consider. In Experiment 1 below, we contrast situations in which participants don't have any expectations about what normally happens, with situations in which participants have statistical, or social expectations. We will now discuss how the model incorporates these expectations.

## Expectations Shape Counterfactual Simulations

No Expectations Let us first assume a situation in which an observer does not have any strong expectations concerning how the balls typically move in the given context. When asked whether A's not hitting B caused B to go through the gate, we have to generate situations in which A would have hit B. This already considerably constrains what kinds of situations we consider. For example, it would be futile to consider situations in which A only starts moving after B already went through the gate, or in which A moved toward the right.

We generated counterfactual samples in the following way: We first discretized the space for the time at which A starts moving $t$, the direction in which it moves $d$, and its velocity $v$. For $t$, we considered all values from 0 to $t_{\text {outcome }}$ where 0 corresponds to the time at which B starts moving and $t_{\text {outcome }}$ to the time at which ball B went through the gate (or hit the wall). For $d$, we considered the full range from A going straight to the left to going straight up. For $v$, we considered a reasonable range from A moving slowly to A moving fast. For each generated world, we noted whether A and B collided, and whether B went through the gate or missed the gate. We then discarded all situations in which the two balls did not collide, and recorded the proportion of situations in which B would have gone through the gate if the balls had collided.

The model makes the following predictions: For the situation in which $B$ is on a path toward the gate (Figure1a), there is a good chance that B would have missed the gate if ball A had hit it. The model predictions are shown in Figure2. As can be seen in the left panel, the CSM concludes that the probability that B would have missed the gate had A hit it is just as high as the probability that B would have passed the gate. By contrast, when B is on a path away from the gate ("missed" in Figure 2, cf. Figure 1 b top right) there is only a
relatively small chance that ball B would have gone through the gate if ball A had hit it. Thus, the CSM predicts that people will be more likely to agree that ball B went through the gate because ball A did not hit it than they will be to agree that ball B missed the gate because ball A did not hit it.
Social Expectations When nothing particular is known about how A and B typically move, the space of counterfactuals from which the CSM samples is relatively wide. It seems plausible, however, that what counterfactual possibilities are considered will be affected by different forms of prior expectations. Imagine, for example, that you learn that two players play a marble game. Player B wants to get her marble into the goal, while Player A wants to make sure that this does not happen. On a particular trial, Player A did not pay attention and forgot to flick his marble. Did Player B's marble go through the gate because Player A's marble did not hit it? When knowing that it is a player's job to prevent a marble from going through the gate, people may expect that this player would not have just flicked her marble randomly. Instead, she can be expected to try her best to make sure that the other marble does not go through the gate. Similarly, consider a situation in which Player A also wants that Player B's marble goes through the gate. In that case, it seems likely that Player A will try to flick his marble so that it makes sure that B's marble will go through the gate.

Figure 1 illustrates how the CSM incorporates how prior expectations constrain the space of counterfactual situations. We assume that the player would first determine a time $t$ at which to flick her marble. For any given point $t$, the player then determines an optimal $d$ and $v$ conditional on the player's goals. For a player who wants to prevent ball B from going through the gate, the player's goal is to maximize the distance between B's position and the middle of the gate. For a player who wants to cause B to go through the gate, the player's goal is to minimize the distance between B's position and the middle of the gate (i.e., she wants B to go right through the middle of the gate). For simplicity, we assume that players can plan their action optimally, but that they have some implementation noise. The CSM models this implementation noise by introducing a small perturbation to the ideal path on which A moves. As is illustrated in Figure1, the CSM incorporates implementation noise by slightly perturbing the "ideal path" vector.

Figure 1 shows the actual path that ball B took, the ideal paths that player A "wanted" the marbles to take, and two examples for paths that ball B actually took after subjecting A's ideal plan to some implementation noise. Notice that the implementation noise has a larger effect in Figure 1b where it leads to a situation in which ball B would have missed the gate even though ball A hit it. In contrast, in Figure 1a the implementation noise has less of an effect. Here, ball B would reliably miss the gate even if we apply some implementation noise to player A's intended plan. Accordingly, the CSM predicts that it is more likely that A's hitting B would have resulted in B missing the gate (when B actually went through,

Figure 1a) than it would have resulted in $B$ going through the gate (when B actually missed, Figure 1b). Since the sample of considered situations is biased toward optimal actions, the CSM predicts that judgments will overall be higher than when an observer does not have any prior expectations. The predictions for this situation are shown in the middle panel in Figure 2.
Statistical Expectations Now imagine that instead of learning anything about agents playing a game you get to see a few situations first that shape your expectations about what tends to happen. We incorporate such "statistical" expectations into the model in the same way in which we handled social expectations. However, we allow for the implementation noise to be different between these situations. Specifically, the size of the implementation noise parameter will depend on the kind of evidence that participants have seen. For example, if one has witnessed a series of trials in which A always hit B in such a way that B went straight through the gate, this would suggest a smaller implementation noise compared to one that is suggested by trials in which A hit B in such a way that B went through the gate in, for example, merely two third of the cases. The predictions for this situation are shown in the right panel in Figure 2.

## Experiment 1

Experiment 1 tests whether the CSM accurately predicts people's causal judgments for omissions in dynamic physical scenes. We look at causal judgments about situations in which ball A failed to hit ball B, and ball B either went through or missed the gate (see Figure 1). In line with the CSM, we predict that the degree to which people judge ball A's not hitting ball B as causally relevant to the outcome would be tightly coupled with the results of a mental simulation about what would have happened if a collision had occurred. Furthermore, we test the hypothesis that different types of expectations (social or statistical) influence people's causal judgments by affecting what counterfactual situations people consider.

## Methods

Participants and Materials 476 participants ( 239 female, $M_{\text {Age }}=33.83$ years, $S D_{\text {Age }}=12.03$ years) were recruited via Prolific Academic (www.prolific.ac) and participated in this experiment for a monetary compensation of $£ 0.25$. The clips were created in Adobe Flash CS5 using the physics engine Box2D.
Design and Procedure All factors were manipulated between subjects. We manipulated what actually happened (actual outcome: missed vs. went through), and the expectations of participants about what will happen (expectation: no expectations, statistical expectation, social expectation). Finally, we varied whether participants answered a causal question, or a (counterfactual) probability question (question: causation vs. probability).

In the "no expectations" condition, subjects simply read that they will see an animation in which a stage with solid

Figure 2: Experiment 1. Mean causal and probability judgments together with the predictions of the CSM. Note: Error bars indicate $95 \%$ bootstrapped CIs.
walls, two balls A and B, and a gate will be displayed. All subjects were shown a graphical illustration of the stimuli. Participants in the "statistical expectation" condition were presented four primer clips in which ball B actually collided with A . One group of subjects saw that the collision always caused B to go through the gate, while the other half always saw that A prevented B from going through the gate (see Figure 1). In the "social expectation" condition, subjects were instructed that the video clip (which was the same as in the "no expectations") shows what happened during a game of marbles played by two agents, Andy and Ben. We manipulated whether subjects believed that Andy wants to help Ben to flip his marble through the gate or whether he wants to hinder Ben from doing so.

Participants in the "causation" condition indicated how much they agreed with the claim that B missed the gate because A did not hit it, or that B went through the gate because A did not hit it, depending on the outcome. Participants in the "probability" condition gave a corresponding probability judgment: they indicated what they believed the chances were that B would have gone through / missed the gate if ball A had hit ball B. Participants indicated their ratings on a sliding scale.

Which outcome participants saw depended on the expectation condition: In the "social expectation" condition, participants who expected the agent to help saw that B actually missed the gate, and participants who expected the agent to hinder saw that B went through the gate. In the "statistical expectations" condition, participants who had seen the causation clips saw that B missed the gate, whereas those who had seen the prevention clips saw that B went through the gate.

## Results and Discussion

Figure 2 shows participants' mean causal ratings (white bars), probability ratings (gray bars), as well as the predictions of the CSM (black bars). The CSM correctly predicts a difference in agreement ratings for both the causal and probability condition as a function of the outcome (went through vs. missed). A global 2 (question) $\times 6$ (combination of expectation and outcome) factorial ANOVA shows a main effect of outcome, $F(5,464)=14.51, p<.001, \eta_{G}^{2}=.61$ but no main effect of question, $F(1,464)<1$. The interaction between question and expectation was significant,
$F(5,464)=2.74, p<.05$ but the effect is small, $\eta_{G}^{2}=.03$.
Importantly, participants saw A's not hitting ball B as more causal when B went through the gate compared to when it missed. This pattern was predicted by the CSM and indicates that participants' counterfactual simulations and their causal inferences were sensitive to the constraints imposed by the virtual physical environment. Because the displayed gate was relatively small, the probability that a collision would change the outcome is higher if B actually went though, than when it missed. Planned contrasts confirmed that the observed differences between "went through" and "missed" were significant in all conditions, with $t(464)=3.21, p<.01, r=.15$ in the "no expectations" condition, $t(464)=2.13, p<.05, r=.10$ in the "statistical expectation" condition, and $t(464)=3.53$, $p<.001, r=.16$ in the "social expectation" condition.

Besides the asymmetry between "went through" and "missed", we also expected to see higher causality ratings in the "statistical" and "social expectation" conditions than in the "no expectation" condition. This difference was predicted because we incorporated an ideal path in these situation that was then perturbed by imposing some implementation noise. As Figure 2 shows, we did indeed observe this pattern. A planned contrast confirmed that this difference was significant, $t(464)=5.98, p<.001, r=.27$.

Concerning the probability ratings, planned contrasts showed that the difference between "went through" and "missed" was significant in the "no expectations condition", $t(464)=2.33, p<.05, r=.11$, and the "statistical expectation" condition, $t(464)=1.73, p<.05, r=.08$, but not in the "social expectation" condition, $t(464)<1$. Concerning the predicted difference between the "no expectations" condition and the other two expectation conditions, Figure 2 shows that we obtained a similar pattern as for the causality judgments. In line with our expectations, the probability ratings for the "statistical expectation" and the "social expectation" condition were higher than the ratings for the "no expectation" condition, $t(464)=2.82, p<.01$, though this effect was smaller than the effect for the causality judgments, $r=.13$.

The results of Experiment 1 show that participants' causal judgments are qualitatively well accounted for by the CSM. The CSM also does a good job in accounting for the pattern quantitatively, as evidenced by a high correlation between model predictions and counterfactual probability judgments ( $r=.97, R M S E=14.00$ ), as well as between model predictions and causal judgments ( $r=.97, R M S E=6.06$ ). The fact that the model accounts slightly less well for the counterfactual probability judgments is mainly due to the relatively large difference between model predictions and probability judgments in the "no expectations" condition.

A key finding in Experiment 1 is the asymmetry in participants' causal judgments as a function of whether ball $B$ went through or missed the gate. The CSM predicts this pattern because it is more likely that A's hitting B would prevent B from going through the gate (cf. Figure 1a) than that it would cause

Figure 3: Illustration of the materials used in Experiment 2. Solid arrows indicate the actual path of the ball; dashed arrows show the hypothetical path of the wall. Graph (a) shows the "went through" and (b) the "missed" condition. The results for both conditions are included in brackets.

B to go through (cf. Figure 1b). One possibility, however, that Experiment 1 cannot rule out is that people are in general more likely to regard omissions as causes when the relevant counterfactual involves preventing compared to causing. In Experiment 2, we investigate whether there is such a general asymmetry between omissive causation and prevention.

## Experiment 2

The goal of Experiment 2 was to rule out that the observed difference between "went through" and "missed" in Experiment 1 came about because people generally treat omissive causation and omissive prevention differently. The CSM only predicts an asymmetry between two situations when the positive event of interest was more likely to make a difference in one situation compared to the other. Hence, our strategy in Experiment 2 was to hold this probability constant. To achieve this goal, we simply replaced ball A with a wall that had exactly the size of the gate. To model "missed" and "went through", we varied whether the wall blocked the gate or not, while a displayed ball always headed toward the gate (see Figure 3). Participants rated how much they agree that "the ball" missed the gate (or went through the gate) because the wall did not move. There is no ambiguity about the relevant counterfactual in this case - it is clear that the outcome would have been different, had the wall moved. Accordingly, the CSM predicts that participants' judgments should be high for both cases, no matter whether the ball went through the gate or missed the gate because of the omission.

## Method

Participants 65 participants ( 40 female, $M_{\text {age }}=32.86$, $S D_{\text {age }}=12.84$ ) who were again recruited via Prolific Academic completed this online experiment and received a monetary compensation of $£ 0.25$.
Design, Materials, and Procedure The final outcome, that is, whether the ball went through or missed the gate (see Figure 3) was manipulated between subjects. The instructions were similar those used in the "no expectations" condition in Experiment 1. Further, participants were presented an illustration showing the materials in which it was made clear that the wall can only be in two different positions, either right
in front of the gate or in the upper left corner of the stage (see Figure 3). Having read the instructions, participants were shown the respective video clip and provided the causal rating after the clip was finished.

## Results and Discussion

As expected, participants gave very high causal ratings for "went through" ( $M=87.51, S D=21.62$ ) and "missed" ( $M=89.00, S D=23.21$ ). As predicted by the CSM, the ratings were not different from each other, $t(63)<1$. The probability that the outcome would have been different in the relevant counterfactual, is close to maximal in both conditions.

The results of Experiment 2 are in line with the CSM. Further, the fact that the causality ratings were both very high and not different from each other rules out the potential alternative explanation that people might generally treat omissive causation and omissive prevention differently.

## General Discussion

We developed an extension of the Counterfactual Simulation Model to account for causation by omission. Based on previous research by Gerstenberg et al. (2014), we reasoned that people's causal judgments are closely linked to their subjective degree of belief that the outcome would have been different had the candidate cause been replaced. We argued that this replacement by a counterfactual contrast is particularly difficult in cases of omissions. The counterfactual contrast to "did not hit" is clearly "had hit", but it remains unclear what would have happened if "hitting" had taken place.

In two experiments we shed light on how to tackle the underspecification problem. We predicted that prior expectations would constrain what counterfactual contrasts people consider relevant to the scenario. Experiment 1 revealed an asymmetry: A's not hitting $B$ was judged less causal when $B$ missed the gate compared to when $B$ went through the gate. This is what the CSM predicts, and the results thus lend additional support to the hypothesis that causal judgments are grounded in counterfactually simulated probabilities. Adding expectations increased both people's causal judgments as well as their subjective degree of belief that a counterfactual collision would changed the outcome. This effect was particularly strong for social expectations, which the CSM explains by assuming that knowledge about intentions of agents limits the range of counterfactuals that are considered. Our results thus add to previous research indicating that intentional actions signal higher causal stability compared to unintentional ones (Lombrozo, 2010), and that causal stability is indeed a relevant dimension that affects causal reasoning (Nagel \& Stephan, 2016).

It might be objected that the asymmetry in causal attribution for "went through" and "missed" in Experiment 1 is not due to a difference in what would have happened in the relevant counterfactual simulations, but rather due to an inherent asymmetry between omissions that prevent and omissions that cause. Experiment 2 addressed this possible con-
found by looking at situations in which the relevant counterfactual event was clear (a wall that could only move in one direction), as well as what would have happened in case that event had happened. Just as predicted, we found that causal ratings were equally high irrespective of whether the ball "went through" and "missed" in this case. Instead of a general asymmetry between prevention and causation, participants judge omissions to be causal the more certain they are that the omission made a difference to the outcome.

As our introductory example demonstrates, omissions are particularly relevant in human interaction, especially so in morally or legally charged situations when we had clear expectations about what a person should have done. In this paper, we have shown how the CSM accounts for people's causal judgments of omissions in situations in a physical domain in which the relevant counterfactuals are relatively well constrained. However, we believe that the CSM has the potential to capture causal judgments about omissions of social agents as well. For example, the extent to which we blame someone for not having helped depends on how easy it would have been for the agent to help (cf. Jara-Ettinger, Tenenbaum, \& Schulz, 2015). In future research, we will explore the CSM in a richer social setup.

#### Abstract

When asked to assess the deductive validity of an argument, people are influenced by their prior knowledge of the content. Recently, two competing explanations for this belief bias effect have been proposed, each based on signal detection theory. Under a response bias explanation, people set more lenient decision criteria for believable than for unbelievable arguments. Alternatively, believable and unbelievable arguments may differ in subjective argument strength for both valid and invalid items. Two experiments tested these accounts by asking participants to assess the validity of categorical syllogisms and rate their confidence. Conclusionbelievability was manipulated either within- or betweengroups. A two-step signal detection model was applied to examine the effects on the relative location of the decision threshold and the distributions of argument strength. Equivalent belief bias effects were found when believability was manipulated within- and between-groups, supporting the view that the belief bias effect is due to response bias.

Keywords: belief bias; deductive reasoning; signal detection theory; response bias

## Introduction

An important phenomenon for theories of reasoning is that people show a belief bias when asked to assess the logical validity of arguments. The tendency to accept or reject a conclusion as valid is not based purely on logical structure but is also swayed by its compatibility with prior knowledge (e.g., Evans, Newstead, \& Byrne, 1993; Markovits \& Nantel, 1989; Shynkaruk \& Thompson, 2006). Table 1 shows typical stimuli - categorical syllogisms - in which the validity of the argument is crossed with the believability of the conclusion. In the validity discrimination task, participants are asked to judge whether the conclusion below the line necessarily follows from the premises above the line. Key findings based on arguments like these are that people are more likely to endorse valid than invalid arguments, but they are also more likely to endorse arguments with believable than with unbelievable conclusions. In many cases these factors also interact; for example, the difference between the acceptance rates of valid and invalid arguments is often greater for unbelievable than for believable arguments (e.g., Dube, Rotello, \& Heit,

2010; Evans, Barston, \& Pollard, 1983; Newstead, Pollard, Evans, \& Allen, 1992; Roberts \& Sykes, 2003).

Table 1: Sample syllogisms.

|  | Believable | Unbelievable |
| :---: | :---: | :---: |
| Valid | No beers are krabbers. Some krabbers are drinks. | No drinks are krabbers. Some krabbers are beers. |
|  | Some drinks are not beers. | Some beers are not drinks. |
| Invalid | No drinks are krabbers. Some krabbers are beers. | No beers are krabbers. Some krabbers are drinks. |
|  | Some drinks are not beers. | Some beers are not drinks. |

Such effects are often seen as evidence that believability affects the quality of deductive reasoning - people's ability to distinguish valid from invalid arguments (see Dube et al., 2010 for a review). Theoretical accounts such as the selective scrutiny model (Evans et al., 1983), misinterpreted necessity model (e.g., Markovits \& Nantel, 1989; Newstead et al., 1992) or the mental models approach (e.g., Oakhill, Johnson-Laird, \& Garnham, 1989) propose explanations in which believability affects how validity is evaluated.

However, deciding whether an argument is valid also involves response bias - the willingness to endorse the argument, regardless of one's ability to discriminate valid and invalid forms. Controversially, recent work has used confidence ratings and signal detection theory to show that belief bias only reflects changes in response bias. That is, people are more willing to respond "valid" for believable arguments (Dube et al., 2010; Trippas et al., 2014). In this view, believability does not change one's subjective evaluation of argument validity.

In reaction to this response bias account, it has been suggested that data patterns consistent with changes in response bias can also be explained by believability affecting the subjective strength of both valid and invalid arguments (Klauer \& Kellen, 2011; Singmann \& Kellen, 2014). Under this alternative argument strength account, if an argument has a believable conclusion (whether valid or
invalid) then it will be viewed as more logically valid and thus garner more endorsements.

In adjudicating between these accounts, a key consideration is that believability is usually manipulated within a single experimental session. The argument strength account is consistent with evidence that response bias is unlikely to change from trial to trial (e.g., Stretch \& Wixted, 1998). However, to our knowledge it is currently unknown how believability affects performance if instead it is manipulated between different groups of participants, where response bias is free to differ. As we explain below, we hypothesized that if the response bias account is correct then the same belief bias effects on model parameters should appear when believability is manipulated within groups and between groups (i.e., equivalent ordinal effects on response bias and no effects on discriminability).

Given the important implications for theories of reasoning, we aimed to extend the investigation of response bias in deductive reasoning. We took three key steps. First, we sought to replicate the within-group findings of Dube et al. (2010) - including confidence ratings - that they used to support the response bias account. Second, we applied an extended signal detection model that was specifically tailored to the two-step task in which participants first make a binary valid/invalid decision, then rate their confidence. Our goal was to confirm whether such a model would still suggest that believability does not affect accuracy, but that the response bias or argument strength accounts are required. Third, to avoid the issue of whether response bias can change trial-by-trial, in a second experiment we manipulated believability between groups. Our goal was to examine whether the key effects generalized to this design, which would support the response bias account.

To this end, in the following sections, we outline (a) how signal detection theory can be applied to deductive reasoning, (b) the novel two-step signal detection model, and (c) two experiments that manipulate believability within or between groups, to which we apply the model.

## Signal Detection Theory and Belief Bias

Signal detection theory (SDT) is a useful framework to examine belief bias because it allows us to separate changes in discriminability (i.e., differentiating valid and invalid arguments) versus response bias (i.e., the "decision stage"; cf. Dube et al., 2010; Rotello \& Heit, 2009). In this framework, arguments fall along a continuum of subjective argument strength, with distinct Gaussian distributions for valid and invalid arguments, as shown in Figure 1. The distance between the means of these distributions reflects how well people can distinguish valid and invalid arguments. People also set a response threshold along the continuum, endorsing any argument that exceeds it in strength (i.e., the tallest "Invalid"/"Valid" threshold in the figure). Thus the hit rate (endorsement rate for valid arguments) is given by the area under the valid distribution to the right of the threshold, and the false alarm rate (endorsement rate for invalid arguments) is given by the
area under the invalid distribution to the right of the threshold. Two important ways that performance can change is by the threshold shifting (i.e., changes in response bias), and/or the valid distribution shifting relative to the invalid distribution (i.e., changes in discriminability or sensitivity).

Figure 1: Standard signal detection model.
Adding confidence judgments to the validity discrimination task allows for a more fine-grained analysis of changes in signal detection parameters. It is assumed that people set a response threshold for $n-1$ response options on the confidence scale - five are shown in Figure 1 for a sixpoint confidence scale. Performance can then be examined using receiver operating characteristic (ROC) curves, which plot hit rates against false alarm rates at different confidence levels (see examples in Figure 2). Evidence for a difference in the discriminability of valid and invalid arguments would be suggested by points from two conditions falling on different curves. Better discrimination is suggested by ROC curves that fall further from the diagonal, towards the upper left - hit rates are higher relative to false alarm rates. In contrast, conventional evidence for a difference in response bias is suggested by points from two conditions falling on different positions along the same curve. A more lenient threshold is suggested by points sitting further towards the right, corresponding to both higher hit rates and higher false alarm rates. Signal detection models can be fit to ROC curves to test for changes in argument discrimination or response bias, which would be supported by reductions in fit due to constraining either the relative location of the valid distribution or the criteria, respectively.

Figure 2: ROC curves from Dube et al. (2010).

An important but controversial result was reported by Dube et al. (2010), who compared and fit ROC curves for believable and unbelievable syllogisms like those in Table 1. Their ROC model fitting showed that argument believability affected response bias but did not affect discriminability. Participants were simply more willing to endorse believable arguments (see Figure 2). This response bias account of belief bias is illustrated in the top panel of Figure 3. Here there are two distributions - one for invalid and one for valid arguments - but two sets of decision thresholds - a more lenient set for believable arguments, and a more conservative set for unbelievable arguments (only three criteria per set are shown, to avoid clutter). A similar account has been proposed for belief bias in causal conditional arguments such as modus ponens (Trippas et al., 2014).

However, this is not the only way to interpret overlapping ROC curves. The response bias interpretation has been contested because an alternative argument strength account is possible, as illustrated in the bottom panel of Figure 3 (Klauer \& Kellen, 2011; Singmann \& Kellen, 2014). This approach assumes a single fixed set of decision thresholds, but four different distributions - distinct invalid and valid distributions for both unbelievable and believable arguments. Discriminability is assumed to be the same for believable and unbelievable arguments, but the believablevalid AND believable-invalid distributions are shifted to the right (i.e., they are stronger on average).
a

Argument Strength

Argument Strength

Figure 3: (a) The response bias account. There are fixed invalid (I) and valid (V) distributions. Criteria are shifted to the left for believable arguments (black lines) relative to unbelievable arguments (grey lines). (b) The argument strength account. There are fixed criteria. Invalid-believable (IB) and valid-believable (VB) distributions are shifted to the right, relative to the invalid-unbelievable (IU) and validunbelievable (VU) distributions.

Resolving this debate has been difficult because in many of the key studies (e.g., Dube et al., 2010; Trippas et al., 2014), believability has been manipulated within a block of arguments. The response bias account assumes that people will shift their criteria on a trial-by-trial basis, depending on whether an argument is believable or unbelievable. However, this assumption is controversial. In the recognition memory literature, although trial-by-trial shifts in criteria are possible, it appears that often this does not occur (Rotello \& Macmillan, 2007; Starns \& Olchowski, 2015; Stretch \& Wixted, 1998). One way to address this issue is to manipulate believability between participants. Uncontroversially, different groups are then free to set different response criteria.

In order to resolve whether belief bias is driven by changes in response bias or argument strength, we carried out two experiments and tested a new signal detection model of reasoning. Experiment 1 confirmed that we could replicate the ROC shifts found by Dube et al. (2010), with believability manipulated within-participants. In Experiment 2, we investigated whether the same effects appeared when believability was manipulated between groups. If the response bias account is correct, then the same distributions of response strength for valid and invalid arguments should apply to those seeing only believable or unbelievable arguments (because there are only two distributions), but the groups will differ in response criteria. Therefore, we would see different hit rates and false alarm rates for the believable and unbelievable argument groups, replicating the Dube et al. (2010) ROC shifts and differences in the response criterion parameter based on model fitting.

Alternatively, if the argument strength account is correct, then the pair of invalid and valid distributions would be in different locations for believable and unbelievable groups. However, each group would be free to set criteria relative to the locations of their invalid and valid distributions - each group has no reason to adopt criteria that are in different locations relative to their distributions. Therefore, we would see the same hit and false alarm rates for both groups, with no ROC shifts nor differences in the criterion parameter.

Accurately testing the competing accounts of belief bias requires model fitting with a model that properly captures the task. Therefore, we extended the signal detection model developed by Dube et al (2010), to treat the valid/invalid decision and confidence judgments as two separate steps. As outlined below, this kind of model is more appropriate for the two-step task than a traditional signal detection model (Moran, Teodorescu, \& Usher, 2015). We first present the model. We then report experiments using within- and between-participant manipulations of conclusion believability and fit the model to these data.

## Two-Step Signal Detection Model

In the two-step validity discrimination task that we use, participants make a "valid"/"invalid" decision, and then rate their confidence. Despite the sequential nature of these judgments, in the standard procedure for generating
empirical ROC curves, data from the response categories are recoded to form a single scale with judgments that range from high-confidence "valid" to low-confidence "valid", then low-confidence "invalid" to high-confidence "invalid" (e.g., Dube et al., 2010; Trippas et al., 2014). Typically, these ROC curves are then fit using the standard single-step SDT model that we outlined above, with a criterion parameter separating each adjacent pair of recoded confidence levels. However, visual inspection of these empirical ROC curves suggests that they differ from the smooth concave curve typically found - they instead exhibit a "hinge" or "elbow" where valid and invalid response categories join, as apparent in Figure 2, particularly for the unbelievable-ROC. In order to successfully model this feature, the standard SDT model was extended to incorporate changes in evidence accumulation and variability in the period between the initial validity judgment and the subsequent confidence judgment.

The two-step SDT model is similar to a standard SDT model with the exception that confidence judgments are based on a noisy version of the evidence value on which the validity judgment was made. Let $x \sim N(\mu, \sigma)$ be the strength of given argument. Let $c$ be a decision criterion such that if $x>c$, respond "valid", else respond "invalid". We propose that a confidence judgment is based on $x^{*}$, a noisy memory trace of argument strength, $x$. That is, $x^{*}=x+x^{\prime}$, for $x^{\prime} \sim N(v, \eta)$. If $v>0$ then additional argument strength is accumulated in the interval between the two decisions (cf., Moran et al., 2015). Suppose, there are $k$ confidence categories labeled, in sequence, from most confident to least confident. Then, associated with these category labels is set of points on the strength continuum, $U=\left\{u_{0}, u_{1}, \ldots, u_{k}\right\}$, such that, $u_{0}<u_{1}<\ldots<u_{k}, u_{0}=-\infty$, $u_{k}=\infty$, and a set of points, $V=\left\{v_{0}, v_{1}, \ldots, v_{k}\right\}$, such that, $v_{0}>v_{1}>\ldots>v_{k}, \quad v_{0}=\infty, \quad v_{k}=-\infty$. Then, if the response is "invalid" and $u_{i}<x^{*} \leq u_{i+1}$ or, if the response is "valid" and $v_{i} \leq x^{*}<v_{i-1}$ then respond with the $i$ th category label.

The hypotheses of interest were primarily tested by comparing the fits of nested versions of this model using the likelihood ratio test. Although the response bias and argument strength accounts are formally identical for a traditional signal detection model, this is not strictly true for the two-step model. Therefore, both accounts can be tested when believability is manipulated within-participants.

## Experiments

In two experiments, participants evaluated the validity of categorical syllogisms, which included logically valid and invalid arguments with believable or unbelievable conclusions in a $2 \times 2$ design. Experiments 1 and 2 manipulated believability within- and between-groups, respectively.

## Method

Participants. One-hundred-and-seventeen students (30 males) at the University of New South Wales, Sydney, participated for course credit. Mean age was 18.8 years (SD $=2.3$ ). Participants were randomly allocated to Experiment $1(\mathrm{~N}=38)$ or one of the groups in Experiment 2 (believable $\mathrm{N}=40$, unbelievable $\mathrm{N}=39$ ).

Stimuli. In Experiment 1, participants evaluated 64 arguments across two blocks of 32 trials, with 16 believable and 16 unbelievable arguments per block - half of which were valid in each case. In Experiment 2, participants evaluated either 32 believable or 32 unbelievable arguments (half valid).

Example stimuli are shown in Table 1. The arguments were based on those of Experiment 2 by Dube et al. (2010), and were constructed using their 16 syllogistic problem frames (e.g., All X are Y; Some Z are not Y; Therefore some $Z$ are not $X$ ). Half were valid and half were invalid. Each problem frame had the conclusion structure, Some $Z$ are not $X$ (or Some $X$ are not $Z$ ), and was assigned content involving a category-exemplar relationship (e.g., drinks-beers, dogspoodles, plants-weeds).

Conclusion believability was manipulated by simply reversing the order of the category and exemplar (e.g., Some drinks are not beers vs. Some beers are not drinks). We verified the believability of the conclusion statements in a separate study by 34 people drawn from a similar population to the main experiments. Based on ratings on a 5-point scale ( $1=$ unbelievable, $3=$ neutral, $5=$ believable), the 32 statement pairs with the most extreme average ratings were selected from a set of 38 pairs (Believable: $\mathrm{M}=4.95$, $\mathrm{SD}=$ 0.09 ; Unbelievable: $\mathrm{M}=1.59, \mathrm{SD}=0.35$ ). To minimize the effects of premise believability, the premises included a nonsense term (e.g., krabbers, junids).

The semantic content was split into four subsets of eight category-exemplar pairs, so the content could be assigned to all four believability-by-validity conditions, counterbalanced across participants. Experiment 1 participants (believable and unbelievable withinparticipants) saw the category-exemplar content once per block and the 16 problem frames twice per block (once as believable and once as unbelievable versions), forming the 64 arguments over two blocks. Content assignment was controlled for this group so that in the second block, each participant saw the same content in the same problem structures as in their first block, but with conclusion believability reversed. At the start of the second block, these participants were warned that there would be similar content but the specific arguments would be different. Experiment 2 participants (believable-only and unbelievable-only groups) saw each category-exemplar content once and the 16 problem frames twice, forming the 32 arguments.

Before beginning the experiment, all participants received two valid and two invalid practice problems with abstract content (e.g., "All M are P...") and different structures that were not included in the main task.

Procedure. Participants were shown the set of arguments in random order, presented one-by-one on a computer, with a line separating the conclusion from the premises. The instructions asked participants to assume that the premises were true and assess whether the conclusion logically followed from them. Valid arguments were defined as those for which the sentence below the line was necessarily true, given that the information above the line was true (and invalid $=$ not necessarily true $)$. Participants were told that the arguments would contain a nonsense word. A trial counter was presented at the top left corner of the screen. Participants clicked on either the "Valid" or "Invalid" button presented underneath a given argument, then rated their confidence on a scale that appeared, ranging from 50 (Guessing) to 100 (Certain) in increments of ten.

## Results

Both experiments replicated previously observed argument endorsement patterns and belief bias effects (see Table 2 ; e.g., Dube et al., 2010; Evans et al., 1983; Newstead et al., 1992). Analysis of variance (ANOVA) revealed that participants endorsed (i.e., responded "valid") valid arguments more often than invalid arguments: Experiment $1, F(1,37)=64.28, p<.001, \eta^{2}=.35$; Experiment $2, F(1$, 77) $=127.24, p<.001, \eta^{2}=.40$. Participants endorsed believable arguments more often than unbelievable arguments: Experiment $1, F(1,37)=38.59, p<.001, \eta^{2}=$ .12; Experiment 2, $F(1,77)=19.92, p<.001, \eta^{2}=.13$. Notably, as shown in the Table, there was a larger difference between the acceptance rates of valid and invalid arguments for unbelievable than for believable arguments: Experiment 1, $F(1,37)=5.50, p=.02, \eta^{2}=.01$; Experiment $2, F(1,77)=9.81, p=.002, \eta^{2}=.05$.

Table 2: Performance in Experiments 1 and 2. Hit rate is p("Valid"|Valid); False alarm rate is p("Valid"|Invalid).

| Experiment | Condition | Hit rate | False alarm rate |
| :---: | :--- | :---: | :---: |
| 1 | Believeable | 0.83 | 0.56 |
|  | Unbelievable | 0.71 | 0.37 |
| 2 | Believeable | 0.82 | 0.58 |
|  | Unbelievable | 0.75 | 0.34 |

The ROC curves for each experiment are presented in Figure 4 (unfilled points). Both show effects that are consistent with shifts in response criteria and comparable to Dube et al. (2010; cf. Figure 2), although we used more confidence response options. In each experiment, the points for believable and unbelievable arguments fall on similar curves, though the believable points are shifted further to the top-right corner than the unbelievable points.

We first fit an unconstrained two-step signal detection model to each experiment. As shown by the filled points in Figure 4, the predicted ROC points correspond reasonably well with the empirical results for both experiments, though there are some small departures for Experiment 1: Experiment 1, $G^{2}(12)=22.54, p=.03$; Experiment 2, $G^{2}(12)=15.83, p=.20$.

Figure 4: Observed ROC curves (Obs) and expected scores from the unconstrained model (Exp), for Experiments 1 and 2 (panels a and b, respectively).

We compared this unconstrained model against two nested models: a constant discriminability model and a constant criterion model in which (respectively) discriminability or the "valid"/"invalid" decision criterion for the initial binary judgment was constrained across believable and unbelievable conditions. For both experiments, the fit of the constant discriminability model did not significantly differ from that of the unconstrained model: Experiment 1, $G^{2}(1)=0.23, p=.63$; Experiment 2, $G^{2}(1)=0.001, p=.97$. This shows that, in line with Dube et al. (2010), discriminability did not differ between believability conditions.

The constant criterion model led to a reduction in fit compared to the unconstrained model: Experiment 1, $G^{2}(1)$ $=47.89, p<.001$; Experiment $2, G^{2}(1)=77.75, p<.001$. This indicates that, in line with the response bias account, the "valid"/"invalid" decision threshold differed between believability conditions. Importantly, this was true both when believability was manipulated within-groups (Experiment 1) and between-groups (Experiment 2).

When a (non-nested) variant of the two-step model was applied to Experiment 1 that allowed the believable distributions to shift (i.e., the argument strength account), we found that it also provided a satisfactory fit to the data: $G^{2}(20)=30.18, p=0.07$. In other words, an argument
strength account of belief bias could also explain the Experiment 1 data. Such a model cannot sensibly be applied to Experiment 2. Nevertheless, as we argued above, the response bias account can more readily explain belief bias effects that occur between-groups.

## Discussion

We investigated whether belief bias effects in deductive reasoning could be explained as a response bias effect. Experiment 1 replicated the belief bias effects of Dube et al. (2010), with conclusion believability manipulated withinblock. We applied a new two-step signal detection model to better suit the two-step task, and confirmed that belief bias effects are consistent with a shift in response bias, rather than discriminability. Experiment 2 extended the same results to an equivalent task with believability manipulated between-groups.

Under the response bias account (Dube et al., 2010; Trippas et al., 2014), this pattern is explained by a shift in decision threshold, such that there is a more lenient criterion for believable conclusions. Under the argument strength account (Klauer \& Kellen, 2011; Singmann \& Kellen, 2014), the belief bias effect reflects higher mean strength for believable-valid and believable-invalid arguments than for unbelievable-valid and unbelievable-invalid arguments.

It could be argued that participants in Experiment 1 were unlikely to change their criteria trial-to-trial for different levels of believability, favoring the argument strength account. However, this account would have difficulty with Experiment 2, where participants saw only believable or only unbelievable arguments. There, the two groups had no reason to position their criteria in different locations relative to their distributions. Thus if belief bias primarily reflects a change in argument strength, the belief bias effects should have disappeared. The fact that they did not suggests that the most plausible explanation of belief bias in the current data sets is a change in response bias.

Therefore, addressing the debate between response bias and argument strength accounts of belief bias, we agree that believable conclusions are most likely to affect the decision stage, lowering the decision threshold rather than appearing more logically valid. Just as people may require stronger evidence to endorse that an unusual event occurred (Starns \& Olchowski, 2015), it seems that people also require stronger evidence to endorse a syllogism with an unbelievable conclusion. As Dube et al. (2010) concluded, this is problematic for theories of reasoning that propose that believability affects the process of evaluating validity (e.g., Evans et al., 1983; Markovits \& Nantel, 1989; Newstead et al., 1992; Oakhill et al., 1989). Future work should address whether the same findings generalize to other reasoning problems such as causal conditionals.

# Rational use of prosody predicts projection in manner adverb utterances 

Jon Scott Stevens, Marie-Catherine de Marneffe, Shari R. Speer, Judith Tonhauser<br>\{stevens.400,demarneffe.1,speer.21,tonhauser.1\}@osu.edu<br>Department of Linguistics, The Ohio State University, Columbus, OH 43210 USA

#### Abstract

Speakers can be taken to be committed to utterance content even when that content is contributed in the scope of an entailment-canceling operator, like negation (e.g., Chierchia \& McConnell-Ginet, 1990). We develop a probabilistic model of this phenomenon, called 'projection', that relies on the prosodic realization of utterances. We synthesize existing theoretical claims about prosody, information structure and projection into a model that assumes a rational speaker (Frank \& Goodman, 2012) who produces utterances with prosodic melodies that can signal which utterance content she is committed to. Predictions of the probabilistic model are compared to the responses of an experiment designed to test the effect of prosody on projection in manner adverb utterances. Key behaviors of the model are borne out empirically, and the quantitative fit is surprisingly good given that the model has only one free parameter. Our findings lend support to analyses of projection that are sensitive to the information structure of utterances (e.g., Simons, Beaver, Roberts, \& Tonhauser, 2017).

Keywords: Projection; prosody; information structure; probabilistic pragmatics; rational speech acts; manner adverbs

## Introduction

Projective content is utterance content that the speaker may be taken to be committed to even when the content is introduced by an expression in the scope of an entailment-canceling operator (e.g., Chierchia \& McConnell-Ginet, 1990). A speaker who utters (1a) is taken to be committed to the content $\phi$ that Sam is ill and to the content that Jo discovered $\phi$. A speaker who utters the negated variant in (1b) or the polar question in (1c) is not taken to be committed to Jo having discovered $\phi$ (rather, Jo's discovery is negated or asked about), but the speaker may still be taken to be committed to $\phi$, that Sam is ill. Hence, $\phi$ is projective content.
(1) a. Jo discovered that Sam is ill. b. Jo didn't discover that Sam is ill.
c. Did Jo discover that Sam is ill?

Simons et al. (2017) develop a question-based analysis of the projection of the content of the complement of predicates like discover according to which the speaker can be taken to be committed to the content of the complement if it is entailed by the Question Under Discussion (Roberts, 2012) that the utterance is taken to address. This analysis correctly predicts that whether the speaker is taken to be committed to the content of the complement depends on the prosodic realization of the utterance (see Tonhauser, 2016, for empirical evidence). For instance, if (1c) is uttered with prosodic prominence on discover, as in (2a), where capital letters indicate prosodic prominence, then the speaker is more likely to be taken to be committed to the content of the complement than if (1c) is uttered with prosodic prominence on ill, as in (2b).
a. Did Jo DISCOVER that Sam is ill?

## b. Did Jo discover that Sam is ILL?

This paper provides conceptual and empirical support for the question-based analysis of projection from a novel empirical domain: utterances with manner adverbs, like Masha didn't run quickly. To formalize the link between prosody, information structure and projection hypothesized in Simons et al. 2017, we develop a Rational Speech Act (RSA) model (Bergen \& Goodman, 2015; Frank \& Goodman, 2012, and many others) that predicts the projectivity of the so-called prejacent (that Masha ran) from the prosodic realization of manner adverb utterances. The model is evaluated based on empirical observations about the projectivity of the prejacent.

## Projective content in manner adverb utterances

In a manner adverb sentence, e.g., (3), a manner adverb like quickly, beautifully or easily modifies the activity-denoting verb. (3) entails that Masha ran (the prejacent). It has been long observed that the prejacent can project and that the projectivity of the prejacent depends on the prosody of the utterance (e.g., Abrusán, 2013; Simons, 2001). For instance, the speaker of (4a), with quickly prosodically prominent, may be taken to be committed to the prejacent even though the sentence is negated. On the other hand, the speaker of (4b), with Masha prosodically prominent, is not typically taken to be committed to the prejacent, i.e., the prejacent does not project. The speaker of (4b) may be committed to a different content, namely that somebody ran quickly. For reasons of space we only consider the prejacent here, though the formal proposal extends to the projectivity of other content.
(3) Masha ran quickly.

## a. Masha didn't run QUICKLY. <br> b. MASHA didn't run quickly.

Simons et al.'s (2017) question-based analysis of projection accounts for the dependence of the projectivity of the prejacent on prosody based on two independently made empirical observations. The first observation is that informationstructural focus can be prosodically indicated in American English (e.g., Eady \& Cooper, 1986). Compared to nonfocused expressions in the same intonational phrase, focused expressions are more likely to be realized with pitch accents, a longer duration, an expanded pitch range and/or greater intensity. Thus, the two manner adverb utterances in (4) are compatible with different expressions being focused, as shown in (5), where focus is marked by angle brackets subscripted with ' $F$ ':

[^205]The focused expression is used to calculate the focus alternatives set of an utterance: following Rooth 1992, a focus alternatives set of $(5 a)$ is the set of propositions of the form 'Masha didn't run $x$ ', with $x$ a modifier, and a focus alternatives set of (5b) is the set of propositions of the form ' $x$ didn't run quickly', with $x$ an entity. Following Beaver and Clark 2008, we assume that alternatives can also be calculated under negation: thus, another focus alternatives set of (5a) is the set of propositions of the form 'Masha ran $x$ ', with $x$ a modifier, and another focus alternatives set of (5b) is the set of propositions of the form ' $x$ ran quickly', with $x$ an entity.

Importantly, the prosody of utterances merely constrains what is focused but does not determine it. Thus, although the prosodic realization of (4a) is not typically compatible with the focus marking indicated in (5b), it is compatible with a larger expression of the sentence being focused, as in (6).

## (6) Masha didn't [run QUICKLY] ${ }_{F}$.

The second empirical observation is that answer utterances are congruent with the interrogative utterances they address (e.g., Paul, 1880; Rooth, 1992; von Stechow, 1990). Consider B's utterance in (7a), and assume that B's utterance is realized with the so-called rise-fall-rise contour, which consists of a rising pitch accent on quickly $\left(\mathrm{L}+\mathrm{H}^{*}\right.$ in the ToBI annotation scheme, Beckman \& Ayers, 1997) and a rising end contour (L-H\% in ToBI notation). When B's utterance in (7a) is realized with the rise-fall-rise contour, it is congruent with, i.e., judged to be acceptable in response to, A's interrogative utterance in (7a). However, because of the placement of the pitch accent on quickly, it is not congruent with A's interrogative utterance in (7b). Likewise, when B's utterance in (7b) is realized with the rise-fall-rise contour, it is congruent with A's utterance in (7b), but not with A's utterance in (7a).

> a. A: How did Masha run?
> B: Masha didn't run $[\mathrm{QUICKLY}]_{\mathrm{F}}$.
> b. A: Who ran quickly?
> B: [MASHA $]_{\mathrm{F}}$ didn't run quickly.

When B's utterances are realized with the rise-fall-rise contour, B indicates that their utterance does not provide a complete answer to the question (see e.g., Wagner, 2012); instead, B's utterance only eliminates a possible true answer to the question. A prosodically motivated model of projection must take these contributions of contours into account.

In alternative semantics, question-answer congruence is accounted for by assuming that a focus alternatives set of a congruent answer includes the denotation of the question, which is a contextually restricted set of propositions. For instance, B's answer in (7a) is congruent with A's interrogative utterance since the focus alternatives set 'Masha ran $x$ ' includes the set of propositions denoted by A's utterance (a subset of propositions of the form 'Masha ran $x$ '), but B's answer is not congruent with A's interrogative utterance in (7b) since the focus alternatives set 'Masha ran $x$ ' does not include the set of propositions denoted by A's utterance (a subset of propositions of the form ' $x$ ran quickly').

Importantly, in naturally occurring discourse, many utterances are not made in response to an interrogative utterance (an explicit question). Simons et al. (2017) assume that such utterances address an implicit question: given questionanswer congruence, the focus marking of an utterance that addresses an implicit question provides a cue to the question that the utterance addresses (e.g., Halliday, 1967; Most \& Saltz, 1979; Roberts, 2012). The potentially implicit question that is addressed by an utterance is called the Question Under Discussion (QUD). It follows that the prosodic realization of a manner adverb utterance provides listeners with a cue to the focus of the utterance, which in turn provides a cue to the QUD that the speaker was intending to address. Thus, (5a) can be taken to address the QUD 'How did Masha run?' and (5b) can be taken to address the QUD 'Who ran quickly?':
(8) a. Possible QUD of (5a): \{Masha ran quickly, Masha ran slowly, Masha ran clumsily,...\}
b. Possible QUD of (5b): \{Masha ran quickly, Jack ran quickly, Sue ran quickly,...\}
To predict projection, Simons et al. (2017) make the following assumption:
(9) Projection under the question-based analysis: Content $\phi$ of utterance $U$ projects if $\phi$ is entailed by each alternative in the QUD addressed by $U$.
The question-based analysis predicts that the prejacent is more likely to project from (4a) than from (4b). If a speaker utters (4a), with prosodic prominence on the manner adverb, and the utterance is taken to have the focus shown in (5a), then she can be taken by the listener to intend her utterance to address the QUD 'How did Masha run?' in (8a). Since each alternative in the QUD has the form 'Masha ran $x$ ', each entails that Masha ran and so the prejacent is predicted by (9) to project. On the other hand, if a speaker utters (4b), with prosodic prominence on the subject, and the utterance is taken to have the focus shown in (5b), she can be taken by the listener to intend her utterance to address the QUD 'Who ran quickly?' in (8b). Since each alternative in the QUD has the form ' $x$ ran quickly', the QUD entails that somebody ran quickly, but not the prejacent, that Masha ran. Thus, the prejacent is not predicted by (9) to project from (4b). Importantly, since prosody does not determine focus, but merely provides listeners with a cue, and since focus does not determine the QUD, but merely provides listeners with a cue, the questionbased analysis does not predict categorical (non-)projection of the prejacent from (4a) and (4b), but merely that the prejacent is more likely to project from (4a) than (4b).

## Modeling projection

For the purpose of modeling the link between prosody and projection, we consider an utterance to be a sentence with a melody. For the utterances considered here, a melody is the combination of a single pitch accent $\left(\mathrm{L}+\mathrm{H}^{*}, \mathrm{H}^{*}, \mathrm{~L}^{*}\right)$, aligned with the stressed syllable of the accented word, and an end contour (L-H\%, H-L\%, L-L\%). Our model considers pitch
accent positions either on the adverb, the verb, the negated auxiliary or the subject of the sentence. For example, $\mathrm{L}+\mathrm{H}^{*}$ $\mathrm{L}-\mathrm{H} \%$, with the $\mathrm{L}+\mathrm{H}^{*}$ realized on the first syllable of quickly may be the melody of the manner adverb utterance in (4a). We develop a probabilistic model of projection based on the assumption of a 'rational speaker', who chooses a melody for a given sentence to most effectively signal the identity of the QUD that an utterance of the sentence is intended to address. Following the basic framework of the RSA model, we begin by developing a notion of speaker utility, which is taken to be the 'usefulness' of a melody for a given sentence as a signal of which QUD is being addressed by the speaker's utterance. More concretely, the utility of a melody $M$ for a given sentence and a target QUD $Q$, is the probability that a hearer would randomly select $Q$, given that the sentence was uttered with melody $M$, and given what the hearer knows about the compatibility between $M$ and possible QUDs. We define this utility as follows, where $Q_{M}$ is the set of possible QUDs addressed by the given sentence that are compatible with $M$ :
(10) $U(Q, M)=\frac{1}{\left|Q_{M}\right|}$ if $Q \in Q_{M}$, else 0

To define what it means for a melody for a given sentence to be compatible with a QUD, we draw on the following independently motivated sets of assumptions from the prosodypragmatics literature:

- Assumption A - Compatibility of pitch accent with focus: A pitch accent on expression X is compatible with focus on $X$ or a constituent that contains $X$ and an immediately adjacent expression (e.g., Selkirk, 1996).
- Assumption B - Compatibility of focus with QUD:

The QUD that is addressed by the utterance must be congruent with the focus marking of the utterance (Beaver \& Clark, 2008, 45).

- Set of assumptions C - Compatibility of pitch contour with QUD:

1. Pitch contours that lack a final fall ( $\mathrm{L}-\mathrm{L} \%$ ) and contain either an $\mathrm{L}+\mathrm{H}^{*}$ pitch accent or a continuation rise ( $\mathrm{L}-\mathrm{H} \%$ ) — $\mathrm{H}^{*} \mathrm{~L}-\mathrm{H} \%, \mathrm{~L}+\mathrm{H}^{*} \mathrm{~L}-\mathrm{H} \%, \mathrm{~L} * \mathrm{~L}-\mathrm{H} \%$ and $\mathrm{L}+\mathrm{H}^{*} \mathrm{H}-\mathrm{L} \%$-are only compatible with incomplete answers to the QUD, i.e., answers that do not pick out a single true alternative (see e.g. Lai, 2012; Wagner, 2012, for evidence that $\mathrm{L}+\mathrm{H}^{*}$ and $\mathrm{L}-\mathrm{H} \%$ signal that the QUD has not been completely answered).
2. Pitch contours that either (i) have a final fall, or (ii) have neither an $\mathrm{L}+\mathrm{H}^{*}$ pitch accent nor continuation rise to suggest incompleteness- $\mathrm{H}^{*} \mathrm{~L}-\mathrm{L} \%, \mathrm{~L}+\mathrm{H}^{*} \mathrm{~L}-\mathrm{L} \%$, L* L-L\%, $\mathrm{H}^{*} \mathrm{H}-\mathrm{L} \%$ and $\mathrm{L} * \mathrm{H}-\mathrm{L} \%$-are only compatible with complete answers to the QUD.
For any melody-QUD pair $\langle M, Q\rangle$ for a given sentence, these assumptions can be used to generate the set $Q_{M}$ and therefore determine the utility of using $M$ to signal $Q$.

Adopting an RSA-based view, we posit a rational speaker who chooses melodies to maximize utility, i.e., maximize the chance that listeners retrieve the QUD intended by the
speaker, though the maximization is approximate, i.e., there still remains some probability of choosing a non-rational (non-utility-maximizing) melody. This is accomplished by setting the probability $P_{S}$ of the speaker producing a melody $M$ given a QUD $Q$ equal to a soft max function of $U(Q, M)$. The soft max function approximates utility maximization using a rationality parameter, $\lambda$, where higher values of $\lambda$ result in lower probability of a non-rational melody being chosen. Thus, in cases where there is a single utility-maximizing melody, the probability of selecting that melody will approach 1 as $\lambda$ increases. The formula for $P_{S}$ is given below, where $M^{\prime}$ is any member of the set of possible melodies the speaker could use:

$$
\begin{equation*}
P_{S}(M \mid Q)=\frac{e^{\lambda U(Q, M)}}{\sum_{M^{\prime}} e^{\lambda U\left(Q, M^{\prime}\right)}} \tag{11}
\end{equation*}
$$

We use Bayes' rule to determine the probability $P_{H}$ of the hearer deciding that the QUD is $Q$ given that she has heard the sentence uttered with melody $M$ :

$$
\begin{equation*}
P_{H}(Q \mid M)=\frac{P_{S}(M \mid Q) \times P(Q)}{\sum_{Q^{\prime}} P_{S}\left(M \mid Q^{\prime}\right) \times P\left(Q^{\prime}\right)} \tag{12}
\end{equation*}
$$

The denominator in this equation is a sum of probabilities over all possible QUDs $Q^{\prime}$, i.e., the set of QUDs that are compatible with any of the melodies we assume could have been used to utter the sentence. For instance, given the sentence Masha didn't run quickly, the set of all QUDs compatible with some melody for that sentence includes 'Who ran quickly?', 'Did Masha run quickly?', 'What did Masha do?', 'What did Masha do quickly?' and 'How did Masha run?', as well as the corresponding QUDs with negation ('Who didn't run quickly', etc.). For current purposes we assume a uniform prior probability distribution over QUDs.

We use $P_{H}$ to calculate the probability that the prejacent of a manner adverb sentence uttered with melody $M$ projects, i.e., that the speaker is taken to be committed to the prejacent. Recall that under assumption (9) from Simons et al. 2017, content projects if it is entailed by the QUD. For manner adverb sentences, the only QUD that entails the prejacent is the set of alternatives obtained by abstracting over the manner adverb (e.g., \{Masha ran $x \mid x$ is a modifier $\}$ entails that Masha ran, as discussed above). We call the prejacent $\phi$, and the prejacent-entailing QUD $Q_{\phi}$. The probability of $\phi$ projecting, given melody $M$, is the probability of the hearer assuming $Q_{\phi}$ given $M$ :
(13) $\quad P(\operatorname{PROJECT}(\phi) \mid M)=P_{H}\left(Q_{\phi} \mid M\right)$

The link between $Q_{\phi}$ and projection is not probabilistic-it is a categorical consequence of the theory set forth in Simons et al. 2017 (see (9)). The probabilistic character of the model results from the fuzzy link between prosodic melodies and the implicit questions that utterances with those melodies are taken to address. The hearer must determine how likely it is that $Q_{\phi}$ is the intended QUD, based on how the speaker selects melodies to convey the QUD she intends to address.

This model operates over the possible melodies that the speaker could use and considers those possibilities when calculating the probability of the projection of the prejacent. To test the model, we examine the model's predictions for two particular melodies and compare those predictions to experimental results. The next section provides information on the two melodies and how their effect on the projection of the prejacent was assessed experimentally.

## Experiment methodology

Using the method of Tonhauser 2016, participants listened to audio recordings of manner adverb utterances and judged whether the speaker was certain of the prejacent.

Participants. We recruited 100 self-reported native speakers of American English on Amazon's Mechanical Turk platform.

Stimuli. Each participant listened to 16 utterances- 10 target utterances and 6 fillers. The target sentences were all of the form, "subject didn't verb adverb", where each adverb was a manner adverb, and where each subject was a proper name. The target sentences were:
(14) a. Amanda didn't clap loudly.
b. Jennifer didn't drive carelessly.
c. Elizabeth didn't leave silently.
d. Linda didn't write neatly.
e. Susan didn't sing beautifully.
f. Jerry didn't knock frantically.
g. Justin didn't smile cheerfully.
h. Alexander didn't sneeze softly.
i. Tyler didn't lie deliberately.
j. Dennis didn't win easily.

The filler items were:
(15) a. Sandy wasn't invited to the party.
b. Did Mario bring a chocolate cake?
c. Who knows if Maggie is at the party?
d. Mike forgot to bring the ketchup.
e. Paul loves that pie!
f. Mandy was out gardening in the yard.

Each target sentence was uttered with one of two possible melodies, $\mathrm{L}+\mathrm{H}^{*} \mathrm{~L}-\mathrm{H} \%$ with the pitch accent on the adverb (the LH-Adverb condition), or $\mathrm{L}+\mathrm{H}^{*} \mathrm{~L}-\mathrm{H} \%$ with the pitch accent on the proper name subject (the LH-Name condition). Fillers were pronounced with pitch accents on words other than the subject noun, and contained a variety of pitch accent and end tone types not used in the target utterances.

In addition to exposing participants to melodies other than the ones used for the target items, filler utterance-question pairs tested whether participants comprehended direct consequences of an action described by the speaker. For example, the utterance, Mike forgot to bring the ketchup was followed by the question, 'Is Debby certain that Mike brought the ketchup?'. Given that Debby's utterance implies that Mike forgot the ketchup, participants were expected to rate the speaker as "not certain", but to reliably respond in this

Figure 1: A screenshot of one experimental item.
way requires attention to the meaning of the utterance as well as its component words.

Each participant was assigned to one of two lists, where the two lists contained the same sentences but were counterbalanced for prosodic condition. The same 6 fillers occurred on both lists.

Procedure. Participants were instructed to imagine themselves at a party, where they overhear Debby, the host, utter various sentences to somebody else. For each of the 16 utterances, the participant was asked to rate on a 7-point Likert scale labeled at 4 points ( $1 /$ "No, not certain", $3 /$ "Possibly not certain", 5/"Possibly certain", 7/"Yes, certain") whether Debby was certain of some content based on what she said and how she said it. On each trial, participants were presented with a display as in Fig. 1, clicked the audio icon, heard an utterance, read the related question, clicked on the radio button that corresponded to their chosen response, and clicked the 'continue' button to proceed to the next trial. For the target item shown in Fig. 1, the utterance was Amanda didn't clap $L O U D L Y$, and the participant was asked to rate the speaker's certainty about the prejacent, i.e., 'Amanda clapped'.
Data exclusion. If participants answered more than one filler incorrectly (an answer greater than 3 on the Likert scale for something that Debby would be uncertain about or an answer smaller than 5 for something that she would be certain about), their responses were excluded from analysis. We excluded 28 participants on these grounds, leaving 72 participants whose responses we analyzed. Whether these participants are excluded does not change the main effect of condition on response.

## Model predictions

If participants take Debby to be committed to the truth of $\phi$, we expect them to respond that Debby is certain that $\phi$. If Debby is not taken to be committed to the truth of $\phi$, we expect participants to respond that Debby is not certain that $\phi$. However, we do not expect mean responses at the extreme ends of the 7-point Likert scale, because it is possible for participants to exhibit uncertainty about whether Debby is committed to $\phi$. Participants can therefore give a response in the mid-range of the scale. To directly compare our model's predictions to the experimental results, we use the model to pre-

Figure 2: Model predictions about the extent to which listeners take the speaker to be certain of the prejacent, given the two melodies. The x -axis represents the $\lambda$-parameter, which encodes the degree to which the predictions reflect utilitymaximizing reasoning. The y-axis is mapped to a 7 -point scale to parallel the experimental task.
dict participants' probabilistic evaluation of whether Debby is certain that $\phi$. The probability $P(\phi \mid M)$ is the probability that Debby is certain that $\phi$, given $M$. This is expected to be 1 when the participant takes $\phi$ to project based on $M$-which occurs with probability $P(\operatorname{PROJECT}(\phi) \mid M)$. When the participant does not take $\phi$ to project based on $M$, we expect some baseline uncertainty about whether Debby is committed to $\phi$, which we encode as a prior probability $P(\phi)$. We thus define $P(\phi \mid M)$ as follows:

$$
\begin{align*}
P(\phi \mid M) & =P(\operatorname{PROJECT}(\phi) \mid M) \times 1  \tag{16}\\
& +P(\neg \operatorname{PROJECT}(\phi) \mid M) \times P(\phi)
\end{align*}
$$

To account for the fact that our stimuli do not provide any prior evidence (i.e., evidence apart from the manipulated prosody) for whether the speaker is committed to $\phi$, we take $P(\phi)$ to be uniform, i.e., equal to 0.5 . Assuming a uniform prior over $\phi$ maintains a model with only one free parameter, the rationality parameter $\lambda$, and makes the model more informative by limiting the range of predictions that it can make.

Fig. 2 shows the model predictions ${ }^{1}$ as $\lambda$ increases to 10 (a relatively high value given ones used in the literature). We see that the modeled participant responses in the two prosodic conditions LH-Adverb and LH-Name diverge rather shallowly, predicting significantly higher certainty in the LHAdverb condition, but not by a huge margin. The model predicts that projection in the LH-Adverb condition, though higher, will not be at ceiling. This is because utterances in the LH-Adverb condition are not only compatible with the prejacent-entailing QUDs but also with QUDs that do not entail the prejacent, and thus the probability of projection never exceeds fifty percent ( 4 on the Likert scale), even for high values of $\lambda .^{2}$

[^206]

Figure 3: Responses by prosodic condition. Violin plots show frequency of participant means. Bar plots show overall means with $95 \%$ bootstrap confidence intervals.

## Experiment results

The experimental results are shown in Fig. 3. Mean Likert scale response in the LH-Adverb condition was 5.7 , compared to 4.8 in the LH-Name condition. This difference is in the expected direction: participants rated Debby as being less certain of the prejacent when the pitch accent was on the subject than when it was on the manner adverb. A mixedeffects ordinal regression model with random intercepts for participant and item and random slope for participant shows responses to be significantly lower in the LH-Name condition than in the LH-Adverb condition ( $\beta=-1.13, S E=0.24$, $z=-4.68, p<0.0001$ ).

The model predictions in Fig. 2 are in line with the experimental results shown in Fig. 3 in three key ways:

1. The model correctly predicts a significant difference in mean responses between the two conditions, with the LHAdverb items showing higher certainty ratings.
2. The model correctly predicts the magnitude of this difference to be rather small (within about one point on the Likert scale).
3. The model correctly predicts that even in the LH-Adverb condition, where projection is expected, the ratings are not at ceiling.
Thus, three qualitative experimental behaviors are accounted for by our RSA model, which builds on existing theoretical assumptions about the links between prosody, the QUD and projection, and incorporates those assumptions into a probabilistic pragmatic model.

The quantitative match with the model's predictions is not exact-certainty is a bit higher across the board than predicted—but as we see in Fig. 4, it is not far off, either. We would expect a more exact match if we experimentally obtained priors over the hearer's evaluation of the speaker's certainty for the various sentences used (instead of assuming a uniform prior of 0.5 ), a possible task for future research.

## Discussion

This paper showed that the question-based analysis of projection developed in Simons et al. 2017 can be extended to manner adverb utterances and formalized in an RSA model.

Figure 4: Model predictions by $\lambda$ value (blue), along with the experimentally observed means (black).

The experimental findings empirically support the predictions of the model and, hence, the question-based analysis of projection. They also add to the growing empirical evidence that formal analyses of projection, including conventional triggering analyses (e.g., Heim, 1983; van der Sandt, 1992), need to be sensitive to information structure (e.g., Beaver, Roberts, Simons, \& Tonhauser, 2017; Tonhauser, 2016). Finally, the RSA model demonstrates the feasibility of formal pragmatic analyses of projection.

Future research needs to investigate the predictions of the model for other projective contents of manner adverb utterances, other prosodic realizations of such utterances, and the projective contents of other utterances. We also observed that the influence of prosody on the projectivity of the prejacent was heterogeneous across items. This observation suggests enriching the model with information about listeners' prior expectations about the prejacent, e.g., about how likely somebody is to smile given that they didn't smile cheerfully.

#### Abstract

Finger gnosis (the ability to identify which finger has been touched) and magnitude comparison (the ability to determine which of two numbers is larger) are surprisingly correlated. We present a spiking neuron model of a common component that could be used in both tasks: an array of pointers. We show that if the model's single tuned parameter is set to match human accuracy performance in one task, then it also matches on the other task (with the exception of one data point). This provides a novel explanation of the relation, and proposes a common component that could be used across cognitive tasks.

Keywords: finger gnosis; magnitude comparison; spiking neurons; neural engineering framework, numerical cognition

## Introduction

Finger gnosis, the ability to differentiate which finger has been touched, in absence of visual feedback, is related to math performance (Fayol, Barrouillet \& Marinthe, 1998; Noël, 2005; Penner-Wilger et al., 2007, 2009, 2014, 2015). Finger gnosis is commonly measured using a finger localization task (Baron, 2004; Noël, 2005), wherein the participant's hand is occluded from their view while a finger, or two fingers, are touched. The participant is then asked to indicate the touched finger(s). Performance is measured in terms of number of fingers correctly identified.

Finger gnosis ability predicts performance on a variety of math measures in children, both concurrently and longitudinally ( $\beta$ 's range from . 22 to .36 ; Fayol et al., 1998; Noël, 2005; Penner-Wilger et al., 2007, 2009). Finger gnosis ability also predicts performance on a variety of math measures in adults ( $\beta$ 's range from .21 to .30 ; PennerWilger et al., 2014, 2015). The relation between finger gnosis and math skill is reproducible across labs, different samples, age groups, and measures of math skill, despite controlling for many other variables (e.g., visuo-spatial working memory, finger agility, processing speed, and nonverbal IQ).

The relation between finger gnosis and math skill is partially mediated by symbolic number comparison performance (Penner-Wilger et al., 2009, in prep.). In symbolic number comparison tasks, participants are shown two digits (e.g., 2 3) and asked to indicate which number is
more (or in some variants asked to compare a target digit to a standard). One robust finding in number comparison is the distance effect - performance is faster and more accurate when numbers are father apart in magnitude (e.g., 2 7) than when they are closer together (e.g., 2 3; Moyer \& Landauer, 1967). The distance effect is proposed to reflect mapping between numerals and their associated magnitude, with greater distance effects reflecting noisier mappings (Dehaene, Dehaene-Lambertz \& Cohen, 1998; cf. Lyons, Nuerk \& Ansari, 2015). Children who perform better in finger gnosis, reflecting a more precise finger representation, also demonstrate smaller distance effects in number comparison, reflecting a more precise number representation (Penner-Wilger et al., 2009).

Why are finger gnosis and math performance, specifically a task indexing the precision/strength of number representations, related? On the redeployment view (PennerWilger \& Anderson, 2008, 2013), the relation between finger gnosis and number representation arises because the two tasks use overlapping neural substrates. On this view, the relation is an example of neural reuse, the use of local regions of the brain to support multiple tasks across domains (Anderson, 2010, 2014). Neural reuse is a dynamic process, impacting the functional organization of the brain across both evolutionary and developmental time, whereby individual regions of the brain contribute to multiple highlevel uses (e.g., finger representation and number representation). There are two forms of neural reuse: redeployment and neuromodulation. In redeployment, the same brain region supports multiple uses, across evolutionary and/or developmental time, while maintaining the same operation (Anderson, 2014). In neuromodulation, the same brain region supports multiple uses, at any given point in developmental time, without maintaining the same operation - its operation is modulated as a result of internal or external variables (Anderson, 2014; Bargmann, 2012; Marder, 2012). The redeployment view posits that the behavioural link between finger and number representations is at least partially explained by neural reuse, and that the specific type of neural reuse involved is redeployment. Thus, one (or more) local brain regions, over evolutionary
and/or developmental time, has come to perform the same operation in support of both uses.

In support of the redeployment view, regions associated with finger gnosis are activated during tasks requiring the representation of number (Andres, Michaux \& Pesenti, 2012; Dehaene et al., 1996; Zago et al., 2001), rTMS and direct cortical stimulation disrupt both finger gnosis and tasks requiring the representation of number (Rusconi, Walsh, \& Butterworth, 2005; Roux et al., 2003), and there is interference between tasks involving finger gnosis and tasks requiring the representation of number (Brozzoli et al., 2008). Zago et al. (2001) pinpointed a region of overlap between finger and number representation in the leftprecentral gyrus (-42, 0, 38). Penner-Wilger and Anderson (2011) conducted a meta-analysis of imaging data to determine the full complement of tasks, across domains, that this ROI was implicated in, with the goal of identifying common requirements across tasks/uses to guide structurefunction mapping. In addition to number and finger representation tasks, the ROI was implicated in generation, inhibition and order tasks. Common requirements across these uses were identified, including ordered storage and mapping, and a candidate working that could implement both these requirements was proposed - an array of pointers. An array is an ordered group, meeting the requirements for ordered storage, and a pointer is a data structure that designates a memory location and can indicate different data types. Thus, an array of pointers allows for storage and access of ordered elements, which are able to point to-or index-representations or locations in memory, allowing for mapping between different representational forms.

The neural overlap between finger and number representation could reflect redeployment, wherein the brain region is reused in both tasks while retaining the same operation. Alternatively, the overlap could reflect neuromodulation, wherein the operation of the region is modulated. In the current paper, we use computational modelling as a means of demonstrating whether the same proposed working -an array of pointers- could contribute to both number and finger representation. The goals of the current research are to evaluate the redeployment view and proposed shared working by (1) providing an in-principal demonstration that the same working could contribute to both uses, (2) determining the psychological plausibility of the model by comparing it to human performance on finger gnosis and number comparison tasks, and (3) differentiating between support for redeployment (same ROI, same working) over neuromodulation (same ROI, but different working).

## Common Component: A Cognitive Pointer

The core theoretical claim here is that both finger gnosis and magnitude comparison could plausibly make use of a neural system that is able to store a list of items, and each of those items can be used to indicate other information. For example, these items could mean a particular number (e.g.

ONE or THREE) or they could mean any other known concept. For the purposes of this paper, we choose these vectors randomly, but we could use other vector-based representation methods such as LSA or word2vec.

To be explicit about what we mean by such a system, let us define it mathematically. First, we need a (small) set of numerical values which are our "pointers": $p_{1}, p_{2}, p_{3}, p_{4}$, and $p_{5}$. For the purposes of this paper, we keep the size of this set to 5 (the number of fingers on a hand). Each of these pointers is a numerical vector, and different values can have different meanings. For example, there could be one value that means the number ONE, with other values meaning other concepts like DOG.

In the absence of input, these pointers should not change their value. However, we also need some way of changing their value when needed. For this, we need two things: a new input value $x$ and a way to indicate which pointer should be set to the new value. This input control we call a mask m and it is a list of values indicating which pointer should be set. For example, if $m=[0,1,0,0,0]$, then the input $x$ will be set to the second pointer $p_{2}$.

Mathematically, we can write this as follows, where $i$ indexes the different pointers:

$$
p_{i} \Leftarrow \begin{cases}p_{i} & \text { if } m_{i}=0  \tag{1}\\ x & \text { if } m_{i}=1\end{cases}
$$

We postulate that the two tasks use this component as follows. For the finger gnosis task, consider what happens if two fingers are touched, the index finger and the ring finger. We can treat each pointer as a separate finger, and load in a vector that means TOUCHED into the correct pointers by setting $x=$ TOUCHED and $m=[0,1,0,1,0]$.

For the magnitude comparison task, we load the first value into the first pointer and the second value in the second pointer. For the case of comparing 5 and 7 this means setting $x=$ FIVE and $m=[1,0,0,0,0]$, and afterwards setting $x=$ SEVEN and $m=[0,1,0,0,0]$. Over time, this process proceeds stepwise as follows, and maintains its state as shown:

## Finger Gnosis Task

| $\boldsymbol{x}$ | $\boldsymbol{m}$ | $\boldsymbol{p}_{1}$ | $\boldsymbol{p}_{2}$ | $\boldsymbol{p}_{3}$ | $\boldsymbol{p}_{4}$ | $\boldsymbol{p}_{5}$ |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |

## Neural Implementation

While the above algorithm gives us a conceptual understanding of this array of cognitive pointers, we also want to determine how neurons could implement such an algorithm. By examining this neural mechanism, we can
gain insights into how accurate it would be in different conditions, and hopefully gain insight into individual differences and cognitive deficits.

For our neurons, we use standard leaky-integrate-and-fire (LIF) neurons. These increase in voltage given their input, and emit a spike and reset when the voltage reaches a threshold. These spikes are transmitted to all neurons that the spiking neuron is connected to, with synaptic weights controlling how much current is added to (or subtracted from) the target neuron each time a spike occurs. Each connection also has a post-synaptic time constant that controls the time it takes for a spike's effect to decay away.

Figure 1: Neural implementation of an array of pointers. Only two pointers are shown.

Figure 1 shows the basic approach used to implement this functionality. The groups of neurons on the right store the individual pointer values $p_{1}, p_{2}$, etc. They are recurrently connected such that they will have stable firing patterns over time (i.e. whatever pattern of firing is present right now will cause a similar firing pattern in the near future).

The connections from $\boldsymbol{x}$ to the channels and from the channels to the pointers are all set such that the neurons simply pass along the value without altering it. That is, if we input a particular value $\boldsymbol{x}$, this will cause a particular (and unique) firing pattern in channel 1 and channel 2. These in turn will cause particular firing patterns in pointer 1 and pointer 2. If $\boldsymbol{x}$ is removed (i.e. set to zero), then the pointer patterns will stay as they were. Thus, they implement a memory of previously presented patterns.

However, we also want to be able to selectively set one or the other pointer. For this reason, we also include the $\boldsymbol{m}$ (mask) input. This can selectively inhibit the channel neurons. If these are inhibited, then they do not fire, and so do not affect the pointer neurons. So, if we want to set the value in pointer 2 only (and not change whatever is stored in pointer 1 ), then we inhibit channel 1 when inputting $\boldsymbol{x}$.

To actually create this network, we use the Neural Engineering Framework (Eliasmith \& Anderson, 2003) and the software toolkit Nengo (Bekolay et al., 2014). In this approach, we assume that $\boldsymbol{x}$ is a vector of some dimensionality that is smaller than the number of neurons in a group. This means that there is redundancy in the neural code, and the value $\boldsymbol{x}$ is distributed across the neural population. Here, for simplicity, we assume $\boldsymbol{x}$ is an 8 dimensional vector. Previous work (Crawford, Gingerich \& Eliasmith, 2013) has shown that 512-dimensions should be sufficient for high-level reasoning applications, but that is not needed for the tasks considered here.

Within each group of 400 neurons, each individual neuron has a randomly chosen preferred vector. That is, each neuron will have some particular $\boldsymbol{x}$ value for which it fires the fastest. This is a generalization of the standard preferred direction vectors observed throughout cortex (e.g. Georgopoulos et al., 1986).

To generate the actual connections between neurons, the NEF uses least-squares minimization to directly solve for the optimal synaptic connection weights that will do the best job of transferring a value $\boldsymbol{x}$ from one group to the next. This same process is used to generate the recurrent connections for the pointers.

The synaptic time constants were set to 10 ms for the feedforward connections (based on the fast AMPA synapses found in cortex) and 100 ms for the recurrent connections (based on the slower NMDA synapses found in recurrent connections in cortex).

It should be noted that there is nothing in the model so far that is fit to a particular task. The optimization of the connection weights is over all possible $\boldsymbol{x}$ values, not the particular $\boldsymbol{x}$ values that mean ONE or TWO or TOUCHED in the magnitude comparison and finger gnosis tasks themselves. This is meant to be a generic component, not one that is specialized for exactly these tasks.

Figure 2: Spiking activity for an example magnitude comparison task. Top row shows input to the model. Other rows show spiking neuron activity over time. The text indicates which vector $\boldsymbol{x}$ is represented by the pattern of activity. Note that pointer 1 and pointer 2 maintain their pattern (approximately) after the input has been removed.

Figure 2 shows the neural activity when this array of pointers is used to store two numbers. Initially, both pointer 1 and pointer 2 are firing with some random background firing rate. At $\mathrm{t}=0.2 \mathrm{~s}$, we set the input $\boldsymbol{x}$ to be the vector for FIVE (randomly chosen) and set the mask such that channel 1 is the only group not being inhibited. This drives the neurons in pointer 1 to also fire with the pattern for FIVE. At $\mathrm{t}=0.4 \mathrm{~s}$, we change the input to SEVEN and change the mask so that channel 2 is not inhibited. This drives pointer 2 to represent SEVEN. Importantly, after $\boldsymbol{x}$ is removed, the neurons in pointer 1 and pointer 2 retain their firing pattern.

While the system described above behaves as desired, note that it is not perfect. The neurons in channel 1 and channel 2 are not perfectly inhibited. Also, the neurons in pointer 1 and pointer 2 do not perfectly maintain exactly the desired firing pattern. This is as expected, as neurons only approximate the desired functions. We can now test whether the resulting model can still perform the two tasks, and whether the errors made by the model due to these imperfections are comparable to the errors made by people.

## Task 1: Magnitude Comparison

The first task believed to make use of this component is magnitude comparison. Two single-digit numbers are presented, and the system must decide which is larger.

To implement this task neurally, we add two new neural groups. First, a comparison group, which takes as input the vectors in the first two pointer populations. This means that the comparison group has a 16-dimensional input, with the value from $p_{l}$ as the first 8 dimensions and the value from $p_{2}$ as the second 8 dimensions. Second, we have an accumulator. This takes as input a single number which should be positive if the first number is larger, and should be negative if the second number is larger. This is recurrently connected to itself, so that even for small inputs, it will eventually build up until it reaches a threshold, making it a standard accumulate-to-threshold decisionmaking system.

Figure 3: The magnitude comparison model. The dotted area indicates the array of pointers.

The connection between the comparison and accumulator neurons needs to convert from 16 dimensions (the two numbers being presented) to 1 dimension (which number to choose). We implement this function by generating 2000 training examples of randomly chosen digits, along with the correct answer of +1 if the first number is larger, and -1 if the second number is larger. We then used Nengo to find the optimal connection weights between these neurons to best approximate this mapping.

To evaluate this model, we collected human participant data from 88 undergraduate students at King's University College who received course-credit for their participation (age: $M=21.28$ years, $S D=3.8$ years; 64 female). Two single digit numbers (ranging from 1 to 9 ) were presented simultaneously on an iPad screen. Participants were asked to choose the numerically larger number as fast as they could without making any errors. Stimuli remained on the screen for 7800 ms or until the participant made a choice, and the time between trials was 1000 ms . Participants performed a total of 72 trials. Dependent measures were reaction time and percent error.

Figure 4: Results from participants and from the model. Standard errors of the mean are shown.

The participant data (Figure 4) displays the expected distance effect: as the difference between the digits increases, accuracies improve and reaction times are quicker. For confirmation, a repeated measures ANOVA with a Greenhouse-Geisser correction revealed that mean RTs differed significantly between distances, $F(4.41$, $383.91)=46.96, p<.01$. A second repeated-measures ANOVA revealed that mean percent error also differed significantly between distances, $F(7,609)=21.37, p<.01$.

Importantly, the model data shows the same effects. To achieve the quantitative fit for the accuracy measure (Figure 4, left side), we only fit one parameter: the strength of the inhibition $\boldsymbol{m}$. That is, rather than having it always be strong enough to completely stop all neurons in the channel from firing ( $s_{\text {inhibition }}=1.0$ ), we allowed this value to be reduced. This causes some "leakage", where values meant for one pointer slightly affect the other pointers, since the other channels are not perfectly inhibited. If there are more than 2 pointers, we assume that the inhibition gets proportionally stronger for pointers farther from the target pointer. For the data shown above, $s_{\text {inhibition }}=0.875$. Surprisingly, this distance effect occurs even though the neural activity pattern for each digit is randomly chosen. See (Stewart \& Penner-Wilger, 2017) for further analysis.

For the reaction time data (Figure 4, right side), two additional parameters were fit. First, we added a fixed reaction-time value (i.e. the amount of time needed for perception and the motor action) $T_{\text {fixed }}$. Second, we allowed a scaling factor on the connection from the comparison neurons to the accumulator neurons. This controls the rate of evidence accumulation $S_{\text {evidence. }}$. This is a common feature of decision-making models. After fitting, $T_{\text {fixed }}=290 \mathrm{~ms}$ and $S_{\text {evidence }}=5.9$. All other parameters in the model were left at their default values.

## Task 2: Finger Gnosis

In the finger gnosis task, two fingers are touched on the participant's hand while that hand is occluded from their view. They must then report which fingers were touched.

To implement this task, we use the same array of pointers, but connect it to a different set of neurons, as depicted in Figure 5. The first group of neurons takes the input from all the pointers and combines them together as one vector. The second group stores the reported answer. As with the previous task, we use Nengo to find the connection weights
that best approximate the function between the combination neurons and the answer neurons. In this case, however, rather than determining which value is larger, here we do not need to perform any complex operation as we just need to extract the information that is already encoded in the neurons. Thus, here we use Nengo to approximate the identity function, where the output is the same as the input.

Figure 5: The finger gnosis model. Only 2 pointers are shown, but the full model uses 5 pointers.

Importantly, if this same array of pointers is to be used in two different tasks, a flexible neural routing system would be needed, so that the output of the pointer array can be sent to this combination system when doing the finger gnosis task, and sent to the comparison system when doing magnitude comparison. We have previously shown how to implement such a routing system using a model of the cortex-basal ganglia-thalamus loop (Stewart, Choo, \& Eliasmith, 2010), and so do not consider that here.

To evaluate this model, we used the same 88 undergraduates as for the first task. Participants first performed the magnitude comparison task, followed by the finger gnosis task as part of a larger study. As shown in Figure 6, a repeated-measures ANOVA revealed that mean percent error differed significantly between distances, $\mathrm{F}(3$, $261)=6.88, p<.01$.

Figure 6 also shows the model performance. Importantly, no parameters were tuned to achieve this result. We used $s_{\text {inhibition }}=0.875$, as that was the best fit value in the first task, and all other parameters were left as they were. The model is statistically significantly different at a distance of 1 , but does not statistically differ for distances 2,3 , and 4 .

Figure 6: Results from participants and model for the finger gnosis task. Standard errors of the mean are shown.

Since the only tuned parameter in the model is $s_{\text {inhibition }}$, we also examined how the model's performance changes on the two tasks as this parameter is varied (Figure 7). From this, we note that the error rates on these two tasks change drastically, given small changes in this parameter. This indicates a strong connection between the model's
performance on one task and on the other. The fact that a similar parameter value is needed in each task in order to fit the human data lends support to the idea that there is a shared working that is redeployed for these two tasks.

Figure 7: Effects of changing $s_{\text {inhibition }}$ in both tasks.

## Conclusions

On the redeployment view (Penner-Wilger \& Anderson, 2008, 2013), finger gnosis and math ability are linked because at least one local brain region, over evolutionary and/or developmental time, has come to perform the same operation in support of both finger and number representation. The goal of the current research was to evaluate the redeployment view and the proposed shared operation - an array of pointers (Penner-Wilger \& Anderson, 2011). To this end, we built a computational model to perform both the standard finger gnosis and number comparison tasks. We then compared the performance of this model to human performance data (RT and accuracy) and showed a close match on both tasks with one parameter ( $s_{\text {inhibition }}$ ) tuned to a common value.

First, our work provides an in-principal demonstration that the same working - an array of pointers - could contribute to multiple uses, as the same system successfully performed two different tasks. Our previous meta-analysis (Penner-Wilger \& Anderson, 2011) also indicates this region may be involved in a variety of other tasks, which we intend to include in future research.

Second, given that the model could successfully perform both tasks using the same operation, and that the model performance mirrored that of human participants, it is a psychologically plausible explanation, which lends support for the view that the observed neural overlap between finger and number representation reflects redeployment (same ROI, same working) rather than neuromodulation (same ROI, different working). It follows that damage to the ROI should impact performance on both finger gnosis and number comparison tasks. We are currently testing this in our computational model and it could be tested in human participants using rTMS applied to our ROI in the left precentral gyrus. Previous work using rTMS applied to the left angular gyrus has already been shown to disrupt performance on both tasks (Rusconi et al., 2005).

Third, by offering another concrete instance of the reuse of a basic operation in a high-level, abstract cognitive task, the model does not just bolster the neural reuse framework, but also serves the goal of enhancing our understanding of the nature of and processes involved in numerical cognition.

Finally, modeling efforts like this potentially enhance our efforts to map the functional structure of the brain. We currently lack the capacity to determine in vivo when neuromodulation has changed the underlying configuration of a local neural network, which hinders our ability to attribute function to structure. This approach offers some first steps toward developing reliable methods for detecting changes to the underlying operation a given local region supports, thereby refining our efforts to describe what the brain is actually doing at any given time.

# Flexible integration of a navigable, clustered environment 

Marianne Strickrodt<br>Max Planck Institute for Biological Cybernetics<br>Heinrich H. Bülthoff<br>Max Planck Institute for Biological Cybernetics<br>Tobias Meilinger<br>Max Planck Institute for Biological Cybernetics

#### Abstract

The representation of navigable space, consisting of multiple interconnected spaces, yet is not well understood. We examined different levels of integration within memory (local, regional, global). Participants learned two distinctive regions of a virtual environment that converged at a common transition-point. Subsequently, we tested their memory with a pointing task, varying body alignment during pointing, corridor distance to and regional belonging of the target. Pointing latency increased with increasing distance to the target and when pointing into the other region. Further, alignment with local, regional and global reference frames were found to facilitate pointing latency. These findings suggest that participants memorized local corridors, clustered corridors into regions, and also formed global reference frames, thus, represented the environment on multiple levels of integration. They are inconsistent with conceptions of spatial memory for navigable environments based either on exclusive representation within a single reference frame or exclusive reliance on local reference frames.

# The Semantic Spaces of Child-Directed Speech, Child Speech and Adult-directed Speech: a Manifold Perspective 

Hao Sun (hsun7@buffalo.edu)<br>Department of Linguistics, University at Buffalo Buffalo, NY 14260 USA<br>John Pate (johnpate@buffalo.edu)<br>Department of Linguistics, University at Buffalo<br>Buffalo, NY 14260 USA

#### Abstract

Child-directed speech (CDS) is a talking style adopted by caregivers when they talk to toddlers (Snow, 1995). We consider the role of distributional semantic features of CDS in language acquisition. We view semantic structure as a manifold on which words lie. We compare the semantic structure of verbs in CDS to the semantic structure of child speech (CS) and adult-directed speech (ADS) by measuring how easy it is to align the manifolds. We find that it is easier to align verbs in CS to CDS than to align CS to ADS, suggesting that the semantic structure of CDS is reflected in child productions. We also find, by measuring verbs vertex degrees in a semantic graph, that a mixed initialized set of verbs with high degrees and medium degrees has the best performance among all alignments, suggesting that both semantic generality and diversity may be important for developing semantic representations.

Keywords: child-directed speech; lexical development; manifold learning; distributional semantics; graph theory

## Introduction

One of the biggest puzzles in cognitive science is how children learn language from language input, namely childdirected speech. Child-directed speech is characterized by simplified sentence structures, restricted vocabulary, exaggerated intonation, and hyperarticulation, and previous work has proposed that these features facilitate language acquisition (Golinkoff and Alioto, 1995; Snow, 1995; Thiessen, Hill, and Saffran, 2005). Here, we compare the semantic spaces of child speech, child-directed speech and adult-directed speech, spanned by verbs, using state-of-theart computational tools.

The contributions of this paper are both theoretical and methodological. Theoretically, we explore various proposals about roles of verbs meanings in CDS, represented using a state-of-the-art distributional semantics approach. Distributional methods map each word to a point in highdimensional space so that words with similar meanings are near each other. We view the semantic structure of the vocabulary as a high-dimensional surface in this space, called a manifold, and compare manifolds estimated from CDS to manifolds estimated from child speech (CS) and adultdirected speech (ADS). Young children often broaden the use
of nouns and verbs and we model such differences in word meaning as a mismatch of data points in a semantic space.

Methodologically, we adapt a novel semi-supervised manifold alignment algorithm to compare semantic spaces (Ham et al, 2005), which maps two manifolds into a common subspace to measure the similarity of these manifolds. This algorithm takes as input a subset of initial points that must be aligned (i.e., pairs of points, one on each manifold, that correspond to the same verb), and produces an alignment for the rest of the verbs. We then measure the similarity of the manifolds in terms of the accuracy of the alignment: how often a verb is mapped to the same region of the common subspace.

We find that alignment between the CS and CDS is more accurate than the alignment between CS and ADS. Additionally, we obtain more accurate alignments when using verbs with many nearest neighbors (which have broader meanings) as the initial points than verbs with few near neighbors. Together, these results indicate that the semantic structure of CS reflects the semantic structure of CDS, and verbs with broad meanings may provide useful cues to children in acquiring the overall semantic structure of verbs. On the one hand, what children can learn from CDS deviates semantically from unfamiliar conversations in ADS, which suggests that further learning is required. On the other hand, caregivers might align their semantic spaces to children's semantic spaces, which lies within the general framework of conversational alignment (Pickering \& Garod, 2004).

## Model Setting

We combine models from two different traditions into a general framework of semantic representation. To compare the semantic spaces of CS, CDS and ADS, we use a manifoldbased algorithm. The similarities between semantic spaces are measured by how easy it is to map one semantic space to another. We represent the meaning of each verb by using the global vector model (Pennington, Socher \& Manning, 2014) to embed words into a 50-dimensional space, which we call a semantic space. . Following the associationist tradition in psychology (Anderson, 1973), we represent the meaning structure of the verbal lexicon as a whole by considering how a collection of verbs is situated in this space, as expressed by a neighborhood graph (Steyvers \& Tenenbaum, 2005).

Estimating verb meanings from different datasets produces different semantic spaces, and we compare the spaces using a semisupervised manifold alignment algorithm (Ham et al., 2005). This algorithm maps verbal semantic graphs into a common semantic space and discovers the data point correspondences by finding pairs of points with the smallest Euclidean distances.

## Lexical Semantic Representation

The past three decades saw efforts to model the mental representation of concepts (Launder \& Dumais, 1997). The inspiration for recent computational work on lexical semantics dates back to Harris's (1954) hypothesis that synonymous words appear in similar contexts.

One of the most successful semantic representation models is proposed by Launder \& Dumais (1997), known as Latent Semantic Analysis (LSA), which uses word-context cooccurrence matrices to produce a low-dimensional representation by singular value decomposition. The lexical semantic representation model used in this paper is based on a state-of-the-art algorithm, GloVe (Pennington, Socher \& Manning, 2014), which is an extension of LSA. Instead of explicitly decomposing a word-context co-occurrence matrix, GloVe implicitly decomposes a word-context logfrequency matrix. GloVe uses a weighted regression objective function to reconstruct a log word-context count matrix $\log (X)$ with bias terms, as shown in Equation (1), where $w$ and $b$ are bias vectors, $X$ is the co-occurrence matrix and $f$ is a heuristic weighting function. The optimization problem is iteratively solved using AdaGrad (Duchi, Hazan \& Singer, 2011).

$$
\begin{equation*}
J=\sum_{i, j=1}^{V} f\left(X_{i j}\right)\left(w_{i}^{T} \widetilde{w}_{j}+b_{i}+\tilde{b}_{j}-\log X_{i j}\right)^{2} \tag{1}
\end{equation*}
$$

Even though GloVe has better performance than traditional singular-value-decomposition-based LSA, careful analysis of the objective function suggests that GloVe is fundamentally probabilistic matrix factorizations (Levy \& Goldberg, 2014).

## Semantic Graphs

The manifold alignment algorithm we use approximates the underlying manifold by constructing a similarity graph $G=$ ( $V, E$ ), where the vertex set $V$ is the set of verbs and the edge set $E$ is a set of pairs of verbs that are near to each other. The weight of an edge is set to the cosine similarity between the verbs associated by the edge. The degree of a vertex is the sum of weights of all the edges linking to the vertex. In semantic networks, vertex degrees can be interpreted as contextual diversity. There are several ways to build such a similarity graph. Ozaki et al (2011) found that undirected mutual $k$ nearest neighbor ( $m k N N$ ) graphs give good performance for alignment of natural language data, so we use $m k N N$ graphs. An $m k N N$ graph has an edge ( $v_{1}, v_{2}$ ) if either $v_{1}$ or $v_{2}$ is within the $k$ nearest neighbors of the other. We set $k$ to 15 for the first experiment. In the second experiment, we increase $k$ to 20 to better investigate the degree effects. The unnormalized graph Laplacian $(L)$ of
graph $W$ is defined in Equation (2). D is the degree matrix, a diagonal matrix with vertex degrees on the diagonal.

$$
\begin{equation*}
L=W-D \tag{2}
\end{equation*}
$$

We use a symmetric graph Laplacian normalized by vertex degree (Shi \& Malik, 2000), as

$$
\begin{equation*}
L_{\text {sym }}=D^{-1 / 2} L D^{-1 / 2}=I-D^{-1 / 2} W D^{1 / 2} \tag{3}
\end{equation*}
$$

## Aligning Semantic Spaces

We compare the semantic spaces of CS, CDS and ADS using the semisupervised manifold alignment algorithm. A manifold is defined as a topological structure with every local point with a neighborhood similar to a Euclidean space. The goal of the manifold alignment algorithm is to pair up data points from two high-dimensional data sets. For example, the algorithm aims to match give in CS to give in CDS. A semisupervised algorithm, using both labeled and unlabeled data as input, combines the strength of supervised and unsupervised learning. The general goal of manifold alignment is to map two high-dimensional data sets to a common low-dimensional space simultaneously (Ham et al., 2005), which essentially is an extension of manifold-based nonlinear dimensionality reduction (Belkin \& Niyogi, 2003). Manifold-based methods are based on the geometric assumption that data in high dimensional space lie in lowdimension manifolds.
Ham et al.'s algorithm defines a function $f$ that maps the first manifold to a common space, and a function $g$ that maps the second manifold to a common subspace. These functions strike a tradeoff between mapping labeled pairs to the same point in the common space, and respecting local structure on the original manifolds as expressed by the graph Laplacian $L^{x}$ for the first space and $L^{y}$ for the second space. As we have both labeled ( $l$ ) and unlabeled (u) points, $L^{x}$ and $L^{y}$ are block matrices:

$$
L^{x}=\left[\begin{array}{ll}
L_{l u}^{x} & L_{u l}^{x}  \tag{4}\\
L_{l u}^{x} & L_{u u}^{x}
\end{array}\right]
$$

The cost of the mapping is then:

$$
\begin{equation*}
\tilde{C}(\boldsymbol{f}, \boldsymbol{g})=\frac{C(\boldsymbol{f}, \boldsymbol{g})}{\boldsymbol{f}^{T} \boldsymbol{f}+\boldsymbol{g}^{T} \boldsymbol{g}} \tag{5}
\end{equation*}
$$

where $\mu$ expresses the tradeoff between mapping points exactly and preserving local structure on the original manifolds. The first term is the sum of distances between paired data points in the common space, and the second two terms represent faithfulness to the graph Laplacian. Ham et al. point out that Equation 4 is unsuitable for optimization, since it ignores simultaneous scaling of $\boldsymbol{f}$ and $\boldsymbol{g}$, and so instead minimize the Rayleigh quotient:

$$
\begin{equation*}
C(\boldsymbol{f}, \boldsymbol{g})=\mu \sum_{i}\left|f_{i}-g_{i}\right|^{2}+\boldsymbol{f}^{T} L^{x} \boldsymbol{f}+\boldsymbol{g}^{T} L^{y} \boldsymbol{g} \tag{6}
\end{equation*}
$$

We set $\mu$ to positive infinity to impose a hard constraint for labeled pairs to be mapped directly on top of each other.

The analytic solution to the optimization is then given by the generalized graph Laplacian $L^{z}$ in Equation 7.

$$
L^{z}=\left[\begin{array}{ccc}
L_{l l}^{x}+L_{l l}^{y} & L_{l u}^{x} & L_{l u}^{y}  \tag{7}\\
L_{u l}^{x} & L_{u u}^{x} & 0 \\
L_{u l}^{y} & 0 & L_{u u}^{y}
\end{array}\right]
$$

The semisupervised manifold alignment algorithm adopted from Ham et al. 2005 is described in Algorithm 1.

## Algorithm 1: Semisupervised Manifold Alignment Algorithm (Ham et al., 2005)

Input: data points from two data sets, with N initially aligned data point pairs
Output: a matching of data points

1. Construct similarity graphs $G_{1}, G_{2}$, for both data sets respectively, using $\mathrm{m} k N N$
2. Compute the symmetric graph Laplacians of $G_{l}$ and $G_{2}, L^{x}$ and $L^{y}$, using Equation (3)
3. Compute a graph Laplacian for a joint graph $L^{z}$ using Equations (6) and (7)
4. Compute the eigenvectors of $L^{z}$ and take eigenvectors corresponding to the smallest non-zero eigenvalues, the results of which are the vectors in a lower-dimensional space
5. Find the data points with smallest Euclidean distance weighted by the inverse of their respective eigenvalues

## Experiment Setup

## Corpora

The training set for CDS and CS is a combined data set from CHILDES (MacWhinney, 2000), which consists of all the data on American English-speaking monolingual 3 to 7 yearold children with typical language and cognitive development, excluding diary studies. To simplify data collection, only utterances annotated as child are considered child speech and only utterances annotated as mother and father are considered as child-directed speech. The CS and CDS corpora contain 5 million and 9 million word tokens, respectively. To prevent the CS from being similar to CDS purely due to priming effects, we divided the data into two halves so that the CDS and CS data were not drawn from the same contexts

Our ADS data is drawn from the spoken portion of the Corpus of Contemporary American English (COCA, Davies, 2008). Although this data may differ from more casual conversations, it provides a large amount of spontaneous speech in the form of unscripted conversations from 150 television and radio programs.

## Materials

The target words used in this model are all verbs, which are understudied in the literature. We included the first 100 English verbs acquired by infants (Fenson et al., 1994), the
most frequent 200 English verbs in adult language productions (Davies, 2008) and verbs that appear in three common constructions (Levin, 1993).

The classes of verbs are the ones that appear in 3 constructions: the ditransitive (John gave Mary a book), the locative (The man loaded hay onto a truck) and the conative (The police shot at the criminal). Since CHILDES suffers from data sparcity, verbs missing in either CS or CDS were excluded from analysis. We end up with 811 data points for CS, CDS and spoken COCA respectively.

## Data Preprocessing

The adult-directed speech data from spoken COCA and the child speech and child-directed speech data from CHILDES data were preprocessed using regular expressions. Verbs in different inflectional forms were treated as separate verb types.

## Model Training

Global Vector Training We used the implementation of GloVe from the Stanford NLP website to train 50dimensional vectors for each of our three datasets (Pennington, Socher \& Manning, 2014). We trained each set of vectors for 50 epochs with a context window size of 10 , used a frequency cut-off of 2 for the CS and CDS datasets and a cut-off of 10 for the ADS dataset.
Similarity Graph Construction We construct mkNN graphs consistently throughout this paper. In the first simulations, we fix the number of mutual nearest neighbors to 15 . In the second simulation, we test the effect of vertex degrees and we set the number of mutual nearest neighbors to 20 to increase the range of vertex degree.
Manifold Alignment The parameters that we need to specify in the manifold alignment module include the initial labeled alignments and the dimensionality of the manifold. In addition to the number of labeled data, the identity of the labeled data can also influence the quality of alignment. The dimensionality of the manifold controls the abstraction of semantic information contained in the word vectors. The lower the dimension, the more abstract the representation.

## Evaluation

Because the alignment algorithm pairs up labeled data points exactly, we only evaluate alignments on unlabeled data. We use a random alignment averaged over 5 times as the baseline condition. Ideally, corresponding data points from two data sets should be mutual nearest neighbor in the lower dimensional space. We relax the evaluation requirements by giving every alignment a k-nearest neighborhood evaluation radius. If one data point is one of the k -nearest neighbors of the corresponding point, we take it as a hit. When the evaluation neighborhood radius equals 1, the measures quantify the exact alignment.

## Simulation 1: Mapping CS to CDS and COCA

In this section, we demonstrate that CS-CDS alignment is a less demanding task than CS-COCA alignment even when potential priming effects from linguistic and non-linguistic contexts are removed. We also predict that with the increase of labeled data, the alignment accuracy also increases.

## Method

We performed verb semantic graph alignments of CS to CDS and to ADS for alignment spaces of dimensionality from 5 to 30. The unlabeled precisions are evaluated by the windowsize at 1 and at 20, as demonstrated in the contour heat maps in Figure 1. The colors of different areas in the contours indicate different levels of unlabeled accuracy and the data points with the same unlabeled accuracy are connected by the isolines in the maps.

Figure 1 Accuracies of mapping CS to CDS and COCA

## Results

The general trend is that the highest unlabeled precisions are found in the upper right corners of the contour maps whereas the lowest unlabeled precisions tend to lie close to the x -axis. The dimensionality of the embedding space can be interpreted as the granularity of children's representations.

The result of the alignments is demonstrated graphically in Figures 1 and 2. In the alignments from CS to CDS and CS to COCA, the CS-COCA alignment achieves only $50 \%$ to $60 \%$ of the unlabeled precision of the CS-CDS alignment. The unlabeled precision of the CS-CDS alignment is consistently higher than the unlabeled precision of the CSCOCA alignment across all conditions. Both alignments have much larger unlabeled accuracy than the random baseline.

The CS data are aligned to both the spoken COCA and CDS corpora. The CS-CDS alignment precision wins over the CS-COCA precision across all conditions. In other words, child speech is much easier to map to child-directed speech than to spoken COCA. This easier alignment can be interpreted as similarity in semantic spaces across corpora.

Since the CS and the CDS word vectors are trained on speech data from different experiments, the relative similarity between CS and CDS lexical semantics, this similarity does not reflect mere priming effects. There are two possible
interpretations for this result. First, the result can be viewed as an imitation effect in which children mirror child-directed speech semantically. Second, adult caregivers might adapt their mental representations to children's when they talk to children, which sits well with the conversational alignment theory (Pickering \& Garrod, 2004). The big semantic gap between initial language input and adult-to-adult conversations on TV shows or radios suggests that learning from CDS alone is not sufficient for real world language processing. Adapting to TV or radio conversations constitute one part of further learning, which supports a continuous theory of language development.

## Simulation 2: Semantic generality

In Simulation 2, we use a fixed list of labeled data to investigate the effect of initialization in alignment, instead of random initialization. The motivation is that language scientists argue for the importance of a few important "pathbreaking" word exemplars in language learning (Ninio, 1999; Goldberg, Casenhiser \& Sethuraman, 2004). Some words attract more vertices than others, which is known as preferential attachment in network growth (Steyvers \& Tenenbaum, 2005). We evaluate the proposal that semantically general verbs are better starting points for language learning than semantically specific verbs, by measuring the vertex degrees.

Figure 2 Unlabeled accuracies of CS-CDS and CS-COCA alignments with a random alignment as the baseline

The degree of a vertex measures the association between a vertex and its neighboring vertices. The prediction is that vertices with large degree are better labeled data than vertices with small degree. Cognitively, the verbs with high degree are semantically general verbs whereas the verbs with low degree are the ones with less general meanings.

## Method

Verbs are ranked based on their vertex degree in a semantic network. As shown in Table 1, what we use as labeled data is 100 verbs with the largest degrees, 100 with the smallest degrees, and medium-degree verbs with degree rank of 201
to 300 . We also mixed half of high degree verbs with half of medium degree verbs in the mixed condition. The baseline condition is averaged over 5 random initializations. We set the number of mutual nearest neighbors, the evaluation radius and the dimensionality all to 20 .

## Results

The alignment precisions shown in Figure 3 show a clear advantage of high-degree and medium degree conditions over the low degree condition, but both high-degree and lowdegree have below random performances. We can also see an advantage of medium degree initialization, which is parallel to the basic level categorization theories. When we use a mixed set of high-degree and medium-degree verbs, we get the best results on all the conditions, which suggests that a diverse-degree initialization facilitates semantic space alignment.

Table 1: Verbs with the largest, medium and smallest vertex degrees in ADS

| largest | medium | smallest |
| :---: | :---: | :---: |
| get | giving | tickles |
| go | tearing | points |
| want | taken | shooting |
| put | poured | design |
| think | tipping | tapping |

## General Discussion

In Simulation 1, we demonstrate that CS has semantic properties very similar to CDS in comparison to ADS. This result supports a usage-based approach to language acquisition: children imitate their caregivers. The results can be interpreted in multiple perspectives. First, the result suggests that child speech is built upon restricted linguistic contexts. One of the biggest characteristics of human memory is context-dependency. Early language experience is built upon restricted contexts and usages requires further learning to achieve the adult form. Second, child-directed speech is used in young children's living environments. Children seem to use words highly consistent with their caregivers. Third, talking to children in child-directed speech is a double-edged sword. On the one hand, children might have an easier time initializing their language capacities at an early language development stage because their hypothesis space is restricted by child-directed speech. On the other hand, the mismatch between child-directed speech and adult-directed speech requires children to shift their semantic representations at later development stages.

In Simulation 2, we show empirically that semantically moderately general verbs are better starting points for language development. Our simulations show mixed results for the "path-breaking" argument that semantically generic verbs are important for language learning (Ninio, 1999). Our results suggest that both semantic generality and semantic diversity play a role here. Although semantically general
verbs help in general, verbs that are semantically too general may not be that helpful.

Figure 3 Unlabeled accuracies of alignments with highdegree, medium-degree, low degree, mixed-degree and random initializations

## Speaker Normalization by Manifold Alignment

In speech recognition and perception, speaker normalization is the task of automatically adjusting to acoustic differences between different speakers. Our work is inspired by Plummer et al. (2010), who proposed manifold alignment as an account for how young children learn to handle phonetic variability in vowel production during language acquisition.

Aside from working with semantic, rather than acoustic, representations, our work differs from theirs in two respects. First, they used synthesized data as input, while we used naturalistic corpus data. Second, since two token pronunciations of vowels will never be the same, they imposed only a soft alignment constraint that labeled pairs be aligned, while we imposed a hard constraint.

## Crosslinguistic Alignment of Polysemous Words

Youn et al. (2016) investigated semantic universals by constructing networks of corresponding polysemous nouns from 81 languages sampled from different language families. Using an approach reminiscent of thesaurus-based synonym induction, they established semantic correspondences between nouns using bilingual dictionaries. The target polysemous words were selected from the Swadesh 200 basic vocabulary list. The procedure described in this paper is automatic and takes into consideration the matching of semantic spaces in one language, whereas Youn and colleagues manually establishes semantic correspondences for a few basic words in bilingual data.

## Conclusions

The contribution of this paper is a novel integrated framework that compares semantic spaces of children and their caregivers based on naturalistic language productions. We combined methods from three traditions, distributed semantic representations, graph theory, and manifold
alignment, into one framework for approaching the semantic structure of the lexicon. We used naturalistic language productions from CHILDES to compare the semantic spaces spanned by verbs and demonstrated that (i) that CDS is more similar to ADS than CS in terms the semantic spaces spanned by verbs and that (ii) verbs with relatively large and diverse degrees are especially useful for aligning semantic structures.

While the general computational framework proposed in this paper does not provide an account of how children might exploit this manifold-based and graph-theoretic information, it does suggest that useful information about the structure of the adult lexicon is available to children. Even though our framework is on the computational level, using Marr's terminology (1982), it is very likely that semantic manifold alignment plays a role in children's semantic development. Additionally, this framework may be of use to other fields that are interested in the semantic structure of different lexicons. For example, this approach may be useful for performing semantic comparisons between languages or across time over the course of language change, and understanding the semantic organization of bilingual lexicons.

#### Abstract

Digital-tablets distribute cognition through visual, auditory and haptic interactivity. We designed a tutor-game that explored how narratives ((S)trong/(W)eak) and gestures ((I)conic/(D)eictic) could be combined to situate embodied learning. Students played seven levels of a fractions game designed to teach them how to create and compare fractions. One hundred thirty-one students ( $\mathrm{N}=131$, age $\overline{\mathrm{x}}=8.78$ yrs, $52.6 \%$ Female) were randomly assigned to one of four groups (SI, SD, WI, WD) in a $2 \times 2$ factorial experiment. Students completed pre/post direct and transfer assessments and tutorgame $\log$ data was mined to explore characteristics of students learning. Results revealed a significant interaction between narrative and gesture moderated by student proficiency. In effect, students new to fractions performed better in an abstract environment using deictic (pointing) gestures. However, as students' proficiencies improved, they learned better using iconically enactive gestures in strong narrative with setting, characters and a plot. This has important implications for designing adaptive learning platforms and curricula for teaching fractions.

Keywords: embodied, situated, grounded cognition; narrative, gestures; design-based research; DBR; data-mining; adaptive learning.

## Introduction

Tutor-games provide learners with dynamic experiences that channel their visual (sight), aural (sound) and haptic (touch) perceptions into their cognitions (Baddeley, 1986; Ricker, AuBuschon \& Cowan, 2010). As virtual portals, digital tablets allow educators to situate learning in various contexts that scaffold the processes that connect concepts (Barab et al., 2007; Brown, Collins \& Duguid, 1989; Saxe, 1988; Lave, 1988; Schwartz \& Bransford, 1999). The touch-based gestural interface of digital tablets accesses the haptic channel as a means for embodying concepts (Varela, Thompson, \& Rosch, 1990; Barsalou, 1999; Glenberg \& Kaschak, 2002; Lakoff \& Johnson, 1980). The multi-modal ecology of digital tablets allows researchers to scaffold experiences that afford (Gibson, 1979) students freedom to explore with feedback that guides their learning (Dewey, 1938/1963).

## Theoretical Background

Developing Narrative. Developing an effective narrative invests the audience in the continuity of the characters,
locations, objects, actions and themes and invests them into the plot's trajectory (Graesser, Singer \& Trabasso, 1994). These details (microstructure) are the access points to a larger interactive narrative (macrostructure) that situates the concepts (van Dijk \& Kintsch, 1983). Thus, designers must create assets that engage players in problem spaces through the processes that foster correct mental model constructions (Johnson-Laird, 1980). Black and Bower (1980) found that the structure of stories, with actors, settings, problems and solutions, aided in participants inference making and recall. In effect, the coherence of narrative schemas helps participants chunk details into mental models (Black, Turner \& Bower, 1979) and ideally, the audiences' investment in the narrative can motivate player's explorations of the processes for creating and comparing fractions in a problem space conducive for discovery (Brown, Collins \& Duguid, 1989).

Developing Gestural Mechanics. Goldin-Meadow, Cook and Mitchell (2009) demonstrated that a pairing gesture (i.e., two fingers to identify two numbers as a pairing) facilitated elementary students strategies for arithmetic problems and demonstrates how gestures as abstractions are still rooted in relation to the body. In the cognitive science literature, gestures have been typically defined as spontaneous co-articulations with speech (Kendon, 1972; McNeill, 1992), but in the digital age, the physicality of gestures has been co-opted into gestural mechanics as an interface with touch and motion based digital technologies. Educators can leverage the mechanics of gestures as communications of concepts and strategies by simulating perceptual states to activate learners' understandings (Goldin-Meadow, 1999).

Exploratory studies (Swart et al., 2014) revealed types of gestures learners used when explaining fractions. Echoing Hostetter's and Alibali's (2008) Gestures as Simulated Action, students majoritively used either iconic gestures (I) (metaphorical, enactive, symbolic) that enact their understandings or deictic (D) gestures (pointing) that identify them (Fig. 1).

Fig. 1: Iconic \& Deictic Gestures

## The Tutor-Game: Mobile Movement Mathematics (M3).

The human ability to think mathematically manifests from the endowments of our perceptual systems. It includes our abilities to estimate the magnitudes of spaces and durations of time as well as enumerate objects by differentiating the intensities of stimuli in our surroundings (Dehaene, 1997). These experiences ground the embodied metaphors of mathematical thinking (Lakoff \& Núñez, 2001; see Fig 2) and we recognize that fractions originate in the processes of fracturing wholes into parts. Thus, we chose to use object fracturing as the metaphor for developing a situatively embodied curriculum.

Fig. 2: Embodied Experiences of Mathematical Fractions
The tutor-game consisted of 7 levels of 5 fractions that were situated in either a strong $(S)$ or weak $(W)$ narrative. The strong narrative had a setting, characters and plot based on the PBS series Cyberchase, and was compared to a weak, non-descript environment without narrative elements (see Fig. 3). We characterized it as "weak" in lieu of "no" narrative to account for researchers inability to control for any internal narratives that students might devise.

Fig. 3. Strong Narrative (L) \& Weak Narrative (R)
To play, students used either iconic or deictic gestures in a 2-part tutor-game: [Part 1] Players estimated, denominated, numerated and re-estimated using the fractivator (a hybrid of a rectangular area model and a number line (Siegler \& Opfer, 2003); [Part 2] Players determined equivalency between fractions by ordering them, magnifying their height and delineating each onto a vertical number line (Fig. 4).

Fig. 4. Part 1 (Obj. Fracturing) \& Part 2: Obj. Equivalency

## The Experiment

In order to isolate for the impact of gesture (I vs. D) and narrative (S vs. W) on learning, we devised, designed and developed 4 versions of the digital tablet tutor-game (M3) that resulted in the following experimental conditions: $S I$, $S D, W I$, and $W D$, and all other factors (curriculum, assets, instructions, feedback, and scaffolding) were held constant.

Under the gesture hypothesis (embodied), iconic gestures with richer perceptual affordances (Black, Segal, Vitale and Fadjo, 2012) should help learners embody mathematical concepts better than deictic gestures. We predicted that iconic gestures, by grounding concepts in real-world actions, connect internal processes of our cognition and affect better than deictic gestures.

For the narrative hypothesis (situated), contextualizing problem spaces (via setting, characters and plot) helps learners engage in the construction of their own conceptual models. By situating learning, we predicted that the strong (S) narrative will produce higher levels of engagement and motivation and higher levels of learning compared to a weak (W) narrative.

The third hypothesis arises from the interplay of design and how independent factors will interact. The interaction hypothesis suggests that combinations of narrative types (S vs. W) and gesture types (I vs. D) will create learning environments that vary in their efficiency for the learner. In favor of the situated and embodied condition, we predicted that the SI condition would perform better than SD and or WI conditions, while the WD condition would perform better than SD and or WI.

The fourth hypothesis stems from our classroom observations of students' play and the prospect for differential efficiencies between SI and WD. The proficiency hypothesis suggests that learners' existing proficiencies at fractions will moderate how they play and learn. In favor of the situated and embodied condition, we predicted that students with lower proficiencies would benefit more from the situated embodied experience of the SI condition while students with higher proficiencies would benefit from the abstractions of the WI condition.

## Methods

Participants. One hundred thirty-one participants from grades $3\left(\mathrm{~N}=131 ; \overline{\mathrm{x}}_{\text {age }}=8.78\right.$ years [1.36], $52.6 \%$ female $)$ at afterschool programs in New York City obtained parental consent to participate in the program.

Procedure. Researchers formally tested a total of 131 students in specially designated classrooms where researchers and monitors proctored over the sessions, administered assessments, collected observational and video record the sessions. In a $2 \times 2$ randomized factorial, students were assigned to play one of four game-based environments (Strong-Iconic (SI, $\mathrm{n}_{\mathrm{si}}=35$ ), Strong-Deictic (SD, $\mathrm{n}_{\mathrm{sd}}=27$ ), Weak-Iconic (WI, $\mathrm{n}_{\mathrm{wi}}=34$ ), Weak-Diectic (WD, $\mathrm{n}_{\mathrm{wd}}=$ 35)). Each student completed 3 one-hour sessions that in total included pre-tests, game play, post-tests and exit-

Fig. 5. $2 \times 2$ Randomize Factorial w Repeated Measures
surveys (see Fig. 5). Students' sessions were run in separate groups of 10 (5/condition) with a total of 2 sessions per day (total of 20 students/day; 5 per condition) for 3 days each week, extended over multiple weeks and some students participated in an optional $4^{\text {th }}$-day clinical interview.

## Materials

## Assessments.

Direct Pre/Post Test: Parallel Forms A \& B of fraction problems directly from the game curriculum. Representations of fractions were similar to static versions of what students saw in the game, including estimation, denomination, numeration and determining equivalency between fractions ( 40 items).

General Pre/Post Test: Parallel Forms C \& D of general fraction assessment that included problems using objects, collections of objects, number lines, numerical fractions, arithmetic, and word problems. Questions included items asking students to estimate, denominate, numerate and determine equivalency between fractions ( 43 items).

## M3: Digital Tablet Tutor-Game.

Log Data: The backend of the game was designed to deliver user $\log$ data (i.e., telemetry data) to helps researchers create profiles of students' learning by tracking players' time, accuracy/error, attempts and strategies during tutor-game play.

## Equipment.

iPad Air \& Sony MDR-ZX100 Headphones: A class set of 10 each; Flip Video UltraHD Camcorder: 2 camcorders w/ Tripods for Video.

## Results

## Formal Assessments

Direct Assessments. ANOVA revealed a significant interaction between gesture and narrative on Direct Assessment Total Difference scores (post - pre), $\mathrm{F}_{(1,126)}=$ $7.324, \mathrm{p}<.008, \mathrm{~d}=.482,(1-\beta)=.766$ (Figure 59). The significance of this interaction supports the both the narrative and gesture hypotheses that each can impact learning. Since the interaction is significant, the main effects of gesture or narrative are unclear. However, Fig. 6 clearly depicts the interaction and illustrates how students in the SI and WD groups show significantly higher rates of learning across amongst all the M3 groups.

T-tests for independence revealed differences between conditions for Direct Assessment Total Difference scores, with students in the SI group ( $\overline{\mathrm{x}}_{\text {pre }}=.208, \mathrm{SD}=0.143$ ) scoring higher than students in the SD group ( $\overline{\mathrm{x}}_{\mathrm{D}}=.143$, SD

Fig. 6. ANOVA revealed a significant interaction between gesture and narrative on Direct Assess total scores.
$=0.138), \mathrm{t}_{(60)}=1.79, \mathrm{p}<.079, \mathrm{~d}=.451$ and significantly higher than students in the WI group ( $\overline{\mathrm{x}}_{\mathrm{D}}=.129$, $\mathrm{SD}=$ $0.147), \mathrm{t}_{(67)}=2.25, \mathrm{p}<.028, \mathrm{~d}=.526$ ) while the WD group $\left(\overline{\mathrm{x}}_{\mathrm{D}}=.215, \mathrm{SD}=0.194\right)$ scored higher than $\mathrm{SD}, \mathrm{t}_{(60)}=1.79$, $\mathrm{p}<.107$ and significantly higher than WI, $\mathrm{t}_{(67)}=2.069, \mathrm{p}<$ $.041, \mathrm{~d}=.486$.

Preliminarily, this suggests that the strong narrative combined with iconic gestures as well as the deictic gestures combined with weak narrative both provide a learning experience significantly more efficient than either the strong-deictic or weak-iconic pairings.

Transfer Assessment. ANOVA revealed no significant main effects of gesture or interaction between gesture and narrative for Transfer Assessment Numeration Difference scores $F_{(1,128)}=1.70, p<.195, d=.229,(1-\beta)=.254$. Though $t$-tests for independence of the difference scores (post - pre) were not significant between groups, the pattern

DIFFERENCE SCORES: TRANSFER ASSESSMENT TOTAL SCORES

Fig. 7. ANOVA revealed a significant interaction between gesture and narrative on Direct Assess total score.s
of results in Fig. 7 show that students in the SI group ( $\overline{\mathrm{x}}_{\text {pre }}=$ $.147, \mathrm{SD}=.192)$ scored higher than students in $S D\left(\overline{\mathrm{x}}_{\mathrm{D}}=\right.$ $.084, \mathrm{SD}=0.180), \mathrm{t}_{(60)}=1.296, p<.20, d=.330$, higher than students in $W I\left(\overline{\mathrm{x}}_{\mathrm{D}}=0.07, \mathrm{SD}=0.246\right), \mathrm{t}_{(67)}=1.272, p$ $<.305, d=.394$, and higher than students in the WD condition ( $\overline{\mathrm{x}}_{\mathrm{D}}=.061, \mathrm{SD}=0.194$ ), $\mathrm{t}_{(68)}=1.857, p<.068, d$ $=.443$.

A one-way contrast showed that the $S I$ group performed
significantly better than the other three groups t (127) $=$ 1.763, $\mathrm{SE}=.122, \mathrm{p}<.080$. Unlike the direct assessment interaction, results from the transfer assessment suggested that the situated and embodied condition (SI) contributed to better transfer. Simply, enacting the processes of fracturing objects while situated in a narratively contextualized problem space seems to contribute to better transfer.

Fig. 8. HLR model regressing PreTest, Telemetry Data and Condition on PostTest scores. Direct Effect of X on Y ; Indirect Effect of X on Y via MEi $=\left(a_{i}\right)\left(b_{i}\right) ; \mathrm{COV}$ on $\mathrm{Y}=c_{i}$

## Tutor-game Log Data

Mediation with a Covariate Models. The next series of analyses looked principally at how condition and tutor-game play account for the variance in students' post-test scores while controlling for pre-test scores. Fig. 8 depicts the conceptual path model used for the stepwise construction of the Hierarchical Linear Regressions (HLR) predicting the variance in the assessment scores.

The path model depicts how the variance in dependent variable ( Y , post-test assessment score) is accounted for by the independent variable ( X , condition - SI, SD, WI, WD), while controlling for a covariate (COV, pre-test assessment score) and mediated by students' tutor-game play (ME, telemetry data).

Direct Assessment Total Post-Test. The first HLR regresses condition, pre-test scores and tutor-game play on direct assessment total scores. The complete meditational covariate model significantly predicted the outcome of students Direct Assessment Post-Test scores $R=.645, \mathrm{~F}_{(7 \text {, }}$ 4577) $=543.80, p<.001$. With the covariance of pre-test controlled, tutor-game play predicted a significant amount of the variance in Direct Post-Test Assessment scores ( $\mathrm{B}=$ $.623, \mathrm{SEB}=0.012, \beta=.607, p<.001,95 \% \mathrm{CI}[.599, .646])$.

Transfer Assessment: Total Score. The complete model significantly predicted the outcome of students Transfer Assessment Total Post-Test scores $R=.632, \mathrm{~F}_{(8,4576)}=$ $379.80, p<.001$. With the covariance of pre-test controlled, tutor-game play predicted a significant amount of the variance in direct post-test assessment scores $R=.626$, $\mathrm{F}_{(3,4580)}=35.47, \mathrm{p}<.001$..

Moderated Mediation Models. With solid evidence that both the SI and WD conditions were efficient environments for learning, it was important to clarify the nature of the
interaction between narrative and gesture and determine if the situated embodied approach (SI) was better for low proficiency students (i.e., early learning is situationally embodied) or those with higher proficiencies. The second path model determines if students' initial proficiencies $\left(\mathrm{MO}_{\mathrm{i}}\right.$, pre-test score) moderated how students played $\left(\mathrm{ME}_{\mathrm{i}}\right.$, telemetry data) and improved on formal assessments $\left(\mathrm{Y}_{\mathrm{i}}\right)$.

Fig. 9. HLR model of PreTest, Telemetry Data and Condition on PostTest scores. Direct Effect of X on Y; Indirect Effect of X on Y via $M E_{i}=\left(a_{i}\right)\left(b_{i}\right) ; \mathrm{MO}_{\mathrm{i}}$ on $\mathrm{X} \rightarrow \mathrm{Y}=c_{i}$ and $M E_{i} \rightarrow \mathrm{Y}$

In Fig. 10, we can see that there are two distinct slopes for the $S I$ ( $R^{2}=.474$ ) and $W D \quad\left(R^{2}=.183\right)$ conditions,
indicating two distinct trajectories of improvement from pretest (xaxis) to post-test (y-axis) scores. The dashed red boxes indicate the

Fig. 10. Scatterplot of Pre-Test (X axis) and Post-Test (Y Axis) scores by groups (SI; WD). median split between low and high initial proficiencies. Visual inspection suggests that the WD group shows better learning when their initial proficiencies are lower while the SI group seems to show better learning when their initial proficiencies are higher.

The moderated meditational model of the proficiency hypothesis confirmed that student performances in the game on formal assessments were significantly moderated by their existing proficiencies with fractions. Fig. 11 (top) shows the moderated mediation of direct assessment scores by condition and proficiency $R=.630, \mathrm{MSE}=122.36, \mathrm{~F}_{(5,2444)}$ $=353.72$, $p<.0001$. Students with lowest proficiencies $\left(10^{\text {th }}\right.$ percentile $\left(\mathrm{x}_{\text {pre }}=11.50 ; \mathrm{B}=-9.32, \mathrm{SE}_{\mathrm{B}}=.832, \mathrm{t}_{(2443)}=-\right.$ $11.20, p<.0001,95 \%$ CI [-10.95, -7.68]), benefitted the most if they were in the WD condition $(\beta<0)$ condition compared to the SI $(\beta>0)$, but as proficiency improved, students began to benefit more in the SI condition ( $90^{\text {th }}$ percentile ( $\mathrm{x}_{\mathrm{pre}}=46.00 ; \mathrm{B}=5.29, \mathrm{SE}_{\mathrm{B}}=.645, \mathrm{t}_{(2443)}=8.21, p$ $<.0001,95 \%$ CI $[4.03,6.56])$. We see a similar transition for low to high proficiencies from WD to SI for the transfer assessment (see Fig. 11, bottom). In this case, the
transition from the WD to the SI condition takes place at lower initial proficiencies for transfer of learning.

Fig. 11a \& 11b. Moderated Mediation of formative assessment scores by the interaction between condition and existing fractions proficiency. Scores on the pre-test are stratified by percentiles along the x -axis $\left(10^{\text {th }}\right.$, $\left.25^{\text {th }}, 50^{\text {th }}, 75^{\text {th }}, 90^{\text {th }} \%\right)$, and values on the $y$-axis are the weights of the $B$ coefficients for changes in Direct Assessment Post-Test scores. Coefficient values below the zero line on the $y$-axis indicate that the WD improved more on post-test at that percentile and coefficient values above the zero line indicate that students in the SI group improved more.

## Discussion

The Gesture, Narrative \& Interactions Hypotheses. The significant interaction between gesture and narrative on the direct assessment of the M3 curriculum shows that types of gestures may be conceptualized differently depending on the contexts in which they are embedded. It calls into question our original theoretical assumptions that situating cognition through narrative and embodying procedural learning through iconic gestures would produce better learning.

The HLRs on students direct and transfer assessment total scores showed that students tutor-game play, including their accuracy denominating, numerating and estimating significantly predicted learning, supporting the position that the act of splitting objects is central to learning fractions (Steffe, 2004; Norton \& Wilkins, 2009). Improvement on transfer assessment seems to suggest that the procedural and conceptual knowledge that players are developing is robust enough that the curriculum prepared
them for future learning (Schwartz \& Bransford, 1998) of near transfer representations and new domains for fraction.

The Efficiency Principle. Although our initial hypotheses predicted the superlative performances by the SI conditions for both assessments, the significant interaction between gesture and narrative suggests that both the SI and WD conditions are both efficient platforms for learning. Schwartz, Bransford and Sears (2005) note that efficiency often means rapid retrieval with accurate appropriation and application of knowledge and skills for understanding, solving and explaining a problem. Though the situated embodied SI environment provided a perceptually rich experience (Black et al., 2012) that promoted better transfer, students using deictic gestures in the weak narrative (i.e., without seductive details, Harp \& Mayer, 1998; Adams et al., 2012) also showed significantly better learning. Might the minimal and abstracted environment of the WD condition make procedures and concepts easily salient?

The Proficiency Principle. Students with low initial proficiencies benefitted more from playing in the WD version of the game, while students with higher initial proficiencies benefitted more in the SI environment. This finding was contrary to our hypothesis and the principle of concreteness fading (i.e., start concrete and fade to abstract; Fyfe, McNeil, Son \& Goldstone, 2014). Still to be determined is how these results fit with The Expertise Reversal Effect (i.e., experts require reduced guidance; Sweller, Ayres, Kalyuga, \& Chandler, 2003). Does the presence of the strong narrative make instruction and guidance invasive (i.e., reduced)? Nonetheless, the current results support findings from a study by Kaminski, Sloutsky and Heckler $(2006 ; 2008)$ that found that students learned division with remainders better using abstract symbols rather than concrete real world depictions.

## Significance

The current research demonstrated that combinations of different narratives and gestures produced differential learning. Ribbons and Malliet (2010) advocate for simulational realism in gaming. They argue that there must be balance between the rules that govern gaming experiences (e.g., gestures) and their relevance to the situated environment (e.g., the interactive narrative). This research suggests that when educators are designing pedagogy and curricula for mathematical fractions, students should begin working with abstractions and as their proficiency improves the learning platform should adapt to concrete experiences.

#### Abstract

Educational software based on teachable agents has repeatedly proven to have positive effects on students' learning outcomes. The strongest effects have been shown for low-performers. A number of mechanisms have been proposed to explore this outcome, in particular mechanisms that involve attributions of social agency to teachable agents. Our study examined whether an expression of high versus low self-efficacy in a teachable agent would affect lowperforming students with respect to their learning outcomes and with respect to a potential change in their own selfefficacy. The learning domain was mathematics, specifically the base-ten system. Results were that the learning outcomes of low-performers who taught a low self-efficacy agent were significantly better than the learning outcomes of lowperformers who taught a high self-efficacy agent. There were no effects from the manipulation of self-efficacy expressed by the teachable agent on changes of the low-performing students' own self-efficacy.

Keywords: social agency; educational software; teachable agent; math self-efficacy; math performance

## Introduction

A teachable agent (TA) is a graphical computer character in a tutee role. The basic idea is that the student instructs and guides the TA (Brophy, Biswas, Katzlberger, Bransford, \& Schwartz, 1999). In essence, TA-based educational software implements the pedagogical approach learning by teaching, (Bargh \& Schul, 1980).

To date a set of TA-based learning games targeting the STEM areas have been developed and evaluated, and repeatedly proven to have positive effects on students' learning outcomes. Some studies have compared effects of TA-based software with ordinary teaching (regular classroom practice) (Pareto, Haake, Lindström, Sjödén, \& Gulz, 2012; Chin, Dohmen, \& Schwartz, 2013). Others have compared educational software versions with and without a teachable agent included (Chase, Chin, Oppezzo, \& Schwartz, 2009; Pareto, Schwartz, \& Svensson, 2009).

An observation from several of the studies is how readily the metaphor of the computer figure as a tutee (digital tutee) is accepted by students. They express engagement for the task of teaching the character, although it is in fact nothing but a computer artifact (Chase et al., 2009; Lindström, Gulz, Haake, \& Sjödén, 2011.) They also make more effort to
learn in order to teach their digital tutee than to learn for themselves (Chase et al., 2009). In effect, students attribute mental states and responsibility to the digital tutee as if it were a social agent (Chase et al., 2009; Lindström et al., 2011). They see the agent as a socio-cognitive actor that can learn (respond to being taught by them) and that can be ascribed traits such as 'brave', 'slow', 'smart', 'forgetful' etc.

## TA-systems and Low-Performing Students

Several studies show that the students who benefit most by educational software with teachable agents - whether compared to equivalent software without TA or compared to ordinary classroom teaching - are the low-performing students. When comparing eleven year olds who used an educational game in biology with or without TA, the former spent more time on learning activities and also learned more, with the effects most pronounced for lower performing students (Chase et al., 2009). In a study by Sjödén and Gulz (2015), 9-10 year-olds used a TA-based educational math game in school over a period of eight weeks. Thereafter, the students were divided into two groups, matched according to their pretest scores, and randomly assigned to a post-test with or without the TA present (the TA did not act in order to influence the test but was merely present). Results showed that low-performers (according to the pretest) improved significantly more than high-performers but only when tested with the TA. Pareto et al. (2009), likewise found a considerably stronger improvement for low ability students than for high ability students when they used a math game with a TA feature compared to the math game without the TA.

## Mechanisms in TA-Systems that may Support Low-Performing Students

A number of explanations for the pedagogical power of TAbased games have been proposed, including some that also provide possible rationales for why the effect is often larger for low-performers.

First, in a TA-based game, the student is positioned as the one that is most able, the one who can teach someone else that knows less. This experience - being someone who is
capable, who knows more than someone else - can potentially affect a student's view on her own competence in a positive way. This will likely benefit low-performers more than high-performers, since the latter are more likely to already have experienced the role of 'teaching someone else' and 'knowing more'. High-performers are more likely than low-performers to spontaneously take a teacher role (or be assigned this role in class). Acting teacher can potentially strengthen the student's belief in her own capability in the domain in question, and this may in turn have effects on performance.

Second, a teachable agent can be a model of learning behaviors (Blair, Schwartz, Biswas, \& Leelawong, 2007). A TA is often designed to model fruitful and productive student behaviors, such as being curious, asking questions, reasoning, being explicit about parts of 'knowledge'. It is, however, more likely that high-performing students already have such behaviors on their repertoire compared to lowperforming students, and that the latter therefore are more helped by being inspired by productive learning behavior in a TA.

Thirdly and crucially a TA is teachable. More specifically a TA models someone who from the beginning has little or no knowledge but learns incrementally or step-by-step. In other words, a teachable agent (re)presents or models an incrementalist theory of competence in contrast to an entity theory of competence according to which some individuals are held to be gifted and others non-gifted. This latter view is quite common among students (Dweck, 2006). Specifically it holds in the domain of mathematics, where it has also been shown that teachers to a larger extent than for other subjects used terms such as 'talented' and 'not talented' (Rattan, Good, \& Dweck, 2012). In principle both high- and low-performing students can have an entity view of competence, and potentially benefit from viewing competence (in this study competence in math) as something that can be changed with effort. However, it is more likely that low-achievers with an entity view of competence are trapped in a circle, where they don't think they are talented and see no meaning in making an effort; therefore make little effort; therefore don't achieve and thus confirm they are not talented. In other words, they create a self-fulfilling prophecy.

Fourthly, Chase et al. (2009), propose a mechanism named ego-protective buffer. In TA-system it is the TA that is tested for its knowledge. When the TA fails at a test, the failure or non-success does not come as close onto the student as when she takes a test herself. Even if students are aware that the TA's knowledge reflects how the TA has been taught by themselves, the responsibility for failing is not only theirs. Instead of bearing the full burden of a failure, the responsibility of failure can be shared between the TA and student. Even though this may benefit highperformers as well, low-performers are more used at failing at school and thus the ego-protective buffer mechanism may
explain why in particular low-achieving students perform better when working with a TA.

In sum, there is a set of proposed mechanisms that may explain why low-performers benefit more than highperformers from using teachable agents. All mechanisms involve the tendency of students to attribute social characteristics and agency to the agent, and interact intellectually and socially with it. For instance, to view the TA as someone that it is possible to share a failure with; to view the TA as someone who can accomplish a task (or not), as someone whose knowledge is different from mine and that I can influence by teaching it; to view that TA as someone that can learn - and as learner be slow, quick, smart, forgetful, etc.

In view of the above, we found it plausible that students would also tend to attribute high or low self-efficacy to an agent, if designed in an adequate manner. Spelled out, they would tend to attribute to an agent high or low belief in its own capability to learn and be successful - in our case with respect to math and base ten problems. The present study thus approaches the trait of self-efficacy, which to our knowledge has not been studied before in teachable agents.

## Does TA Self-Efficacy Matter for Student Progress

Having an ability to learn, i.e. being teachable, is the very essence of a digital tutee or teachable agent. However, whether other kinds of properties are attributed to a TA depends in the first place on how the TA is designed and implemented, and also on the student interacting with the TA. For instance, depending on how it is implemented, a TA can be (perceived as) a quick learner or a learner that needs many rehearsals. A TA can be (perceived as) more or less challenging or questioning (Kirkegaard, 2016).

In our study the TA was designed to express either high or low belief in its own capacity to learn and perform in a math game. We will soon present our predictions but first discuss the phenomenon of self-efficacy in real human students. For human learners we know that there is a relation between self-efficacy and actual performance (Bandura, 1997) in that self-efficacy predicts subsequent performance. Low self-efficacy predicts low performance, and high self-efficacy predicts high performance. Proposed mechanisms are that student's self-efficacy influences how much effort she puts into a task, her tendency to persist, how high she sets her aspirations and her tendency to persevere when being challenged by the task. Individuals with high self-efficacy often achieve more in intellectual terms (Bandura, 1997). Importantly, however, the relations are correlational and on a group level. There are no causal or absolute relations between individual's self-efficacy and her performance; students may over-estimate as well as underestimate their own capacity.

We now return to self-efficacy in teachable agents. The central research question in the present study was whether a teachable agent expressing low or high self-efficacy,
respectively, would have different impact on lowperforming students in terms of their learning and progress. In addition we explored whether there would be any effects on students' own self-efficacy in either of the conditions.

## Research Questions and Predictions

Research Question 1 (RQ1) Will learning and progress differ between low-performing students who teach a TA expressing low self-efficacy (lowSE-TA) and lowperforming students who teach a TA expressing high selfefficacy (highSE-TA)?

As a basis for our predictions we used two different theories: (i) role-modeling theory by Bandura (1977) and (ii) the theory of the TA protégée effect by Chase et al. (2009). This resulted in two alternative predictions that point in opposite directions. As such this is not surprising since the predictions are generated from theories not related to one another.

The first, alternative, prediction in line with Bandura's idea of role modeling focuses on teachable agents as behavioral models, as discussed in the introduction. A highSE-TA models a learner with a strong belief in her own abilities to learn, a willingness to persist and not give up, etc. Together with the TA:s incremental progression (given that it is reasonably taught by the student) this is likely to be a positive model for low-performers, that often themselves have low self-efficacy. Thus we predict that low-performers will make larger progress if they teach a highSE-TA than if they teach a lowSE-TA.

The second, alternative, prediction is based on the protégée-effect mentioned above: in general, students seem to take responsibility for a TA and make an effort to teach it. Now, a lowSE-TA expresses uncertainty in its own capacity, and seems in considerable need for support and engagement from the teacher (i.e. student), whereas a highSE-TA expresses confidence in its own capability to learn and manage and seems in less need for help from the teacher. Therefore low-performers may be more motivated to take responsibility and make an effort to teach a lowSETA compared to a highSE-TA. Consequently they will also themselves make more progress. Thus we predict that lowperformers will make larger progress if they teach a lowSETA than if they teach a highSE-TA.

There is also third possible result, namely that whether the TA expresses low or high self-efficacy will not matter for low-performers progress.

Research Question 2 (RQ2) Will a potential change in selfefficacy in low-performing students differ between those students who teach a TA expressing low self-efficacy and those who teach a TA expressing high self-efficacy?

If the TA functions as a behavioral model with respect to self-efficacy, low-performers are more likely to increase their own self-efficacy if they teach a highSE-TA than if
they teach a lowSE-TA. The reason is that they may be inspired to model the TA along the line "If this character, my digital tutee, believes strongly in its capability, why shouldn't its teacher, that is me, do so too?"'
From the protégée effect no straightforward prediction can be derived on potential self-efficacy change in students, depending on TA self-efficacy. As discussed under RQ1, if the protégée effect is at work, participants will put particularly large effort into teaching a lowSE-TA, since such a TA signals a greater need of help and support than a highSE-TA that signals that can learn on its own. But whether students that take more responsibility and make a larger effort to teach their TA also change their belief in their own capacity to learn is not obvious. On the one hand, an interplay between performance and self-efficacy is likely but such influences may take time.

Again there is a third possible result, namely that whether the TA expresses low or high self-efficacy does not matter with respect to low-performers potential self-efficacy change.

To sum up, the present study made use of a learning game in math including a TA, where we manipulated the TA:s expressed belief in its own capability to perform and learn math as expected in the game. Our two research questions were: RQ1: Would the manipulation of TA self-efficacy have an effect on low-performing students' progress in the game (i.e. their learning math)? RQ2: Would the manipulation of TA self-efficacy have an effect on potential change in self-efficacy in the low-performing students?

## Method

## Participants

Participants were 166 students ( 83 girls and 83 boys) aged 10-11 years from 4 schools and 9 classes in Southern Sweden from areas with relatively low socio-economic status and school performance below average. Students were randomly assigned one of the conditions: teaching a digital tutee that expressed high self-efficacy (highSE-TA) or teaching a digital tutee that expressed low self-efficacy (lowSE-TA). Out of the initial set of participants, 24 were excluded due to missing data points or low attendance. Next, out of the 142 remaining students, the 62 students who performed below the median on a math performance test were selected for further analysis. The math test was based on a representative part of the national tests in mathematics and consisted of 21 problems relating to place value. Thus, in the final data set, there were 28 students in the lowSE-TA condition and 34 in the highSE-TA condition.

## The Educational Game

The TA math game, developed by Lena Pareto (Pareto, 2014), targets basic arithmetic skills related to the place value system, where the student teaches a digital tutee
named Lo, so that Lo can compete against other students' digital tutees or against a computer actor in different digital board games. Lo's knowledge - based on the system's knowledge domain (Pareto, 2014) - develops entirely on the basis of what the student teaches her (and if taught wrong, Lo will learn wrong).

A central part of the student's teaching consists of answering questions from the digital tutee about the math content, specifically regarding place value, via multiplechoice for answering (see figure 1). The other main interaction between student and digital tutee takes place via a free text chat (Silvervarg \& Jönsson, 2011). This is also where Lo, the TA, expresses her self-efficacy (see figure 1).

Figure 1: The math game with multiple choice conversation and 'free text chat' conversation (overlay).

## Self-Efficacy in the Teachable Agent

High or low self-efficacy in or study was defined as high or low belief in ones capability to make progress and perform well in the math game. In turn, this requires making adequate moves and answering questions regarding the place value system correctly. The definition can be compared to a more general definition of self-efficacy in mathematics as the belief in ones capability to successfully learn mathematics (Bandura, 1997).

After each round of the game where Lo (the TA) has been active - observing and posing questions to the student or being guided by student - the chat conversation starts. The chat begins with Lo commenting on the previous round saying for example: "Awesome! We won! I have a good grip now of tens and hundreds and all that you teach me." (reflecting high self-efficacy), "Oh I won, did I? Nice. But I feel very uncertain about how to play well." (reflecting low self-efficacy).

The chat conversation also contains other comments and reflections from Lo on her own learning, for instance: "I'm learning the rules in the math game slowly. I'm not a very brilliant student." (reflecting low self-efficacy), "It's going to get better and better. I have so quickly learned so many
things about how to play the game." (expressing high selfefficacy), and "I am not sure I can learn these things." (expressing low self-efficacy).

The chat always ended with a sentence from Lo regarding her thoughts about the upcoming round, for example: "I have a feeling that the next round will go really well. Let's play!" (expressing high self-efficacy) or "It doesn't seem like I understand much really, but let's play another round." (expressing low self-efficacy).

Lo's utterances had previously been evaluated with regard to whether they sounded as uttered by someone who was confident, not confident, or neither nor in her ability to learn and perform. The evaluators were 22 fourth graders from a school not participating in the study. The evaluation resulted in the removal of a few sentences and slight modifications of others, resulting in a set of 136 sentences, 68 reflecting a digital tutee with high self-efficacy and 68 reflecting a digital tutee with low self-efficacy.

In addition the manipulation - low and high self-efficacy in the TA - was validated within the present study by participating students. At the end of the last study session they were asked to evaluate Lo's belief in her/his own capability to play the math game on a Likert scale. A MannWhitney test showed a significant difference ( $Z=-4.85, p<$ $.001, r=.39$ ) between the low SE-TA and the high SE-TA, confirming that the manipulation had intended effects on the perception of the TAs self-efficacy.

## Procedure

All study sessions took place in ordinary classrooms and lasted about 30 minutes. At the pre-test session, students completed a math pre-test targeting the place value system, and a pre-questionnaire targeting their self-efficacy in math with respect to the place value system. The students' math pre-test scores were used to identify the target group for this study's research questions, i.e. low-performers (in math).

Thereafter students participated during seven gameplaying sessions, once a week. At the post-session, students again filled out the questionnaire targeting their self-efficacy in math and the place value system and were debriefed about the two different types of digital tutees and the purpose of the study.

## Measurements

Performance During Game Play Students' performance while teaching the digital tutee is a reflection on how well they perform themselves. In line with this we calculated a performance score for each student on the basis of the datalogging. Through the game the digital tutee poses questions to the student that concerns the conceptual model and principles of the place value system. For instance: "How many orange square boxes are there in the 2 yellow square boxes on the game board?" and "How many red square boxes are needed to fill a yellow square box?" The tutee
posed three such questions during each game session, and the student had to choose one out of four alternative answers (one correct, two incorrect and the alternative "I don't know."). The performance score was calculated as the percentage of correct answers minus the percentage of incorrect answers. Additionally, a study by Pareto (2014) showed that in-game performance in this math game correlated with standard paper-and-pencil tests on the placevalue system.
Self-Efficacy Change To measure this we used a selfefficacy pre- and post-questionnaire based on Bandura, Barbaranelli, Caprara, and Pastorelli (1996); for this study translated into Swedish

The seven items targeted the students' self-efficacy with regard to the place value system and the question "How good are you at solving this type of task?" Item one to five regarded calculation tasks such as " $1136+346$ ", and item six and seven targeted place value concepts, such as: "Which digit has the highest place value in the number 6275 ?" All items were graded in five steps from "Not good at all" to "Very good at".

## Results

Statistical analyses were conducted in R v3.2.4 (R Core Team, 2016). Of the 142 participants with complete data, the 62 performing below the median on the pre-test in math were included in the analysis.

## Effects TA Self-Efficacy on Low-Performing Students' Performance During Game Play

An unmatched two sample $t$-test showed a significant difference $(t(60)=3.40, p=.0012$, Cohen's $d=0.87$ ) of TA self-efficacy on student performance with the students in the lowSE-TA condition ( $M=54.8, S D=13.7$ ) outperforming the students in the highSE-TA condition $(M=43.7, S D=$ 12.0).

## Effects of TA Self-Efficacy on Low-Performing Students' Self-Efficacy Change

An unmatched two sample $t$-test showed no significant difference $(t(60)=0.35, p=.73)$ of TA self-efficacy on student self-efficacy change between the students in the lowSE-TA condition $(M=1.18, S D=3.81)$ and the students in the highSE-TA condition $(M=1.53, S D=4.00)$.

## Discussion

Teaching a lowSE-TA compared to teaching a highSE-TA made the participants perform significantly better, as measured by their in-game performance scores. But the two conditions did not differ with respect to whether the participants changed their own self-efficacy. Changes were small and did not differ between the conditions.

These results contribute to our knowledge about mechanisms in a TA-based educational game with respect to
why low-performers tend to benefit more than highperformers from these games. First, we showed that a manipulation of expressed self-efficacy in a TA can influence performance for low-performers: a TA that expressed low self-efficacy was more beneficial than a TA that expressed high self-efficacy. The effect as such, regardless of direction, confirms that at least some of the pedagogical power in a TA-based game derives from attributions of social agency to TA:s, in this case attributing to the TA a weak or strong belief in its own capability. Consequently this is one of the traits that a TA designer ought to be aware of; a trait that can explain why lowperformers benefit more than high-performers from TAbased games.

With respect to student performance, we based our predictions on two different theoretical models: role modeling according to which a highSE-TA should have the most positive influence on the performance of lowperformers, and the protégée effect according to which a lowSE-TA should have the most positive influence on the low-performers performance. The latter theory was supported and can be further elaborated on by means of the results of our study. According to the protégée-effect students tend to make more effort and take more responsibility for the task of teaching a TA than for the task of learning for themselves (Chase et al., 2009). In our study the outcome was better when low-performers taught a lowSE-TA compared to a highSE-TA. It is near at hand that they made an even larger effort and took even more responsibility for a TA with low self-efficacy since this TA expresses a low trust in her own ability to learn, and likely comes across as someone who is more in need of help than a TA with high self-efficacy. A highSE-TA, on the other hand, indicates that s/he is capable to learn and perform, and is in less need of help.

The lacking effect on students self-efficacy change, depending on high or low self-efficacy in the TA, means that the role-modeling hypothesis proposed above was not supported. Students were not inspired by a highSE-TA as a model to increase their own self-efficacy. Neither did teaching a lowSE-TA lead to an increase in the students' self-efficacy. However, it did lead to an increase in their performance, and we can thus conclude that the increased performance was not caused by an increased self-efficacy, at least not as measured in our study. It should also be pointed out that an increase in self-efficacy is not always desirable, in particular not for students who overestimate their capabilities. At the same time, given the interactions between self-efficacy and performance, it is often a good thing when students with low self-efficacy in a domain gain more confidence in their abilities to make progress. What is desirable in general is that as many students as possible have an incrementalist rather than an entity view of intellectual capabilities - something that the use of TA-
based educational games may contribute to (Chase et al., 2009).

## Limitations of the Study and Future Research

The study should be seen as a first examination about how the manipulation of self-efficacy in a digital tutee can influence student performance. Some limitations should be kept in mind when interpreting the results. One is that there was no group of students who taught a digital tutee that expressed a neutral mode of self-efficacy. In future research such a condition should be included. Furthermore, rather than aiming to be conclusive, the present study opens up for associated studies. For instance, one relevant question is whether the results will replicate or not with other age groups than 10-11 year olds. Another interesting line of research could be to explore a TA with adaptive selfefficacy that reflects the rate at which it actually learns, which in turn reflects the proficiency of the student that is teaching it.

## Acknowledgments

This research was funded in part by Marcus and Amalia Wallenberg Foundation and the research environment Cognition, Communication and Learning. The authors thank all students and teachers who participated in the study.

# The impact of practice frequency on learning and retention 

Caitlin Tenison (ctenison@ andrew.cmu.edu)<br>Department of Psychology, Carnegie Mellon University

John R. Anderson (ja+@andrew.cmu.edu)
Department of Psychology, Carnegie Mellon University

#### Abstract

The current study manipulated how frequently different problems were practiced during a first day of practice, with the more frequent items being more closely spaced. Fitting the data to a skill acquisition model, we find that greater spacing between items is associated with an increased probability of transitioning to more efficient phases of performance, but with a shallower speedup within each phase. Three days after training, we find that performance is predicted not by the practice frequency during training, but rather by the phase of skill acquisition attained during training. Thus, it is type of processing achieved not the amount and spacing of practice, that determines retention. Spacing, however, promotes learning by driving changes in cognitive processing.

Keywords: Skill acquisition; Practice frequency; Spacing effect; Learning; Retention

## Introduction

A widely held observation, labeled the 'Spacing Effect', shows that increasing the time between practice opportunities improves retention. In contrast, massing practice opportunities together improves performance during training but negatively impacts retention. However, when the amount of time available for practice is limited spacing practice results in fewer total practice opportunities which may negatively impact learning (Anderson, 1982). Given the importance of the trade-off between spacing and amount of practice in understanding how humans learn, along with the clear educational benefits to improving retention, these effects have been studied extensively over the past 100 years. Explanation of both the effects of spacing and practice is critical for understanding skill acquisition. In this paper, we apply a model of skill acquisition (Tenison \& Anderson, 2016) to a spaced-practiced data set to explore how spacing and the amount practice impacts the type of cognitive processes and affects the speed at which those processes are used to complete a task.

To capture the spacing effect, theories must explain both the short-term effects of practice frequency on skill acquisition and the long-term effects of spacing on retention. While several theories explain the locus of the spacing effect, we consider two qualitatively distinct sets of theories that study the processes occurring during practice that contribute to the spacing effect (Bjork \& Allen, 1970). The set of deficitprocessing theories focuses on the role of attention in the encoding of each practice opportunity. These theories hypothesize that, when practice opportunities are massed together, information used to encode and recall items is stored in working memory and little attention is needed to maintain these features. When practiced opportunities are spaced apart, features relevant to encoding are not stored in working memory
and greater attentional resources must be applied to the maintenance and retrieval of memorized associations (Cuddy \& Jacoby, 1982).

The second set of theories attributes the spacing effect to variation in encoding. These theories hypothesize that spacing between practice opportunities increases variability in contextual information used in the encoding of the item. When the item is seen again, the degree to which the item is encoded and associated with prior exposures is mediated by the time and number of items viewed between exposures (Landauer, 1969; Raaijmakers, 2003). This work explains why the benefit of spaced practice becomes apparent when retention is tested after a long period. An interesting phenomenon discussed and modeled by many encoding variability models investigates the increase in probability of recalling two different items, which have been seen only once, when those items were spaced further apart during training (Raaijmakers, 2003; Lohnas, Polyn, \& Kahana, 2011). In this case, as with spacing, the probability of recalling both items at a much later time increases the more separated those items were when first seen.

The two types of theories view learning in terms of strengthening a memory rather than acquiring a skill. While this view may be sufficient for paired-associates task, it potentially over-simplifies the learning processes of more complex procedures. Given that the spacing effect has been observed across domains, including the learning of complex procedures (Shea, Lai, Black, \& Park, 2000) and motor tasks (Shea et al., 2000), we stand to benefit from a closer consideration of how spacing and practice frequency influence procedural skill acquisition. Recent work by Tenison and Anderson (2016) suggests that skill acquisition is best described by both distinct changes in the cognitive processes used to perform a task, as well as quantitative improvements in the speed with which those cognitive processes are executed. With evidence from both behavioral and neuroimaging data, Tenison, Fincham, and Anderson (2016) suggest that these shifts follow the three phases of skill acquisition proposed by Fitts and Posner (1967). In the first phase, the Cognitive Phase, people must execute a series of procedures to perform a task. By the second phase, the Associative Phase, the response has been memorized and the task involves a single retrieval from memory. The third phase, the Autonomous Phase, the retrieval is dropped and the skill becomes a stimulus-response process. While this model has been operationalized in the ACT-R cognitive architecture (Anderson, 1982), prior work modeling the spacing effect within ACT-R predominantly accounts for the
role of forgetting and memory rather than tracking changes in cognitive processing (Pavlik \& Anderson, 2005). While this computational model has successfully modeled the impact of spacing on learning and retention, it is unclear how forgetting may interfere with skill acquisition.

In the current study, we apply an unsupervised learning approach developed to detect the phases of skill acquisition (Tenison \& Anderson, 2016) to the problem solving latency generated in a spaced-practice task. In this task, participants are introduced to a novel mathematics operation and practice a set of problems. Different items receive different amounts of practice within the same learning period, resulting in greater spacing for the less frequently practiced items and less spacing between more frequently practiced items. Using a within-subjects design, participants were each exposed to 4 practice frequency conditions. We look at the effects of this different practice frequency manipulations on both learning during the task and retention three days later. We hypothesize that our manipulation will affect both the rate of achieving more advanced phases and the rate at which problem solving speeds up within a phase. We were interested in determining whether the phase of skill acquisition achieved during study and amount of practice within a phase would predict retention.

## Methods

We ran our experiment on Amazon Mechanical Turk (MTurk). Participants signed up for two sessions, separated by a 66-72 hour period. On Day 1, participants were introduced to a novel math operator and practiced solving a fixed set of repeated problems. On Day 2 of the study, participants returned to complete the test including the items seen on Day 1 and answer questions about the strategies they used to solve the problems.

## Participants

43 participants ( 15 female) completed both days of our experiment. All participants were from the United States. Participants represented a diverse age range, 20 to 53 years ( $\mathrm{M}=30.9, \mathrm{SD}=6.3$ ), and education levels (highest level: 5 high school, 30 college, 8 graduate school). Reviewing the problem solving strategies participants had reported on Day 2, we excluded 8 participants who had used external aids on either day to solve problems. Our final sample included 35 participants. Participants were paid 2 cents for correctly solved problems (up to $\$ 8.60$ on Day 1 and $\$ 3.60$ on Day 2), as well as a $\$ 2$ base pay for Day 1 and a $\$ 10$ bonus for completing both days. This study was approved by the university internal review board and all participants gave informed consent for participation.

## Materials and procedure

Participants learned a novel type of mathematics called a Pyramid problem. Pyramid problems follow the form of Base\$Height, where the base indicates the first term in the additive sequence, and the height determines the number of
terms to be added together (e.g., $8 \$ 4=8+7+6+5$ ). Problem sets included heights of $3,4,5$, and 6 . The bases of our problem set varied from 4 to 11 with the restriction that the minimum base for a given height was height plus one. Because height determines the number of terms to sum, we use this as a means of manipulating problem difficulty. A total of 36 unique problems were used in the experiment. This study, however, will focus on only the 16 unique problems that were practiced on Day 1. For each problem, we recorded the accuracy and problem solving latency.

Day 1 After giving consent and completing a demographic information questionnaire, participants were introduced to the pyramid operation and given two blocks of 36 unique items to solve. Each item was presented on the screen in the form ' $8 \$ 4=$ _'. Following each input, we displayed corrective feedback by showing the expanded calculation and correct answer in the form ' $8+7+6+5=26$ '. After these pre-test blocks, participants then completed 10 practice blocks, which included 40 items each. During the practice period, participants practiced 16 unique problems. Practiced problems were divided into four Practice Frequency (PF) groups. Items in Practice Frequency-1 (PF-1) were seen once per block; in PF-2, twice per block; in PF-3, three times per block; and, in PF-4, four times per block. We included problems of four different heights (3-6) in each PF group, so that each block included 40 items total and 16 unique problems. By the end of Day 1, PF-1 items were seen 10 times, whereas PF-4 items were seen 40 times, as a result, our analyses are sensitive to both the effects of spacing and of general practice. Participants were given 4 hours to complete the tasks in Day 1.

Day 2 Participants were emailed a link to the retention test 66 hours after the initial completion of their Day 1 session. After the link was sent, participants had a total of 12 hours to begin the experiment (once started participants were limited to 2 hours to complete the experiment). Similar to the pre-test collected during the first two-blocks of Day 1, the retention test consisted of 10 blocks of 36 unique problems. This included 20 items that were only seen during the pretest on Day 1 , and 16 problems from the four PF groups.

## Results

The aim of this study is to explore the impact of spacing on the acquisition and retention of procedural skills. We divide our results into three sections. First, we report the general impact of spacing and practice frequency on learning and retention. We next fit the Tenison and Anderson (2016) to the data to generate parameter estimates and phase labels. Finally, we use mixed-effects modeling to explore the relationship between experimental condition and phase of skill acquisition.

## Descriptive statistics

Before fitting a model to the data to identify learning phases, we examined the effect of spacing on the speed and accuracy of problem solving. A repeated measures analysis of

Figure 1: Problem solving latency for items averaged within each experimental block. Separate means are calculated for items of each practice frequency group. (a) indicates performance on Day 1 (b) indicates performance on Day 2. Error bars represent standard error
variance (ANOVA) run on mean, log transformed latency data revealed a significant main effect of practice frequency group $(\mathrm{F}(9,306)=68.6, \mathrm{p}<.001)$ and block $(\mathrm{F}(3,102)=34.2$, $\mathrm{p}<.001$ ), and a significant interaction between PF and block $(\mathrm{F}(27,918)=2.3, \mathrm{p}<.01)$. Figure 1 shows that response latency decreased across blocks and appears lower for higherPF groups than lower-PF groups. The significant interaction suggests that the impact of block on speedup differs between PF groups. The average accuracy of items within the different PF groups also increases from PF-1 ( $\mathrm{M}=92 \%, \mathrm{SD}=.7 \%$ ) to PF4 ( $\mathrm{M}=97 \%, \mathrm{SD}=.2 \%$ ). A repeated measures ANOVA on accuracy data finds a significant main effect of PF group ( $\mathrm{F}(3,102)=8.7, \mathrm{p}<.001)$ such that PF-4 items were more accurate than lower practice frequencies, but the impact of block $(\mathrm{F}(9,306)=.9, \mathrm{p}=.5)$ and the interaction between block and PF group $(\mathrm{F}(27,918)=1.2, \mathrm{p}=.3)$ are not significant.

From the last items practiced on Day 1 to the first item practiced on Day 2, we see average decreases in accuracy from $95.6 \%(.5 \%)$ to $94 \%(1.0 \%)$, and decreases in reaction time from $2.8(.01 \mathrm{~s})$ to $5.4(.02 \mathrm{~s})$. We will focus on latency for Day 2 , which shows the large effect. A repeated measures ANOVA showed a significant main effect of practice frequency group $(\mathrm{F}(3,102)=3.4, \mathrm{p}<.05)$ and problem difficulty ( $\mathrm{F}(3,102)=5.4, \mathrm{p}<.005$ ) but no interaction $(\mathrm{F}(9,306)=1.2, \mathrm{p}=.3)$. The effect of problem difficulty present in all groups suggested that on Day 2 many of these problems were solved rather than retrieved. Furthermore, the mean response times for these items indicated that items in the higher practice frequency groups were solved more quickly. These analyses show that while the effects present in Day 1 remain on Day 2, they are quite attenuated. However, as we will see this is because of the mixing of items that have reached different phases of learning on Day 1.

## Model fitting

We fit the Tenison and Anderson (2016) power-law skill acquisition model to the response latencies for the items solved during the 10 practice blocks completed on Day 1. This
model (refer to Tenison and Anderson (2016) for a detailed description) uses a Hidden Markov model (HMM) to track both the participants learning phase for any given problem and the number of practice opportunities a participant has had within a given phase. Using the within-phase tracking, we estimated parameters for a power-law function to describe speedup in the execution of the cognitive processes specific to each of the phases. However, according to the model, larger, abrupt changes are caused by transitioning to a more advanced phase of processing. We fit our model to each PF group separately. The model was fit separately for each item solved by a participant, but used trends across all participants solving items within a PF group in order to generate parameter estimates. We considered the number of phases that best fit the data by fitting HMMs with 1 through 5 possible phase transitions. Thus, we fit a total of 20 models ( 1 to 5 phases fit for each PF group). We used two measures to evaluate which model best fit the data: Bayesian Information Criterion, which penalizes models for added parameters, and log likelihood generated from a leave-one-subject-out cross validation. We best fit a 3-phase model for all 4 PF groups, replicating the result from our earlier studies. Once we determined the number of phases best fit by a model, we refit it to all the data and labeled each item with the phase the model identifies as most probable.

Because models are fit separately for each practice group, we first needed to establish that the 3 Phases identified by each model were in fact the same cognitive processes. In prior work, we found evidence that participants used calculation strategies in the first learning Phase and retrieval strategies in Phase 2 and 3 (Tenison \& Anderson, 2016; Tenison et al., 2016). Because height determines the number of items participants sum together, we used the four different heights present in each PF group as a stand-in for problem difficulty. We would expect this effect of difficulty to disappear when participants use the retrieval strategies of Phase 2 and Phase 3. In Figure 2, each quadrant illustrates for each PF-group the effect of problem difficulty for the items in each Phase.

Figure 2: Mean problem solving latency for problems of different heights (i.e. difficulty levels) Each quadrant represents a different practice frequency group. Error bars represent standard error

We fit a mixed effects model to participants log latency data (Kliegl, Masson, \& Richter, 2010) with random intercepts for each participant. Our model included an interaction between height and learning phase, along with a fixed-effect for training. We initially fit a maximal model in which we considered a random-effect for each fixed-effect in our model, and then used BIC to test whether or not removing those random effects improved the model fit (Barr, Levy, Scheepers, \& Tily, 2013). Using this approach, we found our model was improved by inclusion of a random-effect for Phase, suggesting some variation across individuals in the impact of Phase on latency. We used the Kenward-Rodger (Kenward \& Roger, 1997) approximation for degrees of freedom . In our final model, we could account for a significant amount of the variance in response time, with a fixed effect for the PF group of the item $(\mathrm{F}(3,1194.8)=22.2, \mathrm{p}<.001)$, problem difficulty $(\mathrm{F}(3,1203.7)=43.9, \mathrm{p}<.001)$ and Phase $(\mathrm{F}(2,44.9)=487.5$, $\mathrm{p}<.001$ ), and a significant interaction between problem difficulty and Phase $(\mathrm{F}(6,1200.3)=34.5, \mathrm{p}<.001)$. This analysis, as evident in Figure 2, shows that for all 4 practice frequency groups there is an effect of problem difficulty present in Phase 1 , but not in Phase 2 or 3 . The main effect of PF group, while difficult to discern from Figure 2, suggests a slight tendency for the more frequent items to be faster.

## Interpreting model parameters

We gain insight into these effects by looking at the parameters of the 3-stage models that were estimated separately for each practice level. In this model, we fit a power function to each stage to reflect the within-stage practice. This is a 3-parameter function:

$$
\begin{equation*}
\mu_{r e t}=I+\beta n^{-\alpha} \tag{1}
\end{equation*}
$$

Where $\mu_{\text {ret }}$ is the time it takes to retrieve the answer, $I$ is
the asymptotic latency (i.e., the fastest possible time), $\beta$ is the amount of latency that can be reduced with practice, $n$ is the number of practice opportunities, and $\alpha$ is the learning rate. Asymptotic latency, $I$, and learning rate, $\alpha$, parameters were estimated across all three Phases, and $\beta$ was estimated separately for each Phase. These parameters capture the speed up within a Phase while our transition parameters, $T_{12}$ and $T_{23}$, describe the probability of transitioning from one Phase to the next. Table 1 shows these parameters. Across models of the different practice-frequency groups the intercepts are essentially zero, implying that practice will always reduce the latency to some degree. The learning rate is controlled by the parameter a, which is small, indicating relatively small within-phase speedup. The parameters are remarkably similar across practice groups. There is a tendency for the speed up parameter to be greater for the higher-practice groups partially accounting for the faster within-phase times in Figure 1.

Table 1: Parameters for the three phase model of skill acquisition for each practice frequency group.

|  | $I$ | $\alpha$ | $\beta_{p 1}$ | $\beta_{p 2}$ | $\beta_{p 3}$ | $T_{12}$ | $T_{23}$ |
| :--- | :--- | :--- | :--- | :--- | :--- | :--- | :--- |
| PF-1 | $3.7 \mathrm{e}-8$ | -.07 | 7.8 | 3.2 | 1.6 | .17 | .15 |
| PF-2 | $9.5 \mathrm{e}-8$ | -.10 | 8.3 | 3.5 | 1.7 | .13 | .09 |
| PF-3 | $3.5 \mathrm{e}-7$ | -.11 | 8.2 | 3.3 | 1.6 | .07 | .06 |
| PF-4 | $5.9 \mathrm{e}-9$ | -.12 | 8.1 | 3.3 | 1.6 | .06 | .06 |

Because the number of practice opportunities vary between PF groups, the number of problems that reach Phase 3 is significantly different between the four groups $(\mathrm{F}(3,102)=6.6$, $\mathrm{p}<.001$ ), with $55.7 \%$ (6.7) of PF-4 problems reaching phase $3,47.1 \%$ of PF-3 (6.1), 50\% of PF-2 (5.7), and 35.6\% of PF1(6.7). However, the transition parameters, $T_{12}$ (Phase 1 to 2) and $T_{23}$ (Phase 2 to 3), are smaller for the high frequency group indicating that high frequency items spend more time in a phase before transitioning into the next Phase. On average, PF-4 items are seen 14.3 (1.1) times before transitioning to Phase 2 and 12.9 (1.0) before Phase 3, whereas PF-1 items are seen 4.7 (.29) times before Phase 2 and 3.6 (.25) times before Phase 3.

## Retention after three days

To understand how the performance on Day 2 was impacted by practice on Day 1, we fit a mixed-effects model to the log latency of the first observation of each problem on Day 2. We explored fixed effects for practice frequency, Phase reached on Day 1, time spent within that Phase on Day 1, and problem difficulty. Fitting a maximal model with all factors and random effects, we systematically removed factors that did not account for variance within the model (see Barr et al. (2013) for method). In fitting our model, we found no improvement justifying the inclusion of random effects; and, we found that neither the practice frequency group nor the amount of practice within the last phase reached accounted

Figure 3: (a) To the left of the vertical line, mean problem solving latency for items in experimental blocks on Day 1; line types distinguish the mean latency for items in each Phase. To the right of the vertical line, mean problem solving latencies for items grouped by last Phase reached on Day 1 (b) Mean latency of first block of Day 2. Line type indicates Phase item reached on Day 1. Error bars represent standard error
for enough variance in response latency to justify either fixed effect. Our final model indicated a significant effect of problem difficulty $(\mathrm{F}(3,515.8)=5.5, \mathrm{p}<.001)$, Phase reached on Day $1(\mathrm{~F}(2,542.5)=20.2, \mathrm{p}<.001)$, and a significant interaction between Difficulty and Phase $(\mathrm{F}(6,519.1)=2.4, \mathrm{p}<.05)$. Figure 3a shows the mean effect of phase. It is striking that the items that were still in Phase 1 show little change in speed, while the items in Phases 2 and 3 slow down from Day 1 to Day 2. Figure 3b shows the mean response latencies for the first items solved on Day 2. The effect of problem difficulty appears to be present for both items that reached Phase 1 and 2 on Day 1, but less of an observable effect for items that reached Phase 3 on Day 1. Our interpretation of these results is that items in Phase 1 on Day 1 stay in Phase 1 and therefore show no changes in their latency patterns. However, some of the items in Phases 2 and 3 slip back a phase over the retention interval and therefore slow down. Items that slip back to Phase 1 will show a problem difficulty effect, possibly explaining the presence of a problem difficulty effect for items in Phase 2 (Figure 3b).

## Discussion

Anderson and Milson (1989) suggest that memory phenomenon represent a joint function between general properties of memory and the strategies individuals use to process information. Our findings are aligned with prior studies that consider the impact of the spacing and practice frequency performance during training. Higher frequency in practice contributes to greater improvements in accuracy and response latency during training (e.g. Cepeda, Pashler, Vul, Wixted, \& Rohrer, 2006). The application of the skill acquisition model gives us insight into how problem solving strategies change in response to practice. We find the problem-solving latency advantage of massed trials is concentrated in the speedup within a phase rather than the transition between phases. This could be envisioned as 'rich get richer' process (Simon, 1955), in which learning strengthens both the probability of applying
the previously used strategy and the speed with which the sub-procedures of that strategy are executed. Items that are spaced further apart exhibit shallower learning rates, which may make the search for a more efficient strategy more rewarding than the learning of problem solving sub-procedures. While theories of deficit processing or contextual variability could provide a mechanism for the differences in within phase speed up, the shift between phases of skill acquisition may be driven by a different mechanism.

Unlike prior work, which largely uses accuracy to measure the impact of spacing on retention, in our study we use response latency and the effect of problem difficulty. When we include information about what phase each item reached on the first day of training, we find that practice frequency no longer accounts for significant variance in problem solving latency at the retention test. Analyzing the speed of problem solving on Day 2, it appears that problems that items that reach Phase 2 and 3 on Day 1 are solved more quickly than items that remain in Phase 1. Additionally, the significant interaction between Phase and problem difficulty suggests that Phase 3 items may still be retrieved on Day 2, while Phase 1 and 2 items are calculated. This work is consistent with findings of Sisti, Glass, and Shors (2007) who found that the survival of neurons in the dentate gyrus and the strength of memory in an animal model was predicted not by whether or not practice was spaced or massed, but by how well the animals learned the task. While this study provides a biological mechanism for memory preservation, it is unclear computationally what memory process would explain the impact of phase on retention, but not on spacing nor general practice. In future work, we will explore how phase impacts retention by incorporating forgetting into our computational model of skill acquisition. In incorporating this capability, we will consider forgetting both in terms of regressing to a prior phase, and as regression within a phase. Additionally, including regression into the model will allow us to explore how spacing and skill acquisition on Day 1 impacts relearning on Day 2. In this
future work we will limit the practice of more frequent items so to dissociate the effects of spacing from those of practice frequency. This work, while in an early stage, suggests that without considering the impact of skill acquisition on problem solving strategies, our models of the spacing effect, and memory more generally, are incomplete.

## Acknowledgments

This work was supported by the National Science Foundation grant DRL-1420008, a James S. McDonnell Scholar Award, and by Carnegie Mellon University's Program in Interdisciplinary Education Research funded by the US Department of Education grant R305B090023. We would like to thank Shawn Betts for his help running the Mechanical Turk study.

# Warm (for winter): Comparison class understanding in vague language 

Michael Henry Tessler ${ }^{1}$, Michael Lopez-Brau ${ }^{2}$, and Noah D. Goodman ${ }^{1}$<br>mtessler@stanford.edu, lopezmic@knights.ucf.edu, ngoodman@stanford.edu<br>${ }^{1}$ Dept. of Psychology, Stanford University, ${ }^{2}$ Dept. of Electrical \& Computer Engineering, University of Central Florida

#### Abstract

Speakers often refer to context only implicitly when using language. The utterance "it's warm outside" could signal it's warm relative to other days of the year or just relative to the current season (e.g., it's warm for winter). Warm vaguely conveys that the temperature is high relative to some contextual comparison class, but little is known about how a listener decides upon such a standard of comparison. Here, we formalize how world knowledge and listeners' internal models of speech production can drive the resolution of a comparison class in context. We introduce a Rational Speech Act model and derive two novel predictions from it, which we validate using a paraphrase experiment to measure listeners' beliefs about the likely comparison class used by a speaker. Our model makes quantitative predictions given prior world knowledge for the domains in question. We triangulate this knowledge with a follow-up language task in the same domains, using Bayesian data analysis to infer priors from both data sets. Keywords: comparison class; pragmatics; Rational Speech Act; Bayesian cognitive model; Bayesian data analysis

If it's $75^{\circ} \mathrm{F}\left(24^{\circ} \mathrm{C}\right)$ outside, you could say "it's warm." If it's $60^{\circ} \mathrm{F}\left(16^{\circ} \mathrm{C}\right)$, you might not consider it warm. Unless it's January; it could be warm for January. Warm is relative, and its felicity depends upon what the speaker uses as a basis of comparison-the comparison class (e.g., other days of the year or other days in January). Comparison classes are necessary for understanding adjectives and, in fact, any part of language whose meaning must be pragmatically reconstructed from context, including vague quantifiers (e.g., "He ate a lot of burgers."; Scholler \& Franke, 2015) and generic language (e.g., "Dogs are friendly"; Tessler \& Goodman, 2016a). The challenge for listeners is that the comparison class often goes unsaid (e.g., in "It's warm outside.").

The existence of comparison classes for understanding vague language is uncontroversial (Bale, 2011; Solt, 2009). Four-year-olds categorize novel creatures (pimwits) as either "tall" or "short" depending on the distribution of heights of pimwits and not the heights of creatures that are not called pimwits, suggesting the comparison class in that context is other pimwits (Barner \& Snedeker, 2008). Adult judgments of the felicity for adjectives like "dark" or "tall" similarly depend upon fine-grained details of the statistics of the comparison class (Qing \& Franke, 2014b; Schmidt, Goodman, Barner, \& Tenenbaum, 2009; Solt \& Gotzner, 2012).

Any particular object of discourse, however, can be conceptualized or categorized in multiple ways, giving rise to multiple possible comparison classes. A day in January is also a day of the year; if it's warm, it could be warm for winter or warm for the year. Why should one comparison class be preferred over another? To our knowledge, this question has not been addressed formally or empirically ${ }^{1}$ We pro-

[^207]pose that listeners actively combine category knowledge with pragmatic considerations to infer the comparison class implicitly used by the speaker. We introduce a minimal extension to the Rational Speech Act (RSA) model for gradable adjectives (Lassiter \& Goodman, 2013) to allow it to flexibly reason about the implicit comparison class.

We derive two novel qualitative predictions from this model. Saying "it's warm" in winter should signal it's warm for winter (as opposed to for the year) more so than saying "it's cold". The opposite relationship should hold in summer, where "it's cold" should signal it's cold for summer more so than "it's warm". This prediction is driven by the a priori probability that the adjective could apply to the class (e.g., the probability that a given day in winter is warm; Prediction 1). In addition, regardless of the season and the adjective form (e.g., "warm" or "cold"), listeners who expect speakers to be informative will prefer classes that are relatively specific (e.g., relative to the current season as opposed to the whole year), as they carry more information content (Prediction 2). We test these predictions by eliciting the comparison class using a paraphrase dependent measure (Expt. 1).

As with any Bayesian cognitive model, explicitly specifying relevant prior knowledge (e.g., beliefs about temperatures) is necessary for the model to make quantitative predictions. The current methodological standard is to measure beliefs by having participants estimate quantities or give likelihood judgments (Franke et al., 2016). We pursue a different methodology. The RSA model captures a productive fragment of natural language; thus, it makes predictions about a related natural language task (Expt. 2). Critically, we can use the model to predict natural language judgments that require the same prior knowledge as in Expt. 1 and use Bayesian data analysis to jointly infer the shared priors. This approach harnesses the productivity of language into experiment design and allows us to reconstruct priors without having participants engage in challenging numerical estimation tasks.

## Understanding comparison classes

Adjectives like warm and cold are vague descriptions of an underlying quantitative scale (e.g., temperature). The vagueness and context-sensitivity of these adjectival utterances can be modeled using threshold semantics $([\llbracket u \rrbracket]=x>\theta$, for utterance $u$, scalar degree $x$, and threshold $\theta$ ), where the threshold is probabilistically set with respect to a comparison class $c$ via pragmatic reasoning (Lassiter \& Goodman, 2013; see also Qing \& Franke, 2014a):

[^208]\[

$$
\begin{align*}
L_{1}(x, \theta \mid u) & \propto S_{1}(u \mid x, \theta) \cdot P_{c}(x) \cdot P(\theta)  \tag{1}\\
S_{1}(u \mid x, \theta) & \propto \exp \left(\alpha_{1} \cdot \ln L_{0}(x \mid u, \theta)\right)  \tag{2}\\
L_{0}(x \mid u, \theta) & \propto \delta_{\llbracket u\rfloor(x, \theta)} \cdot P_{c}(x) \tag{3}
\end{align*}
$$
\]

This is a Rational Speech Act (RSA) model, a recursive Bayesian model where speaker $S$ and listener $L$ coordinate on an intended meaning (for a review, see Goodman \& Frank, 2016). In this framework, the pragmatic listener $L_{1}$ tries to resolve the state of the world $x$ (e.g., the temperature) from the utterance she heard $u$ (e.g., "it's warm"). She imagines the utterance came from an approximately rational Bayesian speaker $S_{1}$ trying to inform a naive listener $L_{0}$, who in turn updates her prior beliefs $P_{c}(x)$ via an utterance's literal meaning $\llbracket u \rrbracket](x)$. Lassiter \& Goodman (2013) introduced into RSA uncertainty over a semantic variable: the truth-functional threshold $\theta$ (Eq. 11). $\theta$ comes from an uninformed prior and is resolved by the listener by reasoning about the likely states of the world $P_{c}(x)$ (e.g., possible temperatures) and the likelihood that a speaker would say the adjective given a state and a threshold $S(u \mid x, \theta)$. The prior distribution over world-states $P_{c}(x)$ is always relative to some comparison class $c$ (Eqs. $1 \&$ (3) but where does the comparison class come from?

When a listener hears only that "it's warm outside" without an explicit comparison class (e.g., "... for the season"), we posit the listener infers the comparison class using her world knowledge of what worlds are plausible given different comparison classes $P(x \mid c)$, what comparison classes are likely to be talked about $P(c)$, and how a rational speaker would behave in a given world and comparison class $S_{1}(u \mid x, c, \theta)$ (Eq. 4.) As a first test of this idea, we consider an idealized case where the comparison class can be either a relatively specific (subordinate) or relatively general (superordinate) categorization (e.g., warm relative to days in winter or relative to days of the year). Crucially in this situation, the listener is aware that the target entity is a member of the subordinate class (e.g., aware that it is winter) and draws likely values of the degree (e.g., temperature) from the subordinate class prior $P\left(x \mid c_{\text {sub }}\right)$. With these assumptions, the model becomes:

$$
\begin{align*}
& L_{1}(x, c, \theta \mid u) \propto S_{1}(u \mid x, c, \theta) \cdot P\left(x \mid c_{s u b}\right) \cdot P(c) \cdot P(\theta)  \tag{4}\\
& S_{1}(u \mid x, c, \theta) \propto \exp \left(\alpha_{1} \cdot \ln L_{0}(x \mid u, c, \theta)\right)  \tag{5}\\
& L_{0}(x \mid u, c, \theta) \propto \delta_{\llbracket u \rrbracket(x, \theta)} \cdot P(x \mid c) \tag{6}
\end{align*}
$$

We are interested in the behavior of the model with the underspecified utterance (e.g., "It's warm"), and we assume the speaker has two alternative utterances in which the comparison class is explicit (e.g., "It's warm relative to other days in winter." and "It's warm relative to other days of the year."). The predictions of this model depend on the details of the listener's knowledge of the subordinate and superordinate categories: $P\left(x \mid c_{\text {sub }}\right)$ and $P\left(x \mid c_{\text {super }}\right)$, as well as the prior distribution on comparison classes $P(c)$ in Eq. 4

Comparison class prior $P(c)$ reflects listeners' expectations of what classes are likely to be discussed. As a proxy
for comparison class usage frequency, we use empirical frequency $\hat{f}$ estimated from the Google WebGram corpus ${ }^{2}$, and scale it by a free parameter $\beta$ such that $P(c) \propto \exp (\beta \cdot \log \hat{f})$.
Degree priors (World knowledge) Only the relative values for $P\left(x \mid c_{\text {sub }}\right)$ and $P\left(x \mid c_{\text {super }}\right)$ affect model predictions. Hence we fix each superordinate distribution to be a standard normal distribution $P\left(x \mid c_{\text {super }}\right)=\mathcal{N}(0,1)$ and the subordinate priors to also be Gaussian distributions $P\left(x \mid c_{\text {sub }}\right)=$ $\mathcal{N}\left(\mu_{\text {sub }}, \sigma_{\text {sub }}\right)$; the subordinate priors thus have standardized units. We will eventually infer the parameters of the subordinate priors from experimental data.

Figure 1: Left: Three hypothetical subordinate class prior distributions over a degree (fixing the superordinate class to be a unit-normal distribution, in grey). Right: Predicted listener inferences for an intended subordinate class interpretation given positive and negative form adjectives with different subordinate degree priors.
Qualitative model predictions Figure 1 (left) shows schematic superordinate and subordinate priors; e.g., temperatures over the whole year (super), in winter (low), fall (medium), and summer (high). The subordinate distributions have lower variance than the superordinate, and the "low" and "high" distributions have different means (e.g., temperatures in winter are expected to be lower and have lower variance than temperatures over the whole year).

Two intuitions explain the inferences of the pragmatic listener model (shown in Figure 1 right). First, certain classes are more or less likely to have an adjective felicitously apply. For example, any given day in winter is less likely to be warm than cold. Thus, hearing "it's warm" (a positive-form adjective) in winter (low prior) will signal it's warm for winter (the subordinate class) more so than hearing "it's cold" (negativeform), because it's more likely to be true (Prediction 1).

[^209]| Scale (adjectives) | Subordinate classes | Superordinate |
| :--- | :--- | :--- |
| Height (tall, short) | (professional) gymnast, soccer player, basketball player | people |
| Price (expensive, cheap) | bottle opener, toaster, dishwasher | kitchen appliances |
| Temperature (warm, cold) | winter, fall, summer (day in Maryland) | days in the year |
| Time (long, short) | video of a cute animal, music video, movie | things you watch online |
| Weight (heavy, light) | grape, apple, watermelon | produce |

Table 1: Items used in Experiments 1 and 2. Subordinate categories were designed to fall near the low end, high end, and somewhere in the middle of the degree scale

Second, the amount of information conveyed by a vague utterance depends upon the variability in the comparison class. Comparison classes that have higher variance will result in relatively less information gain by the listener. All else being equal, listeners will prefer lower variance (e.g., subordinate) comparison classes because they are more informative (Prediction 2). Figure 1 (right) shows that subordinate class interpretations are above baseline regardless of the adjective polarity (positive or negative) or the mean of the subordinate prior (low, medium, high).

In sum, we see two predictions: The pragmatic listener overall prefers subordinate comparison classes, though the extent of this preference is modulated by the a priori probability that the adjective is true of the subordinate category. We test these two predictions in our first experiment.

Overview of data analytic approach As described above, specifying the relevant prior knowledge yields two free parameters per subordinate class. We will put priors over these parameters and infer their likely values using Bayesian data analysis. The data from the comparison class experiment (Expt. 1) would be insufficient, however, to reliably estimate all of the parameters of this data analytic model. To alleviate this, we use the same RSA model to predict additional data about related language use in the same domains (Expt. 2). Specifically, we gather judgments about adjectives when the comparison class is explicit: whether or not an adjective would apply to a subordinate member explicitly relative to the superordinate category (e.g., Is a day in winter warm relative to other days of the year?).

To model Expt. 2 data, we remove comparison class uncertainty by setting $P\left(c_{\text {super }}\right)=1$, since the sentences provide an explicit comparison to the superordinate class. We model sentence endorsement using a pragmatic speaker (following Qing \& Franke, 2014a; Tessler \& Goodman, 2016a, 2016b):

$$
\begin{equation*}
S_{2}\left(u \mid c_{\text {sub }}\right) \propto \exp \left(\alpha_{2} \cdot \mathbb{E}_{x \sim P_{c_{\text {sub }}}} \ln L_{1}(x \mid u)\right) \tag{7}
\end{equation*}
$$

Note that $L_{1}(x \mid u)$ is defined from Eq. 4 by marginalization.
Eqs. 4 and 7 define models for the data we will gather from Expts. 1 and 2, and depend on the same background knowledge $P(x \mid c)$. We can thus use data from both experiments to jointly reconstruct the shared prior knowledge and generate predictions for the two data sets. Experimental paradigms, computational models, preregistration report, and data for this paper can be found at https://mhtess.github.io

## Behavioral experiments

Experiment 1 tests the qualitative predictions of the model. Experiment 2 collects further data about adjective usage in order to constrain the quantitative predictions of the RSA model, which will be used to predict data from both experiments. The materials and much of the design of the two experiments are shared. Participants were recruited from Amazon's Mechanical Turk and were restricted to those with U.S. IP addresses with at least a $95 \%$ work approval rating. Each experiment took about 5 minutes and participants were compensated $\$ 0.50$ for their work.

Materials We used positive- and negative-form gradable adjectives describing five scales (Table 11. Each scale was paired with a superordinate category, and for each superordinate category, we used three subordinate categories that aimed to be situated near the high-end, low-end, and intermediate part of the degree scale (as in Figure 1 left). This resulted in 30 unique items ( $\{3$ subordinate categories $\} \times\{5$ scales $\}$ x $\{2$ adjective forms $\}$ ). Each participant saw 15 trials: one for each subordinate category paired with either the positive or negative form of its corresponding adjective. Participants never judged the same subordinate category for both adjective forms (e.g., cold and warm winter days) and back-to-back trials involved different scales to avoid fatigue.

## Experiment 1: Comparison class inference

In this experiment, we gather human judgments of comparison classes in ambiguous contexts, testing the two predictions described in Qualitative Model Predictions.

Participants and procedure We recruited 264 participants and 2 were excluded for failing an attention check. On each trial, participants were given a context sentence to introduce the subordinate category (e.g., Tanya lives in Maryland and steps outside in winter.). This was followed by an adjective sentence, which predicated either a positive- or negativeform gradable adjective over the item (e.g., Tanya says to her friend, "It's warm."). Participants were asked "What do you think Tanya meant?" and given a two-alternative forcedchoice to rephrase the adjective sentence with either an explicit subordinate or superordinate comparison class:
\{She / He / It \} is ADJECTIVE (e.g., warm) relative to other SUBORDINATES (e.g., days in winter) or SUPERORDINATES (e.g., days of the year)

Figure 2: Empirical comparison class data, inferred world priors, and empirically derived comparison class priors. Top: Experiment 1 results. Comparison class judgments in terms of proportion judgments in favor of subordinate comparison class. Middle: Inferred prior distributions of world knowledge used to model Experiment 1 and 2 data. Bottom: Inferred prior probability of the subordinate comparison classes based on Google WebGram frequencies. Error bars correspond to $95 \%$ Bayesian credible intervals (for bottom plot, derived from the posterior on the $\beta$ scale parameter).

In addition to all of the above design parameters, half of our participants completed trials where an additional sentence introduced the superordinate category at the beginning (e.g., Tanya lives in Maryland and checks the weather every day.), with the intention of making the superordinate paraphrase more salient.

Results We observed no systematic differences between participants' responses when the superordinate category was previously mentioned in the context and those when it was not; thus, we collapse across these two conditions for all analyses. Figure 2 (top) shows the proportion of participants choosing the subordinate paraphrase for each item, revealing considerable variability both within- and across- scales. The predicted effects are visually apparent within each scale (compare with Figure 1 right).

Our qualitative predictions are confirmed using a generalized linear mixed effects model with main effects of adjective form (positive vs. negative) and the a priori judgment by the first author of whether the sub-category was expected to be
low or high on the degree scale, and of critical theoretical interest, the interaction between these two variables. In addition, we included by-participant random effects of intercept and by-subordinate category random effects of intercept and iteraction between form and strength ${ }^{3}$. Confirming our two qualitative model predictions, there was an interaction between form and strength ( $\beta=-3.75$; $S E=0.58 ; z=-6.49$ ) and there was an overall preference for subordinate category paraphrases ( $\beta=1.21 ; S E=0.37 ; z=3.27$ ). The main effects of form and strength were not significant.

We then test the simple effects. For items low on the degree scale (e.g., temperatures in winter), positive form adjectives were significantly more likely to imply subordinate comparison classes ( $\beta=1.41$; SE $=0.15 ; z=9.43$ ), while the opposite is true for items high on the scale (e.g., summer days; $\beta=-2.5 ; S E=0.19 ; z=-13.15)$. Participants reason pragmatically to resolve the comparison class, combining world knowledge with informativity as predicted by our model.

[^210]

Figure 3: Human endorsement of subordinate comparison class paraphrases (middle; Expt. 1) and adjective sentences (left; Expt. 2) as a function of listener model $L_{1}$ and speaker model $S_{2}$ predictions, respectively. The right facet displays a subset of the paraphrase data (Expt. 1) to reveal good quantitative fit even in a small dynamic range. Error bars correspond to $95 \%$ Bayesian credible intervals.

## Experiment 2: Adjective endorsement

In this experiment, we collected data about adjective endorsement that would require the same prior knowledge relevant for Expt. 1. We use this data to further constrain the RSA model's quantitative predictions.
Participants and procedure We recruited 100 participants and 5 were excluded for failing an attention check. On each trial, participants were given a sentence introducing the subordinate category (e.g., Alicia lives in Maryland and steps outside in winter.). This was followed by a question asking if the participant would endorse an adjective explicitly relative to the superordinate category (e.g., Do you think the day in winter would be warm relative to other days of the year?).

Results The judgments in this experiment were consistent with the a priori ordering of the subordinate categories on the degree scale. On the y-axis of Figure 3 (left), we see that the endorsement of adjectival phrases in these domains is markedly more categorical than the comparison class inference task (compare vertical spread of left and middle facets).

## Full model analysis and results

The RSA listener (Eq. 4) and speaker (Eq. 7) models make quantitative predictions about comparison class interpretation and adjective endorsement, respectively. We construct a single data-analytic model with each of these RSA components as sub-models in order to make quantitative predictions about the data from both of our experiments.

The listener and speaker sub-models share their prior world knowledge $P(x \mid c)$ (e.g., temperatures in winter), described in the Degree Priors section. We put the same priors over the parameters of each subordinate distribution: $\mu \sim$ Uniform $(-3,3), \sigma \sim \operatorname{Uniform}(0,5)$, since they have standardized units. The comparison class prior $P(c)$ in Eq. 4
scales the empirical frequency $\hat{f}$ by a free parameter, which we give the following prior: $\beta \sim \operatorname{Uniform}(0,3)$.

The full model has three additional parameters not of direct theoretical interest: the speaker optimality parameters $\alpha_{i}^{\text {expt }}$, which can vary across the two tasks. The pragmatic listener $L_{1}$ model (Eq. 4) has one speaker optimality: $\boldsymbol{\alpha}_{1}^{1}$. The pragmatic speaker $S_{2}$ model (Eq. 7) has two speaker optimality parameters: $\left\{\alpha_{1}^{2}, \alpha_{2}^{2}\right\}$. We use priors consistent with the previous literature: $\alpha_{1} \sim \operatorname{Uniform}(0,20), \alpha_{2} \sim \operatorname{Uniform}(0,5)$

We implemented the RSA and Bayesian data analysis models in the probabilistic programming language WebPPL (Goodman \& Stuhlmuller, 2014). To learn about the credible values of the parameters, we collecting 2 chains of 50 k iterations (after 25k burn-in) using an incrementalized version of MCMC (Ritchie, Stuhlmuller, \& Goodman, 2016).

Results The full model's posterior over the RSA and dataanalytic parameters were consistent with prior literature and intuition. The maximum a-posteriori (MAP) estimate and 95\% highest probability density (HPD) intervals for model parameters specific to the $L_{1}$ model used for Expt. 1 were $\alpha_{1}^{1}=1.6[1.1,2.5], \beta=0.13[0.11,0.19]$. Model parameters specific to the $S_{2}$ model used for Expt. 2: $\alpha_{1}^{2}=3.5[0.6,13.2]$, $\alpha_{2}^{2}=3.2[2.6,3.8]$. The inferred distributions corresponding to subordinate class priors were consistent with the a priori ordering of these subordinate classes (low, medium, high) used in these tasks (Figure 2 middle).

Finally, the full model's posterior predictive distribution does an excellent job at capturing the quantitative variability in responses for Expt. 1: $r^{2}(30)=0.965$, and Expt. 2: $r^{2}(30)=0.985$ (Figure 3). Because of the overall preference for the subordinate comparison class, many of the data points are distributed above 0.5 . Even for these fine-grained differences, the model does a good job at explaining the quantitative variability in participants' data (Figure 3 right).

## Discussion

The words we say are often too vague to have a single, precise meaning and only make sense in context. Context, however, can also be underspecified, as there are many possible dimensions or categories that a speaker might be implicitly referring to or comparing against. Here, we investigate the flexibility in the class against which an entity can be implicitly compared.

We introduced a minimal extension to an adjective interpretation Rational Speech Act model to allow it to flexibly reason about the comparison class. This model made two novel predictions about how listeners should prioritize one class over another. It also made quantitative predictions about how background knowledge about the degree scale should inform this inference in a graded fashion. Both qualitative predictions of the model were borne out in our first experiment, and the quantitative predictions were confirmed using a novel data analytic technique. To our knowledge, this is the first experiment to demonstrate how reference classes for adjective interpretation can adjust based on world knowledge.

We observe in our modeling results for Expt. 1 that a uniform prior distribution over the experimentally supplied comparison class alternatives is unlikely (Figure 2 bottom). For example, the comparison class of "people" for heights of individuals is relatively more salient than the class of "produce" for the weights of fruits and vegetables. We used the frequency of the class in a corpus as a proxy for their prior probability $P(c)$, which was sufficient to account for differences in baseline class probability both between- and within-scales.

Corpus frequency is a composite measurement of factors relevant for speech production. Its utility in this model suggests that utterances without an explicit comparison class (e.g., "It's warm outside") may in fact be incomplete sentences, in a way analogous to sentence fragments studied in noisy-channel models of production and comprehension (Bergen \& Goodman, 2015). Another (non-mutually exclusive) possibility is that the comparison class prior reflects basic-level effects in categorization (Rosch \& Mervis, 1975). Future work should attempt to understand these factors to construct a more complete theory of the comparison class prior.

The second contribution of this paper is a novel dataanalytic approach, where prior knowledge used in the Bayesian language model is reconstructed from converging evidence gathered from related language experiments. In previous work, we have attempted to measure prior knowledge by decomposing what would be a single, implicitly multilayered, numerical estimation question into multiple simpler questions. Then, we construct a Bayesian data analytic model to back out the prior knowledge (Tessler \& Goodman, 2016a, 2016b). We extend this approach by using the same core RSA model to model behavior across two language experiments. The major feature of this method is that participants respond only to simple, natural language questions rather than estimating numerical quantities for which complicated linking functions must be designed (e.g., Franke et al., 2016). The
fully Bayesian language approach we pioneer here also provides a further constraint on the language model, which must predict data from two similar but distinct language experiments. The productivity of natural language can thus be harnessed to productively design experiments that further constrain and test computational models of language and cognition.

#### Abstract

It is well known that, all things being equal, the accuracy of mammalian timing and memory decays gradually with the passage of time. The gradual decay of temporal accuracy is also observed in single-unit neural recordings. Here we review recent modeling work describing a specific mechanism for timing and memory and relevant neural data. The model describes a neural mechanism that can give rise to a logarithmically compressed representation of the recent past. We examine the specific predictions of the model, in particular that the elapse of time is represented by sequentially activated cells which fire for a circumscribed period of time. Such cells, called time cells, have been observed in neural recordings from several brain regions in multiple species. As predicted by the model, the cells show accuracy that decreases with time.

Keywords: scale-invariance, memory, interval timing, time cells.

## Introduction

Behavioral experiments on humans and other animals have demonstrated that the accuracy in estimating the duration of a time interval decays gradually with the interval duration itself. More specifically, the variability of the response is proportional to the interval duration (Rakitin et al., 1998; Ivry \& Hazeltine, 1995). For instance, in interval timing the response distributions appear to be scale-invariant: distributions corresponding to different interval durations overlap when linearly scaled (Roberts, 1981; Smith, 1968). Furthermore, animal literature suggests that in conditioning paradigms, the number of trials needed for an animal to learn the association between conditioned and unconditioned stimuli scales with a ratio of the reinforcement latency and intertrial interval (Gallistel \& Gibbon, 2000), indicating again the scale-invariance in the animals’ behavior (Balsam \& Gallistel, 2009; Shankar \& Howard, 2012; Gibbon, 1977).

In addition to timing, scale-invariance has been argued to be one of the key properties of memory. Gradual decay of memory without a characteristic scale has been observed in a number of behavioral experiments (Anderson \& Schooler, 1991; Chater \& Brown, 2008; Wixted \& Ebbesen, 1991) and it was often refereed to as power-law of forgetting. For example, Donkin and Nosofsky (2012) reported that in item recognition task the strength of the memory was decaying as a power law function of the lag between studied items and a test probe. It has been argued that scale-invariance should be thought of as universal law of cognition (Chater \& Brown, 1999). A number of cognitive models have been
constructed to account for these properties (Brown, Neath, \& Chater, 2007; Howard, Shankar, Aue, \& Criss, 2015; Donkin \& Nosofsky, 2012).

Neural mechanisms that could support the scale-invariance of time and memory are still unclear. It has been argued that working memory is represented with persistent neural activity observed in different areas of the prefrontal cortex (PFC) during for instance a delayed match to sample task (P. S. Goldman-Rakic, 1991; P. Goldman-Rakic, 1995). Even though such persistent activity can account well for the demands of a particular task, it is not clear how it could account for a gradual decay of the memory representation. More recent studies have found that in some behavioral tasks a subset of neurons activates sequentially, tiling the task relevant interval, typically lasting for several seconds (see e.g. Pastalkova, Itskov, Amarasingham, and Buzsaki (2008); MacDonald, Lepage, Eden, and Eichenbaum (2011) for the first reports of such activity). These neurons that fire sequentially, each during a circumscribed period of time, are called time cells (Howard \& Eichenbaum, 2015; Eichenbaum, 2013). It has been argued that time cells play important role in timing and memory (MacDonald, Fortin, Sakata, \& Meck, 2014; Howard et al., 2014; Eichenbaum, 2014).

Time cells provide a direct readout of when the delay interval has started: there is no need for population decoding in a classical sense (Murray et al., 2016; Stokes, 2015). This is because time cells activate sequentially effectively providing temporal basis functions and constituting an internal timeline. As we will discuss later, this timeline is compressed, such that the temporal resolution gradually decays with the elapsed time, just as expected given the behavioral findings on memory and timing we mentioned above. It is unclear, however, what are the neural mechanisms that could give rise to such a compressed timeline.

Here we utilize a computational model for compressed scale-invariant dynamical memory representation introduced in Shankar and Howard (2012). We compare specific predictions of the model with the neural recordings of sequentially activated time cells. The model provides a unique solution to constructing a scale-invariant memory representation (Shankar, 2015). The model has been used to account for results of various timing and memory experiments including judgment of recency and serial scanning in long and short term memory (Howard, Shankar, Aue, \& Criss, 2015). Here

Figure 1: Examples of sequentially activated neurons from tetrode recordings in rat hippocampus (plot a.) and PFC (plot b.). On both plots each row on the heatplot corresponds to a single cell and displays normalized firing rate averaged across trials during a delay interval of a behavioral experiment. Red corresponds to high firing rate, while blue corresponds to low firing rate. The cells are sorted with respect to their peak time. Despite the fact that both recordings are done during a rather different behavioral experiment, they both show similar qualitative properties. In particular we point to two features related to the temporal accuracy: 1) time fields later in the delay are more broad than time fields earlier in the delay (the central ridge is widening as the peak moves to the right); 2) peak times of the time cells are not evenly distributed across the delay, with later time periods represented by fewer cells than early time periods (this is apparent from the curvature of the central ridge; a uniform distribution of time fields would manifest as a straight line). a. Hippocampal CA1 neurons recorded during object-delay-odor sequence task (reprint from MacDonald et al. (2011)). In order to obtain a reward the animals had to memorize the identity of the stimulus during the delay interval and match it to the appropriate odor. b. PFC neurons recorded during a temporal discrimination task (reprint from Tiganj et al. (2016), original data first reported in (Kim et al., 2013)). In order to obtain a reward the animals had to estimate whether the presented delay interval was larger than some baseline duration and make a left or right turn accordingly following the delay.
we focus on the neural side, looking into specific predictions about individual neural activity that can be derived from the model.

## Sequential activation as a neural correlate of timing and memory

Starting with a report from Pastalkova et al. (2008), a number of studies have reported sequential neural activation in different timing and memory tasks from different brain regions: hippocampus (MacDonald et al., 2011; Salz et al., 2016; Gill, Mizumori, \& Smith, 2011; Kraus, Robinson, White, Eichenbaum, \& Hasselmo, 2013; MacDonald, Carrow, Place, \& Eichenbaum, 2013; Modi, Ashesh, \& Bhalla, 2014; Naya \& Suzuki, 2011), PFC (Tiganj et al., 2016) and the striatum (Mello, Soares, \& Paton, 2015; Adler et al., 2012) in a variety of behavioral tasks. This activity has been hypothesized to be a neural basis for representation of memory and elapsed time in a gradually decaying fashion (Howard, Shankar, Aue, \& Criss, 2015; Howard \& Eichenbaum, 2015; Eichenbaum, 2014, 2013). The studies were done on different animals, including rats (MacDonald et al., 2011; Salz et al., 2016; Gill et al., 2011; Kraus et al., 2013; MacDonald et al., 2013; Pastalkova et al., 2008; Mello et al., 2015; Tiganj et al., 2016), mice (Modi et al., 2014) and monkeys (Naya \& Suzuki, 2011; Adler et al., 2012). Even though the majority of studies used tetrode recordings, Modi et al. (2014) used two-photon calcium imaging minimizing the probability that the results were observed due to some sort of recording artifact. Most of the studies were done on animals that were allowed to move, but
some were done on head-fixed animals (MacDonald et al., 2013; Modi et al., 2014; Naya \& Suzuki, 2011; Adler et al., 2012) confirming that the results were not coming from position-related artifacts.

It is worth noting that sequentially activated time cells were observed in these studies despite the different cognitive demands on the animals, which included temporal discrimination (e.g. Tiganj et al. (2016)) or memory demands (e.g. Salz et al. (2016); MacDonald et al. (2011)). The duration of the intervals where such cells were measured was ranging from a couple of seconds up to 60 s (Mello et al., 2015).

Several studies have observed decreasing temporal accuracy as a function of delay, due to spread in time field width (Howard et al., 2014; MacDonald et al., 2011; Mello et al., 2015; Adler et al., 2012; Kraus et al., 2013; Salz et al., 2016; Tiganj et al., 2016) and/or due to a non-uniform distribution of time fields (Kraus et al., 2013; Salz et al., 2016; Mello et al., 2015; Tiganj et al., 2016). Two examples of neural representation with decreasing temporal accuracy are provided in Figure 1.

## Computational model for compressed scale-invariant dynamical memory representation

The computational model reviewed here was initially introduced in (Shankar \& Howard, 2012). It consists of a twolayer feedforward neural network with analytically derived weights. Here we briefly describe the model and then focus on its predictions regarding neural activity. Notice that below
we define the model as a model of memory, as it was initially introduced in (Shankar \& Howard, 2012). Its application in timing is restricted to the stimulus that initiates the delay interval, as the only stimulus that needs to be remembered.

We first define an input vector $\mathbf{f}$ consisting of $N$ elements such that each of its elements corresponds to a unique stimulus. Thus observing for example stimulus $A$ makes an element in $\mathbf{f}$ that corresponds to stimulus $A, f_{A}$, equal to one for the time $A$ is presented and zero otherwise. Each element of the input vector $\mathbf{f}$ has a two-layer dynamical compressed memory representation. The first layer of the network implements an approximation of an integral transform of the input (Laplace transform, but as a function of a real rather than a complex variable). This means that nodes in the first layer, $\mathbf{F}\left(t,{ }^{*}\right)$, act as leaky integrators (first order low-pass filters) with a spectrum of time constant defined with $k /{ }^{*}$, where $k$ is positive integer (Figure 2):

$$
\begin{equation*}
\frac{\mathbf{F}(t, \stackrel{*}{t})}{d t}=-\stackrel{{ }_{*}^{*}}{t} \mathbf{F}(t, \stackrel{*}{t})+\mathbf{f}(t) \tag{1}
\end{equation*}
$$

Leaky integrators project to the second layer, $\tilde{\mathbf{f}}$, through fixed weights that implement an approximation of the inverse of the transform by applying a $k^{\text {th }}$ order derivative with respect to $k /^{*}$, denoted as $\mathbf{F}^{(k)}(t, \stackrel{*}{t})$ (the inverse is derived based on Post's inversion formula (Post, 1930), see Shankar and Howard $(2012,2013)$ for further details on the derivation):

$$
\begin{equation*}
\tilde{\mathbf{f}} t, \stackrel{*}{t})=C_{k}\left(\frac{k}{\stackrel{k}{t}}\right)^{k+1} \mathbf{F}^{(k)}(t, \stackrel{*}{t}) \tag{2}
\end{equation*}
$$

where $C_{k}$ is a constant that depends only on $k$. The cells in the second layer constitute a dynamical memory representation of the input signal. To understand the properties of the memory representation we consider an impulse response of a cell in $\tilde{\mathbf{f}}$. For $f_{A}(\tau)=\delta(\tau=0)$ the corresponding activation of the cells in the second layer is:

$$
\begin{equation*}
\tilde{f}_{A}(t, \stackrel{*}{t})=C_{k} \frac{1}{\underset{*}{*}}\binom{t}{\frac{\tilde{*}}{t}}^{k} e^{-k_{\dot{*}}^{t}}, \tag{3}
\end{equation*}
$$

where $C_{k}$ here is a different constant that depends only on $k$. The activity of each node in $\tilde{f}_{A}\left(t,{ }_{t}^{*}\right)$ is the product of an increasing power term $\left(\frac{t}{t^{*}}\right)^{k}$ and a decreasing exponential term $e^{-k_{\text {仡 }}^{t}}$. Consequently, each node in $\tilde{f}_{A}(t, \stackrel{*}{t})$ has a peak that corresponds to the ${ }_{t}^{*}$ value of that node: $\frac{d \tilde{f}_{A}(t, t)}{d t}=0 \Rightarrow t=\stackrel{*}{\tilde{f}}$. Thus, following a transient input, cells in $\tilde{f}_{A}$ activate sequentially in time constituting a dynamical memory representation of the input $A$ (Figure 3).

This memory representation has perfect accuracy in the limit when $k \rightarrow \infty$. In a realistic biological or artificial neural network, where $k$ is finite and $\stackrel{*}{t}$ is a discrete variable sup-

Figure 2: Constructing a scale-invariant compressed memory representation through an integral transform and its inverse. A transient input stimulus $\mathbf{f}(t)$ (top row) is presented twice and feeds into a layer of leaky integrators $\mathbf{F}\left(t,{ }_{t}^{*}\right)$ with a spectrum of time constants $\stackrel{*}{t}$ constituting a discrete approximation of an integral transform (middle row). The transform is denoted as $\mathbf{L}$ since it is equivalent to the real part of the Laplace transform. Only three nodes in $\mathbf{F}(t, \stackrel{*}{t})$ are shown. Each leaky integrator is characterized with its time constant, ${ }_{t}^{*}$. F projects onto $\tilde{\mathbf{f}}(t, \stackrel{*}{t})$ through a set of weights defined with the operator denoted as $\mathbf{L}_{k}^{-1}$ which implements an approximation of the inverse of the Laplace transform. Nodes in $\tilde{\mathbf{f}}(t, \stackrel{*}{t})$ activate sequentially following the stimulus presentation creating a memory representation. The width of the activation of each node scales with the peak time determined by the corresponding ${ }_{t}^{*}$, making the memory scale-invariant. Logarithmic spacing of the $\stackrel{*}{t}$ assures that the memory representation is compressed.
ported with a limited number of nodes, the memory representation becomes an approximation of the past. The approximation is scale-invariant (Figure 4) since the width of the activation of each node scales with the peak time (this is scale-invariant since rescaling the temporal axis rescales the width of the activation by the same amount). In other words, the accuracy of the memory representation decreases with the elapse of time since the stimulus presentation. With appropriately distributed ${ }^{*}$ the representation can be made logarithmically compressed.

To establish biological plausibility of the model we have shown that leaky integrators with a spectrum of time constants are biologically realistic (Tiganj, Hasselmo, \& Howard, 2015; Tiganj, Shankar, \& Howard, 2013). In addition, taking derivatives with respect to $k / t^{*}$ amounts to lateral inhibition, making it biologically plausible as well (Howard et al., 2014). To implement the derivative it is required that each neurons
a

b

Figure 3: Activity of the cells in the compressed memory representation generated by the model. Analogous to the heatmaps in Figure 1, each row corresponds to a single cell and displays its normalized activity across time. The cells are sorted with respect to the peak time defined by their value of $t$. The two features observed in Figure 1 are fully captured by the model: the time fields later in the delay were more broad than the time fields earlier in the delay and the density of time fields decreased as a function of time ( $\stackrel{*}{t}$ was logartihmically spaced). This illustrates that the model can indeed account for the firing dynamics of the sequentially activated time cells that form a compressed representation of time. The two plots, $\mathbf{a}$ and $\mathbf{b}$, show the activity of the cell ensemble for two different values of parameter $k$. Increasing $k$ makes the firing fields more narrow and the memory representation more precise. Notice that, from the biological perspective, larger $k$ is more difficult to obtain, since it requires higher order of derivative with respect to $k /{ }^{*}$. This requires broader connectivity between the two layers.
of the first layer only projects to the $k$ neighboring neurons of the second layer. The connectivity pattern is the same across the entire projection, since it always implements a derivative with respect to $k /{ }^{*}$. In addition, qualitative alignment of the model with the sequential neural activity as shown in Figure 3 further supports its biological plausibility.

## Discussion

We reviewed the predictions from a computational model for compressed scale-invariant memory representation and compared them to the results from recently-published neural recordings. The model maintains a dynamical representation of the recent past through a set of sequentially activated neurons. Such sequential activation appears qualitatively similar to the data published in multiple studies over the past several years including different regions of the brain including the hippocampus, PFC and striatum.

Several of the studies align with the model exhibiting compressed memory representation. In particular, the width of the time fields increased with the peak time and more cells had time fields earlier than later in the delay interval (notice the common trend in the plots in Figure 1 and Figure 3). These findings suggest that the model can indeed account for the neural representation of the elapsed time.

The model makes specific prediction on the scale-
invariance of the memory representation which was inspired by the behavioral experiments on timing and memory. Existing neural data were thus far not sufficient to explicitly test that prediction. However, the qualitative observations made here are consistent with the scale-invaraince prediction, but they are not sufficient to quantitatively verify it.

In addition to the model described here, several other computational models predict the qualitative properties found in the data. The common aspect of most of such models is the functional form that gives rise to time fields: as in the model described here, the activity increase is governed by a powerlaw and then later attenuated by a damping exponential. In particular, Grossberg and Schmajuk (1989); De Vries and Principe (1992); Machado (1997) propose different mechanistic solutions for achieving such form. However, unlike in the model described here, rescaling the time axis in these models would change the functional form of the representation. Others (for instance Tank and Hopfield (1987); Ludvig, Sutton, and Kehoe (2012)) directly used the functional form that provides spreading temporal basis functions as seen here.

Experimental data allowed us thus far to verify some of the predictions computational models make regarding the compressed representation of time. However, the model described here makes specific predictions regarding how memory is maintained in general. Here we assumed that the stimulus that marks the onset of the delay interval is the only one that has the memory representation. The model is designed to capture a variety of stimuli and maintain an independent compressed memory representation for each of them. In fact, associations between the independent representations allowed us to test the model on a variety of memory tasks (Howard, Shankar, Aue, \& Criss, 2015). It is to be tested whether the neural representation indeed supports such independent, stimulus specific compressed memory representations (see Tiganj, Cromer, Roy, Miller, and Howard (2017) for recent evidence of this).

Maintaining temporal information through sequential activation has a critical computational property in that it provides a direct readout of the elapsed time. Notice that cells in the first layer of the model (leaky integrators) contain the same amount of temporal information as the cells in the second layer (sequentially activated neurons). Thus one could apply population decoding techniques and extract the temporal information from the first layer directly. In fact, this is exactly what the inverse transform is doing. However, instead of training a classifier, which would be a common decoding procedure, it provides a simple form of linear readout using a mechanism analogous to lateral inhibition, which is known to exist in the nervous system. An additional advantage of having such a mechanism is that it provides access to the realvalue Laplace domain, where computations that are otherwise hard to achieve in a neural network become straightforward. These in particular include addition and subtraction of probability distributions as well as temporal translation (Howard, Shankar, \& Tiganj, 2015; Shankar, Singh, \& Howard, 2016).

c

d

Figure 4: Illustration of scale-invariance in the compressed memory representation generated by the model. Scaling the number of cells and the temporal duration by the same factor results in identical memory representation (plots a. to d. appear identical despite the fact that both x and y axes are rescaled on each plot). This property follows from Equations (3) since ${ }^{*}$ and $t$ appear only as a ratio (except for the scaling factor in front that does not influence the functional form). Scale-invariance is consistent with behavioral experiments, but it remains unclear whether neural data exhibits this property as well, even though the results shown in Figure 1 are consistent with scale-invariance.

## Conclusion

We showed that a computational model for constructing compressed dynamical representations of the recent past aligns well with recent neural data showing sequential neural activation. The sequential activation constitutes a compressed supported timeline, providing a mechanism for representing the elapse of time and potentially a mechanism for maintaining a dynamical memory representation.

#### Abstract

English-speaking adults recruit a left-to-right "mental timeline" (MTL) when thinking about time. The origins of the MTL are debated, with some arguing that it is a cultural construct and others arguing that it is rooted in innate associations between time and space. Here we ask whether preschoolers, with limited experience with cultural practices thought to shape the MTL, prefer conventional linear representations of temporal events. English-speaking preschoolers and adults were told stories and asked to choose which of two visual representations best illustrated the story. As expected, adults overwhelmingly preferred images that were linearly ordered from left-to-right. Five-year-olds also preferred left-to-right to right-to-left series, but were equally likely choose left-to-right and top-to-bottom. By contrast, 3-year-olds chose at random, apparently insensitive to the spatial ordering of event-denoting images. These results suggest that attention to the ordinal structure of visual representations of time increases across early childhood, and that adults' preference for horizontal space-time mappings results from increased cultural conditioning.

Keywords: time; space; mental timeline; events; abstract concepts

## 1. Introduction

Time and space are deeply interwoven in human experience and culture. For example, diverse societies use spatial tools to depict, measure, and track time; languages often use the same words to refer to both time and space (e.g., long and short); and readers repeatedly experience temporal narratives unfolding in a particular spatial direction across the page. Behavioral and neuroscientific studies suggest that adults have implicit linear associations between specific locations in time and positions in space (for a review, Bonato et al., 2012). The nature of the relationship between this "mental timeline" (MTL) and cultural practices that link time and space is debated. On the one hand, systematic cross-cultural differences in the direction of the MTL (e.g., Boroditsky, 2011; Bergen \& Lau, 2012) suggest that it is learned. On the other hand, evidence of space-time mappings in infants (e.g., de Hevia et al., 2014; Lourenco \& Longo, 2010; Srinivasan \& Carey, 2010), and the ubiquity of spatial artifacts and metaphors across cultures (Haspelmath, 1997) suggest that some form of MTL may be intrinsic to human cognition. Do cultural tools linking time and space create mental associations across domains, or do they simply capitalize on a low-level,
biological predisposition to think about time spatially? Understanding the development of space-time associations in children who cannot yet read or use spatial artifacts for time could shed light on this question. Here, we test whether 3- to 5-year-old preschoolers show adult-like preferences for linear representations of events.

Cross-cultural comparisons involving adults and school-aged children have revealed reliable differences in the orientation and direction of ordinal space-time mappings (e.g., Tversky, Kugelmass, \& Winter, 1991). The left-to-right (LR) mental timeline is robust in speakers of English and many other languages using an LR orthography, but speakers of languages that are written from right-to-left (RL), often construe of time in an RL line (e.g., Ouellet et al. 2010; Tversky, Kugelmass, \& Winter, 1991). Vertical associations between time and space have also been found in speakers of Chinese, which can be written top-to-bottom (TB) and also contains vertical time-space metaphors (e.g., Boroditsky, 2011). Many cultural and environmental sources of the MTL (and the analogous "mental number-line," MNL) have been posited. These include: reading/writing direction, space-time metaphor in language, exposure to artifacts such as calendars, counting-related practices, early visual experiences, and simply growing up in a community with existing space-time associations.

In contrast to purely cultural accounts, some theories contend that we have an innate predisposition to associate space and time. One such theory posits that space, time, and number rely on a single system for magnitude representation (Walsh, 2003). Consistent with the idea that language and social cues are not the sole sources of the MTL, infants and even neonates appear to make implicit associations between duration and spatial length (e.g., de Hevia et al., 2014; Srinivasan \& Carey, 2010). Going beyond a general magnitude account, others have argued that the ordinal structure of the MTL/MNL also has a neurophysiological and evolutionary basis, and may be LR by default (Chatterjee, 2001; Rugani et al., 2015).

Importantly, cross-cultural differences in the direction of the adult MTL indicate that, even if innate ordinal space-time mappings exist, they can be modulated by reading-writing behavior or other types of cultural conditioning. It is therefore difficult to pinpoint the developmental origins of the MTL, or to disentangle its potential biological or environmental causes, in adults populations with many relevant types of cultural knowledge.

Here, we explore when and how time-space mappings develop in a population whose exposure to cultural input is more limited: children. Because formal instruction in reading/writing and spatial tools for time often begins in the early school years, evidence of linear space-time associations in younger children might suggest these abilities are not critical to the formation of the MTL. The purpose of the current study is to test whether preschoolers already have a preference for visual representations of events depicted in conventional ordered lines. If so, this might suggest that the tendency to form mental mappings between time and space is not entirely culturally constructed.

Several prior studies argue that directional space-number associations are present in preliterate preschoolers (see Nuerk et al., 2015). For instance, English-speaking preschoolers spontaneously count objects from LR, while Hebrew speakers count from RL. Biases on purely spatial tasks such as line-bisection have also been observed in preschoolers. These effects are generally stronger in older children and adults. To the extent that both the MNL and MTL draw on similar spatial representations, we might expect to observe similarly early biases toward LR representations of time in English-speaking preschoolers.

Relatively few studies have investigated space-time mappings in preschoolers. Timeline tasks indicate that 4-year-olds can place events on an LR line more accurately than chance, but that this ability improves considerably over the next $3+$ years (e.g., Hudson \& Mayhew, 2011; Tillman et al., 2017). Importantly, tasks in which a single type of timeline is provided for children to use cannot address whether they privilege particular spatial orientations or directions. However, even without a template, a majority of school-aged children place stickers representing events in ordered lines with a culture-specific direction (e.g., LR for English-speakers; Tversky, Kugelmass, \& Winter, 1991).

In contrast to older children, preschoolers rarely place event-denoting stickers in lines spontaneously, and those who do so show a much more modest, if any, bias toward LR lines (Tillman, Tulagan, \& Barner, 2015). Similarly, older children, but not preschoolers, produce spatial representations of single events in which the agent, object, and recipient are linearly ordered in a culturally-conventional direction (Dobel, Diesendrunk, \& Bolte, 2007). Together, these studies suggest that the automatic deployment and the direction-specificity of the MTL develop slowly in early childhood, and may rely on literacy and/or formal schooling to become fully engrained.

Critically, tasks like those discussed above either require children to use sophisticated artifacts or to create visual representations of time, and therefore may require
significant visuospatial, motor, and working-memory skills. For instance, the sticker-placement task requires an ability to use non-iconic stickers symbolically, sufficient motor control to put them in specific spatial locations, and memory of what previously-used stickers represent. It is therefore possible that the difficulty of these tasks could have masked existing associations between time and space in preschoolers. To address this concern, the present study employs a forced-choice task with minimal response demands to test whether English-speaking preschoolers prefer conventional linear representations of time. Preschoolers were told brief stories describing three-step event sequences, given a choice between two spatial depictions of each story, and asked which of the two was better. In Experiment 1, to test whether children have direction preferences, they chose between (conventional) LR, RL, TB, and bottom-to-top (BT) representations of events. In Experiment 2, to test whether children were sensitive to the ordinality of the images, they chose between ordered and unordered sequences.

## 2. Experiment 1

### 2.1 Methods

2.1.1 Participants. Participants included 62 3-year-old children $(M$ age $=3 ; 6)$, 605 -year-old children $(M$ age $=$ $5 ; 5)$, and 85 adult controls. They were pseudo-randomly assigned to one of 3 conditions: Horizontal ( $\mathrm{n}=213 \mathrm{YO} ; 21$ $5 \mathrm{YO} ; 29$ adults), Vertical ( $\mathrm{n}=203 \mathrm{YO} ; 205 \mathrm{YO} ; 29$ adults), and Mixed ( $\mathrm{n}=213 \mathrm{YO} ; 205 \mathrm{YO} ; 27$ adults). Children were recruited from museums and daycares in the San Diego, CA, area, and adults were workers on Amazon Mechanical Turk. All participants spoke English as their primary language, and none spoke a secondary language with non-LR orthography. Adults and parents of children gave informed consent to participate. Children were awarded a small prize, and adults were compensated $\$ 1$. An additional 9 children were tested but excluded from analysis because either English was not their primary language ( $\mathrm{n}=3$ ), they spoke a second language with a non-LR orthography ( $\mathrm{n}=2$ ), they failed to complete the task $(\mathrm{n}=2)$, developmental delay ( $\mathrm{n}=$ $1)$, or clerical error $(\mathrm{n}=1)$. Five adults were excluded from analysis due to speaking a language with non-LR orthography $(\mathrm{n}=2)$ and lack of attention to the task, as indexed by failing a "catch" trial $(\mathrm{n}=3)$.
2.1.2 Procedure. On each of 8 trials, children heard a story involving 3 steps (see Table 1). The experimenter placed two cards on the table in front of the child, and asked: "Which card shows that story? Which one is better?"

Table 1. Event stories.

| Event | First. | Then.. | And.. |
| :--- | :--- | :--- | :--- |
| Egg | there was an egg | the egg cracked | a baby chick came out! |
| Ice Cream | there was an ice-cream | it started melting | and it was all gone! |
| Drawing | someone started drawing a stem | they added blue petals | it was a flower! |
| Caterpillar | there was a caterpillar | it made a cocoon | it turned into a butterfly! |
| Baby | a baby was born | he started growing | he was a big kid! |
| Apple | there was an apple | someone took a bite | they ate it all! |
| Rose | a rose started growing | it opened | it got big and pink! |
| Watermelon there was a watermelon | we cut it all up | everyone ate it! |  |

After the child pointed to their choice, the cards were removed, and the next trial began.

Participants in the Horizontal condition always chose between one card with three pictures depicting the story in order from left-to-right (LR; see Table 1 and Fig 1A) and another with the same 3 pictures ordered from right-to-left (Fig. 1B). Participants in the Vertical condition chose between cards with images arranged from top-to-bottom (Fig 1C) vs. bottom-to-top (Fig 1D), and, in the Mixed condition, between LR and TB lines (Fig. 1A vs. 1C). The two cards were placed side-by-side in the Vertical and Mixed conditions, but were positioned one above the other in the Horizontal condition. Every child heard the Egg story first. Half the children heard the remaining stories in the order listed in Table 1, and half heard them in the reverse order. The positioning of the two cards was counterbalanced across subjects and items. Adults read the stories on a computer, and clicked the image they thought was better. Data analysis was done using R and the lme 4 package.

### 2.2 Results

2.2.1 Horizontal condition. Participants in the Horizontal condition chose between LR and RL sets of images (e.g., Fig. 1A vs. 1B). To test for direction preferences, we calculated the percentage of trials on which each subject chose the LR card. As expected, virtually all adults ( $\mathrm{n}=28$ of 29) chose the LR card on every trial (Fig 2A). In contrast, the median percentage of LR choices for 5-year-olds was lower, at $75 \%$, and these children were less consistent across trials than were adults (see Fig 2A). The median percentage of LR picks by 3 -year-olds was $50 \%$. Exact Wilcoxon signed-rank tests confirmed that 3-year-olds' performance was consistent with random guessing ( $\mathrm{V}=24.5, p=0.5$ ), but five-year-olds selected the LR card significantly more often than chance $(\mathrm{V}=126.5, p=0.02)$.

Figure 1: Example picture cards. The three images on each card depict the three stages in the Egg story (see Table 1). Cards used in Experiment 1: (A) LR, left-to-right, (B) RL, right-to-left, (C) TB, top-to-bottom, and (D) BT, bottom-to-top. Additional cards used in Experiment 2: (E) Scrambled Horizontal and (F) Scrambled Vertical.
2.2.2 Vertical condition. Participants in the Vertical condition chose between TB and BT images (Fig 1C vs. 1D). As shown in Figure 2B, $90 \%$ of adults ( $\mathrm{n}=26$ of 29) chose the TB card on every trial. A subset of 5-year-olds

## A. Horizontal: LR vs. RL

Figure 2: Direction and orientation preferences. Histograms showing the number of subjects who picked the more conventional representation of time at each degree of consistency.
( $\mathrm{n}=9$ of 20) also showed a strong preference for TB cards, bringing the group median to $63.5 \%$, significantly higher than chance (Exact Wilcoxon signed-rank test, $\mathrm{V}=111, p=$ 0.02 ). The median response among 3 -year-olds was $50 \%$ TB, consistent with random guessing (Exact Wilcoxon signed-rank test, $\mathrm{V}=54, p=0.3$ ).

We next asked whether children's directional biases were stronger along one spatial axis than the other. In other words, did children have a significantly stronger preference for LR in the Horizontal condition than they had for TB in the Vertical condition? We used mixed-effects logistic regression to model the likelihood of a "conventional" choice (i.e., LR in the Horizontal condition; TB in Vertical) as a function of Age Group (3-year-olds vs. 5-year-olds) and Condition (Horizontal vs. Vertical). The model included the interaction of fixed effects as well as a random effect of subjects ${ }^{1}$. Examining this model, we found only a main effect of Age Group ( $\beta=0.65, p=0.01 ; \chi 2(1)=10.1, p=$ 0.002 ). The effect of Condition did not reach significance ( $\beta$ $=0.15, p=0.6 ; \chi 2(1)=0.4, p=0.5)$. Thus, the results

[^211]indicate that children have equally strong (or weak) directional preferences within the horizontal and vertical axes.
2.2.3 Mixed condition. Participants in the Mixed condition chose between (horizontal) LR- and (vertical) TB-ordered images (Fig. 1A vs. 1C). In contrast to their near-perfect consistency in the other conditions, only about half the adult sample ( $\mathrm{n}=12$ of 27 ) chose the LR card on every trial ( $\mathrm{n}=$ 12), resulting in a median response of $87.5 \%$ LR (Fig. 2C). In contrast, the median percentages of LR picks for both 3and 5 -year-olds were $50 \%$, consistent with random guessing (Exact Wilcoxon signed rank tests, $p$ 's $>0.05$ ).

Next, we asked whether children's likelihood of choosing the LR card was impacted by the orientation of the comparison set of images, by fitting a mixed-effects logistic model to data from the Horizontal and Mixed conditions. As predictors, we entered Age Group and Condition, their interaction, and a random effect of subjects. Examining the model, we found significant main effects of both Age Group ( $\beta=0.69, p=0.01 ; \chi 2(1)=9.9, p=0.01)$ and Condition $(\beta$ $=-0.51, p=0.02 ; \chi 2(1)=5.1, p=0.02)$, with no interaction. In other words, when given a choice, children chose LR more often than RL, but not more often than TB.

Together, the results of Experiment 1 suggest that directional linear associations of time emerge between 3 and 5 years of age, and that children's biases within spatial axes develop earlier than biases across axes.

## 3. Experiment 2.

When given choices between two ordinal representations of a story that had different directions, the majority of 3-year-olds in Experiment 1 did not demonstrate a preference. One explanation for this behavior is that, for 3-year-olds, all ordered series of images are equally compelling illustrations of stories. An alternative explanation is that 3 -year-olds simply did not attend to the relative ordering of the images on the cards. Experiment 2 tests this hypothesis.

Rather than choosing between two ordered sets varying in direction, children in Experiment 2 chose between one ordered set (either LR or TB) and one unordered set with the same orientation (horizontal or vertical). If children are sensitive to the ordinal relations among images, we would expect them to choose cards showing ordered temporal sequences (e.g., caterpillar-cocoon-butterfly) more often than cards showing scrambled sequences (e.g., caterpillar-butterfly-cocoon). On the other hand, if 3 -year-olds do not attend to the order of the pictures (in relation to the order of events in the story), we would expect the same pattern of results found in Experiment 1.

### 3.1 Methods.

3.1.1 Participants. Thirty-eight 3-year-olds ( $M$ age $=3 ; 7$ ) were recruited from daycares and museums in the Comox
valley, BC, and San Diego, CA, areas. Nineteen were assigned to the Scrambled Horizontal condition and 19 to the Scrambled Vertical condition. An additional 4 children were excluded because English was not their primary language $(\mathrm{n}=1)$, they spoke a second language with a non-LR orthography $(\mathrm{n}=2)$, and experimenter error $(\mathrm{n}=1)$.
3.1.2 Materials and procedures were identical to those used in the Horizontal and Vertical conditions of Experiment 1, except that each RL card was replaced with a Scrambled Horizontal card (Fig. 1E), and each BT card was replaced with a Scrambled Vertical card (Fig. 1F).

### 3.2 Results and Discussion.

3.2.1 Horizontal Scrambled condition. Figure 3A plots the distribution of children who chose the ordered (LR) card with each level of consistency across trials. The median percentage of LR choices was $50 \%$, again consistent with random guessing (Exact Wilcoxon signed-rank test, $\mathrm{V}=$ $52.5, p=0.3$ ).

Figure 3. Spatial ordinality preferences. Histograms showing the number of 3 -year-olds who picked the ordinal representation of time over an unordered one, at each degree of consistency.

To compare 3-year-olds' performance on the Horizontal Scrambled (Exp. 2) and unscrambled Horizontal (Exp. 1) conditions, we used a mixed-effects logistic model predicting the likelihood of an LR choice as a function of Condition (Horizontal vs. Horizontal Scrambled), with a random effect of subjects. The Condition factor did not improve the fit of the model over a null model $(\beta=0.23, p=$ $0.3 ; \chi 2(1)=1.0, p=0.3)$. Children were no better at choosing the LR card over an unordered sequence than they were at choosing LR over RL or TB in Experiment 1.
3.2.2 Vertical Scrambled condition. Results from the Vertical Scrambled condition are shown in Fig 3B. As in the Horizontal Scrambled condition, most 3-year-olds picked the TB card on $50 \%$ of trials, consistent with chance (Exact Wilcoxon signed-rank test, $\mathrm{V}=44, p=0.4$ ) and the addition of Condition (Vertical vs. Vertical Scrambled) as a factor did not significantly improve the fit of a model predicting children's likelihood of choosing the TB card $(\beta=0.36, p=$ $0.1 ; \chi 2(1)=2.5, p=0.1)$.

Together, the results of Experiment 2 suggest that 3-year-olds are insensitive to the ordinal relationships among images depicting temporal events.

## 4. General Discussion

We explored the development of mental associations between time and space, by asking whether preschoolers prefer visual representations of events that have a conventional linear structure (i.e., left-to-right for English speakers). Consistent with conventions in their culture, we found that 5-year-olds prefered depictions of events ordered from left-to-right to those ordered right-to-left. Furthermore, even though vertical artifacts for time are rare in their culture, 5 -year-olds prefered top-to-bottom representations of events to bottom-to-top ones. However, unlike adults, 5-year-olds showed no preference for horizontal (LR) over vertical (TB) depictions of events. Furthermore, younger preschoolers, 3-year-olds, not only appeared to lack direction or orientation preferences for ordered sequences, but also did not prefer ordered sets of pictures to unordered ones. Together, these findings suggest that children may not initially attend to the ordinal structure of event-depicting images, and that the "mental timeline" is constructed gradually in early childhood.

A substantial body of cross-cultural evidence indicates that the direction of mature linear mappings between time and space varies according to factors such as writing direction (e.g., Ouellet et al., 2015). A smaller number of studies indicate that these differences may emerge in childhood (Dobel, Diesendrunk, \& Bolte, 2007; Tillman, Tulagan, \& Barner, 2015; Tversky et al., 1991). The present study adds to this existing literature, by providing new evidence that cultural factors shape the direction of the mental timeline during childhood. Specifically, we found that preliterate 3-year-olds did not privilege conventional LR representations of time, and that LR biases appeared around age 5 , when literacy often begins to emerge ${ }^{2}$. Going beyond prior work, the current study also suggests that preliterate 3-year-olds may not map sequential temporal events to ordinal lines at all, regardless of the direction of those lines. If so, this suggests that both the directionality and the ordinal structure of the "mental timeline" are constructed during childhood, in response to increased environmental input.

The task used here was designed to give children more scaffolding for the formation of space-time mappings than previous studies have provided, while also making fewer response demands. In contrast to the classic sticker-placement task (Tversky, Kugelmass, \& Winter, 1991), for example, the present task did not require children to produce a spatial representation, or to recruit an implicit mental timeline "from scratch." Our task provided both the

[^212]temporal stimulus (a verbal story) and the spatial stimulus (images in lines) to be associated. The child simply needed to compare the two alternative mappings afforded by the two cards, and to pick the best match of temporal structure to spatial structure. However, given that 3-year-olds' performance in both experiments did not differ from chance, we cannot rule out the possibility that their failure stemmed from some less theoretically interesting incomprehension of the task. For example, it is possible that these children may have failed to recognize the images, or to remember the ordering of the three parts of the story. We are currently conducting a new experiment to test these possibilities.

Our findings are inconsistent with theories suggesting the LR direction of the MTL is a biological default that must be over-ridden to achieve an RL or TB mental timeline (Chatterjee, 2001; Rugani, 2015). Our findings also suggest that perceptual mappings between duration and length observed in infants cannot account for the ordinal MTL observed in adults and older children, in which positions in space (e.g., on the left) represent locations in time (e.g., in the past, see Winter, Marghetis, \& Matlock, 2015, for discussion). Several studies indicate that, if presented with a stimulus that is spatially "long" (e.g., a visual line) and temporally "long" (e.g., an auditory tone), prelinguistic infants associate these two dimensions automatically, and can detect mismatches between duration and length (de Hevia et al, 2014; Srinivasan and Carey). In contrast, preschoolers in the present study did not appear to align 3-part temporal sequences and analogous 3-part spatial representations. It is therefore possible that space-time associations in infancy apply only to temporal properties of single events, not to event sequences.

Our findings in 5-year-olds may also provide a hint into the process by which linear space-time mappings are shaped. In particular, we observed a developmental trajectory in which within-axis direction preferences (LR > $R L ; T B>B T$ ) emerged prior to a preference for one axis over the other. Can a literacy-based theory of MTL-acquisition account for this? In considering this question, it is interesting to note that English orthography has both a horizontal and a vertical component, with text progressing rightward across lines and downward through the page. Indeed, the vertical component of text may be more salient in children's books, which have fewer words per line than books for adults. Additional research will be needed to directly test whether children with more print exposure are more likely to make linear mappings between time and space - whether horizontal, vertical, or both.

# Computational Exploration of Lexical Development in Down Syndrome 

Angel Eugenio Tovar (eugeniot@comunidad.unam.mx)<br>Department of Psychology, UNAM<br>Avenida Universidad 3004, Ciudad Universitaria, Mexico

Gert Westermann (g.westermann@lancaster.ac.uk)<br>Department of Psychology, Lancaster University<br>Lancaster LA1 4YF, United Kingdom

#### Abstract

Research on lexical development in Down syndrome (DS) has emphasized a dissociation between language comprehension and production abilities, with production of words being relatively more impaired than comprehension. Current theories stress the role of associative learning on lexical development. However, there have been no attempts to explain the atypical lexical development in DS based on atypical associative learning. The long-term potentiation (LTP) and long-term depression (LTD) of synapses, underlying associative learning, are altered in DS. Here we present a neural network model that instantiates notions from neurophysiological studies to account for the disparities between lexical comprehension and production in DS. Our simulations show that an atypical LTP/LTD balance affects comprehension and production differently in an associative model of lexical development.

Keywords: Down syndrome; lexical development; associative learning; comprehension/production asymmetries; neurocomputational model.

Down syndrome (DS) is the most common genetic cause of intellectual disability. There has been extensive research in behavioral and neurophysiological sciences to understand how DS affects cognitive development.

One of the behavioral domains that has attracted particular attention in DS is language development, and specifically, lexical development. This is interesting because lexical development has been argued to be based on associative learning mechanisms (McMurray, Horst, \& Samuelson, 2012), while studies on the neurophysiology of DS have consistently described an altered mechanism for synaptic adaptation (Begenisic et al., 2014; Scott-McKean \& Costa, 2011) which lies at the core of associative learning. Nevertheless, the role of atypical associative learning in lexical development in DS has not been explored.

In this paper, we address this gap by describing a neurobiologically informed computational model that implements an altered associative learning mechanism described in DS to account for the atypical lexical development in DS. Our focus is on explaining an apparent dissociation between lexical comprehension and production in DS. We want to address to what extent this observed dissociation is based on general atypical associative learning mechanisms. Our hypothesis is that interactions between experience and the neurophysiological constraints of DS are
sufficient to account for the differences in performance between lexical comprehension and production in this population.

This hypothesis is in accordance with a domain-general view of cognitive development, where the process of associative learning is affected overall, but depending on the demands of the task (i.e., comprehension or production) the observed outcomes are qualitatively different. We test this hypothesis in our computational model of lexical development. Therefore, a second aim of this paper is to provide a computational model of atypical lexical acquisition, biologically informed.

## Lexical development in Down Syndrome (The Process)

Language development in DS, as in other developmental disorders, has attracted considerable attention for both theoretical and practical reasons. On the one hand, descriptions emphasizing a relatively greater impairment in language abilities in DS (Chapman \& Hesketh, 2000; Rice, Warren, \& Betz, 2005; Vicari et al., 2004) have motivated theoretical debate on the nature of language as a process resulting from a cognitive system with domain specific vs. domain general components (Marcus \& Rabagliati, 2006; Stojanovik, 2014; Thomas \& Karmiloff-Smith, 2005). On the other hand, there is interest in understanding atypical language trajectories in DS to develop better interventions and minimize dysfunction in these patients. Among the different domains of language development, in this review we focus on lexical development.

Lexical acquisition is traditionally studied through the number of words produced and number of words comprehended in a certain age range. These numbers are lower in DS when compared to typically developing children (TD) of the same chronological age, but the discrepancy between DS and TD diminishes when DS individuals are compared with TD children of the same mental age (i.e., level of non-verbal cognitive ability) (Galeote, Soto, Sebastián, Rey, \& Checa, 2012).

In DS it is commonly reported that language comprehension abilities exceed language production abilities (Galeote et al., 2012; Kay-Raining Bird, Chapman, \& Schwartz, 2004; Vicari et al., 2004). This pattern replicates a canonical finding in research of lexical development in TD: the number of words comprehended initially exceeds the number of words produced (McMurray
et al., 2012). However, critically, a number of studies have found that the discrepancy between the comprehension and production of words in DS is greater than expected on the basis of mental age, with comprehension at or near mental-age-typical levels, but production selectively impaired (Kay-Raining Bird et al., 2004; Vicari et al., 2004).

Some studies also suggest that production and comprehension of words in DS follow qualitatively different developmental trajectories (Chapman, Hesketh, \& Kistler, 2002; Galeote et al., 2012), with one study reporting that comprehension of words in DS even exceeded the level of non-verbal mental age (Glenn \& Cunningham, 2005). However, in contrast to these results, other evidence has suggested that in DS both expressive and receptive language are significantly more impaired than what is expected on the basis of mental age (Bello, Onofrio, \& Caselli, 2014).

Due to conflicting results it has been difficult to characterize a unique profile of cognitive and linguistic abilities in DS. High inter-individual variability in the DS population (Karmiloff-Smith et al., 2016), along with methodological constraints including small sample size and the use of different measures and procedures, may explain some disparities between studies. In an effort to analyze a larger sample of DS individuals in verbal skills, Næss and colleagues (2011) meta-analyzed data reported by different research groups between 1988 and 2009, and found that performance of children with DS is in line with TD children, matched by mental age, in receptive vocabulary but is significantly impaired in measures of expressive vocabulary.

A number of questions arise from this apparently uneven profile between lexical comprehension and production, and its failed predictability from the overall level of cognitive development: is lexical development in DS only delayed or deviated from the TD pattern? Is there a dissociation between lexical comprehension and production in DS? Is it possible to account for these results with a domain general approach?

## Lexical Acquisition and Associative Learning (The Theory)

There is a vast literature on lexical acquisition and the study of word learning is at the core of this field. Word learning is viewed as the process by which we learn to link a phonological representation with a category of objects. Word learning involves a sequence of complex processes; the learner faces the challenge of selecting discrete phonological representations, picking a specific object in a cluttered visual scene, and creating meaningful representations linking the sounds and the visual objects.

Attempts to explain how the cognitive system deals with such a complexity have been based on three theoretical accounts. First, under the lexical constraints account, word learning is guided by a set of default assumptions (i.e., constraints) on hypotheses (Woodward \& Markman, 1998). For example, the mutual exclusivity constraint describes the process of inferring which word corresponds with which
object on the basis of knowing already the names of the other objects present in the visual scene.

Second, the social-pragmatic account argues that children use cues such as the speaker's (e.g., caregiver) gaze or intention to learn the correspondences between sounds and objects (see Ambridge \& Lieven, 2011). Third, the associative learning account explains word learning as a process governed by the domain-general rules of learning. The focus is on the linkages created between sounds and objects without appealing to any other prerequisites such as lexical constraints or social cues, even when these can exert a modulatory role on word learning. In recent years, this account has been formalized and tested through computational models (Mayor \& Plunkett, 2010; McMurray et al., 2012, Westermann \& Mareschal, 2014). Computational simulations have provided precise descriptions on how the qualitative properties of lexical development, empirically observed, as is the initial asymmetry between comprehension and production, the vocabulary spurt, and mutual exclusivity, emerge in a system that operates by establishing associations with language-like inputs (e.g., McMurray et al., 2012).

In this paper, we focus on analyzing the disruptive effects that atypical mechanisms of associative learning have on word learning for the DS population. For this reason, our approach is based on the model proposed by McMurray, Horst and Samuelson (2012), we call this the MHS model from here on. We selected this model for the following reasons: first, the theoretical account underlying this model distils the process to its basic computational components and develops an approach focused on the role of associative learning, and this is convenient for our purpose of analyzing atypical forms of associative learning on lexical development. Second, the architecture of this model is well suited to incorporating our computational formalization of biological descriptions of atypical learning in DS. Third, by building on previous work, we extend this previous and well accepted model to account for atypical behavior and in this extension (in terms of behavior, and populations) additional evidence is provided for the associative account of word learning.

## Associative Learning in Down Syndrome (The Underlying Mechanism)

From a neurobiological perspective, associative learning results from the adaptation of synaptic connections between neurons. Such adaptations are activity dependent; following Hebbian descriptions high co-activation between pre- and post-synaptic neurons lead to a strengthening of the synaptic connection. Complementary to the Hebbian account, empirical research has shown that decays in the efficacy of synaptic connections are also triggered by the co-activation between the pre- and post-synaptic units. A co-activation threshold is assumed to exist (Bienenstock, Cooper, \& Munro, 1982) so that below-threshold co-activation values produce decays in the synaptic efficacy (i.e. long-term depression or LTD) and above-threshold co-activation
values lead to increase the synaptic efficacy (i.e., long-term potentiation or LTP).

A vast literature on the biological bases of associative learning in DS has described an atypical balance between LTP and LTD in different mouse models of this syndrome. When compared with euploid control mice, LTP is limited and LTD is increased in DS (Begenisic et al., 2014; ScottMcKean \& Costa, 2011; Siarey, Villar, Epstein, \& Galdzicki, 2005). This pattern of synaptic adaptation functionally corresponds with an increased co-activation threshold, where the same level of stimulation produces limited gains and increased decays in the connection strengths in DS relative to TD. An increased co-activation threshold has been proposed for other populations that show cognitive impairment (Meredith \& Mansvelder, 2010).

While considerable progress has been made in the study of LTP/LTD in DS, with an emphasis on the design of pharmacological interventions (e.g., Begenisic et al., 2014), building the bridge from the basic level of altered neurophysiology to the high level of cognitive function has seen less progress. For example, it is not clear what is the role of the altered LTP/LTD balance on language development in DS. Descriptions of the exact way by which biological differences contribute to language impairments in different populations (e.g., TD, Williams syndrome, fragile X syndrome) will inform us on what is common across populations, the nature of language impairments, and how the language capacity is vulnerable (Rice et al., 2005).

Given the evidence from two fields of research, one informed by behavioral studies suggesting a preserved and marked asymmetry between comprehension and production of words, and another informed by neurophysiological studies describing an altered mechanism for associative learning, and in the context of an associative learning account to word learning, in this paper our focus is on exploring, the role of atypical associative learning mechanisms in word learning in DS.

## Computational Model

Overview and Architecture The present model is based on the MHS model. It is designed to analyze the role of associative learning in the establishment of correspondences between auditory word forms and visual objects. In the following, we describe our model and we indicate the differences between the present model and the MHS model.

The present model is composed of a neural network with three layers of units. Two of these layers represent processing in the auditory and visual systems. These layers are used to present input patterns to the network and to collect responses. These layers are not directly connected with each other; instead they are indirectly connected through a third layer of "lexical units" (see Figure 1).

One assumption of this approach is that the auditory and visual systems can already categorize objects and select discrete elements from the environment. The units in the visual and auditory layers are localist; each unit represent only one stimulus.

Figure 1: Architecture of the neural network with the visual, auditory and lexical layers. Only a few connections are shown to represent connectivity from auditory and visual units to lexical units.

The auditory and visual layers have 40 units each. Thus, 40 is the total number of words that the network is able to learn. The lexical layer contains 100 units. There are more lexical units than would be needed to learn 40 words -this allows for better learning (McMurray et al., 2012). Since the model could initially randomly associate two different inputs with the same lexical unit, increasing the number of lexical units prevents mismappings and increases discrimination of words (McMurray et al., 2012).

The architecture of the model is similar to the one presented by McMurray and colleagues (2012), but a key difference is in the number of units. The MHS model has 35 input units in the auditory and visual layers, and 500 lexical units. Our model incorporates more input units and fewer lexical units; thus our model requires less computational power to simulate the learning of a higher number of words.

Each unit in the input layers is connected to all the units in the lexical layer. These connections are bidirectional and their weights are initially randomized. In the MHS model, connections are not functionally bidirectional, since they use a different temperature parameter for feed-forward and feed-back connections.

Activation values of units range between 0 and 1. The activation values of the lexical units are initially normalized, such that the sum of all activation values equals 1 . When an auditory or visual stimulus is presented to the input layers, the unit that represents this stimulus is activated with a value of 1 , and all remaining inputs are set to 0 . The activation flows through the connections and reaches the lexical layer, which then computes the net input as the sum of activations coming from the auditory and visual inputs weighted by the corresponding connection values. The activation values in the lexical layer then go through a process of normalization (Equation 1), during 7 cycles. In our model 7 cycles are optimal to stabilize 100 lexical units. It is not clear how many cycles the MHS model requires.

$$
\begin{equation*}
a_{i}^{(t+1)}=\frac{\left(a_{i}^{(t)}\right)^{2}}{\sum_{i}^{N}\left(a_{i}^{(t)}\right)^{2}} \tag{1}
\end{equation*}
$$

The activation of the lexical units then feeds back to the auditory and visual layers; these units then sum the net input coming from the lexical layer with the activation from direct stimulation. This process allows integration of bottom-up with top-down information. Then, the connection weights are updated according to the rule described below.

Learning The MHS model incorporates a Hebbian learning algorithm that strengthens connections between co-acvtive units. The decay terms in the MHS model weaken the connections when either the lexical-, or the input units are inactive. In our model, the learning algorithm is designed to capture the functional differences in synaptic adaptation between TD and DS, as informed by studies with mouse models. Thus, both strengthening and weakening of connections result from the co-activation of units. Our algorithm incorporates a co-activation threshold ( $\theta$ ). Those co-activation values that surpass $\theta$ lead to gains in the connection weights, and co-activation values below $\theta$ lead to decays in connection weights. The simulations of DS use a relatively higher value for $\theta$ than simulations of TD (i.e., $\theta$ $=0.9$ for DS and 0.7 for TD). Higher values of $\theta$ restrict connection strengthening and increase connection decay; in this way we simulate the atypical pattern of increased LTD and limited LTP that has been described in DS.

To stabilize changes in connection weights we also include a self-adjusting parameter called lambda ( $\lambda$ ). It keeps weights between 0 and 1, by reducing changes as weights approach 1. As shown in Equation 2, for above- $\theta$ values, $\lambda$ depends on the difference between the coactivation and the current connection weight. It is computed by subtracting the value of the current weight from the current co-activation. For below- $\theta$ values, lambda acquires a negative value proportional to the current weight.

$$
\begin{gather*}
\text { If }\left(a_{\mathrm{i}}^{*} * \mathrm{a}_{\mathrm{j}}\right)>\theta, \text { Then } \lambda=\left(\mathrm{a}_{\mathrm{i}} * \mathrm{a}_{\mathrm{j}}\right)-\mathrm{W}_{\mathrm{ij}}  \tag{2}\\
\text { Else } \quad \lambda=-\mathrm{W}_{\mathrm{ij}}
\end{gather*}
$$

Lambda is a multiplicative parameter in the final learning algorithm (Equation 3).

$$
\begin{equation*}
\mathrm{W}_{\mathrm{ij}}(\mathrm{t}+1)=\mathrm{W}_{\mathrm{ij}}(\mathrm{t})+\lambda \beta\left(\mathrm{a}_{\mathrm{i}} * \mathrm{a}_{\mathrm{j}}\right) \tag{3}
\end{equation*}
$$

Changes in weights $\left(\mathrm{W}_{\mathrm{ij}}\right)$ then depend on the co-activation value ( $\mathrm{a}_{\mathrm{i}} * \mathrm{a}_{\mathrm{j}}$ ) modulated by the interaction between the current state of the connection and the co-activation computed by $\lambda$, and a learning rate ( $\beta$ ). We ran two sets of simulations for DS. In the first set (DS-1) we used a relatively lower $\beta$ in DS compared to TD simulations to capture additional neurophysiological abnormalities in DS with impact on computing power, namely, a reduction of synapse density and inhibitory predominance (Dierssen,
2012). In the second set of simulations of DS (DS-2) we kept the same value $\beta$ as the one used in TD. We did this to be able to compare and explore the effects of an increased $\theta$ alone vs. increased $\theta$ and lower $\beta$. $(\beta=0.001$ for TD and DS-2; and $\beta=0.0005$ for DS-1).

## Simulations

Training One auditory object was presented during each training trial along with many visual objects (usually five). These presentations simulate natural scenes where, in a discrete moment, one auditory word form is presented (spoken) to the child in the presence of a cluttered visual scene. For example, the first time a child hears the word /cat/, she can observe a visual scene that contains a cat, but also contains a dog, a container with milk, a ball of yarn, etc. Thus, the word /cat/ could initially refer to any of these visual objects. This problem of referential ambiguity needs to be solved by the child across many trials. Let's consider a second trial when the word /cat/ is presented again, but now the visual scene contains the cat, the container with milk, a pillow, and a table. If the child is sensitive to the environmental regularities, across many trials she will learn the correct correspondences between auditory words and visual objects (Smith \& Yu, 2008). But this is a slow process that requires numerous trials. To capture this process, in our simulations, each time that an auditory word was presented, the correct visual object was presented with another 4 different visual objects. The additional visual objects changed for every trial. We simulated the learning of 40 words, by presenting each auditory-visual pairing a total of 20000 times.

Testing We presented trials to evaluate comprehension and production of words. Tests for comprehension were designed, as in the MHS model, to simulate a traditional test of lexical comprehension, The N -alternative forced choice, where a number of different visual objects are presented to the child and she is asked to point or select one in particular (e.g., where is the pencil? which one is the pencil?). In our simulations one auditory stimulus (e.g., pencil) was active, as well as 4 visual objects (e.g., pencil, cat, table, glass) in the visual layer. Activation flowed from inputs to the lexical layer and back. Then the unit in the visual layer with the highest activation (e.g., pencil) was taken as the response of the model. In this way, comprehension was conceptualized as the correct activation of the visual object in the presence of one particular auditory word form.

Following again simulations in the MHS model, tests for production of words were designed to simulate the "child says" measures of the MacArthur-Bates Communicative Development Inventory. In these trials one single visual object was active and all possible auditory word forms were active. Activation flowed from inputs to the lexical units and back, then the auditory unit with the highest activation value was taken as the response of the model. Production then corresponded to evaluating the activation of auditory word forms in the presence of a particular visual object.

The comprehension and production test trials were run after every 50 training epochs (each epoch was composed of the presentation of the 40 training trials). A total of 400 measures of comprehension and production were obtained for each simulation. We ran 20 simulations of TD, 20 of DS-1 and 20 of DS-2.

## Results and Discussion

Figure 2 shows the mean values of words comprehended and produced for TD, DS-1, and DS-2. The standard deviation values are shown in the error bars (gray areas).

Our simulation of TD (Fig. 2A) shows that comprehension surpassed production in the early stages of learning; then, from the test trial 51 until the end of the simulation, comprehension and production were matched, and show complete learning of vocabulary.

The simulations of DS-1 and DS-2 (Fig. 2 B and C) show a qualitatively different trajectory of lexical acquisition. Some aspects shown by these simulations are of particular interest in the context of our theoretical and empirical review. First, performance in the comprehension task is always above the performance in the production task. Moreover, production of words never reaches the maximum possible value of 40 words. Second, DS-1 is more affected than DS-2. DS-1 used a higher co-activation threshold with a lower learning rate, while DS-2 used the higher coactivation threshold with a high learning rate. Data from DS-2 suggests that the atypical synaptic learning process in DS has a direct consequence on lexical development on its own, and the difference between DS-1 and DS-2 suggests that the learning rate has an additional effect. Third, the standard deviations show that the performance in the DS

groups was more variable than the performance in TD. DS-1 showed the highest variability. These patterns replicate the high inter-individual variability usually observed in DS compared with TD (see Karmiloff-Smith et al., 2016).

Comprehension and production tests were different tasks in our simulations. Comprehension required the selection of a visual stimulus from a sample of a few objects, while production, a more demanding task, required the selection of an auditory stimulus from the total number of auditory word forms. These tasks were designed to reproduce the top-down and bottom-up interactions that a child processes when she produces names vs. when she comprehends auditory words. Then, in our model, the asymmetries between comprehension and production are (partially) explained by the properties of the tasks. Remarkably, the disparity between comprehension and production in TD was overcome as training continued, but this disparity persisted for the DS simulations, thus pointing to the atypical associative learning mechanism as an explanation for the persistence and more marked disparity between comprehension and production of words in DS.

Other factors may as well contribute to the lexical comprehension/production asymmetry in DS, such as an atypical physical development that affects correct articulation of words and therefore restricts experience with lexical production. Our model, however, shows that the atypical pattern of synaptic strengthening directly affects lexical development.

Our approach supports a domain-general view of cognitive development, and we argue that it also strengthens the associative learning account to lexical development, since it explains a pattern of uneven development of lexical abilities in Down syndrome as a result of an altered domain-

Number of Test Trials

# The temporal dynamics of base rate neglect: People may not be intuitive statisticians after all 

Eoin Travers<br>Institute of Philosophy, University of London<br>Jonathan J. Rolison<br>Department of Psychology, University of Essex<br>Aidan Feeney<br>School of Psychology, Queen's University Belfast

#### Abstract

According to a classic view of reasoning, intuition is fast but fallible, while reflection is slow but reliable. Biases, therefore, emerge when a reasoner's intuitions are wrong and they fail to notice. Recent evidence, however, suggests that people may be aware when their intuitions are incorrect. A possible explanation reason for this is that both correct and incorrect responses are cued in parallel, but the strongly-cued incorrect response is given unless people can inhibit it. We tested this explanation using base rate neglect problems, and recorded participants' mouse cursor movements as they chose between possible answers under time pressure. Descriptions affected both participants' early movements and ultimate responses, and interfered with their use of the base rates, while base rates rarely interfered with participants' use of descriptions, and then only at a later point in time. Thus, despite suggestive findings elsewhere, our results support the classic of view reasoning.

# Promoting Spontaneous Analogical Transfer by Idealizing Target Representations

#### Abstract

Recent results demonstrate that inducing an abstract representation of target analogs at retrieval time aids access to analogous situations with mismatching surface features (i.e., the late abstraction principle). A limitation of current implementations of this principle is that they either require the external provision of target-specific information or demand very high intellectual engagement. Experiment 1 demonstrated that constructing an idealized situation model of a target problem increases the rate of correct solutions compared to constructing either concrete simulations or no simulations. Experiment 2 confirmed that these results were based on an advantage for accessing the base analog, and not merely on an advantage of idealized simulations for understanding the target problem in its own terms. This target idealization strategy has broader applicability than prior interventions based on the late abstraction principle, because it can be achieved by a greater proportion of participants and without the need to receive target-specific information.

Key words: analogy, transfer, idealization, retrieval

## Introduction

Analogical reasoning represents a powerful heuristic for creative problem solving. By matching an unsolved situation (the target analog) to a stored exemplar whose solution is known (the base analog), the base solution can be transferred to the target problem. One of the most robust findings in the experimental literature on analogical transfer is that people often fail to spontaneously retrieve analogous situations when they do not share surface features with the target situation being processed (Gick \& Holyoak, 1980; Keane, 1987; Trench, Oberholzer, \& Minervino, 2009, for a discussion of naturalistic findings, see Trench \& Minervino, 2015).

A considerable body of research has sought to enhance spontaneous analogical retrieval by means of promoting a more abstract encoding of the base analogs, so as to render them more accessible during later encounters with analogous situations lacking surface similarities with the base analogs. Two successful interventions have consisted in presenting the base analog together with its abstract schema (Goldstone \& Wilensky, 2008) or with a second analogous situation
(Catrambone \& Holyoak, 1989), and asking participants to compare them. More stripped-down interventions include asking participants to discuss the base analog with another student (Schwartz, 1995), to explain the problem to themselves (Ahn, Brewer, \& Mooney, 1992) or to construct a structurally equivalent problem (Bernardo, 2001). Even if participants are not asked to elaborate on the base situations, transfer advantages can still be obtained by means of removing irrelevant information in the base analog (Goldstone \& Sakamoto, 2003), and even by replacing domain-specific terms of the base situation with domaingeneral ones (e.g., replacing "typing" by "writing", Clement, Mawby, \& Giles, 1994). What all of these interventions have in common is the highlighting of the abstract structure of the base analogs. As future, relationally similar examples will have a stronger match with such stripped-down representations than they will with specific examples having surface features that mismatch, the future retrievability of relationally encoded base analogs increases. Despite the relative success of these interventions, they cannot be applied to already learned situations or procedures that had not been originally encoded in ways that highlighted their abstract structure.

## The late abstraction principle

Kurtz and Loewenstein (2007) reasoned that as retrieval depends on the degree of match between the stored items and the memory probe, the beneficial effect of relational schemas should also apply when elaborating on the target analog at retrieval time. The removal of lower-level information was hypothesized to increase distant retrieval (1) by granting more weight to structural predicates due to the normalization of content vectors, and (2) by reducing the unwanted activation of competing situations that maintain only superficial similarity with the target. To gather behavioral evidence for this theoryladen prediction, Kurtz and Loewenstein (2007, Experiment 1) assessed the effectiveness of an intervention that consisted in providing participants with a second (unsolved) problem that was isomorphic to the target problem to be solved, and asking them to compare both problems prior to attempting their solution.

As was the case with the "base comparison" interventions, the abstraction process induced by this "target comparison" procedure resulted in enhanced transfer of the base solution as compared to the standard base-target paradigm. In subsequent work, Gentner, Loewenstein, Thompson and Forbus (2009) generalized the benefits of the target comparison strategy to autobiographical memories that were acquired several years prior to the experimental session, and also simulated the process of backward transfer using a retrieval algorithm and a set of stories that were developed before the late analogical encoding hypothesis had been proposed. To carry out these simulations, Gentner et al. (2009) fed MAC/FAC (Forbus, Gentner, \& Law, 1995), with either the original stories from the Karla the Hawk series of studies (Gentner, Rattermann, \& Forbus, 1993) or with their respective abstract schemas, and had it run on a long-term memory comprising analogical matches, mere appearance matches, and several filler stories. In line with the target-comparison studies, MAC/FAC retrieved more analogical matches when using the schemas rather than detailed stories as working memory cues.

As suggested by the results of the target-comparison studies, the process of late analogical abstraction opens a promising avenue for retrieving base situations whose initial encoding was not especially engineered to highlight their abstract properties, and which represent the vast majority of the situations we learn within and outside instructional settings. In contrast to the widespread potential applicability of the late analogical abstraction principle, however, the specific targetcomparison intervention falls short of representing a truly portable cognitive strategy because participants will depend on the external provision of a second analogous problem for every new target problem they are to solve.

With the aim of helping learners capitalize on late analogical abstraction without needing to be provided with additional information about the target, Minervino, Olguín and Trench (2017) demonstrated that analogical transfer from a distant source analog can be enhanced by asking participants to invent a new unsolved problem analogous to the target. Even though successful problem constructors were much more likely than unsuccessful constructors to transfer the base solution to the target problem, only a small proportion of participants succeeded at fabricating an analogous problem, an activity that seems to require a great deal of worldknowledge and above-average intellectual engagement.

In order to devise more widely applicable ways of capitalizing on the late abstraction principle, in the present study we identified an easily executed strategy credited with having enhanced the retrievability of base analogs during their initial encoding, and assessed whether its application to the target analog proves advantageous for retrieving analogous problems lacking surface similarities.

## Concrete vs. idealized representations

Goldstone and Sakamoto (2003) examined whether there was an effect of training with concrete or idealized graphics on spontaneous transfer of a general principle called "competitive specialization." Participants were trained with
an Ants and Food simulation with concrete graphics (black ants and small fruit) or idealized elements (black dots and green blobs) as shown in Figure 1. Afterwards they were asked to explore another instance of the competitive specialization principle in which initially undifferentiated matrices progressively learn to respond to a predefined set of letter inputs. Results revealed that participants in the idealized condition showed better transfer to the Sensors and Inputs quiz than in the concrete condition.

Figure 1. Snapshots of the concrete and idealized simulations of base analogs employed by Goldstone and Sakamoto (2003).

In order to assess whether a comparable transfer advantage can be obtained by inducing a more idealized representation of the target analog at retrieval time, we had three groups of participants learn how to solve a "collision" problem in which a plane and a helicopter travelled towards each other at different speeds. After a distracting task, participants were presented with a problem pertaining to a different family of algebra problems (i.e., "work problems"), but whose abstract structure was similar to that of the learned problem. In this problem, participants had to calculate the time that two painters would need to jointly paint a wall, given the times that each of them would have needed to paint it on his own. Before being asked to actually solve the problem, two of the groups were presented with a set of manipulatives and were tasked with carrying out an approximate representation of the situation described by the target problem as it unfolded from the initial moment until the moment when the wall got completed. While participants in the concrete condition received a realistic illustration of a horizontally laden wall and two smaller rectangles printed with drawings of painters, participants in the idealized condition received similarly sized paper rectangles without any figurative illustrations.

## Experiment 1

## Method

Participants and design A total of 90 participants were recruited from the Department of Psychological and Brain Sciences participant pool at Indiana University-Bloomington. All participants signed an informed consent for participation in the study, and were compensated with course credit. An equal number of participants $(N=30)$ were randomly assigned to the idealized, the concrete, and the no simulation conditions.

Procedure and materials The experimental session was introduced to participants as dealing with the effectiveness of instructions for solving different kinds of algebra problems. Participants were told that for most of the problem types to be covered during the session, they would begin by trying to solve a problem of such type on their own, follow by reading instructions on how to solve such problem, and finish by applying the learned strategy to a subsequent problem of the same type. Unbeknownst to participants, the first block served to encode a base analog and its solution, the third block was used as a test of whether participants spontaneously applied the base solution to a seemingly unrelated problem that admitted a similar solution strategy, and the middle block served to contextually separate the first and third blocks. Upon receiving a booklet containing the materials, they were told that they would be informed in advance how much time they would have for carrying out each of the tasks, and that they could only proceed to the following page of the booklet once the experimenter had notified them that the allotted time for the current activity had elapsed. Participants were also provided with a pencil, an eraser, and an electronic calculator. The session was administered in small groups ranging from one to ten, with each participant working individually.
During the first block of problems (i.e., the encoding phase), participants of all groups were presented with a typical "collision" problem in which a plane and a helicopter initially located at two cities 2000 miles apart started travelling towards each other at different speeds (See Table 1). Participants were allotted 5 min to calculate the time the aircrafts would need to pass next to each other. Once the allotted time had elapsed, they were given 3 min to read a worked solution to such problem that included a standard illustration in which the plane and the helicopter were located at their respective cities A and B , which were in turn connected by a straight horizontal line. Participants were given 4 more min to apply the learned strategy to a similar problem in which a helium balloon and an elevator located at the top vs. bottom of a tall building begin travelling toward each other at different speeds (see Table 1). Given that achieving a basic understanding of the base problem and its solution represents a necessary prerequisite for subsequent transfer to occur, participants who failed to apply the base solution to this second problem were withdrawn from further analysis.

Table 1: Base and target problems used in Experiment 1

Base problem: A plane flies at 600 mph , while a helicopter flies at 100 mph . Imagine that the plane starts flying from City A to City B at the same time that the helicopter departs from city B to City A. How long will it take them to pass each other, if the cities are 2000 miles apart?
Base problem 2: While a helium balloon goes up at a speed of 2 feet per second, an external elevator travels at a rate of 4.5 feet per second. Suppose that the elevator starts descending from an altitude of 100 feet at the same moment that the balloon is freed from street level. How long will it take them to pass each other?
Target problem: Fred can paint an 18 -feet wall in 8 hours, while Bob can paint such wall in 5 hours. How long will it take
them to paint such wall in case they painted it together?

The second block of problems had the same structure and time allowances as the encoding phase, with the difference that it involved learning and applying a simple procedure for solving combinatorics problems that were unrelated to the prior problems. It thus served to contextually separate the encoding and transfer phases.
The third section (i.e., the transfer phase) was presented to participants of all groups as dealing with "work" problems, and had a different structure than the two previous phases. For brevity, we begin by describing the procedure followed by the concrete simulation group, and proceed by describing how the other conditions differed from such condition.

Participants of the concrete simulation condition received a typical work problem in which they had to calculate the time that two painters would need to jointly paint a wall, given the times that each of them would have needed to paint it on his own (see Table 1). They were given 2 min to read the problem very carefully, but they were asked to refrain from attempting a solution until explicitly indicated by the experimenter. Right below the problem text, the page displayed a 6.37 in $x$ 1.84 in sized illustration of a brick wall printed in greyscale. Upon receiving two small paper rectangles each one illustrated with a figurative drawing of a painter (one grey and one black, see Figure 2), participants were asked to take advantage of these manipulatives to carry out an approximate representation of how the painting of the wall unfolds over time, from the moment the painters start their job until the moment when it gets completed. In order to get a record of the specifics of each participant's simulation, the next page included three similar walls meant to represent three different snapshots of the dynamic simulation they had just performed. Upon receiving four additional paper painters (two grey and two black) and a glue stick, they were allotted 2 min to produce a record of the simulation they had just performed by means of sticking two painters onto each wall in a manner faithful to the locations of each of the painters at three different moments: (1) at the exact moment when they started painting [top wall], (2) at an intermediate stage of the process [center wall], and (3) at the exact moment when the painting job was completed [bottom wall]. Once the time allotted to this activity had elapsed, participants were given 5 min to solve the problem by any means.

The procedure followed by the idealized simulation group was identical to that of the concrete simulation condition, with the difference that the manipulatives used during the simulation were relatively more abstract. While the wall consisted of a white 6.37 in $x 1.84$ in sized rectangle, the two painters were represented by 1.6 in $x 0.75$ in sized grey/black paper rectangles.
The procedure followed by the no simulation group was identical to that of the simulation conditions, with the difference that participants were not asked to simulate the situation models of the target problem prior to attempting its solution.

Figure 2: Manipulatives employed for the idealized (top panel) and concrete (lower panel) representations of the target problem.

Data analysis Two independent judges sorted the solutions to the posttest (the "collision" problem featuring a balloon and a helicopter) as either correct or incorrect. Solutions were scored as "correct" whenever (1) the collision time obtained was expressed with at least one decimal position and coincided with the exact solution, and (2) the participant showed how such result was derived. Eight participants (five from the concrete simulation condition, three from the no Simulation condition and one from the idealized Simulation condition) were not able to apply the base solution to the balloon problem, and were thus removed from further analyses. Two additional judges blind to the purposes of the experiment followed the above criteria to score participants' solutions to the target problem. Judges reached $94 \%$ agreement regarding solutions to the balloon problem and $96 \%$ agreement regarding solutions to the target problem. Cases of disagreement were resolved by discussion.

## Results and Discussion

The rates of correct solutions to the target problem were $36 \%, 79 \%$, and $51 \%$ for the concrete, idealized and no simulation conditions, respectively. The spontaneous transfer rate in the idealized condition was reliably greater than those obtained in the concrete, $\chi^{2}(1, N=54)=10.43, p=.0012$, and in the no simulation conditions, $\chi^{2}(1, N=56)=4.7, p=.0302$.

The rates of spontaneous transfer did not differ between the concrete and the no simulation conditions, $\chi^{2}(1, N=52)=1.32$, $p=.2506$ These results indicate that idealized representations were more advantageous than concrete representations for eliciting correct answers to the work problem. On the other hand, the fact that the idealized simulation condition also outperformed the no simulation condition suggests that there are genuine benefits of idealization as opposed to disadvantages due to concrete representations.

In a manner similar to the transfer advantage of comparing two analogous targets (Gentner et al. 2009), the observed advantage of the Idealized Simulation Group in generating correct solutions suggests that there is a general advantage of lean representations for accessing analogous situations lacking superficial similarities with the target. However, an alternative explanation could be that the concrete representations of the painters might have invited a dynamical representation that was inconsistent with the "convergent" representation that characterized the base problems. If the concrete simulation of the painters' activity recruited a "socially laden" representation in which the painters advance in parallel fashion-e.g., to talk to each other-rather than in the more transfer-appropriate "converging" motion, this idiosyncratic accidental feature could have contributed to their inferior transfer performance. In order to assess this possibility, we sorted participants' representations as "convergent" vs. "non convergent" according to the way in which they had glued the painters onto the three walls that were meant to record three informative snapshots of how participants intuitively imaged the process as it unfolded over time. This analysis revealed a nonsignificant trend towards a greater use of the convergent representation in the concrete simulation condition (96\%) than in the idealized simulation condition (76\%), $p=.056$ (Fisher exact test). Given that the opposite trend would have been expected under the socially-laden interpretation account, the relative advantage of idealized simulations appears not to be due to an intrinsic advantage this kind of representations for prompting a convergent motion simulation.

Another alternative explanation for the superiority of target representations for eliciting correct solutions to the work problem could be that such advantage was originated, not in the benefits of our idealized materials for analogical transfer (as posited here), but rather in their potential to promote a better understanding of the target problem in its own terms, thus leading to a higher probability of solving such problem by first principles. According to various authors (see Belenky \& Schalk, 2014 for a discussion) learning is facilitated when representations convey the minimum detail that is necessary to grasp the quantitative structure of a problem. As an example, the removal of potentially distracting irrelevant features like the quasi-regular pattern of the bricks or the left vs. right handedness of the painters could have helped participants build a more accurate representation of the temporal dynamics of the problem (e.g., the different speeds of each painter), which may in turn serve as a secure foundation from which to control the accuracy and soundness of algebraic manipulations (Minervino, Trench, \& Oberholzer, 2009).

In order to assess how the concrete and idealized simulations enforced in Experiment 1 impacted the raw probabilities of solving the target problem in a non-analogical fashion, in Experiment 2 the transfer phases of the idealized, concrete and no simulation conditions were not preceded by the presentation of a structurally equivalent base analog.

## Experiment 2

## Method

Participants and design A total of 90 participants ( $N=30$ per condition) were recruited from the Department of Psychological and Brain Sciences participant pool at Indiana UniversityBloomington, and were compensated with course credit.

Procedure and materials The experimental session was introduced to participants as dealing with the effectiveness of different instructional aids for solving algebra problems, and took place after participants completed an unrelated experiment whose length was roughly equivalent to the time taken by participants of Experiment 1 to complete the encoding plus distracter phases. Upon receiving a booklet containing the materials, they were told that they would be informed in advance how much time they would have for carrying out each of the tasks, and that they could only proceed to the following page of the booklet once the experimenter had notified them that the time allotted to the current activity had elapsed. Participants were also provided with a pencil, an eraser, and an electronic calculator. The session was administered in small groups ranging from one to ten, with each participant working individually.
Participants of the simulation conditions received the painters' problem coupled with the same manipulatives and the same simulation tasks as in the corresponding groups of Experiment 1. After completing the simulation tasks, they were given 5 min to try solving the problem by whatever means. The procedure followed by the No Simulation Group was identical to that of the simulation conditions, with the difference that participants were neither provided with manipulatives nor invited to simulate the situation model of the problem prior to attempting its solution. Coding of correct solutions followed the same criteria as in Experiment 1, with judges reaching total agreement.

## Results and Discussion

The rates of correct solutions to the target problem were $37 \%$, $30 \%$, and $33 \%$ for the concrete, idealized and no simulation conditions, respectively. The rate of correct solutions in the idealized condition did not differ from that obtained in the concrete condition, $\chi^{2}(1, N=60)=0.3, p=.5839$. Similarly, differences were neither found between the no simulation and the idealized simulation conditions, $\chi^{2}(1, N=60)=0.08, p=.7773$, nor between the no simulation and the concrete simulation conditions, $\chi^{2}(1, N=60)=0.07, p=.7913$. The fact that the rate of correct solutions obtained by the Idealized Simulation Group was not even numerically higher than those of the concrete and the no Simulation conditions (in fact it was slightly lower) confirms that the advantage of idealized simulations over the
other conditions of Experiment 1 did not originate in their ability to promote a better comprehension of the target problem, but rather in an advantage for transferring a previously learned solution to a superficially dissimilar target.

## General Discussion

The present results are compatible with Gentner et al.'s (2009) late abstraction principle, which postulates that just as source abstractions can be beneficial for later analogical retrieval (i.e. forward transfer), manipulations aimed at highlighting the structure of the target can enhance the retrieval of superficially similar base analogs whose encoding was not intended to emphasize their structural features. It should be noted, however, that the perceptual nature of our concrete vs. idealized manipulation is very different from the "conceptual" abstraction induced by Kurtz and Loewenstein (2007) or Minervino et al. (2017), and computationally simulated by Gentner et al. (2009). In the above studies (see Trench \& Minervino, 2017 for a review), the domain-specific elements of the original problems (e.g., "destroy a tumor") are allegedly replaced by more domain-general expressions (e.g., "neutralize a central target"), which could promote distant retrieval in at least two different ways: (1) by granting more relative weight to the relational predicates of target representations, and (2) by decreasing the retrieval of mere appearance matches that could outcompete useful base situations with dissimilar surface features but similar structure. The fact that we obtained similar results by means of removing perceptual detail from the target representations suggests a subtle parallelism between the abstraction process that takes place in tasks like problem comparison or problem construction and the kind of idealization induced by our manipulation of the target. Akin to the advantage of abstract retrieval cues in the MAC/FAC simulations of the late abstraction principle, the observed advantage of idealized simulations of the target analog might have originated in their tendency to be, on average, perceptually more similar to the superficially dissimilar base analogs compared to their alternative concrete representations, as well as in their being less likely to evoke superficially matching situations that could outcompete the base analog. The present results thus contribute to enlarging the empirical basis of the late abstraction principle, while at the same time broadening its scope so as to include a perceptual dimension that has not been thus far discussed in the existing literature.

Much of the excitement over target elaborations stems from the possibility of retrieving base analogs learned under conditions that were not especially engineered to highlight their abstract features. If the encoding specificity hypothesis applied, however, any advantage of distilling abstract or idealized representations of the target would be limited to maximizing the retrieval of stored representations whose initial encoding had already emphasized those same features (Tulving \& Thompson, 1973). As discussed in more detail elsewhere (Trench \& Minervino, 2017), there are several ways in which a base analog can be suboptimally encoded, and yet benefit from a more structural representation of the target.

Beyond their relevance for theoretical models of analogical retrieval, the present results bear implications for the design of interventions aimed at fostering a flexible use of learned contents. On the one hand, the fact that asking participants to carry out idealized simulations led to higher solution rates than not requiring them to perform any kind of simulation indicates that the superior performance of the idealized condition was not based on an intrinsically detrimental effect of concrete simulations. More importantly, the activity of constructing idealized representations of the target overcomes important limitations of previous instantiations of the late abstraction principle. With regards to Kurtz and Loewenstein's (2007) target-comparison intervention, an important shortcoming had to do with the need to provide participants with a second analogous target for every problem to be solved by analogy. Even though Minervino et al.'s (2017) target-construction intervention was not subject to this crucial limitation, only a small proportion of participants were able to generate an isomorphic problem. In contrast to the above instantiations of the late abstraction principle, the cognitive strategy assessed in the present study can be easily implemented by a great majority of participants, and without needing to be provided with additional information about the target. Future research should assess whether the advantages of target idealization can be combined with the benefits of strategic search (see e.g., Trench, Olguín, \& Minervino, 2016), as well as whether they generalize to other educationally relevant activities such as generating explanatory hypotheses for poorly understood phenomena or communicating complex ideas to others.

#### Abstract

Real-time sentence processing involves connecting linguistic input with knowledge. Here, we ask how variability in semantic memory (specific domain knowledge) may influence semantic access in realtime sentence processing. We recorded EEG while participants more/less knowledgeable about the narrative world of Harry Potter (HP) read sentences. In Experiment 1, all participants showed N400 predictability effects for general-knowledge sentences, but only those with high HP knowledge showed predictability effects for sentences about Harry Potter. This effect was driven by graded brain responses to predictable endings as a function of knowledge. Experiment 2 revealed greater semantic activation (inferred from N400 effects) for HP items participants reported knowing. Highknowledge participants also showed greater semantic activation for items they reported not knowing/remembering. These findings suggest that amount and/or functional organization of knowledge has real-time consequences on written sentence processing and implicate implicit/partial access to domain knowledge for experts when information is not explicitly recalled.

Keywords: sentence processing; knowledge; ERPs; individual differences

## Introduction

Depending on your background, the question, "What's your patronus?" might leave you bewildered. But if you've spent a sizable chunk of your life obsessing over the fictional world of Harry Potter created by J.K. Rowling, you might have a response quickly at hand (e.g., a dolphin or a cat).

Variability in individual experiences helps determine an individual's knowledge, whether the domain is a fictional narrative world like Harry Potter, a game like chess, or an academic discipline, like physics. Moreover, knowledge differences in many domains have been shown to systematically influence various aspects of the organization of knowledge, including depth, breadth, and hierarchical information structure (Chi, 2006). Such differences in knowledge seem likely to impact real-time semantic access, including perceiving an utterance (or text), relating it to prior knowledge, and forming expectations about upcoming content. Yet despite the inevitable link between an individual's knowledge and semantic access, the specific role(s) of knowledge variability has received relatively little attention in models of real-time language processing.

Decades of psycholinguistic research have revealed that language processing is incremental: we update our mental representations word-by-word (e.g., Tanenhaus et al., 1995; Kamide, Altmann, \& Haywood, 2003). Upon encountering an incoming word, world knowledge is used as soon as possible (e.g., Kutas \& Hillyard, 1980). Real-time access to such knowledge is influenced by a host of contextual factors,
both linguistic and nonlinguistic, including sentence and discourse context (Kutas \& Hillyard, 1980), discourse context (Nieuwland \& Van Berkum, 2006), and who the speaker is (Van Berkum et al., 2008).

These (and many other) studies have used event-related brain potentials to investigate the activation and organization of the semantic system during real-time language processing. A well-known ERP signature called N400 (a broad centroparietally distributed, negative-going potential peaking approximately 400 ms after stimulus onset) shows finegrained sensitivity to semantic relationships, with stronger relations between context and input yielding less negative- or more positive-going potentials between 200-500 ms postinput onset (Kutas \& Federmeier, 2000).

The content and organization of long-term memory (i.e., knowledge) influence semantic access as reflected in N400 modulation both within sentences and simpler (or even no) context. For words presented in isolation, N400 amplitude is reduced for high-, compared to low-frequency, words (Kutas \& Federmeier, 2000). Moreover, N400 amplitude is sensitive to category membership. Following a category label (e.g., 'a type of bird'), typical category exemplars ('robin') yield reduced N400 amplitude compared to atypical exemplars ('turkey'), and both are reduced compared to unrelated words ('broom') (Federmeier, Kutas, \& Schul, 2010).

Such effects rely on long-term knowledge likely available due to years of experience with concepts like birds. N400 studies, however, have also revealed sensitivities to culturally-specific information (e.g., the fact that Dutch trains are yellow, not white; Hagoort et al., 2004) and fictional information (Nieuwland \& Van Berkum, 2006; Filik \& Leuthold, 2013). Taken together, these N400 findings offer a window into the relationship between language input and structured, flexible knowledge use. Moreover, N400 amplitude provides an excellent proxy measure of the ease of access to semantic information.

Here, we use the N400 to explore the notion that systematic variability in the content and organization of individuals' knowledge, as a function of their expertise, will have systematic influences on real-time semantic access. To that end, we conducted two ERP studies with individuals varying in their knowledge of the narrative world of Harry Potter. We first asked whether domain knowledge will systematically influence N400 effects, possibly reflecting ease of semantic access and/or availability of information in long-term memory (Experiment 1). Next, we dissociated knowledge of individual facts from domain knowledge, allowing us to ask whether or not, and if so how, domain knowledge influences ease of semantic access when individuals think they know, or don't know/remember, the information (Experiment 2).

## Experiment 1

In Experiment 1, participants ranging in their knowledge of Harry Potter (based on an objective offline measure) read Control sentences about general, real-world topics as well as sentences about the narrative world of Harry Potter (HP) while we recorded EEG. Sentences of both types ended with either a Predictable or an Unpredictable word.

Based on the literature (Kutas \& Federmeier, 2000), we expected predictability effects for Control sentences, with Predictable items eliciting reduced N400 amplitudes compared to Unpredictable items. Moreover, we expected that for HP sentences, specific knowledge of Harry Potter would have its effect during this N400 time window, with knowledgeable individuals showing a reliable predictability effect and less knowledgeable individuals showing a smaller (or no) difference between Predictable and Unpredictable words.

Though our study focused on predictions during the N400 time window, we also anticipated later positive effects. Late positive complexes, often occurring post-N400, have been related to attention-driven processing, including integration, revision, or updating of ongoing interpretations in the presence of unexpected items (e.g., Van Petten \& Luka, 2012; Brouwer et al., 2012). We suspected that we might observe effects of Predictability on late positivities to words ending Control sentences, and possibly (for knowledgeable individuals) to words ending HP sentences, to the extent that individuals revise their interpretations.

## Methods

Participants 40 right-handed students at UCSD participated for partial course credit and some monetary compensation.

Sentence Materials During the ERP portion of the study, participants read sentence pairs of two types. Control sentences described commonplace scenarios and ended in a Predictable (Offline Cloze > 87\%) or an Unpredictable (Offline Cloze $=0 \%$ ), albeit plausible, word, determined by offline norming studies. Harry Potter (HP) sentences described situations and entities from the Harry Potter book series and ended in a Predictable (book-consistent) or an Unpredictable (book-inconsistent) word. Unpredictable words were matched to Predictable words for the broad classes of words they belonged to (common noun, proper noun, Harry Potter-specific noun) and in many cases belonged to the same, more specific category. For example:
(1) Control: We had been watching the blue jay for days. The bird laid her eggs in the nest. (Predictable) yard. (Unpredictable)
HP: The character Peter Pettigrew changes his shape at times. He takes the form of a rat. (Predictable)
dog. (Unpredictable)

[^213]The Predictable Harry Potter sentence endings were only predictable assuming perfect knowledge of the books. Unpredictable endings were inconsistent with the books but were designed to be similarly plausible endings, assuming no knowledge of the books. A total of 216 sentence frames (108 Control, 108 HP) were constructed, each with two ending types (Predictable, Unpredictable). Two lists were constructed such that each sentence frame appeared with only one ending type. Participants therefore saw a total of 216 sentences ( 54 sentences of each type).

Experimental Procedures Participants were told they would be reading sentences for comprehension and that they would be asked questions about the materials at the end of the study. After a practice session, blocks of Control sentences were presented first, followed by blocks of HP sentences. For each sentence pair, the first sentence appeared all at once in the center of the screen. When ready, participants pressed a button to move on to the second sentence, presented one word at a time in the center of the screen with a 500 ms SOA (200 ms on, 300 ms off). Immediately following the ERP study, participants were given a Control memory quiz followed by an HP memory quiz. For each, participants saw a list of 90 words, 60 of which had appeared in sentence-final position (half Predictable, half Unpredictable). They were instructed to circle the words they remembered as an ending to the second sentence of each pair in the study. After clean-up, participants completed 10 multiple-choice questions about the Harry Potter books. Raw scores are henceforth referred to as HP Knowledge. A median split on these scores determined High- and Low-Knowledge Groups.

ERP Recording and Data Analysis The electroencephalogram (EEG) was recorded from 26 tin electrodes geodesically arranged in an ElectroCap, with impedances kept below $5 \mathrm{~K} \Omega$. Recordings were referenced online to the left mastoid and re-referenced offline to an average of the left and right mastoids. EEG was recorded by Grass bioamplifiers with a bandpass of $.01-100 \mathrm{~Hz}$ at a sampling rate of 250 Hz . Trials contaminated by artifacts (e.g., eye movements or blinks) were not included in analyses.

Grand average ERPs to sentence-final words were computed across all 26 recording sites by Sentence Type (Control/HP) and Ending Type (Predictable/Unpredictable). We performed statistical analyses on mean amplitudes of these waveforms in two time periods: a canonical N400 time period ( $250-500 \mathrm{~ms}$ ) and a post-N400 period ( $500-750 \mathrm{~ms}$ ) relative to a 500 ms pre-stimulus baseline. For each time period, we subjected data to an omnibus ANOVA including Channel ${ }^{1}$ ( 26 levels), Sentence Type (Control, HP), Ending Type (Predictable, Unpredictable) as within-subjects factors and Knowledge Group as a between-subjects factor. Subsequently we focused on a region of interest (ROI) including 8 centro-parietally distributed channels (MiCe, LMCe, RMCe, MiPa, LDPa, RDPa, LMOc, and RMOc).

Channel in the N400 region reflect the fact that N400 amplitude (and N400 effects) are largest over the middle and back of the head.

## ALL PARTICIPANTS HIGH HARRY POTTER LOW HARRY POTTER KNOWLEDGE <br> KNOWLEDGE

GENERAL KNOWLEDGE SENTENCES (CONTROL)

Figure 1: ERPs from a central-parietal ROI to sentence-final critical words from Experiment 1 are plotted for Predictable (black lines) and Unpredictable (red lines) endings relative to a 200 ms baseline for illustrative purposes. Shaded regions depict the area between 250 and 500 ms (N400 time window). All participants showed Predictability effects for Control sentences while Predictability effects for HP sentences were driven by the High-Knowledge group.

## Results

Memory task Participants correctly recognized an average of 15 out of 60 Control words ( $25 \%$ ) and false alarmed to an average of 2 words (7\%). On the HP recognition test, participants correctly recognized an average of 30 out of 60 HP words ( $50 \%$ ) and false alarmed to an average of 2 words (7\%). Participants were therefore able to discriminate between words they had and had not seen for both the Control and HP memory tests.

To control for false alarms, we subtracted the number of false alarms for each memory test (Control, HP) from the number of items correctly recognized. We subjected these to a repeated measures ANOVA with Sentence Type (Control, HP) and Ending Type (Predictable, Unpredictable) as factors. There was a main effect of Sentence Type ( $p<.0001$ ), with higher accuracy for HP compared to Control sentences. There was also an interaction between Sentence Type and Ending Type ( $\mathrm{p}<.001$ ); while memory for HP words was similar irrespective of the Ending Type (corrected accuracy for Predictable $=44 \%$; corrected accuracy for Unpredictable $=$ $40 \%$ ), memory for Control words was better for Unpredictable words (22\%) compared to Predictable words (15\%).

As predicted, HP knowledge was not correlated with accuracy for Control words, but HP knowledge was correlated with accuracy for HP words (Predictable: $r=.471$, $\mathrm{p}<.005$; Unpredictable: $r=.478, \mathrm{p}<.005$ ).

ERPs ERPs from our centro-parietal ROI are shown in Fig. 1. ERPs for both Control and HP sentences are characterized by two early sensory components, a negative-going peak around 100 ms (N1) and a positive-going peak around 200 ms (P2). Across all participants, for Predictable endings, the P 2 is followed by a positivity in the N 400 time window
( $\sim 250-500 \mathrm{~ms}$ ). For Unpredictable endings, the P 2 is followed by a relative negativity in this window.

Effects of knowledge during the N400 time window. Our primary hypothesis was that specific domain knowledge would influence semantic access, reflected by interactions between Knowledge Group, Sentence Type, and Ending Type during the N400 time window ( 250 to 500 ms ). In the omnibus ANOVA, we observed a main effect of Ending Type ( $\mathrm{p}<.005$ ) but no effect of Sentence Type, reflecting the pattern observed in Fig. 1: for both sentence types, N400 amplitude is reduced for Predictable items. Of note, Knowledge Group interacted with Sentence Type ( $p<.005$ ), and a three-way interaction was observed between Knowledge Group, Sentence Type, and Ending Type (p < .05).

To follow up on the effects of Knowledge Group, Sentence Type, and Ending Type on N400 amplitude, we examined Control and HP sentences separately at our centro-parietal ROI. Within Control sentences, there was an effect of Ending Type on N400 amplitude ( $\mathrm{p}<.0001$ ) but no main effect of Knowledge Group or interaction between Knowledge Group and Ending Type. Conversely, within HP sentences, there was a main effect of Ending Type ( $p<.0001$ ), and an interaction between Knowledge Group and Ending Type (p $<$ .005). Follow-up t-tests revealed a larger reduction in N400 amplitude for Predictable versus Unpredictable endings for the High-Knowledge Group compared to the LowKnowledge Group ( $\mathrm{p}<.01$ ), supporting the notion that specific knowledge at the level of the individual reduces N400 amplitude (see Fig. 2). Furthermore, the differential knowledge had its effect primarily for Predictable endings, as High-Knowledge and Low-Knowledge individuals showed differences in N400 activity to Predictable endings ( $\mathrm{p}<.05$ ) but similar N400 activity to Unpredictable endings ( $\mathrm{p}=.630$ ).

GENERAL KNOWLEDGE SENTENCES (CONTROL)

HARRY POTTER
SENTENCES

Figure 2. Difference ERPs for Unpredictable minus Predictable endings from Experiment 1 are plotted for the High HP Knowledge Group (solid lines) and the Low HP Knowledge Group (dashed lines) relative to a 200 ms baseline. Predictability effects for Control sentences were similar for both groups but only the High HP Knowledge Group showed sizable Predictability effects for HP sentences.

Analysis involving our continuous measure of HP Knowledge coincided with this pattern of results. We observed a graded relationship between the N400 effect (mean amplitude to Unpredictable minus Predictable endings) and knowledge scores, $r=.457, \mathrm{p}<.005$; this relationship was driven by the correlation between knowledge and mean amplitude to Predictable endings ( $r=$ $.473, \mathrm{p}<.005$ ) whereas no correlation obtained between knowledge and mean amplitude to Unpredictable endings ( $r$ $=.171, \mathrm{p}=.293$ ).

Effects of knowledge post-N400 (500-700 ms). In the omnibus ANOVA, we observed an interaction effect of Sentence Type and Ending Type ( $p<.01$ ), which resulted from a significant difference between Predictable and Unpredictable endings to Control sentences ( $\mathrm{p}<.0001$ ), with Unpredictable endings associated with greater positivities, but only a marginal difference between Predictable and Unpredictable endings for HP sentences, with the reverse pattern ( $\mathrm{p}=.08$ ). Apart from effects involving Channel, there were no other main effects or interactions in this analysis. ${ }^{2}$

## Experiment 2

Experiment 1 demonstrated that specific domain knowledge influences real-time semantic access, inferred from N400 predictability effects. This pattern could obtain for multiple reasons. By definition, experts know more information, but expert knowledge also may be functionally organized differently, with greater structure and/or depth than that of less-knowledgeable individuals (Chi, 2006). We expect that this organization, in whichever form it may take, may influence semantic access above and beyond the successful retrieval of any given known item.

[^214]To tease apart contributions of (1) knowledge of individual items and (2) knowledge of the domain (Harry Potter) to semantic access, we asked participants to read sentences, all of which were consistent with the world of Harry Potter, and to respond with judgments of their knowledge along with their confidence in them. We were particularly interested in whether domain knowledge might have independent effect on semantic activation (inferred from N400 amplitude) for (a) items people say they know, (b) items people say they don't know, or (c) both.

## Methods

Participants 41 right-handed students at UCSD participated for partial course credit and some monetary compensation.
Sentence Materials Materials consisted of 172 sentence pairs describing the world of Harry Potter, including the 108 from Experiment 1 plus an additional 64. All sentences ended in a word consistent with the Harry Potter books (i.e., the Predictable endings from Experiment 1).

Experimental procedure Sentence presentation was as in Experiment 1. After each sentence pair was presented, participants were first asked to make a non-speeded judgment about whether they knew the information in the sentences ahead of time, followed by a judgment of their certainty (we report only on responses to the first question in this paper).

After clean-up, participants completed 40 multiple-choice questions about the Harry Potter books (including the 10 questions used in Experiment 1). Raw scores are henceforth referred to as HP Knowledge. A median split on these scores was used to determine High- and Low-knowledge groups.

ERP recording and data analysis ERPs were recorded and processed as in Experiment 1. Because the design of Experiment 2 involves binning data based on subject responses, we used mixed-effects models (Baayen et al., 2008), which allow for the analysis of unbalanced data (e.g., Tibon \& Levy, 2015). For both N400 and post-N400 time windows, we start by employing models that include fixed effects of (1) Judgment of Knowledge (two levels: "Yes," "No") and (2) HP Knowledge (continuous measure) along with random by-items and by-subjects intercepts. To unpack interactions, we follow up with similar mixed-effects models designed to isolate the $\operatorname{root}(\mathrm{s})$ of the interactions. These models were applied to data from our centro-parietal ROI (see Experiment 1). As in Experiment 1, we examined a window centered around the N400 $(250-500 \mathrm{~ms})$ and a postN400 window ( $500-750 \mathrm{~ms}$ ). For illustrative purposes, when plotting these data, we weight trials equally (rather than plotting grand averages as is typical, where each subject is weighted equally).

[^215]

Figure 3: (A) ERPs from a central-parietal ROI to sentence-final critical words from Experiment 2 are plotted for words judged as known (black lines) and unknown (red lines) relative to a 200 ms baseline. Shaded regions depict the area between 250 and 500 ms (N400 time window). Across all participants, words judged as known led to more positive-going waves during this time. (B) During the N400 time window, HP Knowledge influenced mean amplitude only for Unknown (red), but not known (black) items.

## Results

Behavior On average, participants responded that they knew 102 out of 172 items ( $60 \%$ ). As expected, high-knowledge participants reported knowing more items (80\%) than lowknowledge participants (38\%), with a strong correlation between HP Knowledge and number of items judged as known, $r=.85, \mathrm{p}<.0001$.

We trimmed response times three standard deviations greater than the mean for all responses. Response times for judgments of knowledge were overall slower for "No" responses ( 1015 ms ) than "Yes" responses ( 851 ms ), p < .0001. Moreover, HP knowledge interacted with Judgment of Knowledge ( $\mathrm{p}<.0001$ ): high-knowledge individuals responded faster for "Yes" responses ( 809 ms ) than "No" responses ( 1193 ms ) ( $\mathrm{p}<.0001$ ), but Low-Knowledge individuals showed only slightly faster RTs for "Yes" (943 ms ) than "No" ( 964 ms ) (n.s.). Pair-wise differences between High- and Low-Knowledge Groups were significant for "No" responses ( $\mathrm{p}<.005$ ) but not for "Yes" responses. Individuals therefore responded with similar speed when they judged items as known, but those with greater HP knowledge took longer to judge an item as unknown.

ERPs Grand average ERPs to sentence-final words were computed across all 26 recording sites grouped by participants' responses. See Fig. 3 for plots from the centroparietal ROI.

Effects of knowledge during the N400 time window. As expected, we observed overall more positive-going waveforms during the N400 time window for highknowledge compared to low-knowledge individuals (p $<$
.005). In addition, positive Judgments of Knowledge (i.e., "Yes" responses) resulted in reduced N400 amplitudes (p $<$ .0001; see Fig. 3). We also observed an interaction of Judgment and HP Knowledge ( $\mathrm{p}<.005$ ). Follow-up comparisons revealed that this interaction was driven by effects of HP Knowledge on N400 amplitude for "No" responses ( p .05 ) but not for "Yes" Responses, demonstrating that specific domain knowledge has its primary influence on items which participants say they did not know (recollect) at the time.

Effects of knowledge post-N400 (500-750 ms). Mean amplitude during the post-N400 window was influenced both by HP Knowledge ( $\mathrm{p}<.05$ ) and Judgments of Knowledge ( p $<.0001$ ), with the two terms also interacting ( $\mathrm{p}<.0001$ ). Overall, "Yes" responses yielded more positive-going waves than "No" responses, and greater HP Knowledge was also related to more positive-going potentials. Follow-up analyses revealed that this interaction was driven by an effect of HP Knowledge on "No" responses ( $\mathrm{p}<.05$ ), with no relationship between HP Knowledge and positive-going potentials for "Yes" responses $(p=.869)$. For "No" responses, individuals with more knowledge had more post-N400 positive-going activity.

## General Discussion

We set out to investigate the relationship between specific domain knowledge and semantic access during real-time written sentence processing. Experiment 1 provided a strong indication that knowing about a domain (in our case, the narrative world of Harry Potter) influences semantic access, but only within that domain. As predicted, we observed no effects of Harry Potter-specific knowledge on processing of sentences about general topics. However, Harry Potterspecific knowledge did mediate N400 effects for Harry Potter sentences. We found that the size of the N400 predictability effect was correlated with HP knowledge score, with the correlation being driven by a graded relationship between knowledge and the neural response to predictable words.

In many ERP studies of sentence processing, predictability is defined using offline Cloze norming measures (that is, how likely an individual is to provide a word given a sentence context). It is worth noting that offline Cloze measures for our Harry Potter sentences provide a different type of metric than for our Control sentences. That is, predictable endings for Harry Potter sentences are predictable by virtue of being factual (within the narrative world); predictable endings for Control sentences are predictable based on world knowledge, but have no "correct" ending. Even so, our analyses revealed no main effect of sentence type (general/control vs. Harry Potter sentences) in Experiment 1. That is, across the whole group, we observed similar N400 effects of predictability for both Control and Harry Potter sentences (see Fig. 1). Our findings concur with many reports that N400 amplitude is sensitive to a word's predictability and/or contextual fit, in factual and non-factual scenarios (e.g., Hagoort et al., 2004).

Our finding that semantic access (inferred from N400 effects) is driven by knowledge is not surprising. In order to
access information, the information must exist in the first place. However, there are at least two reasons why HP knowledge might relate to N400 predictability effects in Experiment 1: (1) low-knowledge individuals know fewer facts than high-knowledge individuals on average; and (2) there are potentially additional contributions of domain knowledge on semantic processing when individuals know (or don't know) items, respectively. In Experiment 2, we examined these possibilities by asking participants whether they knew each item (i.e., each Harry Potter fact) ahead of time. While both high- and low-knowledge groups showed large differences in N400 activity based on their own (metacognitive) judgments of whether they knew specific items, high-knowledge (compared to low-knowledge) individuals showed greater positivities during the N 400 window even for information they reported not knowing at the time.

There are multiple reasons why domain knowledge might modulate N400 amplitude for items that are not immediately recognized. We cannot currently rule out the possibility that high- vs. low-knowledge individuals perceive different task demands or use different criteria when making judgments.

We believe a more likely explanation is that enhanced N400 reduction for high- compared to low-knowledge individuals suggests some level of implicit activation of information outside of conscious awareness. This activation may be restricted to a specific word and its semantic features or it may extend to related words / concepts. The precise nature of such implicitly activated information, and precisely how it is modulated by variation in level or amount of knowledge, have yet to be determined. Some possibilities include information that is taxonomically / categorically related to a predictable word (e.g., Federmeier \& Kutas, 1999) and information related to the scenario / event being described (e.g., Metusalem et al., 2012).

As for post-N400 activity, we observed systematic effects of both HP Knowledge and judgments of knowledge on late positivities in Experiment 2, with high-knowledge individuals showing greater positivities than low-knowledge individuals for items they did not know. One way of interpreting this interaction is that when high-knowledge individuals do not know an item, they continue to search for it (perhaps because they believe they may know, but not currently be able to retrieve, the knowledge).

Our findings build on work showing that the functional organization of long-term memory plays an important role in the real-time construction of meaning (e.g., Federmeier \& Kutas, 1999). We have demonstrated that variability among individuals in their knowledge of a domain is an important contributor to real-time access to meaning. More specifically, our data suggest that the amount and/or organization of domain knowledge appear to influence access to knowledge above and beyond explicit knowledge of individual items: expert-like knowledge organization in a domain may lead to implicit or partial activation of domain-related information, even when individuals do not explicitly recall a given piece of information.

# Inhibitory Control Supports Referential Context Use in Language Production and Comprehension 

Alison M. #### Abstract

Using referential context in language (e.g., saying "blue pen" when two different-colored pens are visible) makes communication efficient. But it is still unclear which general cognitive processes support the use of context in conversation. Research on pragmatic use in language implicates working memory and inhibitory control; however, no studies have shown evidence of a shared cognitive mechanism in both production and comprehension within an individual. The current study asked a) whether referential context use is supported by the same cognitive mechanisms in production and comprehension, b) which processes are implicated, and c) whether the nature of the context itself affects processing. Participants completed a referential communication eye-tracking task in which a disambiguating adjective was either necessary or over-informative, as well as a cognitive test battery. The results implicated inhibitory control in both production and comprehension (although the comprehension results were more variable), suggesting a shared underlying cognitive mechanism across domains.

Keywords: language production; language comprehension; discourse; pragmatics; inhibitory control; working memory

## Introduction

The ability to take context into account often facilitates communication in interactive settings. Imagine you are cooking with a friend. There are two identical spoons on the table: one next to a big bowl, and one next to a small bowl. You may know that you would like you friend to hand you the former; however, if you just say, "hand me the spoon next to the bowl," he will likely not understand which one you mean. Thus, in order to effectively communicate your intent, you would need to use a disambiguating adjective (i.e., "hand me the spoon next to the big bowl"). On the other hand, if only one spoon and one bowl were visible, saying "hand me the spoon next to the big bowl" would be confusing, as it implies to your listener that there is more than one option to choose from. This paper investigates how speakers and listeners behave in situations when adding or subtracting an adjective is most appropriate for clear communication given the referential context.

Related to the idea that listeners and speakers will tailor their language to the referential context is the Gricean Maxim of Quantity (Grice, 1975), which specifies that speakers should make their utterances only as informative as is required. Thus, enough information should be provided to
distinguish the intended referent from its potential competitors (e.g., the big bowl when two bowls are visible), and providing information that is not necessary (e.g., the big bowl, when no other bowls are in view), should be avoided. Although, ideally, following this maxim would help to make communication maximally efficient, in reality, speakers and listeners and often fail to behave in a completely Gricean manner (e.g., Deutsch \& Pechmann, 1982; Sedivy, 2005).

Speakers' and listeners' ability to make their utterances optimally informative, or to appropriately interpret the utterance they are hearing, within the current referential context may depend upon the cognitive demands that this process places upon them. Referential context adaptation (RCA) is a complex process, involving not only language production or comprehension, but also selectively attending to certain objects in one's surroundings, remembering what information has already been introduced into the discourse, or refraining from mentioning irrelevant or confusing information, to name a few. Therefore, general cognitive functions, such as working memory (WM) and inhibitory control (IC), could play an important role in RCA.

The current work investigates whether the ability to take referential context into account is supported by the same cognitive processes in language production and comprehension, and under different linguistic demands. If so, we would expect (a) individuals with better RCA to demonstrate this ability in both production and comprehension, and (b) the same general cognitive operations to drive referential context consideration in comprehension and production, and perhaps in situations with different linguistic demands.

## Pragmatic Language Use and Cognitive Abilities

The fact that speakers often fail to observe the Gricean Maxim of Quantity provides evidence that taking referential context into account may be a cognitively demanding process. While research in this field has not previously addressed the relationship between RCA and general cognitive abilities, some work on a related linguistic process, perspective-taking, has attempted to identify the cognitive processes underlying pragmatic language use. Perspective-taking and RCA are similar in that both involve the on-line incorporation of referential context in interactive conversation. Thus, it is possible that a similar set of
cognitive mechanisms supports both processes.
In one study of perspective-taking, speakers were tested on their ability to refrain from producing descriptions that were over-informative from the perspective of their listener (e.g., "the big star" when two stars are visible to the speaker, but only one is visible to the listener; Wardlow, 2013). The results showed that this ability was correlated with both WM and IC. In comprehension, Brown-Schmidt (2009) found that participants with greater IC were more likely to take the experimenter's perspective when interpreting their questions about a display containing some pictures that were visible to only the listener. Lin, Keysar, and Epley (2010) found that comprehenders with higher WM capacity performed better on a similar task.

While these studies all point to a role for general cognitive resources in perspective-taking, an important question remains: Do the same abilities underlie perspective-taking in production and comprehension? The two studies that have investigated perspective-taking in both domains within the same individuals found contradicting results: Ryskin, Benjamin, Tullis, \& Brown-Schmidt (2015) found WM to be correlated with perspective-taking in production, but none of their executive control measures were correlated with comprehension. On the other hand, Nilsen and Graham (2009) found that IC negatively correlated with egocentric behaviors in a comprehension task in 3-5 year olds; however, none of their executive control measures correlated with production. The question, thus, remains: is the ability to take into account the referential context the same in both domains?

## The Current Study

The current study investigates how speakers and listeners adapt their language processing to referential context when observing the same visual display. Specifically, we asked: is the ability to take referential context into account related in production and comprehension, and under different linguistic and contextual demands? To this end, each participant took turns as both speaker and listener in a referential communication task with a visual world design, and their eye fixations, as well as their utterances (when acting as speakers) were recorded. Two conditions with different contextual demands were created: in the Adj+ condition, the most felicitous utterance required the inclusion of an adjective (e.g., "Click on the heart under the green gorilla," Figure 1a). In the Adj- condition, the most felicitous utterance was one without an adjective (e.g., "Click on the heart under the gorilla," Figure 1b). To test which cognitive processes underlie RCA in production and comprehension, each participant also completed a battery of tasks that included three WM and three IC measures. The WM measures were selected so as to include a mixture of both linguistic and non-linguistic tasks. The IC measures were selected to probe both competitive inhibition (the ability to inhibit a strongly competing response, e.g., not saying red gorilla in Figure 1a.) and global inhibition (the ability to inhibit a prepotent response, e.g., refraining from
using an adjective in Figure 1b.) (Munakata et al., 2011). Due to the rich set of independent and dependent variables in the current design, we adopted a statistical approach that is well-suited to handling this type of data structure: partial least squares path modeling (PLS-PM). This method allows us to look at multiple dependent variables simultaneously. In addition, this method allows us to similarly group WM and IC tasks into latent constructs in order to minimize taskspecific effects and avoid the issue of collinearity.

Figure 1: Example Adj+ (a) and Adj- (b) displays used in the referential communication task.

## Methods

## Participants

Twenty-eight native English speakers, ages 18-30, participated for $\$ 40$.

## Materials

Referential Communication Task Each display consisted of four black card suit shapes (club, diamond, heart, or spade). Above each shape was a drawing of an animal. The animal stimuli were chosen to be cohort competitors with either a size or color adjective (e.g., big buffalo, green gorilla). On each trial, the target and competitor shapes were the same (e.g., both spades), ensuring that the target shape always needed to be disambiguated from the competitor by describing the animal above the target. Trials were presented in one of four fixed random orders.

There were two critical trial types. On Adj+ trials ( $n=96$ ), the same cue animal appeared above the target and competitor shapes in two different colors or sizes. Critically, the animal above the target shape was rendered in its cohortcompetitor adjective (e.g., green gorilla). These trials were designed such that, if participants used RCA, in production, they would include the adjective necessary to disambiguate the target cue from the competitor cue, and in comprehension, upon hearing the initial phoneme of the adjective (e.g., the /g/ in green), they would interpret this sound as the beginning of an adjective, and not a noun, and as a result fixate more on the cue above the target (green gorilla) than the cue above the competitor (red gorilla) (Table 1).

On Adj- trials ( $\mathrm{n}=96$ ), different cue animals appeared
above the target and competitor shapes. The cue animal above the target shape was always a cohort competitor with the adjective corresponding to the cue above the competitor shape (e.g., red gorilla vs. green raccoon). These trials were designed such that, if participants used RCA, no adjective would be produced in production, as it would be overinformative, and in comprehension, upon hearing the initial phoneme of the target noun (e.g., the $/ \mathrm{g} / \mathrm{in}$ gorilla), the participant would interpret this phoneme as the onset of a noun (gorilla), and not of the adjective preceding the competitor cue (green raccoon) (Table 1).

Table 1: Felicitous utterances on Adj+ and Adj- trials.

|  | Adj+ | Adj- |
| :---: | :---: | :---: |
| Production | Say "the heart under <br> the green gorilla." | Say "the heart under <br> the gorilla." |
| Comprehension | Upon hearing "heart <br> under g..." look for <br> "green," not "gorilla" | Upon hearing "heart <br> under g.." look for <br> "gorilla," not "green" |

## Cognitive Battery

A spatial WM task (Corsi Block, Kessels et al., 2000) and two linguistic WM tasks (Category and Rhyme Probe, Freedman \& Martin, 2001), measuring semantic and phonological WM respectively, were administered. Three IC measures were also employed: Fish Flanker along with embedded NoGo (Nozari, Trueswell, \& Thompson-Schill, 2016), as well as semantic blocking elicited through cyclic naming (e.g., Schnur et al., 2006), in which participants named twelve sets of six images, either in semanticallyhomogenous or heterogeneous blocks. Semantic blocking was determined as the difference in response latencies between the two block types.

## Procedure

Participants completed two sessions 3-7 days apart. Each session began with the eye-tracking task, followed by half of the cognitive measures. Stimuli were displayed using MATLAB and Psychophysics Toolbox (Brainard, 1997), and the participant's eye movements during the referential communication tasks were recorded using an Eyelink 1000 Plus desktop-mounted eye-tracker (SR Research).

Referential Communication Task, Session 1. On each trial, a fixation cross was presented for 500 ms before the stimuli appeared. After a 1500 ms preview period, a tone sounded and the target shape began to flash, cuing the participant to begin speaking. After 2.5 seconds, a lower tone sounded, indicating the end of the trial. The participant and experimenter viewed separate monitors containing the same stimuli. The participant instructed the experimenter to click on the target shape that was cued on the participant's screen, using sentences with this structure: "Click on the
[target shape] under the [adjective, if needed] [target cue]." They were told that the goal of the task was to provide instructions as quickly as possible, and to avoid unnecessary words to meet the temporal deadline, thus motivating them to drop the adjective when not necessary.

Referential Communication Task, Session 2. Participants followed instructions like the ones they had given during Session 1. Each trial began with a 500 ms fixation point. The stimuli then appeared onscreen, and after a 1000 ms preview period, a pre-recorded instruction played, instructing the participant to click on one of the shapes. Instructions were always pragmatically appropriate (i.e., an adjective was always provided on Adj+ trials, and no adjective was provided on Adj- trials).

## Analyses

## Behavioral

Participants made a total of 345 infelicitous utterances out of 5376 critical trials ( $6.4 \%$ error rate, $M=12.3$ errors, $S D=$ 8.5). Of these infelicitous utterances, 187 were made on Adj+ trials (i.e., adjective underuse), while 157 were made on Adj- trials (i.e., adjective overuse). Participants were expected to perform near ceiling on the comprehension task, so no accuracy measures were collected.

## Eye-Tracking

In production, eye-tracking analyses combined each card suit and its animal cue into a single region. Data was analyzed from $400-1350 \mathrm{~ms}$ post-target cuing, comprising the time period between the minimum and maximum proportion of fixations to the competitor after attention was initially drawn to the flashing target (see Figure 2a). Competitor fixations were considered critical because, in order to establish the referential context of the display, participants needed to divert their attention from the extrinsically-cued target to its competitor. Thus, our dependent measure of analysis was a competitor advantage score, or the proportion of fixations to the competitor minus the proportion of fixations to the target.

In comprehension, eye-tracking analyses were completed on the target advantage score (proportion of fixations to the target and its cue minus the proportion of fixations to the competitor and its cue) over a time window beginning 300 ms before the onset of the critical word (cue noun in the Adj- and cue adjective in the Adj+ condition) and ending 200 ms after the onset of the critical word (see Figure 2b). The time window was chosen in order to encompass coarticulatory cues from the word preceding the critical word, as well as processing of the initial cohort phoneme of the critical word. This target preference measure should indicate how well participants took referential context into account (i.e., disregarded the competitor). By using target advantage as a DV in comprehension and competitor advantage in production, we ensured that in both cases, a more positive eye-tracking score would index better RCA.

Figure 2: Time course of eye-tracking data for all critical trials in Production (a) and Comprehension (b). Highlighted regions indicate windows of analysis.

## Partial Least Squares Path Modeling (PLS-PM)

Analyses were conducted using partial least squares path modeling, implemented in the plspm package in $R$ (Sanchez, 2013). PLS-PM is a partial least square approach to Structural Equation Modeling suitable for analyzing the relationship between latent variables (psychological constructs such as WM) and manifest variables (observed data from tasks assumed to index these variables) as a network of multiple interconnected linear regressions.

Figure 3a shows our initial theoretical model. The model has three latent variables: RCA, Working Memory (WM), and Inhibitory Control (IC), each measured through a number of manifest variables. The direction of the arrows indicates the direction of causal influence.

Model quality assessment takes three general steps. The first is to verify the relationship between manifest variables and the latent variables hypothesized to underlie them. This is done by first assessing unidimensionality, or the extent to which a change in the latent variable affects all manifest variables in the same direction. Unidimensionality is indexed by Dillon-Goldstein's rho (DG rho). A DG rho above 0.7 is favorable. Second, the relative contribution of the latent variable (vs. noise/task-specific factors) to each manifest variable is calculated. Indicators with a loading of

Figure 3: Structure of initial path model (a) and revised model for production data only (b).
less than 0.6 are not good indices of the latent construct. Third, the cross-loadings of the manifest variables are checked to ensure that the loading of a manifest variable is indeed highest on the latent variable it is assumed to represent, and not on another latent variable in the model.

The first three steps are used to revise the model by dropping manifest variables or re-partitioning the latent variable constructs. The revised model is then re-checked.

Once a viable model is obtained, the overall fit is assessed, which also includes the relationship between the latent variables. $\mathrm{R}^{2}$ is reported for the latent variable of interest, and similar to simple regression models, indicates the amount of variance explained by the independent latent variables (WM and IC).

The part of the model that answers questions about the contribution of general cognitive functions on RCA is the inner model, or the links between latent variables. Its output is similar to that of any generalized linear model. Significance levels of path coefficients are estimated via bootstrapping with 1000 iterations.

## Results

## Model 1: General Model

Model 1 is based on the following theoretical assumptions: (a) the three WM tests measure a unified WM construct, (b) the three IC tests measure a unified inhibition construct, and (c) all the RCA scores measure a unified RCA construct.

Examination of this general model resulted in three main revisions: (a) Rhyme Probe was dropped because it did not contribute substantially to the latent WM construct (loading
$=0.12$ ) (b) The loadings and cross-loadings of the latent variables revealed that the IC variable had low unidimensionality ( DG rho $=.11$ ). NoGo errors had a large negative loading on the IC latent variable ( -0.93 ), while the other two IC manifest variables had positive loadings, indicating that the NoGo errors were measuring a fundamentally different construct. Thus, the IC latent variable was broken down into two variables: indirect competitive (CI; Semantic Blocking and Flanker) and global (GI; NoGo) to reflect two types of IC that have been shown to have different cognitive and neural underpinnings (Munakata et al., 2011). (c) While all measures of RCA in production had factor loadings above 0.6 on the RCA latent variable, RCA measures in comprehension had low factor loadings and low unidimensionality across Adj+ and Adjconditions. This finding points to dissociation of the RCA construct in production and comprehension and calls for separate examination of the two tasks.

## Model 2: Production

This model is shown in Figure 3b, and includes only manifest variables indexing RCA in production. RCA had a DG rho of 0.86 , and high factor loadings for all four manifest variables. This finding supports defining RCA in language production as a unified construct, regardless of linguistic demands. DG rho's for WM and CI were 0.7 and 0.63 respectively, with $\mathrm{R}^{2}$ of 0.51 .

Table 2 shows the results of the bootstrapping on Model 2. The only latent variable that significantly predicted RCA in production was GI. Post-hoc modeling of Adj+ and Adjmanifest variables separately also revealed a reliable contribution of this variable to RCA in both trial types.

Table 2: Results of Bootstrapping for Model 2. $\mathrm{CI}=$ Competitive Inhibition; GI = Global Inhibition; WM = Working Memory.

| Latent <br> IV | Path <br> Coeff. | Bootstrapping <br> Means | SE | Lower <br> $95 \%$ <br> CI | Upper <br> $95 \%$ <br> CI |
| :--- | :---: | :---: | :---: | :--- | :--- |
| WM | 0.18 | 0.20 | 0.20 | -0.24 | 0.54 |
| CI | 0.26 | 0.18 | 0.28 | -0.42 | 0.57 |
| GI | -0.56 | -0.54 | 0.18 | -0.80 | -0.21 |

Analysis of eye-tracking data in production showed that participants' average competitor advantage scores were positively correlated with RCA accuracy in both the Adj+ and Adj- condition ( $r=.45$ and .58 , respectively; $p$ 's $<.05$ ), and that eye-tracking performance itself was highly correlated across the two conditions ( $r=.96, p<.001$ ).

## Analysis of Comprehension Data

In the path model, the two measures of RCA in comprehension had opposite loadings on the RCA latent variable, thus forcing us to examine them separately. To understand why the eye-tracking measures in comprehension had opposite effects on the RCA variable,
we first examined the correlation between participants' target advantage scores in the Adj+ and Adj- conditions. The two measures showed a significant negative correlation ( $r=-.47, p=.01$ ), in contrast to the production results. Nearly half of the participants (13 of 28) showed a negative target advantage score in one condition and a positive score in the other, indicating that in one condition, participants systematically interpreted the critical cohort phoneme as the onset of the competitor, instead of the target. Recall that in the Adj+ condition, the target word was always an adjective and its cohort competitor was always a noun, while in the Adj- condition, the opposite was true. Thus, it appears that these participants adopted a strategy of always interpreting the cohort phoneme as being from the same part of speech.

Because our main question of interest was whether RCA in production and comprehension rely upon the same cognitive processes within an individual, we directly compared performance in these two domains within the subset of participants who were clearly engaging in RCA during comprehension (Adapters; $\mathrm{n}=11$ ). While no relationship was found between production and comprehension on Adj+ trials, on Adj- trials, these participants' eye-tracking performance in comprehension was significantly positively correlated with their production accuracy ( $r=.63, p<.05$ ) and marginally positively correlated with their eye-tracking performance in production ( $r=.49, p=.12$ ).

We also tested whether the same cognitive abilities were responsible for performance across conditions in Adapters. Due to the univariate nature of the dependent measures in these analyses, we ran multilevel models separately on Adj+ and Adj- eye-tracking data, with all six cognitive tests included as predictor variables. While none of the cognitive measures predicted performance on Adj+ trials, RCA on Adj- trials was significantly predicted by the Flanker ( $t=$ $6.2, p<.01$ ) and NoGo tasks ( $t=5.1, p<.05$ ).

In summary, comprehension results differentiated two groups of individuals: those who flexibly adapted their processing to referential context and those who did not. In those who did, RCA abilities were correlated in production and comprehension, at least on Adj- trials, and in both cases they were well predicted by a measure of IC.

## Discussion

This experiment tested three central questions: 1) Which cognitive processes underlie RCA? 2) Are these processes consistent across production and comprehension? 3) Do situations in which better RCA is marked by addition of an adjective differ from those in which it is marked by omission of an adjective? In answer to question 1, we observed a clear effect of IC across the domains of production and comprehension. In production, NoGo scores were predictive of better RCA for both Adj+ and Adj- trials. In comprehension, amongst Adapters, scores on both NoGo and Flanker tasks predicted performance on Adj- trials. These findings suggest a definite role for IC in RCA. Since common to both production and comprehension, this finding
most likely points to the role of IC in capturing the critical contrast by preventing fixed attention to the target (hence ignoring the critical competitor).

Two lines of evidence can be used to answer question 2. First, the fact that IC played a role in RCA for both production and comprehension is evidence that the RCA abilities are related in the two domains. Second, performance on Adj- trials was correlated between production and comprehension amongst Adapters. Together, these findings provide the first piece of evidence for a common basis of RCA in production and comprehension.

In answer to question 3, production analyses strongly suggested RCA ability was independent of trial type: Eyetracking measures across Adj+ and Adj- trials were highly correlated, PLS-PM revealed the RCA latent variable in production to be a highly coherent construct, and the same underlying cognitive mechanism, global inhibition, was implicated in both Adj+ and Adj- trials. In comprehension, more variability across conditions and participants was observed. PLS-PM showed a lack of unidimensionality across comprehension conditions, and further inspection of the data revealed that nearly half of the participants did not use referential context. Even within Adapters, only RCA on Adj- trials correlated with production and was predicted by measures of IC. This is in part due to low internal reliability of RCA in comprehension ( $\rho^{*}=.34$ for $\operatorname{Adj}-$ and $\rho^{*}=-.16$ for $\mathrm{Adj}+)^{1}$, as also reported by Ryskin et al. (2015), which stands in sharp contrast to the high split-half reliability of RCA in production ( $\rho^{*}=.97$ in both conditions). However, our results suggested that apart from consistency issues, listeners did often default to a fixed strategy, as opposed to flexibly adapting to context, as they did in production.

In summary, these results represent the first evidence for shared underlying cognitive mechanisms of pragmatic processing in production and comprehension. In production, this mechanism, global inhibition, was recruited regardless of the particulars of the referential context, while in comprehension, results were less uniform across conditions, pointing to specific strategies adopted by listeners in locating the referent. These findings provide insights into the cognitive processes that drive pragmatic use during spoken language comprehension and production, and help to situate pragmatic processing within a larger and more general cognitive framework.

# A Dynamic Process Model for Predicting Workload in an Air Traffic Controller Task 

Martina Truschzinski (mtru@hrz.tu-chemnitz.de)<br>Department of Automation Technology<br>Technische Universität Chemnitz<br>Chemnitz, Germany<br>Maria Wirzberger (wirm@hrz.tu-chemnitz.de)<br>Department of E-Learning and New Media<br>Technische Universität Chemnitz<br>Chemnitz, Germany

#### Abstract

We present a dynamic process model for workload, developed according to a conducted experiment, which recorded the pupil dilation during an air traffic controller simulation. We describe how we built such a dynamic system based on the collected data. Logged events that happened in our simulation were used as system input and the recorded pupil dilation as output. Afterwards, we used the MATLAB system identification toolbox to identify the transfer function between input and output. The identified model is validated with a validation data set that has been excluded from the identification process. Results show that we are able to explain nearly $50 \%$ of the variance of the recorded pupil dilation data in the air traffic controller simulation. Moreover, the model explains some contrary results of the statistical analysis from our experiment.

Keywords: Dynamic process model; System theory; Workload; Pupillometry; Air traffic controllers

## Introduction

According to current statistics, the amount of airline passengers will continue its positive development over the next years, with expected annual growth rates of up to five percent (IATA, 2017; Boeing, 2017). To maintain the resulting needs and ensure smooth and safe traveling, the duty of air traffic controllers (ATCs) is of high importance. However, tasks like this are rather complex and put high demands on the available resources of such job holders (Mogford, Guttman, Morrow, \& Kopardekar, 1995). Beyond this, it is proven that predefined factors like traffic volume or frequency congestion influence ATCs' mental workload (Mogford et al., 1995).

As discussed by Gopher and Donchin (1986), the concept of mental workload enfolds various dimensions and facets. Although it has been broadly inspected, deriving a clear definition forms a rather difficult matter. Nevertheless, there are two constituting aspects that build a common ground in most cases. While task difficulty results from the demands required to successfully solve a task in a given time (Galy, Cariou, \& Mélan, 2012), resource supply refers to the information processing capacity available for this purpose. In this vein, mental workload comprises the difference between required capacities of the information processing system to achieve satisfying task performance and available capacity at a given time (Gopher \& Donchin, 1986; Wickens, 2008). Based on the assumption that tasks with increased difficulty require additional resources, a significant decrease in performance due
to the lack of resources should appear as soon as resource demands exceed resource supply (Wickens, G., Banbury, \& Parasuraman, 2013).

There are different possibilities to estimate human workload (Prewett, Johnson, Saboe, Elliott, \& Coovert, 2010; Beatty \& Lucero-Wagoner, 2000; Reiner \& Gelfeld, 2014) and build workload models (Gopher \& Braune, 1984; Wickens, 2008). Beatty and Lucero-Wagoner (2000) described nonreflexive phasic pupillary movements as indicators for brain processes that underlie dynamic, intensive aspects of human cognition. In several research investigating the cognitive functions, task-evoked responses of the pupil (TERPs) (Beatty, 1982; Beatty \& Lucero-Wagoner, 2000) were used to measure cognitive effort, workload and cognitive load (Haapalainen, Kim, Forlizzi, \& Dey, 2010; Wierwille, 1979; Paas, Tuovinen, Tabbers, \& Van Gerven, 2003). Therefore, in our approach we used the measured TERPs to model and validate a dynamic workload model to investigate and simulate workload in ATC tasks.

## Experiment

We collected data from 25 volunteers located at the campus of University Pompeu Fabra ( $M_{\text {Age }}=28.12$; SD $=5.67,64 \%$ male). The majority of $84 \%$ participants had no prior experience in ATC tasks (including, but not limited to, video games).

Figure 1: Experimental procedure with preparation phase, practice session and two different conditions. Measures on personality (BFI) and mood (MDMQ) are not reported in this paper.

## Experimental Design

In our 2 (workload condition) x 3 (events) within-subjects design, each participant completed a simulated ATC task. The simulation was divided into a practice session and two conditions of 4 min , a low workload condition (LWC) with a lower degree of difficulty and a high workload condition (HWC) with a higher degree of difficulty. In the LWC, participants had to manage and control less airplanes appearing at a lower frequency (airplanes appeared every $4-8 \mathrm{~s}$ ). This results in an easy task difficulty with lower time pressure, since participants had more time to handle each airplane. In the HWC, participants had to manage a greater number of airplanes appearing in a higher frequency (airplanes appeared every $1-5$ s), which resulted in higher task difficulty and time pressure to avoid collisions between airplanes.

Workload Measurement Since Beatty and LuceroWagoner (2000) reported a significant increase in pupil dilation due to an increase in workload, we recorded the pupillary response during each condition. We used the mobile eye tracking headset from Pupil Labs with a sample rate of 60 Hz and analyzed the TERPs by calculating the mean pupil dilatation during an 1.5 s window for three classes of events that were assumed to trigger an increase in workload. The time window of 1.5 s was chosen in line with Beatty and LuceroWagoner (2000), who identified that TERPs are recognized due to an increase in mental workload between 1-2 s after the presentation of a stimulus.

One class of events included all collisions caused by the participant, another one included participants actions of changing height or direction of an airplane. The third class of events included system-induced occurrences of a new couple of airplanes. All events were logged by a self-programmed protocol system, which was part of the simulated scenario. The obtained log files included timestamps for each pupillary response, which were sent to the system via a wlanconnection, as well as simultaneously recorded timestamps for each event occurrence.

## Procedure

The study was conducted in a virtual reality room, called XIM, and participants were recruited directly from the campus plaza. After completing the consent forms, they were invited to enter the XIM. For each participant, the experiment started with a preparation phase, where the eye tracking glasses were put on, the Big Five Inventory (BFI) was completed and some instructions regarding the virtual reality room were given (see Figure 1). In addition, there was a calibration phase that also ensured stable light conditions with and without planes presented on the screen. Afterwards, the practice session started, in which participants received an instruction on how to structure their commands to change airplane routes (see Fig. 2) and how to avoid collisions between airplanes. Following this instructions, participants had to manage the airplanes appearing at the screen on their own.

Figure 2: Experimental setup with eye-tracking device.

This section was finished as soon as participants were able to manage the scenario, measured by 10 correct answers in a row. After the practice section, participants were exposed to two trial sections presented in static order, the LWC followed by the HWC.
In each section, the airspace was divided in several airspace areas, whereof the subjects were responsible for the middle airspace (green rectangle). At a predefined frequency (HWC: $1-5 \mathrm{~s}$; LWC: 4-8 s) two airplanes with a given number and a random height appeared from both sides or from top and down heading to the same randomized point in the responsible airspace. During the whole experiment, participants had to keep in mind that airplanes, which do not collide in a 3D space, could appear at the same screen location due to the 2D display. This indirect 3D perception demands information processing resources as well (Wickens et al., 2013), but since all participants were exposed to comparable requirements, we did not expect additional effects on the measured level of workload. For avoiding collisions, participants had to use control commands with a similar structure compared to real ATC commands (see Figure 3). In detail, they had to provide to the number of the chosen airplane plus the information about what they want to change, for instance the direction or height of the airplane. The experimenter in the back adopted the role of the pilot, controlling the airplanes by sending special keyboard sequences to the simulation. Each session comprised a break as well. During this time span, participants reported their mood state by completing the Multidimensional Mood State Questionnaire (MDMQ). After finishing the LWC and HWC, the experimenter removed the eye tracker glasses.

## Data Analysis and Model Preparation

After conducting the experiment and preparing the pupil dilation data, we analyzed the data statistically and computed a dynamic model of workload over the task with an identified and fitted dynamic system (Isermann \& Münchhof, 2011). With reference to the latter, we developed some hypothetical assumptions based on the curve progressions of figure 6 in Beatty (1982). We assumed that dealing with appearing airplanes and setting a command will increase participants' workload (see Fig. 4). If a collision happened, we expected participants to immediately recognize their mistake and think about. However, at the same time the complexity of the air space should be reduced due to the reduced number of air

Figure 3: Schematic representation how participants had to change the height of an airplane.
planes on the screen. On this account, we assumed an initial increase in workload after collisions, directly followed by a decrease caused by the reduced amount of airplanes.

## Data preparation

To calculate the mean pupil dilation, the recorded data had to be cleaned from artifacts, blinks and other undesired patterns in the data stream (Beatty \& Lucero-Wagoner, 2000). Therefore, we used MATLAB-functions to implement standard methods for cleaning and analyzing pupil dilation data. First, we deleted all blinks in the signal, which are characterized by zero values in the data stream. Then, we interpolated the missing values and used a median filter in order to clean the signal from outliers. Participants with more than $18 \%$ blinks or zeros in the data stream were excluded from the statistical analysis, as the filtering functions and the evaluation could be falsified by very noisy signals. For the statistical approach, we calculated the respective level of workload for the events "collision", "disappear" and "appear" as mean of all occurred TERPs after the system had logged the collision or the appearance of airplanes. Due to the fact that our simulation only recognized if an airplane changed its direction or height, we measured the level of workload for the event "action" from TERPs calculated during an 1.5 s window before the change happened. Within our statistical analyses, we calculated the mean of the pupil dilation of LWC and HWC as measure of workload for the particular condition.

## Statistical Results

We conducted a repeated measures analysis of variance (ANOVA), to validate TERPs as predictor for workload. Event ("collision" vs. "appear" vs. "disappear") and workload condition (LWC vs. HWC) were regarded as independent variables and the recorded TERPs as indicator of workload were defined as dependent variable. Mauchly's test indicated a violation in the assumption of sphericity for the main effect of event, $\chi^{2}(5)=73.049, p<.001$, as well as the interaction between condition and event, $\chi^{2}(5)=$ $42.331, p<.001$, thus degrees of freedom were corrected using Greenhouse-Geisser estimates of sphericity for event, $\varepsilon=.388$, and the interaction, $\varepsilon=.573$. We found a significant main effect for event, $F(1.17,19.79)=12.394, p<.05, \eta_{p}^{2}=$ 0.42 , but no significant main effect of workload condition. Post-hoc pairwise comparisons with Bonferroni correction

Figure 4: Assumed schematic curve progression of TERPs during different events.
pointed out that the workload after an action $(p<.001)$ and after a collision ( $p<.05$ ) was significantly higher than the average workload in the whole condition. However, the workload after the appearance of an airplane was significantly lower ( $p<.05$ ). Moreover, a significant interaction effect between condition and event showed up, $F(1.72,29.24)=$ $3.701, p<.05, \eta_{p}^{2}=.18$, indicating a difference in the workload between events in both conditions. Since we had a static order, the level of workload in the HWC could have been influenced by the LWC. To control for this effect, we computed pupil dilation means during a 1 s window at the beginning of the LWC and HWC and conducted a paired-samples t-test. It did not show significant results, $t(19)=-1.927, p>.05$, thus we can assume that there was no influence on workload evoked by the static order.

## Workload Model

We assume that different levels of workload in both conditions result from task difficulty and the different events corresponding to the behavior of simulation and participants. Therefore, each simulated event as well as the spoken commands should have a direct influence on the level of workload in each condition, resulting in different TERPs. Thus, in the dynamic approach, the pupil dilation as level of workload is described as output that is dependent on the events, which are described as inputs. If there was a stable unique relation between input and output, we should be able to find a mathematical model for the temporal behavior of the workload (TERPs) from the measured input of the events.

## System Description

In system theory, such model can be described as multiple input and single output model (MISO), at which appearance, disappearance and collisions of airplanes as well as actions commanded by the participants are inputs, whereas the obtained TERPs are regarded as output. In detail, we measured a continuous time signal, with pupillary response and the related events as impulse responses appearing in each condition. An impulse response can be defined as the output of a process being excited by an impulse $(\delta(s)$ ) (Isermann \& Münchhof, 2011).

$$
\delta(t)=\left\{\begin{array}{lll}
\infty & \text { for } \quad t=0  \tag{1}\\
0 & \text { for } \quad t \neq 0
\end{array}\right.
$$

For a better understanding, while the step response or impulse response can be measured easily in many cases, we modeled our input events as step functions, whereas a step $(\sigma(s))$ can be obtained by integrating the impulse with respect to time $t$ (Isermann \& Münchhof, 2011).

$$
\sigma(t)= \begin{cases}1 & \text { for } \quad t \geq 0  \tag{2}\\ 0 & \text { for } \quad t<0\end{cases}
$$

To estimate important system parameters, such as settling time or the the damping coefficient and other characteristic values, we can use the following generic transfer function

$$
\begin{equation*}
G(s)=\frac{y(s)}{u(s)}=\frac{b_{0}+b_{1}(s)+b_{m-1}(s)^{m-1}+b_{m}(s)^{m}}{a_{0}+a_{1}(s)+a_{m-1}(s)^{m-1}+a_{m}(s)^{m}} \tag{3}
\end{equation*}
$$

which is the Laplace transformation of an ordinary differential equation (ODE) for a lumped parameter system (for further details see Isermann and Münchhof). Since we model our input data with step responses, we can directly take some individual characteristic values from the calculated step response of the system, which might be used to determine coefficients of special transfer functions by means of simple calculations (Isermann \& Münchhof, 2011). With the system identification toolbox, MATLAB offers a great database of identification methods to solve such process identification problems. Therefore, we used MATLAB to identify our workload model based on the data we collected during the experiment.

Modeling the input For modeling the system input, we used the timestamps of appearances and disappearances of airplanes as well as collisions and actions within the tasks from participants' $\log$ files. Based on this, we created several time series for each event class, which contained a step response at each event timestamp recorded by the simulation. Since airplanes stayed on the screen till they disappeared, we had to take into account that appearance and disappearance of airplanes have a different influence on the resulting workload compared to commands and collisions. Thus, the $\sigma$-function of appear is increased by two if an airplane couple appeared on the screen and the $\sigma$-function of disappear is increased by the number of airplanes which left the air space unharmed. By contrast, the influence of actions and collisions lasted only a limited time (an action during the time the participant spoke and the collision as long as the collision sound was played and the airplanes disappeared). Therefore, the $\sigma$-function of action was set to 1 for the time frame of 2 s before an action happened (see Fig. 5(a)). We chose these time window because the middle duration of commands was 2 s . Due to the fact that an airplane collision reported relatively short by a collision sound, we modeled the $\sigma$-function of collision by setting it to 1 for the time frame of 1 s after a collision happened (see Figure 5(b)).

Identify the types of transfer functions for events After modeling the input, we analyzed the behavior of the pupil

Figure 5: Example step response function of all events.
dilation over 4 s time windows during the recorded events. The chosen time windows doubled the recommended 2 s time window (Beatty \& Lucero-Wagoner, 2000), as for identifying the dynamic of the system we had to ensure that the eventrelated response was included even with potential reaction time differences between participants. Moreover, the additional information of the signal behavior could help to find the right time constants.

In system theory, there exist several LTI(Linear-Time-Invariant)-systems, which describe different patterns of behavior in signals with linear ODEs. In the mathematical view, this behavior is described with the transfer function $G(s)$, which describes how a step response(s) influences the output signal. For example, a transfer function for an $P T_{1}$-system can be described by

$$
\begin{equation*}
G(s)=\frac{y(s)}{u(s)}=\frac{b_{0}}{1+a_{1} s}=K \frac{1}{1+T_{1} s} \tag{4}
\end{equation*}
$$

in which $P T_{1}$-system results depend on an step response in an increase of K during the time $T_{1} / \mathrm{T}$, whereas T is the sampling rate of the signal. Thus, the time constant $T_{1}$ describes how fast the signal reached the value K. In terms of the workload description such a system would describe how the workload will be influenced over time. Whereas $T_{1}$ describes how fast the workload is increased and $K$ describes the absolute increase or decrease of the workload after an event is recorded. A more detailed view and the explanation of all types of LTIsystems are described in Isermann and Münchhof (2011).

Since we focused on developing a general model for each event and there might be some disturbing influences within recorded TERPs, we calculated the mean of all TERPs and regarded this as a baseline within our identification process. Such disturbing influences could be seen in miscalculated workload within overlapping, unrecognized or overwhelming events. By calculating the mean progression of the TERPs

Figure 6: Curve progression of TERPs at different events.
during the events, we assume that disturbing influences might distracted from the characteristic behavior. In Figure 6, we show the behavior of the TERPs based on this means (black lines in each figure). Moreover, it outlines that we identified transfer functions for the each step function of several events, therefore the mathematical description of our transfer function could be seen as the mathematical description of our TERPs depending on event inputs (colored lines). We identified a $P T_{2}$-system for the action, which shows a short initial decrease in workload, followed by a steep increase. The under-dumped $P T_{2}$-system with a death time for the behavior of collision, shows that there was no significant increase in workload after a collision but a decrease after $0.5-1.0 \mathrm{~s}$. The identified system of appear comprises a $D T_{2}$-system with a death time, which shows a significant increase in workload during an spoken command. The signal of disappearance reveals that the reaction of this event is very small (signal range is between 0.08 and -0.05 ). Potential reasons might be the lack of reaction in pupil dilation to this event or an ineptly small size of the chosen time window for identifying a significant change. Thus, we have to handle the identified $P T_{2} Z$ system with death time carefully, since it might be incorrect. Of course, these identified models are "ideal" models to the mean behavior of the TERPs, but they can provide a hint on the type of underlying system and a clue for the range of the used time constants. Such applies in particular for collision and action, since these events are most likely to trigger direct and fast input-response behavior.
Identify the overall system behavior Based on the identified dynamic system for the TERPs, we aimed to identify the

Table 1: Identified parameters of the mean curve progression of all event-based TERPs.

| System | K | $T_{1}$ | $T_{2}$ | $T_{z}$ | $T_{d}$ | $T_{w}$ | $\zeta$ |
| :--- | :---: | :---: | :---: | :---: | :---: | :---: | :---: |

(b) LWC of participant 25 .

Figure 7: Comparison of recorded and modeled pupil dilation for participants 8 (training data) and 25 (validation data).
underlying dynamic system behavior of pupil dilation for the whole conditions. We assumed that the measured pupil dilation reflects the sum of responses to the input. For validating our model, we divided the data in a training data set, containing 16 participants ( $80 \%$ of the sample), and a validation data set, containing four participants ( $20 \%$ of the sample). Data of LWC and HWC were represented as independent experiments and contained the time series of the events (see Figure 5) and the corresponding recorded measurements of the pupil dilation. We defined the types of systems and their possible range of parameters detected in the TERP-analysis as system structure, to identify the complete model of pupil dilation behavior. Afterwards, we used the system identification toolbox to identify the best model describing change of pupil dilation over time depending on the event inputs. Figure 7(a) shows the simulated and the experimental output of the dynamical pupil dilatation system of two examples of the training and validation data set. We see the typical increase of the pupil dilation during the conditions of participants 8 and 25 (black lines) and the corresponding model outputs (red lines) with their exponential curve progression. The goodness-of-fit is calculated by the normalized root mean square error $\left(P_{8}=46.06 \%, P_{25}=45.68\right)$ and shows that the peaks in the pupil dilation are the result of TERPs from actions and the dips are the result of TERPs from happened collisions. The fitted model parameters for different transfer functions are displayed in table 2. As expected, in the fitted time constants of appear and disappear event-related influences are very slow ( $T_{1 a p}=104.2 ; T_{1 d i}=211.2$ ), compared to action and collision ( $T_{1 a c}=1.72 ; T_{1 c o}=1.5$ ). Furthermore, the absolute influence of an action and a collision ( $K_{a c}=2.77$; $K_{c o}=-9.58$ ) to the workload is greater than the appearance and disappearance of airplanes ( $K_{a p}=0.93 ; K_{d i}=-1.0$ ).

Table 2: Identified parameters of event-based TERPs based on pupil dilation data of the whole conditions.

| System | K | $T_{1}$ | $T_{2}$ | $T_{z}$ | $T_{d}$ |
| :--- | :---: | :---: | :---: | :---: | :--- |
| Action | 2.77 | 1.72 | 1 |  |  |
| Appear | .93 | 104.2 | .61 | -.62 | .6 |
| Collision | -9.58 | 1.5 | .96 |  | 1.14 |
| Disappear | -1 | 211.2 | 55.65 |  | .74 |

Figure 8: Comparison of experiment and fitted model data

Validation of the model The model described above was identified by data from the LWC and HWC of the first 16 participants. To measure how good our model can represent the recorded data of participants the model never seen, we calculated the deviation between model and experiment data over all participants and conditions by the normalized root mean square error (NRMSE) and the normalized coefficient of determination $\left(N R^{2}\right)$. In Figure 8 shows the goodness-of-fit-results of our training data set and the validation data set. For the NRMSE, we reached mean values of $28.87 \%$ for the validation data set and $32.99 \%$ for the training data set. If we look at the $N R^{2}$, the model is able to explain $49.42 \%$ of variance in the validation data and $55.10 \%$ in the training data.

## Discussion

We developed and identified a dynamic model for the TERPs within a simulated ATC scenario. Corresponding to our expectations, statistical analyses show a significant increase in participants' TERPs due to collisions and actions, indicating metacognitive reflections about commands or mistakes. Contradictory results show up with a significant decrease in TERPs after the appearance of a couple of airplanes that afterwards increases again (see Figure 6(b)). These effects are very slow and the sole calculation of state based statistics is prone to loose this information. On this account, we built and validated a dynamic model to predict workload of ATC-Tasks based on the experimental results. We used different models for each event logged in the session, and thus can conclude that not each visual input provides the same TERPs (Beatty \& Lucero-Wagoner, 2000). Furthermore, we show that the resulting workload in our condition is the sum of the responses of our system to the events. However, the increase is not a straight line, but rather an exponential increase, which might occur as well in similar experiments that investigate workload. Moreover, we can conclude that there is a stable unique relation between events in the simulation and the resulting TERPs, as we were able to find a mathematical model for the temporal behavior of the pupil dilation. Still, this model is just an approximation of the dynamic processes of workload that might be limited by the underlying linear process model. Nevertheless, we were already able to explain and predict nearly $50 \%$ of the variance in the resulting workload.

## Further steps

In the next instance, we will conduct another experiment with a duration of 7 min and two conditions, an emotional and a neutral session. In this vein, we can validate our identified workload progression for the extended time frame and furthermore investigate how the emotional influence in the second condition changes the dynamics of our model. Based on these results, we will extend our model by an emotional component, simulating and predicting the influence of emotions to the workload and TERPs.

# The Dynamics of Selective Integration during Rapid Experiential Decisions 

Konstantinos Tsetsos (k.tsetsos@uke.de)<br>Department of Neurophysiology \& Pathophysiology, University Medical Center Hamburg D-20246 Hamburg, Germany

#### Abstract

When making decisions humans often violate the principles of rational choice theory. Recent experiments, involving rapid experiential decisions, uncovered a mechanism that is responsible for various rationality violations. According to this selective gating mechanism, incoming value samples are accumulated across time, but prior to their accumulation they are weighted in proportion to their momentary rank-order. Here, using a data-driven approach, I present a dynamic extension of this mechanism, which involves potentially asymmetric inhibition between the inputs. As a result, and contrary to the previous selective gating implementation, the vigour of gating is modulated by the difference between two value samples (a distance effect) as well as by the absolute magnitude of the samples (a magnitude effect). This extension offers a superior explanation to existing and new data; and links high-level decision phenomena with computational principles previously described in theories of selective attention and visual search.

Keywords: Selective integration; Experiential decisions; Risk-seeking; Intransitivity

## Introduction

Behaving organisms update their preferences in response to changes in their internal status and the state of the world; but they also do so in the absence of such changes. For instance, people are found to prefer $A$ (e.g., fresh fish) over $B$ (e.g., steak), when these two alternatives are offered, but $B$ over $A$ when a third - inferior and unchosen- alternative, $C$ (e.g., frozen fish), becomes available (Huber, Payne, \& Puto, 1982). Reversals of preference, as in the example above violate the axioms of rational choice theory (Von Neumann \& Morgenstern, 2007) and indicate that the valuation of an alternative is context-sensitive, not only dependent on the agreement between the goals of the decision-maker and the properties of the judged alternative but also dependent on the properties of other alternatives in the choice set.

Context-sensitive valuation (hereafter CSV) phenomena are reported as preference reversals (Tsetsos, Usher, \& Chater, 2010) or transitivity violations (Tversky, 1969), elicited in multiattribute choice experiments. Recently, analogues of these CSV phenomena were obtained in a rapid experiential decision task, labelled value psychophysics (Tsetsos, Chater, \& Usher, 2012; Tsetsos et al., 2016). Obtaining CSV phenomena in a psychophysical task enabled the detailed computational modelling of the involved decision processes, pointing to a selective integration model (hereafter SI) that underlies several rationality violations.

According to SI, value information is accumulated across time but, prior to accumulation, higher value samples suppress lower samples via a selective gating mechanism. In the extant implementation of the model the vigour of this suppression is constant. For instance, a value sample of 60 will suppress a competing value sample of 59 in the same fashion
that it would suppress a competing value sample of 49 . Here, I focus exclusively on binary choices and show that this invariant mechanism fails to capture some qualitative patterns in past data. To overcome this limitation, I propose a dynamical mechanism in which the inputs compete against each other via potentially asymmetric inhibition.

In what follows, I describe the extant implementation of the SI model and its trademark behavioural signatures. Then, I use previously published data and outline qualitative patterns that SI in its current form cannot explain. These patterns are replicated in a new experiment. Third, I propose three extensions of the selective integration model and fit these extensions to the new data. Finally, I present results from a new experiment that decisively disentangles these three selective integration extensions.

## Selective Integration: description and behavioural signatures

In the SI model for binary choices, value samples in support of the two alternatives arrive simultaneously ${ }^{1}$ and are accumulated over time, as in sequential sampling models of perceptual discrimination and categorisation (Bogacz, Brown, Moehlis, Holmes, \& Cohen, 2006). Importantly, the values that are momentarily higher are passed onto the accumulation layer unaffected but the relatively lower values are truncated, akin to an attentional process that selectively prioritises the accumulation of local winners over local losers. In this section I outline the mathematical details of the extant implementation of selective integration for binary choices and point to key behavioural phenomena predicted by the model.

## Model description

The model described here applies to decisions based on two sequences of inputs, presented simultaneously. The two sequences have thus the same number of samples and each pair of samples is presented at a discrete time-step, for a fixed time interval. Here, based on the findings in Tsetsos et al. (2016), I assume that the incoming samples are not corrupted by noise prior to accumulation. The two sequences are labelled $S_{A}$ and $S_{B}$, with $S_{A}(t)$ indicating the value of sequence $A$ at the (discrete) sample $t$. Two accumulators ( $Y_{A}$ and $Y_{B}$ ) integrate the values of the sequences across time according to the following difference equations:

[^217]\[

$$
\begin{align*}
& Y_{A}(t)=(1-\lambda) \cdot Y_{A}(t-1)+I_{A}(t)+\xi \cdot \zeta_{A}(t)  \tag{1}\\
& Y_{B}(t)=(1-\lambda) \cdot Y_{B}(t-1)+I_{B}(t)+\xi \cdot \zeta_{B}(t) \tag{2}
\end{align*}
$$
\]

In the above $t$ indicates the current discrete time-step (or sample), $\lambda$ is accumulation leakage, $I_{A, B}(t)$ is the input to the two accumulators on a given time-step, $\xi$ is the standard deviation of the noise at the accumulation level and $\zeta_{A, B}(t)$ are standard Gaussian samples, independent from each other and across time-steps. The accumulators are initialised at 0 : $Y_{A}(t)=Y_{B}(t)=0$. At the end of the accumulation period (at $t=T$, with $T$ being the total number of samples presented in each sequence) a decision is made in favour of the accumulator with the higher tally. If both accumulators end up with equal tallies, a decision is made randomly.

The inputs to the two accumulators $\left(I_{A, B}(t)\right)$ reflect the modified sequence values after the selective integration filter is applied. I refer to this filter as selective gating. Selective gating is implemented as follows.

$$
\begin{align*}
& I_{A}(t)=\theta\left(S_{A}(t), S_{B}(t)\right) \cdot S_{A}(t)  \tag{3}\\
& I_{B}(t)=\theta\left(S_{B}(t), S_{A}(t)\right) \cdot S_{B}(t) \tag{4}
\end{align*}
$$

Function $\theta$ returns a value of 1 if the first argument is equal or larger than the second and a value $w$ (selective gating parameter) otherwise:

$$
\theta(x, y)=\left\{\begin{align*}
1 & \text { if } x>=y  \tag{5}\\
w & \text { if } x<y
\end{align*}\right.
$$

## Behavioural signatures of selective integration

Pro variance (PV) effect. Consider two sequences, $A$ and $B$, with values sampled from normal distributions with means $\mu_{A}, \mu_{B}$ and standard deviations $\sigma_{A}, \sigma_{B}$. The pro variance effect (PV) occurs when participants choose more often sequence $A$ when $\mu_{A}=\mu_{B}$ and $\sigma_{A}>\sigma_{B}$. Equivalently, the PV effect is present when accuracy is higher in trials where $\mu_{A}>\mu_{B}$ and $\sigma_{A}>\sigma_{B}$ (correct answer is $A$ ) relative to the accuracy in trials where the means are swapped ( $\mu_{A}<\mu_{B}$ and $\sigma_{A}>\sigma_{B}$; correct answer is $B$ ). The PV effect was originally demonstrated in Tsetsos et al. (2012) and it was robustly replicated in Tsetsos et al. (2016). SI explains the PV effect as follows: a losing sample from the high variance distribution will more likely have low value. In the low variance distribution, a losing sample will more likely have a mediocre value. Multiplicatively downweighting a low value results in a smaller loss relative to downweighting a mediocre value (for a value of 30 and for $w=0.5$ the loss is 15 ; for a value of 50 the respective loss is 25 )(Tsetsos et al., 2012).

Frequent-winner (FW) effect. Consider two sequences $A$ and $B$, consisting of the same three low $(L)$, medium $(M)$ and high $(H)$ value samples such that $H-M=M-L$. The order of appearance of these three samples differs in the two sequences: $A \rightarrow L M H$ and $B \rightarrow H L M$. Thus, when presented
simultaneously in that order, sequence $A$ wins locally twice by a small margin ( $M$ vs. $L$ and $H$ vs. $M$ ) and loses once by a larger margin ( $L$ vs. $H$ ). According to the SI model ( $w<1$ ) a choice bias in favour of sequence $A$ is expected since $M+H+L \cdot w>L \cdot w+M \cdot w+H$ or $M>M \cdot w$. This frequent-winner effect (hereafter FW) can also appear when accuracy is higher in trials in which all values in $A$ are augmented by a small constant $c$ (such that $A$ has a higher total value and dominates $B$ in 2 out of 3 samples), relative to the accuracy in trials in which all values of $B$ are augmented by a small constant $c$ (in that case $B$ has a higher value but $A$ still dominates $B$ in 2 out of 3 samples). Importantly, SI can lead to intransitive preference cycles when a third sequence $C$ with values $M H L$ is considered. In that case, in the respective binary choices, $A$ will be preferred over $B, B$ will be preferred over $C$ and $C$ will be preferred over $A$. The FW effect, and the corresponding weak stochastic transitivity violations, were robustly obtained across 4 experiments, in which participants had to choose between bars of different length, presented sequentially (Tsetsos et al., 2016).

## Challenges for Selective Integration

Under the selective integration framework the PV and FW effects occur due to the same mechanism, controlled by the selective gating parameter. It is therefore expected that the two effects will be strongly correlated across participants. However, a re-examination of the 4 experiments reported in Tsetsos et al. (2016) $(N=93)$ reveals no correlation between the two effects $(r=0.000)$. On the contrary, the effects predicted by fitting the SI model show indeed significant positive correlation ( $r=0.323, p=0.002$ ). Additionally, for the same parametrisation, the SI model predicts a much stronger FW than PV effect (difference in the predicted effects: $M=$ $0.128, S E=0.014, t(92)=9.150, p<0.001)$. However, in the observed data this difference does not occur (difference in the observed effects: $M=0.006, S E=0.023, t(92)=$ $0.240, p=0.811$ ). The model predicts well the magnitude of the FW effect but, although the predicted PV effect is significant $(M=0.036, S E=0.004, t(92)=9.177, p<0.001)$, it is much smaller than the observed one (observed and predicted difference for the PV effect: $M=0.102, S E=0.014, t(92)=$ $7.274, p<0.001$ ).

The lack of correlation between the PV and FW effects and the underestimation of the PV effect challenge the existing implementation of SI. It is conceivable, however, that these patterns are specific to the design and stimuli used in Tsetsos et al. (2016) (i.e. accumulation of lengths) and do not reflect generalisable limitations of the model. I examine next whether this is the case by characterising the PV and FW effects in an experiment that involves the accumulation of numerical values (c.f. Tsetsos et al. (2012)).

## Experiment 1

Participants. 25 participants $\left(M_{\text {age }}=28.1, S D_{\text {age }}=6.4,14\right.$ female) with normal or corrected-to-normal vision and no
history of neurological or psychiatric impairment were recruited from Birkbeck's (University of London) participants pool. All participants gave informed consent to participated and all procedures were approved by the local ethics committee.

Task \& Procedure. On each trial, participants observed pairs of black 2-digit numerical values presented rapidly and sequentially, to the left and right of a central fixation point and against gray background. The viewing distance was 60 cm and each numerical character was $0.93^{\circ}$ wide and $1.5^{\circ}$ long. After the presentation of 9 pairs of numbers, the central fixation point turned blue and participants were asked to choose which stream had on average the higher value. After giving a response the blue dot turned green (red) to indicate a correct (incorrect) response. The presentation rate of the numbers was 800 ms and 1 second gap was left between trials. Overall there were 4 blocks with 65 trials each. At the end of each block participants could see their accuracy so far. At the end of the experiment participants received $£ 7$ and a $£ 2$ bonus if their accuracy exceeded $75 \%$.

Design. There were 4 types of trials ( 65 trials per type) in the experiment, presented in random order. In all trials there was a correct answer, with the sum of the higher sequence differing from the sum of the lower sequence by 72 units. Two types of trials were associated with the PV effect while the other two with the FW effect. In the PV trials the sequences were generated from Gaussian distributions, with the mean of the higher sequence $\left(\mu_{H}\right)$ sampled from $\mu_{H} \sim U(45,65)$. The mean of the lower sequence was $\mu_{L}=m u_{h}-8$. In one type of PV trials, referred to as $\mathrm{PV}_{1}$ trials, the standard deviation of the higher sequence was $\sigma_{H}=20$ while the standard deviation of the lower sequence was $\sigma_{L}=10$. In $\mathrm{PV}_{2}$ trials the standard deviations changed with $\sigma_{H}=10$ and $\sigma_{L}=20$. The accuracy difference between $\mathrm{PV}_{1}$ and $\mathrm{PV}_{2}$ trials quantifies the PV effect. In the FW trials, the mean values of the higher and lower sequences were matched to those in the PV trials. However, the temporal distribution of the sequences was manipulated such that one alternative always dominated the other in 6 out of 9 samples (see also Tsetsos et al. (2016)). In $\mathrm{FW}_{1}$ trials the higher sequence dominated the lower sequence more often. When the higher sequence dominated, it did so by $U(23,28)$ units and in the less often cases when the lower sequence dominated it did so by $U(22,32)$ units. In $\mathrm{FW}_{1}$ trials the higher sequence dominated the lower sequence in 3 out of 9 samples only. When the higher sequence dominated it did so by $U(38,48)$ units and when the lower sequence dominated it did so by $U(7,13)$ units. The accuracy difference between $\mathrm{FW}_{1}$ and $\mathrm{FW}_{2}$ trials quantifies the FW effect. In all trials the generated sequences were constrained so as to involve only 2-digit numbers ranging from 10 to 90 .

Results. Participants performed above chance in all trials (accuracy: $M=0.774, S E=0.023$ ). Accuracy in $\mathrm{PV}_{1}$ trials was higher than in $\mathrm{PV}_{2}$ trials $(M=0.167, S E=$ $0.032, t(24)=5.170, p<0.001, d=1.034)$ replicating thus
the PV effect obtained elsewhere (Tsetsos et al., 2012, 2016). Accuracy in $\mathrm{FW}_{1}$ trials was higher than in $\mathrm{FW}_{2}$ trials $(M=0.050, S E=0.017, t(24)=2.897, p=0.008, d=$ 0.579 ). This finding replicates with different stimuli (i.e. numbers) the effect reported in Tsetsos et al. (2016). Contrary to what SI predicts, there was no correlation between the two effects ( $r=-0.014, p=0.949$ ) and the FW effect was weaker than the PV effect.

## Extensions of selective integration

The challenges that were identified for SI using the datasets from Tsetsos et al. (2016) persist in Experiment 1: the two critical effects were not correlated and the PV effect was larger than the FW effect. To address these challenges I here propose 3 extensions of the SI model. One extension is static, with selective gating invariance as in the original model, while the other two are dynamic and biologically inspired. The primary aim of these extensions is to decorrelate the PV and FW effects. Hereafter, the baseline SI model described earlier will be referred to as $\mathcal{M}_{S 0}$.

## A static extension

The first SI extension involves a transducer function that transforms objective values into their subjective counterparts. The model is thus identical to the one described in Eq. 1-5, with the exception that Eq. 3-4 take the form:

$$
\begin{align*}
& I_{A}(t)=\theta\left(S_{A}(t)^{\alpha}, S_{B}(t)^{\alpha}\right) \cdot S_{A}(t)^{\alpha}  \tag{6}\\
& I_{B}(t)=\theta\left(S_{B}(t)^{\alpha}, S_{A}(t)^{\alpha}\right) \cdot S_{B}(t)^{\alpha} \tag{7}
\end{align*}
$$

Exponentiating the inputs allows the PV effect to occur independent of the selective gating parameter when $\alpha>1$. In such cases the value function is convex resulting in a riskseeking bias. Although convex low-level representation is undocumented in numbers (Feigenson, Dehaene, \& Spelke, 2004) or lengths (Stevens, 1957)), it is possible that, at a higher processing level, large quantities stand out. This model will be referred to as $\mathcal{M}_{S 1}$.

## Dynamic extensions

Implementations $\mathscr{M}_{S 0,1}$ are static in nature. Here I explore dynamical implementations, in which selective gating falls out from continuous competition between the input units. The competition is mediated by inhibition as in models of visual attention (Lee, Itti, Koch, \& Braun, 1999). To illustrate the basic idea, the incoming values compete against each other and the activation states of the input units feed continuously, in cascade (McClelland, 1979), to the accumulation level (variables $Y$ in Eq. 2). Almost equivalently, and to maintain comparability between static and dynamic SI implementations, I assume that a given accumulator receives discrete updates. These updates are equal to the temporal average of the activation in the corresponding input unit, for the period during which the stimulus was presented. The first dynamic model, labelled $\mathscr{M}_{D 1}$, involves mutual inhibition between the
input units (Usher \& McClelland, 2001). Eq. 1-2 remain intact but Eq. 3-5, which implement the selective gating filtering, are replaced as follows:

$$
\begin{align*}
I_{A}(t) & =\frac{\int_{0}^{P} X_{A}(x) d x}{P}  \tag{8}\\
I_{B}(t) & =\frac{\int_{0}^{P} X_{B}(x) d x}{P} \tag{9}
\end{align*}
$$

Variables $X_{A, B}$ reflect the input units. Variable $P$ is the duration (in units of time) that a given pair of samples is presented for and $d x$ is a small time interval (set in simulations to $d x=0.001$ seconds). The input units are initiated at 0 and their dynamics are governed by the following coupled differential equations:

$$
\begin{align*}
d X_{A} & =\left(-\kappa X_{A}-\beta f\left(X_{B}\right)+S_{A}(t)\right) d x  \tag{10}\\
d X_{B} & =\left(-\kappa X_{B}-\beta f\left(X_{A}\right)+S_{B}(t)\right) d x \tag{11}
\end{align*}
$$

In the above, $\kappa$ is a leak parameter (set to 1 throughout this paper), $f$ is the identity function $(f(x)=x)$ and $\beta$ is the strength of mutual inhibition. The two input units thus reflect sustained input, corresponding to the presented values, $S_{A, B}(t)$ at time-step $t$. For simplicity, the above equations are deterministic, consistent with the finding that during value psychophysics noise at the representation level is negligible (Tsetsos et al., 2016). The input units are subject to a reflecting boundary at 0 that prevents activation states from being negative:

$$
\begin{align*}
& X_{A}=\max \left(X_{A}, 0\right)  \tag{12}\\
& X_{B}=\max \left(X_{B}, 0\right) \tag{13}
\end{align*}
$$

When $\beta=0$, the two input units quickly converge to their nominal values. When inhibition is present, the larger value suppresses the smaller value, implementing that way a form of selective gating. Figure 1a shows examples of the evolution of activation states in the input units.

The second dynamic extension $\left(\mathcal{M}_{D 2}\right)$ is identical to $\mathcal{M}_{D 1}$ with the exception that, following Brown and Holmes (2001), each unit inhibits the other via a sigmoid activation function.Thus, $f$, which was the identity function in $\mathcal{M}_{D 1}$, now becomes:

$$
\begin{equation*}
f(x)=\frac{1}{1+e^{(-g(x-b))}} \tag{14}
\end{equation*}
$$

In the above, $g$ is the slope of the activation function (here set to 1 ) and $b$ the inflection point of the sigmoid. In other words, $b$ controls when selective gating will kick in while the inhibition strength $(\beta)$ controls the strength of selective gating. The difference between $\left(\mathcal{M}_{D 1}\right)$ and $\left(\mathcal{M}_{D 2}\right)$ is that, in the former, inhibition is mutual while in the latter inhibition can be non-reciprocal (Figure 1b) and inactive from inputs of low value.

Figure 1: (a) Input activation trajectories for $\mathscr{M}_{D 1}$ for different value samples and for $\kappa=1$. Leftmost panel depicts the special case without inhibition. (b) Same as (a) but for $\mathcal{M}_{D 2}$ and $b=38, g=1$ and $\kappa=1$.

## Comparison of selective integration extensions

## Quantitative comparison of the models

Here I fit the models to the choice data of each participant from Experiment 1. Model predictions for each trial are derived numerically. The negative log likelihood of each parametrisation is calculated on a trial-by-trial basis and summed across trials. $\mathcal{M}_{S 0}$ has three free parameters $(w, \xi, \lambda)$ and $\mathcal{M}_{S 1}$ has one extra free parameter ( $\alpha$ ). For the dynamic extensions, some parameters are set to fixed values ( $\kappa=1, g=1, P=500 \mathrm{~ms}, d x=1 \mathrm{~ms}$ ), which leaves $\mathcal{M}_{D 1}$ with 3 free parameters $(\sigma, \lambda, \beta)$ and $\mathscr{M}_{D 2}$ with a fourth parameter (b). The models are compared based on their BIC values, aggregated across participants, and also on a participant-byparticipant basis (i.e. the proportion of participants for which a model has the lowest BIC score). Additionally, the correlation between the PV and FW predicted effects is examined. The results are summarised in Table 1.

Table 1: Model comparison in Experiment 1.

| Model | Total BIC | \% BIC lowest | $r$ |
| :--- | :--- | :--- | :---: |
| $\mathcal{M}_{S 0}$ | 8,458 | $28 \%$ | 0.736 |
| $\mathcal{M}_{S 1}$ | 8,554 | $0 \%$ | 0.254 |
| $\mathcal{M}_{D 1}$ | 8,441 | $24 \%$ | 0.779 |
| $\mathcal{M}_{D 2}$ | 8,398 | $48 \%$ | 0.087 |

$\mathcal{M}_{D 2}$ explains the data best and succeeds to decorrelate the PV and FW effects (last column in Table 1). It is also the only model that does not underestimate dramatically the PV effect and predicts that it will have higher magnitude than the FW effect (Figure 2). In this model, the PV effect is partly driven by parameter $b$. If this parameter is set above the middle of the value range, selective gating will be inactive for comparisons between mediocre and low values, further exaggerating

Figure 2: Data and model fits in Experiment 1. Error bars correspond to 2 SE .
the choice bias for a high variance sequence. The FW effect is independent of the $b$ value (as long as it is not too high, deactivating altogether selective gating). $\mathcal{M}_{S 1}$ also succeeds to decorrelate the effects but provides a poor fit. Importantly, $\mathcal{M}_{D 1}$ appears to suffer from the same limitation as $\mathcal{M}_{S 0}$ : selective gating is controlled by one parameter $(\beta)$ and the PV and FW are strongly correlated.

## Qualitative differences among models

The distinction between the four selective integration implementations is the way selective gating is implemented. In the two static implementations $\left(\mathcal{M}_{S 0,1}\right)$ the weight applied on the local loser is invariant to the difference between the winning and losing value samples. On the contrary, in the dynamic extensions, this difference matters. In Figure 3, I show the effective weight applied on the losing sample for several combinations of pairs of values (c.f. Figure 1). Static implementations predict, by definition, invariance of weighting (here for $w=0.5$ ). $\mathcal{M}_{D 1,2}$ both predict that as the difference between the two inputs increases (c.f. leftmost and middle bars), suppression of the loser increases too. This is reminiscent of the distance effect encountered in numerical cognition (Moyer \& Landauer, 1967).

Adding a constant to both input samples (c.f. leftmost and rightmost bars) results in opposing predictions in the two dynamic models. $\mathcal{M}_{D 1}$ predicts weaker suppression for increased values, since the competition between the two inputs takes longer to resolve. $\mathscr{M}_{D 2}$ predicts a stronger suppression of the loser, since the winning unit will breach first the $b$ barrier and will start inhibiting the other unit strongly, resulting in enhanced winner-take-all dynamics (Figure 1, rightmost panels). All models thus make distinctive qualitative predictions regarding a magnitude effect, which I exploit in the next experiment.

## Experiment 2

In this experiment I examine how the PV effect changes when all sequence values increase or decrease by the same constant amount (Figure 4a). According to static models no change

Figure 3: Effective weighting is the ratio between the filtered lower sample and the corresponding unfiltered values. The unfiltered values in static models are nominal values (without selective gating, $w=1$ ) and in dynamic models values, as per Eq. $8-9$, in the $\beta=0$ instantiation. The values of the different pairs are given in the x -axis.
is expected, since selective gating is invariant to the magnitude of the values. $\mathcal{M}_{D 1}$ predicts weaker selective gating for high values, while $\mathscr{M}_{D 2}$ predicts a stronger PV effect for high values.

Participants. 18 participants $\left(M_{\text {age }}=26.4, S D_{\text {age }}=5.2,11\right.$ female) took part. The rest of details are as per Experiment 1.

Task \& Procedure. The task and procedure was identical to Experiment 1 except that there were 12 samples in each stream and that the presentation rate was 0.5 seconds. Overall participants did 6 blocks with 50 trials each.

Design. The PV effect was elicited as in Experiment 1, using two trial types ( $\mathrm{PV}_{1,2}$ ) and examining the accuracy difference between them. Here, there were 3 conditions giving rise to 6 trial types ( 50 trials for each type, randomly presented). In the baseline condition $\left(\mathrm{PV}_{B_{1,2}}\right)$, the correct sequence had always a mean of 50 and the incorrect a mean of 42 . In the negative offset condition $\left(\mathrm{PV}_{-1,2}\right)$, for a given trial, 6 pairs of values were created as per the baseline condition. The remaining 6 pairs were created by subtracting from the mean of both Gaussians a constant $(c=15)$. The regular and lower pairs were presented in random order in a given trial. Equivalently, in the positive offset condition ( $\mathrm{PV}_{+_{1,2}}$ ) a constant $(c=15)$ was added to the values of 6 pairs.

Results. The PV effect increased as both sequences increased in absolute values as indicated by a repeated measures ANOVA $\left(F(2,34)=18.74, p<0.001, n^{2}=0.524\right)$. Tukey post-hoc tests revealed that the PV effect was lower in the negative offset condition relative to the baseline ( $p<$ 0.001 ) and the positive offset ( $p<0.001$ ) conditions. The difference between the baseline and the positive offset condition was not significant ( $p=0.171$ ). As predicted, this PV increasing pattern was solely captured by $\mathscr{M}_{D 2}$. The advan-

Figure 4: (a) Outline of experimental design. (b) PV effect as a function of negative offset (N), baseline (B) and positive offset ( P ) conditions for data and models (colour code for models as per Figures 2-3). Error bars correspond to $95 \%$ CI.
tage of $\mathscr{M}_{D 2}$ in this experiment was clear also in quantitative comparisons (data fitted for each participant separately) using BIC (Table 2).

Table 2: Model comparison in Experiment 2.

| Model | Total BIC | \% BIC lowest |
| :--- | :---: | :---: |
| $\mathcal{M}_{S 0}$ | 5,976 | $6 \%$ |
| $\mathcal{M}_{S 1}$ | 5,466 | $0 \%$ |
| $\mathcal{M}_{D 1}$ | 5,448 | $6 \%$ |
| $\mathcal{M}_{D 2}$ | 5,253 | $88 \%$ |

## Conclusion

Selective integration is a decision making model that has successfully explained several rationality violations. One potential criticism against this model is that its applicability is limited to rapid decisions from experience, in which attentional demands are increased. However, it has been previously shown that selective gating increases under lower attentional demands (Tsetsos et al., 2016). Additionally, behavioural signatures that are routinely obtained in high-level decisions are also obtained in rapid experiential decisions, implying that the latter can offer a window to more complex choice mechanisms.

Here I presented challenges for the extant implementation of selective integration. These challenges were successfully addressed by a dynamic extension of the model, in which the inputs compete for accumulation via inhibiting each other, as in models of selective attention and visual search. This dynamic extension predicts that the vigour of selective integration increases both when the distance and the absolute magnitudes of the two inputs increase. This prediction was experimentally confirmed. Oveall, this dynamic and biologically inspired (Usher \& McClelland, 2001) extension presented here, significantly improves the descriptive adequacy of the selective integration framework and facilitates its validation at the neurophysiological level.

## Acknowledgments

#### Abstract

A large literature shows that language influences cognition. Yet, we know very little about when and how linguistic influences on cognition become important in development. Here we test the proposal that one pathway by which language affects cognition is by activating category information which influences visual processing, and that this influence starts early. Across two experiments, we show that category information affects visual processing and that words can activate category information in young children.

Keywords: language; attention; cognitive development; vision.

## Introduction

A large literature has documented that linguistic information changes other cognitive processes. Evidence for this comes from laboratory tasks in which people perform differently if they experience the same event associated with different kinds of linguistic information (Feist \& Gentner, 2007; Loftus \& Palmer, 1974) or associated with linguistic information vs. information presented in another modality (Lupyan \& Spivey, 2010; Lupyan \& Thompson-Schill, 2012), and from cross-linguistic research that shows influences of language on presumably non-linguistic processes (Fausey \& Boroditsky, 2011; Levinson \& Haviland, 1994). Taken together, these results show that language - and words, in particular - changes how adults perform on a wide variety of tasks, and that these cognitive processes are permeable to linguistic information.

Despite this wealth of evidence, we know very little about when and how linguistic influences on cognition become important in development. Understanding the development of linguistic effects on cognition is essential to understand the development of human cognition and the nature of individual differences in cognitive abilities - differences that start early and have downstream consequences into later development (Morgan, et al., 2015; Stanovich, 1986). One possibility is that language influences cognition by activating information about the objects or events to which it refers, and this information changes how visual information is processed. This hypothesis is plausible for three reasons. First, there is evidence supporting the link between language and visual processing. For example, adults listening to spoken sentences look at possible visual referents even when the visual array is irrelevant to the task (see Huettig, Rommers \& Meyer, 2011), and when adults
hear a word (e.g. "snake") they are likely to look at objects that share aspects with the referent of the word (e.g. a rope, similar shape, Huettig \& Altmann, 2007). Similarly, adults’ ability to detect a visual item is boosted by labeling the item (Lupyan \& Spivey, 2008), and children's ability to find a target in a cluttered display is boosted by hearing the spoken name of the target object (Vales \& Smith, 2015).

Second, word learning and object recognition are two related developmental achievements. Children's ability to identify visually degraded objects (Pereira \& Smith, 2009), to attend to the configuration among the parts of a novel object (Augustine, et al., 2011), and to recognize sparse versions of known object categories (Smith, 2003), all are positively related to the number of words a child knows. Object recognition continues to be coordinated with word comprehension into adulthood (Huettig et al., 2011).

Third, there is evidence suggesting that words activate knowledge about the categories to which they refer. Words - object names in particular - do not refer to a specific item but rather to more abstract knowledge. Empirical results have shown that, relative to other cues (e.g. environmental sounds), words activate more decontextualized, categorical knowledge (Edmiston \& Lupyan, 2015; Lupyan, 2008).

Taken together, this evidence supports our proposal that one pathway by which language affects human cognition is by activating category information which then influences visual processing, and that this pathway likely starts in early childhood. To directly test this proposal, in Experiment 1 we asked whether visual processing can be influenced by visual category information, and in Experiment 2 we examined whether category information activated by words can also influence visual processing. We tested 3-year-old children, who know several hundreds of object names and are at the start of the long developmental course in visual object recognition and in language development.

## Rationale for the experiments

A large literature on categorical perception suggests that categorical information activated through visual means can change how adults process visual stimuli (Beale \& Keil, 1995; Daoutis, Pilling \& Davies, 2006; Goldstone, 1995; Goldstone, Lippa \& Shiffrin, 2001; Livingston, Andrews \& Harnad, 1998). By hypothesis, having learned that items belong to the same category changes in-task perceived similarity, making within-category discriminations harder than between-category discriminations. This idea that
within-category comparisons are more difficult than between-category comparisons has been conceptually replicated with multiple kinds of tasks and stimuli (Jonides \& Gleitman, 1972; MacKain, Best \& Strange, 1981; Newell \& Bülthoff, 2002), including some with infants and children (Eimas, Siqueland, Jusczyk \& Vigorito, 1971; Jusczyk, Rosner, Cutting, Foard \& Smith, 1977; Massaro, 1984).

To test if categorical information influences visual processing in young children, the present experiments tested children's ability to find a target in a cluttered array. The visual arrays were composed of items of the same category as the target (Within-Category search) or items of a different category than the target (Between-Category search). In Experiment 1, the category information was instantiated via visual information, and in Experiment 2, the category information was instantiated via linguistic information. In both experiments, we used two categories that share visual similarity but minimal conceptual similarity, and that children are likely to be familiar with: cakes and hats.

## Experiment 1

If categorical information instantiated by visual information changes children's ability to visually process a visual array, then searching for a target amidst items of the same visual category should be more difficult than searching for that target amidst items of a distinct visual category.

## Methods

Participants. Thirty-two children ( 15 females, $\mathrm{M}_{\text {age }}=36$ months, $\mathrm{SD}=1.92$ ) were randomly assigned to either the Within- or the Between-Category condition. Children had no developmental disorders, and English was the main or only language spoken by all families. Two additional children were recruited but not included due to experimenter error and being unable to follow task instructions during the familiarization phase. Parental consent was obtained for all participants, and all children received a toy for participating.
Apparatus and Stimuli. Stimuli were presented on a 17 " touchscreen monitor. E-Prime (PST, Pittsburgh, PA) was used to present the stimuli and to record participants' responses. The stimuli were placed in 16 possible locations. The stimulus set is depicted in Figure 1A; four hats and four cakes were selected in pairs and recolored in red scale, such that a hat and a cake in the same pair were similar to each other in color appearance, overall shape, and details (e.g. in pair 1, both items have stripes and a smaller component at the top). The Within- vs. Between-Category manipulation was realized by changing target/distractor assignments; for instance, for pair 2, the Within-Category search array was composed of hat 2 as the target and hats 1,3 , and 4 as distractors; for the Between-Category search, cake 2 served as the target amidst the same (i.e. 1, 3, and 4) hat distractors.

To ensure that young children could recognize the items used, 12 children who did not participate in the main experiments ( 7 females, $\mathrm{M}_{\text {age }}=36$ months, $\mathrm{SD}=2.67$ ) were tested in a 4-alternative forced choice recognition task; on
each trial, children were asked to select the picture that matched the heard word (e.g. "Where is the cake?"). Each child was asked to recognize all the items in the stimulus set twice, with target category (hat vs. cake) blocked, order of block presentation counterbalanced across children, and items presented in random order. On average, children selected the correct item on $81 \%$ of the trials ( $\mathrm{SD}=0.22$ ). No differences in accuracy were found across the two category of items $(t(11)=1.11, p=0.29)$, or time taken to respond to cakes vs. hats items $(t(11)=1.92, p=0.08)$.

Figure 1, A: Full stimulus set. The hat and cake stimuli were used as targets and distractors in Experiment 1. The ambiguous items were used as targets in Experiment 2.

B: Experiment 1, Trial structure.
Because the visual search task requires participants to discriminate the items in the search array from each other, 8 additional children ( 2 females, $\mathrm{M}_{\text {age }}=36$ months, $\mathrm{SD}=1.04$ ) were tested in an immediate match-to-sample task that probed their ability to discriminate pairs of stimuli. On each trial, children were presented with a sample object at the top center of the screen and then asked to indicate which of two options at the bottom matched the sample; if children could discriminate the two stimulus pictures, then they should be able to correctly select the option that matched the sample. All possible combinations of items that would be presented as targets and distractors in the visual search were tested. Each child was asked to discriminate one hat and one cake from the remaining items; this was done so that, for each child, a foil never became a target and vice-versa. The target category (hat vs. cake) was blocked, order of block presentation was counterbalanced across children, and items were presented in random order. Each child was tested on a given contrast (e.g. hat 1 vs. hat 2) twice. On average, children selected the correct option on $89 \%$ of the trials ( $\mathrm{SD}=0.19$ ). No differences were found in children's ability to discriminate Between- vs. Within-category items $(t(7)=1.07, p=0.32)$ or time taken to respond to cakes vs. hats items $(t(7)=0.41, p=0.69)$.
Design and Procedure. Each trial started with a "fixation" slide that encouraged children to rest their hands on the table. The experimenter made sure the child was looking at the screen before displaying a preview of the target. After 1 s , the search array was automatically displayed and the child was asked to find the target picture and touch it; the trial ended once a manual response was detected (see Figure

1B). Children had up to 15 secs to make a response, and were encouraged to find the picture as fast as possible. Across test trials, the target was displayed equally often on the left and right side of the screen. Prior to the test phase, children were familiarized with using the touch screen and with the idea of searching for the object that matched the visual preview as fast as possible. Each child was assigned to one target, and searched for that target for 24 trials. None of the objects were labeled. The experimenter gave general encouragement (e.g. "thanks for your help finding the pictures") but no feedback was provided. Children received stickers to maintain their interest in the task.

## Results and Discussion

Initial inspection of the data suggested that participants were, on average, both faster and more accurate in the Between-Category condition than in the Within-Category condition. Traditional analysis of variance would require analyzing response time and accuracy separately, which implicitly assumes that these two variables are independent (e.g. Davidson \& Martin, 2013). Instead, we analyzed RT and accuracy together by comparing the relationship between RT and accuracy across the two conditions. Figure 2A depicts this relation and shows that the two conditions differ in how time taken to respond (plotted as quantiles) influences the likelihood of correctly identifying the target; accuracy in the Between-Category condition was overall higher and less influenced by response time. A generalized linear mixed effects analysis was performed using the geepack package (Højsgaard, Halekoh \& Yan, 2006) in the R environment. The model was fit with a logit link function, a binomial variance function, a scale parameter fixed at 1 , and an independent correlation structure. The variables Condition (Between-Category vs. Within-Category) and RT (as a continuous variable) were included as fixed effects with the interaction term, and participant was included as a random effect; RT was centered to decrease the differences in the scales of the model parameters. Odds Ratios were calculated by exponentiating the model estimates.

The model showed that Condition (Odds Ratio, OR=0.2, $p<0.001$ ) and the interaction between condition and RT ( $\mathrm{OR}=0.43, p<0.05$ ) were significant predictors of accuracy. RT was marginally predictive of accuracy, $\mathrm{OR}=1.8, p=0.08$. This suggests that processing the visual information in the within-category condition is challenging, and when children are asked to find a target amidst distractors of the same visual category they either cannot maintain the target active for more than a few seconds, or they disengage with the task if they fail to find the target within a few seconds. Notice that visual category information affected visual processing even though children could discriminate pairwise presentations of within- and between-category items equally well in the calibration study, even though children searched for the same visual target across all trials and thus should be able to remember the particular visual target, and even though the visual properties of the items were equated as best as possible across the two conditions.

## A. Experiment 1

B. Experiment 2

Figure 2, Mean proportion of correct responses per Reaction Time quantiles. Dashed line: Between-Category, Solid line: Within-Category.

These results show that category information presented through visual means influences visual processing in young children; this is, to the best of our knowledge, the first demonstration that visual categories directly influence visual processing in young children. This result adds to past research showing that infants, children, and adults (e.g. Eimas, Siqueland, Jusczyk \& Vigorito, 1971; Goldstone, Lippa \& Shiffrin, 2001; Massaro, 1984) are sensitive to category information, showing that category information matters for how children visually process a scene. When children encoded, for example, a hat target and saw the other hats in the within-category search array, that samecategory information seems to have disrupted their ability to find the target hat. In sum, Experiment 1 shows that categorical information perceived in a visual scene can directly influence visual processing, as predicted by our proposal. In Experiment 2 we test the hypothesis that words, through activating categorical information, should also change the perceived target-distractor similarity, and therefore change visual processing.

## Experiment 2

The goal of Experiment 2 was to test the hypothesis that hearing the spoken name of an object activates information about that object's category, which influences visual processing. This hypothesis predicts that, for example, if an ambiguous target is labeled as a hat and is placed amidst other hat distractors, it should be more difficult to find than when that target is labeled as a cake and is placed amidst the same hat distractors. In other words, when presented with the same visual information in the search array, children should be better able to find a target if it was labeled as a category other than the distractors.

## Methods

Participants. Thirty-two children ( 18 females, $\mathrm{M}_{\mathrm{age}}=36$ months, $\mathrm{SD}=2.12$ ) were randomly assigned to either the Within-Category or the Between-Category condition. These children did not participate in Experiment 1. Four additional children were recruited but not included due to refusal to participate $(\mathrm{N}=3)$ and failure to follow task instructions.
Stimuli and Procedure. Four ambiguous items were created by blending together the two items (cake and hat) of
each pair (see Figure 7, rightmost column); the ambiguous items included aspects of both the cake and the hat of the pair (e.g. the frosting and the ribbon), and were edited to look like a plausible visual object (e.g. smooth surface, even coloring, even edges). The Within- vs. Between-Category manipulation was realized by changing how the target object was labeled during the visual preview. For instance, in the Within-Category condition, children would preview the ambiguous item \#2 and hear it labeled as hat, and then be asked to find it amidst hats 1,3 , and 4 . In the BetweenCategory condition, children would preview the same ambiguous item \#2, but hear it labeled as cake and then be asked to find it amidst hats 1,3 , and 4 . Notice that the visual information presented in the preview and in the search array is exactly the same in both conditions - the difference between the two conditions is whether the ambiguous target is labeled a member of the same vs. a different category as the distractors while it is previewed prior to search. All other aspects of the procedure for the visual search were the same as Experiment 1.

To ensure that the ambiguous stimulus pictures were equally likely to be recognized as hats and cakes, 8 additional children ( 6 females, $\mathrm{M}_{\text {age }}=36$ months, $\mathrm{SD}=2.62$ ) were tested in a 4-alternative forced choice recognition task similar to the one used in Experiment 1. Each child was tested with all the ambiguous items, two of them as "cake" and the other two as "hat"; across children, each ambiguous item was equally likely to be tested as "hat" and as "cake". The target category (hat vs. cake) was blocked for each child, the order of block presentation was counterbalanced across children, and the presentation order of the items was randomized within each block. On average, children selected the ambiguous items as "cake" on $81 \%$ ( $\mathrm{SD}=0.40$ ) of the trials, and as "hat" on $84 \%(\mathrm{SD}=0.35)$ of the trials (paired $t(7)=0.16, p=0.88$ ) - suggesting that the ambiguous items were equally likely to be recognized as hats and cakes. Children took a similar amount of time to respond to cakes vs. hats trials $(t(7)=0.45, \mathrm{p}=0.67)$. In addition, to ensure that children were not selecting the ambiguous items merely because they looked more unfamiliar or novel than any of the foils, children were presented with 4 "catch" trials (2 after each block) where they were asked to find a balloon; on these "catch" trials, one of the foils was a novel-shaped object and the other two foils were known objects. Children correctly identified the balloon on $91 \% ~(\mathrm{SD}=0.18)$ of the trials, suggesting that they were not relying on novelty to respond in this task.

## Results and Discussion

Similar to Experiment 1, initial data inspection suggested that participants were both faster and more accurate in the Between-Category condition than in the Within-Category condition. Figure 2B shows that the relationship between RT and accuracy is the same across conditions, in that participants' accuracy does not depend on time taken to respond, but participants in the Between-Category condition were more accurate than participants in the Within-Category
condition. A generalized linear mixed effects model (fit in the same way as in Experiment 1) showed that Condition was the only significant predictor of accuracy, $\mathrm{OR}=0.12$, $p<0.001$. Time taken to respond $[\mathrm{OR}=1.1, p=0.8]$ and the interaction between Condition and RT [OR=0.8, $p=0.4]$ were not predictive of accuracy. This suggests that hearing the name of an object activates visual information about that objects' category, which affects visual processing. When presented with the same visual information, children's ability to find a visual target in a cluttered array depended on how that visual target had been labeled while it was being previewed. This is a robust demonstration of the effect of language on visual processing - encoding an ambiguous object as a hat or as a cake changed children's ability to find that object amidst the same set of distractors.

## General Discussion

The experiments presented here support our proposal that language affects human cognition by activating category information, which in turn influences visual processing. In Experiment 1, children's ability to find a visual target was hindered by the presence of same-category distractors; this influence of categorical information on visual processing was instantiated through visual means. Experiment 2 extended those results by showing that words can also activate categorical information which influences visual processing. Together, these results show that visual processing is influenced by categorical information, and that heard words can instantiate categorical information.

How does categorical information - through visual or linguistic means - influence visual processing? Past research on categorical perception suggests that categorical information changes the perceived similarity among the items, with items that belong to the same category being perceived as more similar to one another than items that belong to different categories (Goldstone \& Hendrickson, 2010; see also Sloutsky \& Fisher, 2004 for a related developmental model). This perceived similarity could influence visual processing in multiple ways. One possibility is that perceiving an item as a member of the same category as the distractors - and consequently as more similar to the distractors - lowers the threshold for accepting an item in the array as the target (e.g. Elman, 1979). Another possibility is that perceiving all the items as items of the same category influences children's ability to bind all the features of the target object together (Treisman \& Schmidt, 1982); there is evidence that object feature binding is still developing in late childhood (Lorsbach \& Reimer, 2005) and that children are prone to making conjunction errors (Dessalegn \& Landau, 2008). Through increasing the perceived similarity between the target and the distractors, category information might lead children to incorrectly bind features of the target and the distractors, increasing the likelihood of making an incorrect selection. Interestingly, language has been suggested to play a role in the binding of visual features in young children (Dessalegn
\& Landau, 2008; 2013), perhaps through the activation of categorical information.

These are empirically testable possibilities that merit future research. But notwithstanding the specific process by which children's ability to find a target was impaired by the presence of distractor items of the same category as the target, the point is that it was impaired - both when the categorical information was presented through visual means (Experiment 1) and through language (Experiment 2). The current results support the idea that words influence visual processing by highlighting information about the objects' category. This idea has important consequences to conceptualize the pathway by which words change visual object processing in young children, proposing that words activate categorical information that may change how objects are perceived and processed. Future research should examine what specific aspects of the objects' category are being activated when a word is heard. The ability to recognize the components of an object, and how those components relate to each other, is one critical aspect of visual object recognition (Tarr \& Bülthoff, 1998), and the developmental literature on visual object recognition suggests a long and protracted development on the ability to use configural information (Augustine et al., 2011: Jüttner et al., 2013). Given the strong links between word learning and visual object recognition in early childhood (Augustine, et al., 2011; Pereira \& Smith, 2009; Smith, 2003), it is possible that language comes to change what aspects of the objects children attend to.

These results also highlight the importance of understanding the nature of visual processing in young children. Contemporary accounts of visual processing in adults propose a reciprocal interaction between the shortterm encoding of visual information and long-term visual representations (e.g. Brady, Konkle, \& Alvarez, 2011). Research across levels of analysis suggest that both processes might be permeable to top-down influences (e.g. Hemmer \& Steyvers, 2009; Olsson \& Poom, 2005), but we have very little understanding of how these develop. That is, what information do children use to visually process objects in the moment, what do those visual representations include, and what factors influence the long-term encoding and fidelity of those visual representations? All these processes are likely to mature and improve with age (e.g. Burnett Heyes et al., 2012; Simmering \& Perone, 2012) and might be weak in children (Riggs, McTaggart, Simpson \& Freeman, 2006; Zhang, Shen, Tang, Zhao \& Gao, 2013). Importantly, visual processing and visual working memory have been shown to be immature in children with language impairments (Collisson et al., 2015), further underscoring the importance of understanding the development of these processes.

In sum, we documented that words influence visual processing, likely by highlighting information about the objects' category. This fits with our proposal that one pathway by which language influences human cognition is by activating category information, which influences visual
processing, and that this pathway likely starts in early childhood.

## Acknowledgments

The authors thank Brianna Le, Lizzie Hart, and Adriana Valtierra for their help with stimuli creation, recruitment, and data collection; and the parents and children who participated in these studies. This work was supported by a Graduate Fellowship from the Portuguese Foundation for Science and Technology (SFRH/BD/68553/2010) awarded to CV and a grant from the National Institute of Child Health and Development (HD28675) awarded to LBS.

# Looking for the Cat and Seeing the Dog: Using Visual Search to Study Semantic Knowledge in Children 

Catarina Vales (cvales@andrew.cmu.edu)<br>Layla Unger (lunger@andrew.cmu.edu)<br>Anna V. Fisher (fisher49@andrew.cmu.edu)<br>Carnegie Mellon University, Department of Psychology, 5000 Forbes Avenue<br>Pittsburgh, PA 15214 USA

#### Abstract

Semantic knowledge influences various higher-order cognitive processes; therefore, it is important to understand how it changes with development. The Match-to-Sample task is perhaps the most common paradigm for studying changes in semantic knowledge over development, yet this paradigm has a number of limitations. Here we provide initial evidence validating a Visual Search paradigm as a measure of semantic knowledge in preschoolers, and discuss the potential of this paradigm to address the limitations posed by the Match-toSample task to study semantic knowledge development.

Keywords: semantic knowledge; visual attention; visual search; match-to-sample; language; children.

## Introduction

Knowledge about the world supports efficient behavior. For example, knowing that cats are often playful and have sharp claws makes one careful when playing with a cat, and knowing that light bulbs generate light makes one likely to check the light bulb if a lamp stops working. This knowledge about objects, facts, and concepts (Clark, 1973) is thought to be represented in a semantic network that links entities by multiple meaningful relations (McClelland \& Rogers, 2003). Structured semantic knowledge influences multiple cognitive processes, including memory, reasoning, word learning, and visual attention (Bower et al., 1969; Chi et al., 1981; Moores et al., 2003; Roediger \& McDermott, 1995; Xu \& Tenenbaum, 2007), and individual differences in semantic knowledge have been putatively related to the ability to make inferences about novel instances (Coley, et al., 2004; Gobbo \& Chi, 1986; Fisher, 2015).

## Developmental changes in semantic knowledge

As semantic knowledge plays an important role in supporting efficient behavior, there is a large literature investigating what aspects of semantic knowledge change over development to give rise to mature, adult-like behavior. One of the most widely used tasks to study the development of semantic knowledge is the Match-to-Sample task; in this task, participants are shown a target object (e.g. chicken) and asked to match it with one of two options - often a thematic match (an item that is likely to co-occur with the target item, such as pig) and a taxonomic match (an item that belongs to the same stable category of items that share intrinsic properties, such as eagle). Research using this task has documented marked age-related changes starting in the
preschool years in preferences for matching items on the basis of different types of relations (Smiley \& Brown, 1979; Walsh, et al., 1993). However, the Match-to-Sample task presents two main limitations to study developmental changes in semantic knowledge. First, this task cannot be used with young children who are unable to follow verbal instructions and indicate their choices. Prior research examining semantic knowledge development in infants and toddlers has used other tasks (e.g. Arias-Trejo \& Plunkett, 2009; Chow et al., 2017), which may result in confounding developmental changes and task demands. Second, because the Match-to-Sample task requires participants to make explicit judgments about the items, performance in this task might stem not only from knowledge of semantic relatedness but also from other deliberative processes. Indeed, past research with children has shown that performance in the Match-to-Sample task is modulated by the wording of instructions (e.g. Waxman \& Namy, 1997), suggesting that interpreting the pragmatics of the task plays a role in which objects children select. In sum, this task is not ideally suited to study changes in semantic knowledge.

Priming procedures have been used to bypass the limitations of the Match-to-Sample task in adults; however, traditional priming paradigms are difficult to implement with young children. Although several studies have used semantic priming paradigms in infants using looking behavior measures (vs. manual response times) (e.g., AriasTrejo \& Plunkett, 2009), paradigms developed for infants are often not suitable for older children who are not content to inspect visual displays in the absence of an overt task. Below we suggest that a measure of visual attention has the potential to address the limitations outlined above and be used to study semantic knowledge over the lifespan.

## The Visual Search paradigm

Research with adults has used visual attention measures to study knowledge associated with concepts (e.g. Huettig et al., 2011). In these studies, participants are cued about an upcoming target (e.g. by hearing a word or a sentence) and asked to locate the target in a cluttered display. Participants' response times to detect the target (Moores et al., 2003) or their gaze while scanning the array (Huettig \& Altmann, 2005; Mirman \& Magnuson, 2009) are taken as a proxy for the co-activation of concepts related to the target.
A Visual Search paradigm has two main advantages for studying the development of semantic knowledge. First,
visual search tasks have been successfully implemented across the lifespan (Gerhardstein, \& Rovee-Collier, 2002; Vales \& Smith, 2015), in children with developmental disorders (Kaldy et al., 2011), and with varying degrees of language knowledge (Vales \& Smith, 2017). Thus, a Visual Search paradigm is well suited to studying developmental changes in semantic knowledge, reducing differences in task demands from using different tasks with different populations. Second, the Visual Search task allows semantic knowledge to be measured by manipulating the distractors present in the array; because participants do not make explicit judgements about these related distractors, deliberative processes are greatly reduced (see Chun \& Jiang, 1998 for evidence that people are often unaware of experimental manipulations in the visual array). In sum, the Visual Search task is a good candidate to address the limitations of the Match-to-Sample task outlined above.

## The current study

In this study, we seek initial evidence that a Visual Search paradigm can provide estimates of semantic relatedness that are broadly consistent with the estimates from tasks used in prior research. If this is the case, then items judged as more strongly related in a Match-to-Sample task should also more strongly influence performance in a Visual Search task. To this end, we used the Match-to-Sample task to select pairs of target-distractor items. Each potential distractor was tested against a foil that we identified as more distantly related to the target. Measuring the rate at which children chose each distractor versus the foil allowed us to calibrate two distractors for each target, one strongly- and one weakly-related. While the Match-to-Sample procedure suffers from low resolution to detect graded responses, as it allows only binary judgements on each trial, it should still provide a coarse measure of semantic relatedness. We then tested the effect of target-distractor strength in a Visual Search task by asking children to indicate if a target was present in an array of distractors. Across trials, we manipulated the presence of the related distractors; performance in the critical trials in which a related distractor was present was compared with performance in baseline trials in which the related distractors were replaced by items unrelated to the target object. The degree to which children performed more poorly in the presence versus absence of a related distractor was used as the measure of the strength of the perceived relation. As in previous studies with adults and infants (e.g. Chow et al., 2017; Moores et al., 2003), we focused our analyses on target-absent trials, because participants' attention to the target on target-present trials leaves little room for related distractors to influence performance. Target-present trials were included to ensure that children were completing the target identification task.

Prior work using the Match-to-Sample task suggests that children under the age of four are unlikely to consistently select an item related to the target if the foil is a strong competitor (e.g. a visually similar item; Godwin \& Fisher, 2015). As such, we recruited 4 and 5-year-old children, as
this is the youngest age group that we can confidently expect to complete the Match-to-Sample task and thus provide reliable relatedness judgements.

## Methods

We first describe the Match-to-Sample task used to select pairs of items, and report the items selected. Next, we describe the Visual Search paradigm used to test the hypothesis that items judged as more similar in the Match-to-Sample task should also more strongly influence performance in the Visual Search task.

## Stimuli Selection: Match-to-sample task

To select pairs of items with varying strength, we conducted a calibration study with 16 children $\left(M_{\text {age }}=4.9\right.$ years, range $=4.0-5.9,6$ females); children were recruited from local preschools and from a university-affiliated laboratory school in Pittsburgh, PA and tested in a quiet location.

We selected 10 target objects that were likely to be recognized by young children from a prior study investigating the role of semantic relations in a Visual Search task (Moores et al., 2003). For each target, we selected four related items to be tested in the Match-toSample task with the goal of selecting two related items (one strong relation and one weaker relation); the relation strength between each target and each related item was tested in the presence of the same foil, judged by the authors to be a plausible competitor. For example, to test the strength between cat and the items bear, bird, dog, and mouse, participants were presented with the following triads: cat-bear-butterfly, cat-bird-butterfly, cat-dogbutterfly, cat-mouse-butterfly. Two testing sets were created by randomly selecting two of the four triads for each target. Each participant completed one of the sets, for a total of 20 test trials; the order of the trials was randomly determined for each subject, with the constraint that the same target was not presented on consecutive trials. The target was displayed at the top center of a computer screen, and followed by the presentation of the two options (related item and foil); these were presented on the left and right bottom of the screen, with side counterbalanced across trials.

To ensure that children understood the task and were not arbitrarily selecting items, five "catch" trials were randomly placed amid the test trials. These catch triads were intended to introduce no conflict and included items not used in the test trials (e.g. cherries-apple-stapler). On average, children selected the related object on $95 \%(S D=0.12)$ of the catch trials, suggesting that they understood the task (one additional child failed to complete at least 3 out of the 5 catch trials correctly and was not included in the sample). Additionally, because the Match-to-Sample task presented the same foil for each target (and thus children saw the same target- $X$-foil triad more than once), we checked that children were not learning to reject the foil for each target by presenting a block of 10 "control" trials after the experimental trials. In these control triads, the foil used on the test trials was presented against an item judged to be
unrelated to the target (e.g. cat-butterfly-watch). If children were learning to reject the foil over the course of the experimental trials, they should select the non-foil item (the watch in this example); on the other hand, if children were responding to each triad by considering how the items are related, they should select the item that is more strongly related to the target within each triad, even if previously they have not selected that item (the butterfly in the example above). On average, children selected the related item (the butterfly in this example) on $81 \%(S D=0.24)$ of the control trials; this suggests that children were considering how the items were related within each trial.

For each target, we selected two related items that varied in the degree of semantic relatedness, a strongly-related item (selected by most children) and a weakly-related item (selected at a lower rate, at or above chance). Two targets items (banana and cow) failed to produce relations that satisfied these conditions and were not used in the Visual Search task. Table 1 presents the eight sets of items consisting of a target, strongly-related item, and weaklyrelated item to be used in the Visual Search task and the proportion of trials in which each related item was selected in the Match-to-Sample task. On average, strongly-related items were selected on $94 \%(S D=0.09)$ of the trials and weakly-related items were selected on $61 \%(S D=0.10)$ of the trials in the Match-to-Sample task, $t(14)=6.97, p<0.001$. These sets of items were used to create 16 target-related match pairs for the Visual Search task.

Table 1: Proportion of trials each related item was selected in the Match-to-Sample task.

| Target | Strongly-related |  | Weakly-related |  |
| :--- | :--- | :---: | :--- | :--- |
| bike | skateboard | 0.86 | train | 0.71 |
| carrots | rabbit | 0.78 | horse | 0.58 |
| cat | dog | 1.00 | mouse | 0.67 |
| chair | table | 0.89 | bed | 0.57 |
| chicken | turkey | 1.00 | eagle | 0.55 |
| drum | guitar | 1.00 | piano | 0.57 |
| foot | shoe | 1.00 | glove | 0.77 |
| lamp | flashlight | 1.00 | candle | 0.44 |

## Visual search task

Participants. Twenty-four children $\left(M_{\text {age }}=4.8\right.$ years, range $=4.0-5.8,12$ females) were recruited from a universityaffiliated laboratory school in Pittsburgh, PA and tested in a quiet location; these children had not participated in the calibration study. One additional child was recruited but not included in the final sample due to computer malfunction. Children had no known developmental or visual impairments, and English was their only or main language.
Apparatus and Stimuli. Stimuli were presented on a 15.6" touchscreen laptop and responses (accuracy and latency) were recorded using E-Prime (PST, Pittsburgh, PA). To prevent color information from guiding participants' search,
each image was recolored in sepia; recolored images were rendered in a $200 \times 200$ pixel area on a white background. The audio files used to present the spoken names of the targets were recorded by a female native speaker of English.

Design and Procedure. There were six trial types, resulting from all combinations of target presence (present/absent) and related distractor presence (strong present, weak present, related absent), with equal occurrence of each trial type. On each trial, children saw four objects, one on each quadrant of the screen and all equally distant from the center of the screen. Depending on the trial, the four objects were combinations of target, related distractor, and random distractor objects. The order of the test trials was randomly determined for each child, provided that the same target did not appear on consecutive trials. Across trials, the target and related distractors appeared equally often on the left and right side of the screen. A unique token of each concept was used on each trial; for example, each trial probing cat used a different token (see Figure 1 for examples).

Figure 1: Tokens used to instantiate the concept "cat".
Figure 2 shows the temporal order of events on each trial. A "fixation" slide encouraged the child to rest their hands on the table before the trial started (Fig. 2a); the experimenter ensured that the child had their hands down and was looking at the screen before starting a trial. The spoken name of the target (Fig. 2b) was then presented and followed by the search array (Fig. 2c); upon viewing the search array, children had to indicate if the target was present or absent by touching one of two buttons.

Figure 2: Visual Search, trial structure. The target (carrots) is absent and the strong distractor (rabbit) is present.

Children sat in front of the laptop and were told that the goal of the game was to look for pictures on the screen. They were first shown which buttons to touch ("Touch this button if you see the picture on the screen and this button if you do not see the picture on the screen"); the location of the two buttons was counterbalanced across participants. Children were asked to repeat the instructions ("Can you show me which button you touch if you do not see the picture on the screen?") and all children correctly repeated the instructions. Next, children completed 4 "warm-up" trials in which they were familiarized with putting their
hands down during the "fixation" slide, listening to the audio cue, and touching the appropriate button to indicate the target's presence or absence; feedback was provided and children were reminded of the instructions if necessary. Children then completed 48 test trials. The experimenter gave general encouragement throughout the task (e.g. "You are doing great") but did not provide explicit feedback. A short break was introduced every 16 trials during which children could stamp a progress chart.

## Results

To confirm that children were performing the task, we start by analyzing performance on target present trials. Next, we focus on target absent trials to test the hypothesis that items judged as more similar to the target in the Match-to-Sample task also more strongly influence performance in the Visual Search task. We used linear mixed models to analyze the effect of target-distractor relatedness on the time taken to indicate the target's absence (RT). Differently from a traditional analysis of variance, which requires data to be aggregated and incorrect trials to be excluded, a mixed model can include all data and take accuracy into account by modeling the data at the trial level. We included both subject and target item as random factors, that is, varying around a group mean; modeling both subject and target item as random effects is particularly important in experimental designs in which the two factors are fully crossed (Baayen, Davidson, \& Bates, 2008; Jude, Westfall, \& Kenny, 2012).

## Target present trials

Children correctly indicated the target's presence on $83 \%$ ( $S D=0.37$ ) of these trials, suggesting they were trying to locate the target. No main effect of distractor strength on accuracy was found, $F(2,46)=1.78, p=0.18$.

## Target absent trials

Children correctly indicated the target's absence on $91 \%$ ( $S D=0.28$ ) of these trials. This supports the conclusion from target present trials that children were searching for the target. However, there was a main effect of distractor strength on accuracy, $F(2,46)=10.49, \quad p<0.001, \quad$ as participants were less accurate when the strongly-related distractor was present in the array ( $M_{\mathrm{acc}}=0.84, S D=0.36$ ) than when the weakly-related distractor was present in the array ( $M_{\text {acc }}=0.95, S D=0.22$ ) or when all items in the array were unrelated to the target $\left(M_{\mathrm{acc}}=0.95, S D=0.21\right)$. Analyzing RT for correct trials only would exclude different amounts of data from each condition; instead, we include accuracy as a factor in the analyses below. The same pattern of results is found when we consider only correct trials.

Figure 3 depicts mean RT across the three types of trials. Relative to baseline trials ( $M=3.6 \mathrm{~s}$ ), children took over a second longer to judge the target's absence in the presence of a strongly-related distractor ( $M=4.7 \mathrm{~s}$ ), but only slightly longer in the presence of a weakly-related distractor ( $M=3.8 \mathrm{~s}$ ). To assess how the strength of the distractors influenced the ability to correctly indicate the target's
absence, we implemented a linear mixed model using the lme4 package (Bates et al., 2015) in the R environment. We specified accuracy (correct, incorrect) and strength of the distractors (unrelated, weak, strong) as fixed effects, and subject and target item as random effects. The RT outcome variable was log-transformed. Wald $F$ tests and respective $p$-values were calculated using Kenward-Roger's approximation. The model showed only a significant main effect of distractor strength, $F(2,16.19)=3.64, p<0.05$. The main effect of accuracy $[F(1,13.45)=2.40, p=0.14]$ and the interaction between accuracy and distractor strength $[F(2,415.42)=0.14, p=0.87]$ were not significant predictors of RT. Planned contrasts (adjusted using a Bonferroni correction) showed that participants were significantly slower when a strongly-related distractor was present in the array compared to baseline trials in which no related distractor was present, $F(1,16.70)=7.64, p=0.003$. The difference between weakly-related distractor trials and baseline trials, $F(1,16.76)=0.60, p=1.00$, and the difference between strongly-related and weakly-related distractors, $F(1,17.03)=2.77, p=0.34$, were not significant.

Figure 3: Mean RT per trial type in the Visual Search task. Error bars display standard errors of the mean.

## Discussion

The goal of this experiment was to examine if estimates of semantic relatedness as measured by a Match-to-Sample task converged with performance in a Visual Search task. Specifically, for each target item we selected two related items that varied in how strongly they were judged to be related to the target (one strongly-related and one weaklyrelated distractor) in a Match-to-Sample task, and tested the effect of each type of distractor on children's ability to search for that target. Our finding that strongly- but not weakly-related items influenced children's ability to indicate the absence of a target provides initial evidence that Visual Search task performance is influenced by semantic relation strength in children. As such, the Visual Search task is a promising alternative to the Match-to-Sample task, addressing the limitations of this task as outlined above.

## Using Visual Search to study the development of semantic knowledge

Semantic knowledge exerts a pervasive influence on cognitive processes. This knowledge about objects, facts,
and concepts deeply influences how people search for information in the environment (Moores et. al, 2003), retrieve information from memory (Bower et al., 1969), make predictions about objects (Coley et al., 2004), or make sense of events (McNamara \& Kintsch, 1996). Despite the important role that semantic knowledge plays in organizing efficient behavior, we still have a limited understanding of how this knowledge is acquired and how its structure changes with experience. Currently, one obstacle to study the development of semantic knowledge and how it changes with experience is the lack of measures that can be used across the lifespan; as outlined in the Introduction, the most commonly used measure, the Match-to-Sample task, is not well-suited to do so. Visual search paradigms may be a viable alternative as they have been extensively used with adults to study many facets of knowledge (Huettig et al., 2005), and some recent work with toddlers shows similar evidence in younger populations (Chow et al., 2017).

This paradigm also shows promise in capturing individual variation among children. Figure 4 shows participants RT (subtracted from baseline trials RT) to indicate the target's absence from the visual array when the strongly-related and the weakly-related distractors were present. Each bar depicts the relative response time of a single participant, indicating how much that participant was affected by the presence of the related distractor. The range of variability suggests that this task may be a promising tool to study how individual differences in semantic knowledge contribute to individual differences in processes theorized to rely on semantic knowledge (e.g. Fisher, 2015).

Together, the present data suggest that a Visual Search paradigm both complements the Match-to-Sample paradigm and potentially addresses many of its limitations. Below we discuss some of the unresolved questions and important future directions of this work.

Figure 4: RT difference scores, calculated as: related-absent trials (i.e. baseline) minus related present trials.

## Unresolved questions and future steps

The present study revealed no evidence that the presence of a weakly-related distractor influenced search performance. One possibility is that our RT measure was insufficient to detect subtler effects of semantic relatedness. More finegrained moment-to-moment measures taken while children
are looking for the target may detect these effects. Indeed, prior research that found graded effects of knowledge associated with a target concept made use of higher resolution measures, such as eye-tracking or mouse-tracking (e.g. Mirman \& Magnuson, 2009). Another possibility is that children's performance in the Match-to-Sample task is idiosyncratic, and the findings of our calibration study do not generalize across children. To address this possibility, we retested in the Match-to-Sample task all children who participated in the Visual Search task; the estimates were comparable across the two samples, lending some confidence to the estimates from the stimuli selection study.

As this was the first attempt at using the Visual Search task to measure semantic knowledge in young children, we were agnostic as to which relations to probe and thus imposed no constraint when selecting the target-distractor pairs. In the current set of items, some items are linked by multiple relations (e.g. chair and table are both furniture items and often co-occur in the environment, and thus share two types of relations), while other items share only one type of relation (e.g. carrots and rabbit). Previous research using a spatial arrangement task showed that young children seem to consider items that share multiple relations as being more strongly related than items that share only one relation (Unger et al., 2016), and thus it is possible that items that are related in more than one way more strongly influence performance in a Visual Search. Future work can more closely test this prediction by systematically selecting stimuli that vary in the types of relations depicted.

We also did not control for visual similarity between targets and distractors. It is well known that visual similarity influences visual search (e.g. Vales \& Smith, 2015); when selecting the visual tokens, we selected items that were easily discriminable both within- and between-categories, but we did not empirically measure visual similarity. Although it is not trivial to obtain a pure measure of similarity (see Medin et al., 1993; Chow et al., 2017), some recent work has tried to address these issues (e.g. De Groot et al., 2016), and as such it will be important to try to more systematically measure visual similarity in future studies.

## Conclusions

The present study demonstrates the Visual Search paradigm as a feasible approach to investigate the development of semantic knowledge. In contrast with paradigms commonly used in prior research, this paradigm is age-appropriate across a wide developmental range, and greatly reduces the influence of deliberative processes on performance. Thus, the Visual Search task has the potential to shed new light on the development of semantic knowledge and its role in a variety of cognitive processes.

# Interactivity and Ego Depletion in Insight Problem Solving 

Frédéric Vallée-Tourangeau<br>Department of Psychology, Kingston University<br>Kingston-upon-Thames UNITED KINGDOM KT1 2EE<br>f.vallee-tourangeau@kingston.ac.uk

#### Abstract

In the triangle of coins problem coins are arranged to create a triangle pointing down and the solution involves moving a few coins to change its orientation. The task ecology can be designed such that participants can work on it in a low interactivity environment, maintaining a mental representation of simulated moves, or in a high interactivity environment, thinking with and through a physical model of the problem. These task ecologies involve working memory to a different degree: Problem solving draws more on working memory the lower the degree of physical interaction. Participants first engaged in a writing task that required vigilance to inhibit common word choices, a degree of self regulation designed to induce a so-called ego depletion; participants then worked on the ToC problem in either a low or high interactivity environment. Solution rates were determined by level of interactivity; the preceding depletion experience did not impact performance.

Keywords: Interactivity, ego depletion, insight problem solving, working memory

## Introduction

The relative contribution of working memory in analytic and insight problem solving has been explored using a broad range of methodologies. Prototypical analytic problems such as those requiring arithmetic operations would involve the maintenance and updating of interim results, the strategic allocation of attentional resources, and retrieval of long term memory knowledge, processes that draw heavily on working memory resources; high working memory capacity (WMC) is a reliable predictor of analytic problem solving performance (Wiley \& Jarosz, 2012). In turn, insight problems are designed to resist initial analytic efforts or the direct transfer of long term memory knowledge. They are presented in a manner that trigger prepotent responses, but these lead to an impasse. Solving these problems then requires letting go of the incorrect interpretation. Less rather than more focus and attentional control might facilitate abandoning the incorrect interpretation, and hence a lower or transiently lowered WMC may better predict insight problem solving success (DeCaro \& Beilock, 2010).

However, there is also evidence that working memory capacity is involved in solving insight problems (Gilhooly \& Fioratou, 2009). For example, verbal working memory scores predict solution rates for compound remote associates (Chein \& Weisberg, 2014) and spatial working memory scores correlate significantly with solution rates for the nine-dot problem (Chein, Weisberg, Streeter, \& Kwok, 2010). Weisberg's (2015) integrated framework stresses the central role of analytic processes in solving insight problems, processes that draw on WMC.
A temporary reduction in deliberate executive function skills using a self-control exercise prior to engaging in an insight problem solving task might offer an interesting means to throw light on these somewhat conflicting findings. Hoffman, Schmeichel and Baddeley (2012) proposed that key features of executive functioning subserve self-regulation. So-called ego depletion tasks involve participants actively inhibiting a response set; these inhibitory efforts have negative aftereffects in subsequent tasks that require executive functions. For example, in Schmeichel (2007) participants' backward digit span was significantly lower after they engaged in a writing task that prohibited the use of the letters $a$ and $n$ than after an unconstrained writing task. Such findings support a fuel metaphor: executive control processes rely on a limited resource that fluctuates as a function of effort, rest and, more controversially, glucose level. The transient depletion of executive functions may impact analytic and insight problem solving differently. For example, performance on a mental arithmetic problem that requires temporary storage, retrieval of long term arithmetic knowledge and the strategic allocation of attentional resources, might be influenced by prior exposure to an ego-depletion manipulation. The prediction for insight problem solving however depends on the purported involvement of WMC. If a looser focus and 'leaky' attention (Wiley \& Jarosz, 2012) are important, then ego depletion might actually enhance insight problem solving. In contrast, if, as Weisberg (2015) contends, analytic processes are implicated in insight problem solving, then an ego-depletion manipulation should have a negative aftereffect on performance.

## Interactivity

The debate concerning the mental processes and capacities involved in problem solving reflects a commitment to methodological individualism (ValléeTourangeau \& Vallée-Tourangeau, 2017): that the locus of cognition is person, or more specifically, skull bound. Problem solving outside the laboratory naturally involves interacting with the world, recruiting artefacts, building models of proto solutions, assembling non-mental resources that scaffold creativity and problem solving. The world is there to see and act upon, its dynamic configuration triggers different actions and guides attention. As such, then, the working memory burden of keeping a detailed representation of the problem is not the same when participants can interact with a physical model of the problem. In some sense, interactivity might result in a functional increase in WMC (Vallée-Tourangeau, Sirota, Vallée-Tourangeau, 2016), and profiling participants in terms of their WMC might not be as informative as profiling the working memory resources of the agent-environment system created through interactivity.

Figure 1: The triangle points down: Which three coins should be moved to make the triangle point up? Solving the triangle of coins problem involves moving the coins that mark the three vertices.

Real-world interactivity can be scaled down under laboratory conditions if the problem solving environment, or the cognitive ecosystem (Hutchins, 2010) affords interacting with a physical model of the problem (ValleeeTourangeau, Sirota, Vallée-Tourangeau, \& Makri, 2015). For example, Fleck and Weisberg (2013) used the triangle of coins problem (ToC see Fig. 1), among other insight problems, to explore problem solving strategies (based on verbal protocols). For this problem, they supplied participants actual coins to manipulate to determine the solution. They quote, at length (see p. 452) the protocol of one participant who works on the problem by initially moving coins in a trial and error fashion. The changes in the problem configuration guide and constrain the problem solving trajectory. Fleck and Weisberg also
describe what they term 'data-driven' restructuring, or how a productive interpretation of the problem is triggered by manipulating the physical model; for example, an exploratory rotation of the entire model helped a participant notice that only the three vertices should be moved and the hexagonal core should be untouched (see pp. 452-453). Thus a productive strategy to solve the problem was triggered by changes in the physical model of the problem, not through the mental manipulation of a problem representation.

## The Present Experiment

The present experiment explored the impact of an ego depletion task and level of interactivity on insight problem solving using the ToC problem. The experiment employed a $2 \times 2$ between subjects design. The first independent variable was the nature of a six-minute writing task before participants tackled the ToC problem: Half the participants had to closely monitor and inhibit certain responses to ensure that words containing the letters $a$ or $n$ were not used, while the other half wrote freely. The second independent variable was the level of interactivity. After the writing task, half of the participants worked on the ToC in a low interactivity condition, that is by looking at a static visual display of the problem and dictating possible moves to an experimenter. They did so by keeping their hands palm down in front of them and could not point at the coins or simulate movements with their fingers. The other half of the participants worked on the problem in a high interactivity condition: Participants were presented with a physical model of the problem and they could touch, point to or move the tokens in determining which three could be moved to change the triangle's orientation. The low interactivity condition draws more heavily on WMC since participants must mentally simulate move, keeping track of the simulated movements of certain tokens, while evaluating the movement of which other token(s) would mentally change the orientation of the triangle. None of this mental activity could be supported with complementary actions (Kirsh, 1995). To the extent that the constrained writing exercise prior to working on the ToC problem depletes executive functions and solving the ToC problem requires analytic processes that draw on WMC, then performance should be better after the free writing session than after the constrained writing session. On the other hand, if solving the ToC does not proceed from focused deliberate analytic efforts, then participants might actually perform better with prior exposure to the ego depletion task, that is a transient reduction in executive functions might be beneficial. Participants working on the ToC in the high interactivity condition are not confronted with the same kind of WMC taxing environment, and as such we predict a much higher rate of problem solving success in the high than in the low interactivity condition. In the high interactivity condition,
participants think with and through the physical model of the problem. Transient executive functions depletion might have little or no impact on problem solving performance.

## Method

## Participants

Eighty undergraduate and postgraduate students (60 females) received course credits for their participation ( $M_{\text {age }}=24.2, S D=7.3$ ).

## Procedure

Participants were tested individually in a quiet cubicle. The experimental session was composed of three parts. Once an information sheet was read and understood and a consent form signed, participants first engaged for six minutes in a writing exercise modelled after the one reported in Schmeichel (2007). They were instructed "to write a short story describing a trip you have taken recently". Half of the participants experienced the depletion version of the task, where they were further instructed that the letters ' A ' or ' N ' could not be used: "you must pay close attention to the words you are using and aim to describe the trip with words that don't use these two letters". The other participants wrote freely without having to inhibit word choice responses.
During the second part of the experiment, all the participants were shown a sheet of paper (size A4) on which 17 digits were randomly printed. They were instructed to add these numbers as quickly and accurately as possible; however, participants had to keep their hands palm down on the table top and hence the mental arithmetic could not be supplemented or supported by complementary actions, such as touching the printed numbers of pointing at them.
In the third and final part of the experiment participants worked on the triangle of coins problem for five minutes; half of the participants were allocated to the low interactivity condition, half to the high interactivity condition. The problem was illustrated on a 9 x 9 grid printed on a sheet of paper: Columns were labelled with letters (A-I) and rows with numbers (1-9). Ten tokens were arrayed on that grid, each token labelled with an individual letter (see Fig. 2); the solution to the problem involved moving tokens R, W, A to cells E4, B7, and H7 to reorient the triangle such that it pointed up rather than down. Participants in the low interactivity condition worked on the problem with hands palm down on the table top, and voiced their proposed moves to the experimenter in groups of three moves: They would name the token and then the cell coordinate where it should be moved. The experimenter noted the moves on a record sheet hidden from the participants' view, and provided feedback. It's important to note that the problem configuration always
remained the same, that is participants had to mentally project moves on the grid and verbalise these moves, while looking at the instruction sheet show in Figure 2; the experimenter never modified the triangle as such, and only provided feedback. In addition, feedback provided was all or none, that is participants were not informed if the projected position of one or two tokens was right on a given trial. In the high interactivity condition, participants worked with a laminated 9 x 9 grid (measuring 21 cm x 29 cm ) with rows and columns labelled as in the low interactivity condition. Ten tokens ( 2.2 cm in diameter) were arrayed as in the low interactivity condition, creating a triangle pointing down; each token had a letter printed on it, just as it did in the low interactivity condition. The token and grid coordinates helped the experimenter record the participants' moves, but the participants were not required to verbalise moves by identifying tokens and cell destinations. Rather participants were invited "to touch the tokens" and "trace their movement with your finger". If after moving the three tokens, the pattern created did not result in the correct answer, the experimenter put the tokens back to their original place, and participants could try to move a new set of three tokens

The triangla points to the bottorn of the board.

Which set of 3 tokens can be moved to make the triangle peint to the top of the boand? To solve the problem, think of a set of three, announce their movement to the experimenter. The experimerter will note your proposed set and will give you foedback. if the set you propose is incorrect, you will be asked to propose another set of three. You have five minutes to propose as many sets of three as you want.

To announce a set of moves, you need to say which token you wart to move. and idersty the coortinates on the grid of where you think the token should be placed. For example, imagine you worked on a different probiem and warted to propose that token $Z$ move from $A 1$ to $A 2$, then you would say $Z$ from $A 1$ to $A Z^{\prime}$.

As with the riertal arithmetic task, you must place your handa in front of you flat on the tabietop. You are not allowed to touch the lokens or use your fingers to indicate where a token should be placed. Aather, you till the experimenter which set of three lokene should be moved and where.
Figure 2: The problem instructions in the low interactivity condition.

The experimental design was thus a 2 (Depletion: constrained writing or free writing) x 2 (Interactivity: low, high) between subjects design. Participants were allocated randomly to each of the four experimental conditions.

## Results

The mean number of words written in the constrained-ego depletion version of the story writing task ( $M_{\text {depletion }}=28.7$, $S D=12.26$ ) was significantly lower than in the unconstrained free version of the task ( $M_{\text {no depletion }}=122.7$, $S D=25.48), t(56)=-20.8, p<.001$ (the degrees of freedom were adjusted to account for heterogeneity of variance). Thus participants complied with the task instructions and struggled to write a story when they had to suppress words containing the letters $a$ or $n$. However, performance on the mental arithmetic task, immediately following the story writing task, was unaffected by the prior exposure to the ego depletion manipulation in terms of the magnitude of absolute calculation errors $\left(M_{\text {depletion }}=\right.$ $\left.3.45, S D=5.16, M_{\text {no depletion }}=5.23, S D=8.18\right) t(66)=-$ $1.16, p=.250$, or latency $(\mathrm{s})$ to solution $\left(M_{\text {depletion }}=71.1\right.$, $\left.S D=42.64, M_{\text {no depletion }}=79.4, S D=57.81\right), t(72)=-0.729$, $p=.469$ (degrees of freedom were adjusted to account for heterogeneity of variance).
Performance on the triangle of coin problem is illustrated in Figure 3. With low interactivity, 4 participants (or 20\%) solved the problem following the constrained writing task, while 5 (or $25 \%$ ) did so after the unconstrained writing task. With high interactivity, 14 participants (or $70 \%$ ) and 10 (or $50 \%$ ) solved the problem following the constrained and unconstrained writing task, respectively. Summing across depletion levels, more participants ( $60 \%$ ) solved the ToC problem in the high interactivity condition, than in the low interactivity condition ( $23 \%$ ), $\chi^{2}(1, N=80)=11.61, p$ $=.001$; solution rates between the two high interactivity conditions did not differ significantly, $\chi^{2}(1, N=40)=$ $1.67, p=.196$.

Figure 3: Percentage of correct solutions for the triangle of coins problem in the low and high interactivity task environment after engaging in a self-regulation task (depletion) or not (no depletion).

The solution rate data were analysed using a binary logistic regression. The outcome variable was the probability of solving the triangle of coin problem. Three models were tested: the first included only depletion as a predictor variable, the second included both depletion and interactivity as predictors, and the third model included depletion, interactivity, and their interaction as predictors. The first model was not significant, $\chi^{2}(1)=0.465, p=$ .495; adding interactivity produced a significant model, $\chi^{2}$ (2) $=12.026, p=.001$, Nagelkerke $R^{2}=.195$; however, adding an interaction term did not increase the significance of the model, $\chi^{2}(1)=1.280, p=.258$. The only significant predictor of success using the Wald criterion was level of interactivity ( $p=.001$ ) with an odds ratio of 5.231 (see Table 1).

Table 1: Summary of Binary Logistic Regression with the Model Involving Depletion and Interactivity as Predictors.

|  |  | $95 \%$ C.I. for OR |  |  |  |  |  |
| :--- | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| Variable | $B$ | $S E$ | OR | Lower | Upper | Wald | $p$ |
|  |  |  |  |  |  |  |  |
| Depletion | 0.363 | 0.494 | 1.438 | 0.546 | 3.789 | 0.541 | .462 |
| Interactivity | 1.655 | 0.500 | 5.231 | 1.962 | 13.947 | 10.937 | .001 |

## Discussion

The triangle of coins problem was difficult to solve within the time allocated for participants in the low interactivity conditions; the success rate was very similar between those who had undergone the ego-depletion manipulation and those who had engaged in the free writing exercise. In turn, the success rates were substantially higher for participants in the high interactivity conditions. The interaction between ego-depletion and level of interactivity was not a significant predictor of the solution rate, however.
The level of interactivity afforded by the thinking environment substantially influenced problem solving performance, and corroborates recent findings with other types of insight problems (e.g., matchstick algebra, the 17 animals problem, see Weller, Villejoubert, \& ValléeTourangeau, 2011; Vallée-Tourangeau, Steffensen, ValléeTourangeau, \& Sirota 2016). The overall solution rate in the high interactivity condition in this experiment is similar to the one reported in Fleck and Weisberg (2013) who presented the ToC problem in a high interactivity environment, even if their work did not explicitly explore and contrast levels of interactivity in insight problem solving. A physical and modifiable model of the problem reduces working memory demands because changes in the problem configuration cue new actions and guide attention. Moves need not be premeditated, and need not be mentally simulated; participants observe the results of their action, and changes in the world, that is changes in the physical model of the problem, convey new information. Participants can more readily see how to solve the problem, they need not mentally represent possible changes, imagine their outcome, and while maintaining
this simulated modification to the problem in working memory, project and simulate the next move.
As for the ego-depletion manipulation, whether the constrained writing task achieved its purpose of temporarily reducing executive functions, remains uncertain. On the one hand, word production was much lower in the constrained writing condition than with the free writing task. This suggests that participants complied with the task instructions and struggled to write. Assuming that the sustained inhibition of common word choices led to a depletion in executive functions, the predicted impact of such transient depletions on insight problem solving depends on the prominence attributed to deliberate analytical processes. What is less controversial is how such an ego-depletion manipulation should have influenced performance on the mental arithmetic task immediately following the writing exercise, but it did not; if anything absolute calculation errors were marginally lower following ego depletion. As for the ToC problem, performance in the low interactivity conditions was very poor, and such a floor effect might have masked any influence of ego depletion. Thus, on the one hand, the potential window on the importance of WMC in insight problem solving that a purported depletion in executive functions might offer was undermined by the very low rates of success in both low interactivity conditions. On the other hand, the mental arithmetic data suggest that the depletion manipulation did not work. In the final analysis, the controversy surrounding the very existence of the egodepletion phenomenon (Hagger, Chatzisarantis, Alberts, Anggono, Batailler, et al., 2016) suggests that such a manipulation does not offer an interesting tool to gauge the importance of WMC and executive functions in problem solving. There is also the possibility that the mental effort invested in the mental arithmetic task depleted executive functions more so than the constrained writing exercise, and the low solution rate in the low interactivity conditions reflects this depletion. Thus, possible avenues for future research involve eliminating the intervening mental arithmetic task (and devising an alternative ego depletion manipulation check) or employing a more exacting depletion task such as a computation span test of the kind used to gauge WMC.
Fleck and Weisberg (2013) reported that some participants solved the ToC problem through an analytic and incremental strategy while for others the solution appeared to reflect a non-incremental insight. On the basis of concurrent verbal protocols or post-participation interviews future research could thus better determine the strategies and processes employed by a given participant, and make more specific predictions as to the degree of WMC involvement in solving that particular problem (I thank Robert Weisberg for this point).
In light of the controversy surrounding the concept of depletion and its potential negative aftereffects on performance, perhaps an altogether more productive
research programme could look at burdening working memory with a secondary task (e.g., Lavric, Forstmeier, \& Rippon, 2000) to determine how it would affect insight problem solving as a function of the level of interactivity afforded by the task environment. Recent work suggests that the impact of articulatory suppression on mental arithmetic was much greater in a low than in a high interactivity environment (Vallée-Tourangeau et al., 2016). Such a paradigm might be usefully employed with insight problem solving, not only as means to adjudicate the different proposals concerning the involvement of working memory but also to assess how working memory capacity is functionally enhanced in a high interactivity environment.

## Concluding Remarks

Individual differences in cognitive capacities and thinking dispositions are often measured to throw light on thinking processes (e.g., Stanovich \& West, 1998). Correlational and latent variable analyses are conducted to determine the underlying factors that best account for thinking performance. This strategy is employed in problem solving research as reviewed earlier (see also Chuderski, 2014). The tests designed to measure cognitive capacities-such as working memory-and the problem solving tasks typically involve little or no interactivity with physical problems. Thus, the commitment to methodological individualism is implicitly reinforced rather than challenged. The substantial improvement in problem solving performance in the high interactivity environment observed in this and other experiments (e.g., ValléeTourangeau, Abadie, \& Vallée-Tourangeau, 2015; ValléeTourangeau et al., 2016) suggests that researchers should be mindful of the importance of interacting with a physical model when solving a problem.

## Acknowledgements

I would like to thank Juan Aracena and Paige Edwards for recruiting and running the participants, as well as Emma Henderson, Gaëlle Vallé-Tourangeau and Robert Weisberg for thoughtful comments on a previous version of this manuscript.

# A computational model for decision tree search 

Bas van Opheusden, Gianni Galbiati, Zahy Bnaya, Yunqi Li \& Wei Ji Ma<br>Center for Neural Science \& Department of Psychology, New York University<br>\{basvanopheusden,gianni.galbiati,zahy.bnaya,yunqi.li,weijima\} @ nyu.edu

#### Abstract

How do people plan ahead in sequential decision-making tasks? In this article, we compare computational models of human behavior in a challenging variant of tic-tac-toe, to investigate the cognitive processes underlying sequential planning. We validate the most successful model by predicting choices during games, two-alternative forced choices and board evaluations. We then use this model to study individual skill differences, the effects of time pressure and the nature of expertise. Our findings suggest that people perform less tree search under time pressure, and that players search more as they improve during learning.

Keywords: Sequential decision-making, Behavioral modeling, Expertise

## Introduction

Imagine you are deciding if you should run for President of the United States in 2020. To make that choice, you have to consider a sequence of future decisions. Will you run as a Republican, Democrat or Independent? If Democrat, will you run as a moderate or progressive candidate? What positions will you take on abortion or gun control? How will you distinguish yourself during the primaries? What line of attack will you choose in the Presidential Debates? You face a sequence of decisions, which together determine your electoral success. In short, you have to explore a decision tree.

Although the computations underlying human decisionmaking are extensively studied, the process by which people explore decision trees is less understood. Most work focuses on the neural implementation of learning and decisionmaking in small decision trees (Solway \& Botvinick, 2015; Simon \& Daw, 2011). However, with more choices and more available options, the decision tree grows exponentially, and people need to prune the tree (Huys et al., 2012).

There exists a large literature exploring human decisionmaking in chess, starting with de Groot's seminal article (A. D. de Groot, 1946). One central question in this literature is whether the superior performance of experts relies primarily on enhanced pattern recognition (Chase \& Simon, 1973), increased tree search (Holding, 1985), or both. The relation between tree search and expertise is especially controversial, with both positive (Campitelli \& Gobet, 2004) and negative (A. D. de Groot, 1946) results.

In this article, we investigate sequential decision-making in a two-player board game, which is much simpler than chess, but much more complex than traditional decision-making tasks. We develop a computational model that predicts people's choices on individual trials, and fit this model to data from individual participants. We then ask whether the computations performed by our model mimic the process by which people arrive at their decisions. Finally, we use our model to investigate the nature of expertise in our game.

## Experiments

Task. To investigate the computations underlying sequential decision-making, we collected data from people playing a variant of tic-tac-toe, in which players need to make 4-in-arow on a 4-by-9 board (figure 1A). Despite these simple rules, the game is surprisingly challenging and fun to play. Because the game is deterministic without hidden information, it is theoretically solvable. Using alpha-beta pruning and threat tree search (Allis et al., 1994), we were able to derive a weak solution: the first player can force a win by opening on the central square. However, with perfect defense, the second player can delay the win for 17 moves.

Figure 1: Task. A. Two players take turns placing black or white pieces on a 4-by-9 board, and the first to achieve 4-in-a-row (horizontal, diagonal or vertical), wins the game. B. In the 2AFC task, participants see a board and two candidate moves, and indicate their preferences. C. In the evaluation task, participants see a board position and report their estimated winning chances on a 7 -point scale.

Participants. We conducted four experiments: human-vshuman ( $N=40$ participants), generalization ( $N=40$ ), time pressure $(N=30)$, and learning $(N=30)$. We recruited participants through the NYU psychology research participant system, flyers, a sign-up link on our lab webpage or personal communication. We did not collect demographic data. We compensated participants 12 per hour, but did not incentivize task performance.
Procedure. In the human-vs-human experiment, we divided participants into pairs. Participants in each pair played games against each other without time constraints for 50 minutes, switching colors every game. In the generalization experiment, participants performed three tasks: playing the game against a computer opponent for 30 minutes, 82 trials of a two-alternative forced-choice (2AFC) between moves in a given board position (figure 1B), and 82 board evaluation trials, in which they rated their winning chances in given board positions on a 7 -point scale (figure 1C). The time pressure experiment was identical to the human-vs-computer component of the generalization experiment, except that for each game, we added a time limit randomly selected between 5, 10 or 20 seconds per move. If participants exceeded the time
limit, they lost the game. The learning experiment consisted of 5 sessions, no more than 3 days apart. In sessions $1,3 \&$ 5 , participants played against computers for 30 minutes, then completed 60 trials each of the 2 AFC and evaluation tasks. In session $2 \& 4$, they played against computers for the entire 50-minute session.

In all human-vs-computer games, the computer opponents implemented an early version of our computational model for people's decision-making process, with parameters adapted from fits on human-vs-human games. We created 30 AI agents, grouped by playing strength into 6 groups of 5 agents each, and matched participants with AI opponents through a one-up, one-down staircase procedure.

In the 2 AFC and evaluation task, each participant completed the same trials in shuffled order. We selected board positions and move options that maximize an approximation to mutual information between model parameters and move choice, in order to present participants with interesting and informative choices.

## Model

Value function. The core component of our model is an evaluation function $V(s)$ which assigns values to board states $s$. We use a weighted linear sum of 5 features: center, connected 2-in-a-row, unconnected 2-in-a-row, 3-in-a-row and 4-in-arow. The center feature assigns a value to each square, and sums up the values of all squares occupied by the player's pieces. This value of each square is inversely proportional to its Euclidean distance from the board center. The other features count how often particular patterns occur on the board (horizontally, vertically, or diagonally):
Connected 2-in-a-row: two adjacent pieces with enough empty squares around them to complete 4-in-a-row.
Unconnected 2-in-a-row: two non-adjacent pieces which lie on a line of four contiguous squares, with the remaining two squares empty.
3-in-a-row: three pieces which lie on a line of four contiguous squares, with the remaining square empty. This pattern represents an immediate winning threat.
4-in-a-row: four pieces in a row. This pattern appears only in board states where a player has already won the game.

We associate weights $w_{i}$ to these features, and write

$$
V(s)=c_{\text {self }} \sum_{i=0}^{4} w_{i} f_{i}(s, \text { self })-c_{\text {opp }} \sum_{i=0}^{4} w_{i} f_{i}(s, \text { opponent })
$$

where $c_{\text {self }}=C$ and $c_{\text {opp }}=1$ whenever the player is to move in state $s$, and $c_{\text {self }}=1$ and $c_{\mathrm{opp}}=C$ when it is the opponent's move. The scaling constant $C$ captures value differences between "active" and "passive" features. For example, a three-in-a-row feature signals an immediate win on the player's own move, but not the opponent's.

Tree search. The evaluation function guides the construction of a decision tree with an iterative best-first search algorithm. Each iteration, the algorithm chooses a board position to explore further, evaluates the positions resulting from each
legal move, and prunes all moves with value below that of the best move minus a threshold. After each iteration, the algorithm stops with a probability $\gamma$, resulting in a geometric distribution over the total number of iterations.

Noise. To account for variability in people's choices, we add three sources of noise. Before constructing the decision tree, we randomly drop features (at specific locations and orientations), which are omitted during the calculation of $V(s)$ anywhere in the tree. During tree search, we add Gaussian noise to $V(s)$ in each node. Finally, we include a lapse rate $\lambda$.

The components of our computational model are inspired by behavioral studies of human decision-making. Tree search, as a mechanism whereby people mentally simulate the consequences of available actions, is similar to "levelK reasoning" (Arad \& Rubinstein, 2012) in behavioral economics. In other decision-making tasks, people have been shown to prune away options leading to immediate losses but long-term gains (Huys et al., 2012). Feature dropping reflects shift in endogenous attention (to spatial locations, orientation or feature types), corresponding to participants overlooking relevant features on the board. Finally, feature-based evaluation functions, value noise and lapse rates are all common in reinforcement learning.

There also exists neural evidence consistent with our model. In rats, dynamic search and exploration of possible paths at junctions in a T-maze have been linked to preplay sequences in hippocampal place cells (Johnson \& Redish, 2007). In humans, tree search is associated with neural activity in the ventral striatum (Simon \& Daw, 2011) and ventromedial prefrontal cortex (Lee, Shimojo, \& ODoherty, 2014).

## Methods

Estimating task performance. To quantify task performance in human-vs-computer games, we use the Elo rating system (Elo, 1978), which estimates playing strength from game results, independent of the moves played. We append the results of games from all 4 experiments to a computer-vs-computer tournament, and estimate ratings jointly for all humans and computers with a Bayesian optimization algorithm (Hunter, 2004). To calculate performance in the 2AFC task, we calculate the agreement between a participant's choices and those of an optimal agent with random tie-breaking. In the evaluation task, we define performance as the correlation between a participant's choices and the optimal rankings.

Estimating model parameters The model has 10 parameters: the 5 feature weights, the active-passive scaling constant $C$, the pruning threshold, stopping probability $\gamma$, feature drop rate $\delta$ and the lapse rate $\lambda$. We infer these parameters for individual participants and individual learning sessions or time limit conditions with maximum-likelihood estimation. We estimate the log probability of a participant's move in a given board position with inverse binomial sampling (M. H. de Groot, 1959), and optimize the log-likelihood function with multilevel coordinate search (Huyer \& Neu-
maier, 1999). We account for potential overfitting by reporting 5 -fold cross-validated log-likelihoods, with the same testing-training splits for all models.

## Model comparison

To test how well our model predict participants' choices, we compare its log-likelihood on human-vs-human games to that of 25 alternative models (figure 2). We test four categories of alternative models: lesions, generated by removing model components; extensions, generated by adding new model components; modifications, generated by replacing a model component with a similar implementation; and controls, which are structurally different from the main model.

Figure 2: Cross-validated log-likelihood/move for our main model and 25 alternatives on the human-vs-human data. The bars show mean and s.e.m. across participants $(N=40)$. The main model fits better than lesions, most controls and some modifications, and approximately equally good as extensions or some other modifications.

Lesions. We create lesion models by forcing either one of the feature weights to zero, or removing the feature dropping, pruning, value noise, active-passive scaling or the entire decision tree. The no-tree model evaluates the positions after each possible move, and chooses the one with maximum value. It contains feature dropping and value noise but no pruning.

Extensions. We consider extending the model with a feature that recognizes to a three-piece pattern arranged in a triangle, or multiplying the weights for diagonally and vertically oriented features by scaling constants $c_{\text {diag }}$ or $c_{\mathrm{vert}}$, respectively. Alternatively, we extend the main model by allowing feature drop rates to differ between features of different types (2-in-a-row, 3-in-a-row, etc) or orientations. Finally, we test a model in which all weights for the opponent's features are scaled by a factor $c_{\text {opp }}$, which thereby controls the balance between attack and defense.

Modifications. We modify the model by fixing the number of iterations of the search algorithm to a constant instead of the geometric distribution prescribed by the main model. Alternatively, we amend the search process to explore each branch of the tree up to fixed depth, or the pruning rule to keep only the $K$ best moves (according to the evaluation function), where the branching factor $K$ is again fixed. For a more drastic modification, Monte Carlo Tree Search (MCTS) estimates state values not by calling the evaluation function $V(s)$, but by aggregating outcomes of simulated games between notree agents. It also extends the best-first search algorithm by adding a term that favors exploration (investigating unexplored moves) over exploitation (further investigating already explored moves). We consider fixing the feature weights to the optimal solution, i.e. those weights that maximize the correlation between $V(s)$ and the game-theoretic value of the position $s$. Finally, we modify the attention mechanism from dropping random features from the evaluation function to dropping random branches from the decision tree.

Controls. We consider MCTS with completely random playouts, or a mixture model between optimal and random play. The optimal agent enumerates all candidate moves that preserve the game-theoretic value of the position, and chooses randomly between them. Another control model, labeled soft-max, assigns a value to each square on the board (enforced to obey reflection/rotation symmetry), and chooses a move with a softmax decision rule, constrained to unoccupied squares.

All lesioned models fit worse than the full model. The most impactful lesions are specific features (3-in-a-row, connected 2-in-a-row and center) and sources of variability (value noise and feature dropping). Lesioning the pruning mechanism or the entire tree search algorithm has a less dramatic effect, which can be partially explained by parameter trade-offs. Finally, some lesions (active-passive scaling, unconnected 2-in-a-row and 4-in-a-row) cause only small reductions in loglikelihood. Most modifications also worsen the main model, but the Monte Carlo Tree Search model is equally good and the "fixed iterations" model slightly outperforms it. The model extensions also slightly increase the main model's performance. Finally, all control models fit much worse than the main model.

Unfortunately, the model comparison does not reveal a unique best-fitting model, meaning that we did not collect enough data to determine precise details of people's thought process. For example, we cannot distinguish between tree search algorithms (best-first search or MCTS) or determine specifics of the best-first search algorithm (pruning and number of iterations). Alternatively, different participants may use different strategies. However, the model comparison does suggest that any model that can predict human choices needs to contain a feature-based evaluation function, and mechanisms for attentional oversights and tree search.

## Generalization to 2AFC and Evaluation

Next, we show that the model can generalize by estimating parameters from subjects' choices in games against computers and predicting their choices in the 2AFC or evaluation tasks with minimal additional assumptions. To select an option on a 2 AFC trial, the only change we make is to initialize the tree search algorithm with a three-node decision tree with the current board position as the initial node and the two available candidate moves as children. On an evaluation trial, we execute the tree search algorithm as usual, then measure the value of the root node. We then convert this value to a seven-point scale by transforming $v \rightarrow 3+4 \tanh (v / 20)$ and rounding to the nearest integer.

Figure 3: A. Histogram of the percentage of correctly predicted 2AFC choices by our model across $N=40$ participants. We fit parameters for each participant on their choices in games against computers. The dashed line indicates the accuracy of a random prediction. B. Same for the evaluation task, where we quantify goodness-of-fit as the correlation across trials between rankings predicted by the model and reported by a participant.

The average accuracy of the model prediction on 2AFC data is $58.6 \pm 1.0 \%$ (figure 3A), the average correlation between predicted and observed evaluations is $\rho=0.38 \pm 0.04$ (figure 3B). The prediction is better than chance for $36 / 40$ participants in the 2AFC task, and 37/40 for evaluation.

Even though our model predicts participants' choices in these additional tasks well on average, the goodness-of-fit is highly variable across participants. This variability in goodness-of-fit is correlated across subjects between the three tasks (2AFC-evaluation: $\rho=0.54, p<0.001 ; 2 A F C$-games: $\rho=0.35, p<0.05$; evaluation-games: $\rho=0.24, p=0.12$ ). Moreover, on the 2AFC and evaluation task, goodness-offit correlates with participants' objective task performance (2AFC: $\rho=0.56, p<0.001$; evaluation: $\rho=0.96, p<$ 0.001 ). This suggests that the variability in goodness-of-fit can at least partially be explained by differences in intrinsic variability across participants.

## How experimental manipulations affect model parameters

To further support the model, we investigate whether its parameters respond in predictable ways to experimental manip-
ulations. As our first manipulation, we introduce time constraints of 5,10 or 20 seconds per move. Second, we conduct an experiment in which participants play the game for 5 sessions.

Given a set of parameters for an individual participant in a time limit condition or learning session, we simulate moves made by the model in a database of pre-determined positions and measure 3 statistics of its process: the percentage of dropped features, the value quality (correlation between $V(s)$ and the game-theoretic value $\left.V^{*}(s)\right)$ and the mean tree size (number of nodes in its decision tree). Note that tree size incorporates both the width and depth of the decision tree.

Based on the literature on expertise and time pressure in chess, we expected that time constraints would reduce tree size but not affect value function quality. In the learning experiment, we expected the value function quality to increase across sessions and the tree size to remain constant or increase only slightly. Since chess algorithms often do not explicitly include feature dropping or similar mechanisms, we made no predictions for its trajectory. Finally, we predict that experience increases participants' task performance while time pressure reduces it.
Time pressure To test the effectiveness of time constraints to manipulate participants' behavior, we first plot the distribution of response times in the three conditions, as well as the response times from the unconstrained (generalization) experiment (figure 4A). Adding time pressure causes an overall shift in the response time distribution regardless of the time limit. Additionally, participants play faster with shorter time constraints. Surprisingly, there is no consistent effect of time constraints on participants' performance (figure 4B).

Figure 4: A. Empirical cdf of response times in the three conditions of the time pressure experiment (red), and the generalization experiment (blue). In the latter experiment, players could take arbitrary amounts of time, which we denote as an infinite time limit. People play faster with shorter time limits. B. Task performance, quantified by Elo rating, for the same experiments and conditions. Error bars indicate mean and s.e.m. across participants $(N=30)$. The effect of time limits on performance is unclear.

In figure 5 (top), we show the feature drop rate, value function quality and tree size in different time limit conditions. Compared to the unconstrained experiment, participants build
smaller trees and drop more features, while the value function quality is similar. The impact of the time constraint on tree size becomes larger with shorter time limits, but the feature drop rate shows the opposite trend and is at its highest in the 20 -second condition. We speculate that the stress of potentially losing on time causes participants to pay more attention with shorter time limits, whereas with 20 seconds, they are more relaxed and make more attentional lapses.

Figure 5: Top row. Estimated model parameters in the time pressure and generalization experiments. Error bars denote mean and s.e.m. across participants. The model infers a relation between time limit and tree size, but unclear effects on feature dropping and the value function quality. Bottom row. Model parameters and Elo rating for each participant in each time limit condition. The tree size and feature drop rate correlate with Elo rating, but value function quality does not.

To understand the surprising negative result of figure 4, we investigate how Elo rating and parameter estimates correlate across both individuals and time limit conditions (figure 5, bottom). Stronger players (in all time limit conditions) are estimated to build larger decision trees and drop fewer features. Therefore, the increased tree size with longer time limit predicts a performance increase, but the increased feature drop rate predicts decreased performance. These opposite effects happen to be approximately equal, which explains the lack of correlation between time limit and Elo rating.
Learning We first validate that experience affects participants' behavior by plotting Elo rating as a function of session number (figure 6). Next, we investigate changes in parameters across sessions (figure 7, top). Tree size increases across sessions, feature drop rate decreases and value function quality remains constant. As in the time pressure experiment, tree size and feature drop rate correlate with Elo rating on an individual level (figure 7, bottom), and the change in parameter estimates across sessions explains changes in task performance. Experienced players build larger decision trees and drop fewer features, both of which predict increased playing strength, which matches the data.

Figure 6: Elo rating of $N=30$ participants in the learning experiment (mean and s.e.m. across participants). As participants gain expertise, they play stronger.

Figure 7: Top: Model parameters as a function of sessions completed in the learning experiment. Over the course of learning, tree size is estimated to increase while feature dropping decreases. The value function quality decreases, but only slightly. Bottom: Model parameters and Elo ratings for each participant in each session of the learning experiment. Both tree size and feature dropping correlate with Elo, but value function quality does not.

## Discussion

Limitations. Our model has three conceptual limitations. First, although its parameters shift as participants acquire expertise, the model does not describe how these shifts arise from their experience (their specific move choices and rewards). Instead, model parameters are stationary within each session. Moreover, because model parameters are constant while participants play against multiple AI opponents per session, the model cannot capture strategic adaptations based on an opponent's game play. Finally, the model assumes that people make decisions independently on every move, ignoring potential long-term planning or caching of partial game trees between moves. We make these assumptions out of necessity, because parameter inference is already challenging.
Relation with chess literature. Contrary to the chess literature, in which the superior pattern recognition of chess experts is evident from board reconstruction experi-
ments (Chase \& Simon, 1973) and eye movements (Reingold, Charness, Pomplun, \& Stampe, 2001), we find no changes in value function quality with expertise or individual skill differences. Stronger players might use features outside our model space, and the lack of correlation could be a false negative. Alternatively, perhaps chess and 4-in-a-row are qualitatively different domains of expertise. Chess contains many non-obvious features (pawn structure, the bishop pair) or non-obvious feature weights (bishops and knights are equally strong). By contrast, in our task, people's intuitive priors (three-in-a-row is good) happen to be correct.

Our finding of increased tree search with longer time controls is consistent with chess studies that conceptualize pattern recognition and tree search as fast and slow processes, respectively (Chabris \& Hearst, 2003). However, the strong dependence between expertise and tree search is unexpected. We first investigate whether this effect could have arisen from incorrect model assumptions. Specifically, players may use unmodeled features, stronger players may assign those features higher weights, and those feature weights may trade off with additional tree search in our model. However, by analyzing parameter estimates in lesion models, we find no such trade-offs. Therefore, our results reflect differences between 4-in-a-row and chess, or a methodological improvement. Conclusions about tree search in chess derive almost solely from verbal reports, whereas we use the more principled method of parameter inference in a behavioral model.

## Conclusion

We built a computational model that predicts people's choices in a two-player board game. The model posits three computational principles for sequential decision-making: a featurebased evaluation function, attentional oversights and tree search. All three components are necessary to explain participants' behavior, but the data does not constrain details of their implementation such as the order by which nodes are visited during search, or how long the search process continues before players finalize their decision.

The model generalizes to predict choices in a twoalternative forced-choice task and a board evaluation task. This suggests that the model doesn't just fit a mapping from boards to moves, but that it captures aspects of the computational process that underlies decision-making in all three tasks. Furthermore, the feature drop rate and tree size change in predictable ways when we expose participants to manipulations in time pressure and experience. These changes account for participants' task performance, suggesting that these specific parameters reflect some task-relevant characteristic of participants' cognitive process. Furthermore, these two behavioral characteristics are dissociable, since in the time pressure experiment, both tree size and feature dropping increase across conditions, whereas in the learning experiment, tree size increases while feature dropping decreases. In the future, we aim to further support our model as a description of the computational process underlying people's move choices
by using it to predict response times and eye movements.

#### Abstract

The lexical frequency of an upcoming word affects reading times even when the upcoming word is masked from readers (Angele et al., 2015). One explanation for this observation is that readers may slow down if there is high uncertainty about upcoming material. In line with this hypothesis, this study finds a positive correlation between predictive entropy and self-paced reading times. This study also demonstrates that such predictive entropy can be effectively approximated by the surprisal of upcoming observations and that this future surprisal estimate is more predictive of reading times when the grammar is more granular, which would be prohibitively expensive for predictive entropy. These results suggest readers engage in fine-grained predictive estimations of certainty about upcoming lexical and syntactic material, that such predictions influence reading times, and that estimating that uncertainty can be done less expensively and more robustly with information-theoretic surprisal. Keywords: Self-Paced Reading; Information Theory; Language Modeling; Corpus Studies

## Introduction

The lexical frequencies of upcoming words affects reading times even when the upcoming word is masked from readers (Angele et al., 2015). Angele et al. suggest that the driving factor behind their result may be anticipation of upcoming difficulty. For example, a less constraining context (i.e. less predictable upcoming words) may produce slower reading. This study uses informationtheoretic entropy to test their hypothesis and to investigate the level of linguistic detail predicted by readers.

This work is scientifically important because it uses a large self-paced reading corpus to show that reading times are influenced both by uncertainty over upcoming syntactic constructions and by uncertainty over upcoming lexical items, which supports the hypothesis of Angele et al. (2015) that anticipation of upcoming difficulty influences reading times. While previous work has found evidence of prediction during language processing through responses to violated predictions (Wicha, Moreno, \& Kutas, 2004; Van Berkum, Brown, Zwitserlood, Kooijman, \& Hagoort, 2005; Fine, Jaeger, Farmer, \& Qian, 2013; DeLong, Troyer, \& Kutas, 2014), the present work demonstrates that the influence of prediction can be reliably detected in reading times prior to any violation of that prediction. Other work, for example using a visual world paradigm (Altmann \& Kamide, 1999; Kamide, Altmann, \& Haywood, 2003; Ito \& Speer,
2008), has also demonstrated predictive processing absent a prediction violation, but the present work demonstrates that such an effect is also observable in a broadcoverage self-paced reading corpus such as can be collected via Mechanical Turk. Finally, Roark, Bachrach, Cardenas, and Pallier (2009) have previously shown that the entropy of upcoming syntactic categories influences self-paced reading times, but their entropy measure is extremely expensive to compute, they used a much smaller corpus, ${ }^{1}$ and they did not find an influence of upcoming lexical uncertainty on reading times, unlike the present work.

In addition, this work demonstrates that surprisal (Hale, 2001; Levy, 2008), typically only used to estimate responses to observed stimuli, can be used to quantify predictive influences as well. From a computational perspective, this work provides an inexpensive way to estimate the uncertainty experienced by readers, which will allow future studies to test the cognitive plausibility of various grammars and parsing algorithms, providing a tool with which to probe predictive human sentence processing outside of highly constraining experimental stimuli.

## Background

Angele et al. (2015) wanted to test whether lexical successor effects (influences of upcoming material) could be elicited even when readers were unable to view the upcoming words. They used a moving mask to hide upcoming words from readers but still found that the trigram predictability of the next hidden word was a significant predictor of reading times. Angele et al. (2015) hypothesized that readers may anticipate upcoming difficulty and slow down. That is, an unconstrained context with several plausible continuations might produce slower reading (due to each continuation's low predictability) than a highly constraining context with a smaller number of plausible continuations. To test this hypothesis, we use information-theoretic entropy to predict reading times.

Under information theory (Shannon, 1948), the entropy $(H)$ of a random variable $(X)$ is defined by the component probabilities of each possible value $(x)$ of that

[^218]variable:
\[

$$
\begin{equation*}
H(X)=-\sum_{x \in X} \mathrm{P}(x) \log \mathrm{P}(x) \tag{1}
\end{equation*}
$$

\]

In the case of language processing, the possible values are words that have yet to be observed, and entropy is typically computed from the conditional probability of each possible value given the observations that have already been made.

Linzen and Jaeger (2015) distinguished single-step predictive entropy (uncertainty about the next processing step) from full entropy (uncertainty about the rest of the sentence). Since Angele et al. (2015) found that lexical frequency successor effects were only dependent on the word following a fixation, the present work is concerned with single-step predictive entropy. Linzen and Jaeger (2015) found that when single-step predictive entropy was computed over upcoming syntactic constituents based on verb subcategorization biases, it was not predictive of self-paced reading times. However, they hypothesize that the fit of entropy may improve when computed over finer-grained categories (they only computed probabilities for 6 subcategorization classes). The results in Analysis 4 of this paper support their hypothesis.

Roark et al. (2009) defined two variants of single-step predictive entropy to distinguish syntactic uncertainty from lexical uncertainty. Syntactic entropy is computed over the conditional probability of each preterminal $(p)$ in the grammar $(G)$ given the previously observed lexical sequence $\left(w_{1 . . i-1}\right)$ :

$$
\begin{align*}
& \operatorname{Syn} H_{G}^{1}\left(w_{1 . . i-1}\right) \stackrel{\text { def }}{=} \\
& \quad-\sum_{p_{i} \in G} \mathrm{P}_{G}\left(p_{i} \mid w_{1 . . i-1}\right) \log \mathrm{P}_{G}\left(p_{i} \mid w_{1 . . i-1}\right) \tag{2}
\end{align*}
$$

Syntactic entropy is computed in practice by generating all possible syntactic derivations ${ }^{2}$ that can generate each possible upcoming word $\left(w_{i}\right)$ in the vocabulary $(V)$ and then subtracting from each derivation's probability the emission probability of generating $w_{i}$ from the chosen preterminal $\left(p_{i}\right)$.

Lexical entropy is computed over the conditional probability of each possible upcoming lexeme, given the previously observed lexical sequence:

$$
\begin{align*}
& \operatorname{Lex} H_{G}^{1}\left(w_{1 . . i-1}\right) \stackrel{\text { def }}{=} \\
& \quad-\sum_{w_{i} \in V} \mathrm{P}_{G}\left(w_{i} \mid w_{1 . . i-1}\right) \log \mathrm{P}_{G}\left(w_{i} \mid w_{1 . . i-1}\right) \tag{3}
\end{align*}
$$

Roark et al. (2009) found that syntactic entropy was predictive of self-paced reading times but that lexical entropy was not, which we were able to replicate on the corpus in this study as well. Roark et al. suggested that the

[^219]failure of lexical entropy to predict reading times may be due to the fact that their grammar was trained on the relatively small Brown portion of the Penn Treebank (Marcus, Santorini, \& Marcinkiewicz, 1993), so their lexical probabilities may not have been robust enough.

It is interesting to note that 'single-step prediction' was defined slightly differently for these two sets of authors. Roark et al. (2009) define it as a prediction over the next word in a lexical sequence, while Linzen and Jaeger (2015) define it as a prediction over the next syntactic category (e.g., noun phrase) that will branch from a partial derivation ending in a verb phrase. To avoid making a commitment as to the particular parsing strategy adopted by readers, this paper will use the definition of 'single-step prediction' from Roark et al. (2009) to mean uncertainty about the next lexical observation.

## Data

This study makes use of the Natural Stories self-paced reading corpus (Futrell et al., in prep). The corpus is a set of 10 texts ( 485 sentences) written to sound fluent but still containing many low-frequency and marked syntactic constructions. The sentences within each text were presented in order, and self-paced reading time data was collected from 181 native English speakers. Reading times were excluded if they occurred at the beginning or end of a sentence, or if they were less than 100 ms or greater than 3000 ms . Approximately one third of the sentences (255,554 events) were used for exploration and two thirds of the sentences ( 512,469 events) were used as a confirmatory partition for significance testing to reduce the risk of false positives due to multiple comparisons. All significance results reported in this paper are from the confirmatory partition.

## Models

This study fits reading times using linear mixed effects models computed with the lme4 (version 1.1-7) R package (Bates, Maechler, Bolker, \& Walker, 2014). All models include a baseline of fixed effect predictors for word length, sentence position, and 5 -gram surprisal. ${ }^{3}$ The models also include random intercepts for each word, each subject, and each subject/sentence pair. The last random intercept corrects for the fact that multiple nonindependent observations are drawn from each sentence. Finally, each model includes by-subject random slopes for all the fixed effects. All predictors were z-transformed prior to fitting. Significance values for each predictor were obtained using a likelihood ratio test between two

[^220]mixed models: one of which contained both a by-subject random slope and a fixed effect for the predictor of interest, and the other of which omitted the fixed effect for that predictor.

## Analyses

## Analysis 1: Single-Step Predictive Entropy

First, we test whether the original finding of Roark et al. (2009) that syntactic predictive entropy positively correlates with reading times holds up on the Natural Stories corpus (Futrell et al., in prep). We compute single-step predictive syntactic and lexical entropy using the Roark (2001) top-down incremental parser. Our findings are consistent with those of Roark et al. (2009): syntactic entropy has a significant positive effect on selfpaced reading times in the Natural Stories confirmatory partition over the baseline model $(\hat{\beta}=4.53, \hat{\sigma}=0.54$, p -value $<0.001$ ), and lexical entropy is not a significant predictor of reading times.

As Roark et al. (2009) point out, the lack of predictivity of lexical entropy may stem from the sparseness of the training data. Unfortunately, computing predictive entropy is very expensive since it requires predictively running the parser over a large set of hallucinated observations whose cardinality is the size of the vocabulary for for each actual observation. Therefore, meaningfully increasing the vocabulary is not generally practical. ${ }^{4}$

## Analysis 2: Surprisal as Entropy Approximation

Angele et al. (2015) found that the trigram surprisal of an upcoming word is predictive of reading times and speculated that such an effect could be driven by uncertainty over future events, so this section tests whether the predictive entropy effect observed in Analysis 1 can be approximated by the PCFG surprisal of the upcoming word.

Roark (2011) showed that single-step predictive lexical entropy is mathematically equivalent to the expected value of total surprisal $S$ :

$$
\begin{align*}
& \quad S_{G}\left(w_{i}, w_{1 . . i-1}\right) \stackrel{\text { def }}{=}-\log \mathrm{P}_{G}\left(w_{i} \mid w_{1 . . i-1}\right)  \tag{4}\\
& \operatorname{Lex} H_{G}^{1}\left(w_{1 . . i-1}\right) \\
& \stackrel{\text { def }}{=} \sum_{w_{i} \in V}-\mathrm{P}_{G}\left(w_{i} \mid w_{1 . . i-1}\right) \log \mathrm{P}_{G}\left(w_{i} \mid w_{1 . . i-1}\right)  \tag{5}\\
& =\sum_{w_{i} \in V} \mathrm{P}_{G}\left(w_{i} \mid w_{1 . . i-1}\right) S_{G}\left(w_{i}, w_{1 . . i-1}\right)  \tag{6}\\
& =\mathrm{E}\left[S_{G}\left(w_{i}, w_{1 . . i-1}\right)\right] \tag{7}
\end{align*}
$$

[^221]where $w_{i}$ is the current lexical item, $w_{1 . . i-1}$ is the sequence of previously observed lexical items and $V$ is the vocabulary of the language.

Therefore, surprisal is a single sample from the conditional probability distribution over which single-step lexical entropy is computed, where the sampled observation is the occurrence that ultimately is observed. Over several trials, then, future surprisal should approximate entropy since each observed occurrence should happen proportionately to its expected occurrence frequency. As a moving window self-paced reading corpus, participants were physically unable to see upcoming words, similar to the masked condition used by Angele et al. (2015).

To test surprisal as an approximation of entropy, we use the Roark (2001) parser's estimate of surprisal of each observation to predict the reading time of the preceding observation. This measure (future surprisal) also has a significant positive effect on reading times ( $\hat{\beta}=4.96, \hat{\sigma}=0.63, \mathrm{p}$-value $<0.001$ ). This measure may be thought of as an aggregate approximation to entropy, whereas the lexical entropy output by the Roark (2001) parser may be thought of as a point-wise approximation to entropy. That is, Roark lexical entropy approximates the true lexical entropy for each new observation as the weighted average of the conditional probability distribution at that point according to the parser's grammar, while future surprisal approximates the true lexical entropy over the entire corpus (aggregated over all observations) by sampling from the conditional probability distribution for each observation. The fact that future surprisal is able to fit reading times more consistently than point-wise lexical entropy gives hope that this less expensive aggregate approximation of entropy is a more robust means of computing entropy than a point-wise approximation.

## Analysis 3: $N$-grams as Better Entropy Approximation

Since the Roark (2001) parser computes surprisal based on a relatively small and coarse-grained Penn Treebank grammar, the previous results may be skewed by the small amount of training data. In order to obtain conditional probabilities based on more data, we use a 5 gram back-off model computed with the KenLM toolkit (Heafield, Pouzyrevsky, Clark, \& Koehn, 2013) on the Gigaword 4.0 corpus (Graff \& Cieri, 2003), which consists of 2.96 billion words from English newswire text. Again, the 5-gram surprisal of each word was used to predict the reading time of the preceding word. Similar to future Roark surprisal, future 5 -gram surprisal has a significant positive correlation to reading times $(\hat{\beta}=4.49$, $\hat{\sigma}=0.57$, p-value $<0.001$ ), and when future 5 -gram surprisal is in the model, future Roark surprisal ceases to be a significant predictor of reading times.

This result aligns with work by van Schijndel and Schuler (2016) who found that future PCFG surprisal,
computed with a Penn Treebank PCFG, is an effective predictor of reading times in eye-tracking, but that it ceased to be predictive when future $n$-gram surprisal was included in their model. They also found that future $n$ gram surprisal was only predictive for one or two words following a fixation, similar to the finding of Angele et al. (2015) that only the frequency of the word following a fixation was predictive of reading times.

## Analysis 4: Fine-Grained Syntactic Prediction

Although future $n$-gram surprisal seems to account for a lexical entropy effect, it is unable to account theoretically for the effect of Roark syntactic entropy, since $n$-gram surprisal reflects lexical probabilities and syntactic entropy reflects syntactic probabilities (without lexical emission probabilities). However, future Roark PCFG surprisal using the default set of Penn Treebank syntactic categories was unable to predict reading times when future $n$-gram surprisal was in the model. Previous work on predictive processing has suggested that predictions can be relatively fine-grained (Luke \& Christiansen, 2015; Kim \& Lai, 2012), so this section explores whether humans predict upcoming material with finegrained syntactic specificity.

Whereas the above experiments used the Roark (2001) parser with the default Penn Treebank tag set, this section uses the van Schijndel, Exley, and Schuler (2013) parser, which computes surprisal using the Petrov, Barrett, Thibaux, and Klein (2006) latent-variable grammar computed from sections 2-21 of the Wall Street Journal portion of the Penn Treebank and thereby achieves higher parsing accuracy than the Roark parser (van Schijndel et al., 2013). The latent-variable grammar is derived from a split-merge algorithm that creates finegrained subcategory tags from the basic Penn Treebank category tags. For this experiment, the grammar underwent 5 split-merge operations to obtain optimally tuned tags, following the recommendations of Petrov et al.

When future surprisal is computed with a finergrained tag set, it is able to obtain a significant positive correlation with reading times, even in the presence of future 5 -gram surprisal and syntactic entropy ( $\hat{\beta}=4.10$, $\hat{\sigma}=0.74$, p-value $<0.001$ ).

## Discussion

Much previous psycholinguistic and neurolinguistic work has shown that prediction plays a role in language processing (DeLong et al., 2014; Kuperberg \& Jaeger, 2015). Angele et al. (2015) observed that even when upcoming material is masked, its predictability can affect reading times. They suggest that their observation is likely driven by readers predicting difficult material and slowing in anticipation of it. The findings in this paper of a positive correlation between self-paced reading times

|  | $\hat{\beta}$ | $\hat{\sigma}$ | t |
| :--- | ---: | ---: | ---: |
| Syntactic Entropy | 4.53 | 0.54 | 8.36 |
| Future Roark Surprisal | 4.96 | 0.63 | 7.85 |
| Future 5-gram Surprisal | 4.49 | 0.57 | 7.89 |
| Future Fine PCFG Surprisal | 4.10 | 0.74 | 5.58 |

Table 1: Effect sizes for each predictor of interest over the baseline described in the Models section. Each predictor was tested over the baseline factors and all predictors listed above it in the table. Future Roark Surprisal is not significant once Future 5 -gram surprisal is added.
and predictive entropy are consistent with that hypothesis and suggest that, in particular, readers slow due to increased probabilistic uncertainty over upcoming material.

Previous studies have claimed that a positive correlation between entropy and reading times would indicate that there is a competition cost between multiple parse hypotheses (Linzen \& Jaeger, 2015), but this is not the only possible explanation for such a correlation. For example, similar reasoning to the Uniform Information Density hypothesis (UID; Jaeger, 2010) might apply to readers. That is, if readers have more uncertainty about upcoming material, they may anticipatorily slow their reading in order to better process the less expected information (reducing their expected per-millisecond surprise to channel capacity). If, instead, readers are reasonably confident about what words they are about to encounter, they may speed up in order to maximize the per-millisecond informativity of their observations. This sort of tuning may be exaggerated in the moving window self-paced reading paradigm, where readers will be unable to regress if they speed past an unexpected observation, which could be why previous work using eye tracking has only been able to find an effect of future $n$ gram surprisal on reading times (Angele et al., 2015; van Schijndel \& Schuler, 2016), while the present self-paced reading study also found an effect for future PCFG surprisal.

The fact that both future 5 -grams and future PCFG surprisal are predictive of reading times suggests that predictions of upcoming difficulty are being made both about lexical items and syntactic constructions. Surprisal is computationally much less expensive than entropy, and therefore it can provide samples from a much finer-grained conditional probability distribution over possible analyses than would be practical for entropy calculation.

The present results show that future latent-variable PCFG surprisal can fit reading times even when the coarser Roark et al. (2009) surprisal and lexical entropy cannot, which suggests that humans predict upcoming material at a relatively fine-grained level (both syntactic and lexical) as suggested by previous work (Luke
\& Christiansen, 2015; Kim \& Lai, 2012). These results further indicate that the fit of entropy to reading times improves as the granularity of the grammar becomes finer, which supports the hypothesis of Linzen and Jaeger (2015) that their subcategorization entropy was likely too coarse-grained to reveal entropy's influence.

The finding that Roark syntactic entropy retains its reading time predictivity in the presence of future 5gram surprisal and future latent-variable surprisal suggests that humans estimate certainty about upcoming parses based on multiple samples from the distribution over upcoming observations. Such a finding is consistent with parallel models of sentence processing but may be problematic for serial processing models. Another interpretation of this finding is that a point-wise entropy approximation is more stable and so can serve as a back-off for the less stable but more nuanced aggregate approximations provided by both the $n$-gram and latent-variable surprisal models. It is left to future work to differentiate between these two possibilities.

It may seem strange that total latent-variable surprisal was used in this study instead of syntactic latent-variable surprisal (without lexical probabilities) since the goal of moving beyond future $n$-gram surprisal was to capture something of syntactic entropy, which omits lexical emission probabilities; however, explorations on the development partition revealed that total surprisal generally provides better fits to reading times than syntactic surprisal even in the presence of future 5 -gram surprisal. In any case, the goal was not necessarily to approximate Roark syntactic entropy but to capture an aspect of the uncertainty experienced by readers, of which Roark lexical entropy and Roark syntactic entropy are themselves approximations. In fact, the consistent correlation between future surprisal (both $n$-gram and latent-variable) and reading times compared to Roark lexical entropy suggests that fine-grained aggregate entropy approximation via future surprisal is more robust than the coarser but more intuitive point-wise lexical entropy approximation output by the Roark (2001) parser.

The entropy findings in this paper are distinct from those in the entropy reduction literature. The Entropy Reduction Hypothesis states that readers slow according to the informativity of the words they encounter (as measured by a decrease in entropy; Hale, 2006). It is possible that the two effects are independent and that people slow down before areas of greater uncertainty, while also slowing down due to larger information gains. These effects are not necessarily mutually exclusive because entropy reduction deals with changes in entropy while predictive entropy deals with the overall level of uncertainty in a text. That is, an entropy reduction of $k$ may predict the same $k \cdot \beta_{\Delta H} \mathrm{~ms}$ effect on reading times whether the resulting entropy is low or high. In contrast, the experiments in this paper highlight a broad-
coverage correlation of fine-grained predictive entropy to self-paced reading times.

## Conclusion

This paper has replicated previous findings that singlestep predictive entropy is positively correlated with selfpaced reading times and presented new results that show this correlation can be inexpensively approximated using both future $n$-gram surprisal and future latent-variable PCFG surprisal. The present results also demonstrate that such approximations improve as the granularity of the approximation increases. By showing that greater uncertainty over upcoming words and syntactic constructions slows reading times, these results support the hypothesis of Angele et al. (2015) that anticipation of upcoming difficulty affects reading.

# The Development of Structural Thinking about Social Categories 

Nadya Vasilyeva (vasilyeva@berkeley.edu), Alison Gopnik (gopnik@berkeley.edu), Tania Lombrozo (lombrozo@berkeley.edu)<br>Department of Psychology, University of California, Berkeley, 3210 Tolman Hall, Berkeley, CA 94720 USA

#### Abstract

Representations of social categories help us make sense of the social world, supporting predictions and explanations about groups and individuals. Here we explore whether children and adults are able to understanding category-property associations in structural terms, locating an object of explanation within a larger structure and identifying structural constraints that act on elements of the structure. We show that children as young 3-4 years of age show signs of structural thinking, but that this capacity does not fully develop until after 7 years of age. These findings introduce a viable alternative to internalist accounts of social categories, such as psychological essentialism.

Keywords: structural explanation, structural factors, social categories, essentialism, category representation

Imagine that a school introduces a dress code stating that all items of a student's clothing must match in color. When school begins, most boys show up wearing blue, and most girls show up wearing pink. What explains the correlation between gender and color? One explanation is that boys naturally prefer blue, and girls pink. But a quick glance at history shows that in the $19^{\text {th }}$ century, pink was considered the vigorous, masculine color, whereas girls wore "delicate and dainty" blue (Fausto-Sterling, 2012). If an explanation that appeals to intrinsic preferences is inadequate, an alternative might be to appeal to a structural feature of the environment: department stores reliably stock more pink options for girls than for boys. In this case, availability could be a sufficient explanation for the observed correlation.
This example illustrates what we call "structural thinking." A hallmark of structural thinking is locating an object of explanation within a larger structure and identifying structural constraints that act on components of the structure to shape the distribution of outcomes for each component. In our example, girls occupy a position within larger social and institutional structures that make them more likely than boys to choose pink over blue. A structural approach to social categories differs from internalist approaches, which focus on essential or inherent properties of the category itself. In the current paper, we ask whether and when children develop the ability to think about social categories in structural terms.
Internalist approaches to category representation. One prominent approach to theorizing about the representation of social categories (such as "girl") is based on the notion of psychological essentialism, which refers to the tendency to represent (some) categories in terms of an underlying essence that is constitutive of category membership and/or causally responsible for key category features (Gelman, 2003). Psychological essentialism can support efficient generalizations about natural kinds, but can also lead to unwarranted normative expectations about categories, stereotypical generalizations, and prejudice (Leslie, 2015).

A related internalist approach comes from Cimpian and Salomon (2014), who argue for the inherence heuristic, defined as the tendency to explain observed patterns in terms of the inherent properties of the objects that instantiate them. If girls wear pink, people might infer that it must be due to something inherent about pink ("it is delicate") and/or girls ("they are attracted to delicate colors"), rather than considering a broader range of external, historical factors. Cimpian and Salomon argue that the inherence heuristic is distinct from, but potentially a precursor to, essentialized representations of social categories.
A final approach, the aspect hypothesis, comes from Prasada and Dilllingham (2006, 2009), who offer a nonessentialist account of categorical representation. On this view, some features of a category are viewed as aspects of the kind. For example, "fighting crime" is an aspect of being a police officer (in contrast to merely statistical associations, such as between police officers and "eating donuts").
While psychological essentialism, the inherence heuristic, and the aspect hypothesis are importantly distinct in their commitments regarding categorical representations, they all support internalist explanations for associations between a category and a feature (e.g., "she chose pink because girls like warm colors"), as well as formal explanations that appeal to category membership (e.g., "she chose pink because she is a girl"). By contrast, they lack mechanisms for differentiating kinds (i.e., "girls") from the structures in which they are embedded (i.e., the social position occupied by girls). As a result, they cannot readily accommodate the kind of structural thinking supported by a structural approach.
A structural approach to category representation. Our study explores an alternative to internalist accounts. According to a structural view of categorical representation, reliable connections between properties and categories can be represented as a consequence of stable structural constraints acting on categories from the outside.
This approach is based on the notion of structural explanation developed in philosophy of social sciences, where it is defined by situating the object of explanation in a network of relationships within a larger, organized whole (a structure), and identifying how relationships to other parts of the whole modify the probability distribution over possible states of the part whose behavior is explained (relative to a hypothetical case outside a structure, relative to other nodes within the structure, or relative to different structures; Haslanger, 2015). For example, an internalist explanation for why many women in heterosexual relationships leave their jobs after having a child might appeal to women's priorities or abilities, whereas a structural explanation would identify constraints that affect women in virtue of their position within the social structure (e.g., lack of paid parental leave, a
gender wage gap, etc.). These structural constraints shift the probability distribution across different outcomes for women versus men. For another position subjected to different structural constraints (e.g., "men," "women in a different culture"), the same event (having a child) need not trigger the same outcomes. Rather than pinpoint triggering causes (e.g., the baby's arrival), structural explanations identify constraints that shape the causal relationships between triggering causes and their effects (Dretske, 1988).
The structural view capitalizes on the distinction between nodes (positions within social structures) and node-occupiers (categories that occupy those positions, and come to possess particular properties by virtue of their location within the structure; Haslanger, 2015). This distinction brings to light a potential ambiguity in formal explanations (e.g. "Smith quit her job after having a baby because she is a woman"), given that the term "woman" can refer to either the node or the node-occupier. Such explanations could attribute properties directly to the node (i.e., women's location in a structure), without necessarily tying them to its inherent nature (i.e., to women themselves). In other words, a formal explanation could support both structural and internalist interpretations, a prediction that our experiments test.
Structural vs. other externalist approaches. One way to appreciate what constitutes a structural explanation is to consider what it is not. Structural explanations are not merely "situation" explanations from the traditional person-situation dichotomy (Ross \& Nisbett, 2011), nor "causal history of reasons" explanations from Malle's (2004) taxonomy, which are narrower in their restriction to intentional behavior, yet broader in allowing for non-structural antecedents to reasons. Structural explanations are a sub-type of externalist explanations that invoke stable constraints acting on a category in virtue of its position in a structure.
It's useful to think of structural explanations in terms of the ANOVA or "cube model" (Kelley, 1973), in which a behavior is attributed to co-varying factors (person, situation, or stimulus). However, the cube model assumes that the data (behaviors) come from an "unconfounded" factorial design, where person and external factors vary independently. Structural thinking is instead sensitive to confounds between people and situations; within a social structure, categories are often constrained by their nodes. The category "women" can only occupy the "women" node, which constrains the range of properties the occupier can display.
The notion of a confound between a category and its social location also helps to position the structural view of categories relative to role-based categories, such as guest, which specify a role in a relational structure (Asmuth \& Gentner, 2016; Markman \& Stilwell, 2001). Role-based categories involve relational structure, but structural thinking about social categories critically applies to cases in which a relational position is confounded with membership in a (perceived) taxonomic category.
Cross-cultural research on independent vs. interdependent (object vs. field) construals (Nisbett, 2003) suggests that the reasoning style associated with structural thinking is not as "unnatural" as it may seem. Research on analogy (Gentner,

1983; 2005) and recent work on role-based concepts (Goldwater, Bainbridge, \& Murphy, 2016) offer additional indications that people have the representational capacities to reason about structures. If people possess the requisite resources for engaging in structural reasoning, the question is: do they? And if so, when does this capacity develop? These are the questions our study addresses.
The development of structural thinking. Our study evaluates two competing hypotheses. Hypothesis 1 is that young children lack the conceptual prerequisites and/or knowledge to engage in structural thinking. Hypothesis 2 is that young children can successfully engage in structural thinking from an early age.
Each hypothesis receives some support from existing research. In favor of the first hypothesis, prior work demonstrates that children view some social categories (such as gender) as essentialized natural kinds from an early age (Rhodes \& Gelman, 2009; Taylor, 1996), even when cultural input suggests otherwise (Astuti et al., 2004). There is also evidence that young children have trouble endorsing environmental mechanisms that could produce category features (Rhodes \& Taylor, 2009), although the "environmental factors" that were examined were primarily non-structural in nature. Finally, as young as 4-5 years of age, children tend to generate and endorse "inherent" explanations of categorical patterns over "extrinsic" ones (Cimpian \& Markman, 2011; Cimpian \& Steinberg, 2014).
Beyond evidence of early essentialist and inherence-based reasoning, there is evidence that children lack capacities involved in structural thinking. Structural explanation could rely on structure-wide counterfactual alternatives, which do not fully emerge until age 7-8 (Beck et al., 2006; Rafetseder, Cristi-Vargas, \& Perner, 2010). Structural reasoning also relies on representing relations, and research on relational reasoning suggests a developmental shift in relevant capacities throughout and beyond the preschool years (e.g., Gentner, 1988; Richland, Morrison, \& Holyoak, 2006).
On the other hand, there is evidence that potentially favors Hypothesis 2. Several findings suggest that young children appreciate external constraints on social categories. Seiver, Gopnik, and Goodman (2013) demonstrated that children as young as 4 can use situational information in explanation and prediction when appropriate covariation evidence is available. Four-year-olds also recognize moral constraints on their own behavior (Chernyak \& Kushnir, 2014) and acknowledge that the behavior of members of a social category can be driven by common norms (Kalish, 2011; see also Kalish \& Shiverick, 2004; Rakoczy, Warneken, \& Tomasello, 2008; Smetana, 1981; Turiel, 1983). ${ }^{1}$

[^222]A final and more intriguing possibility is that young children may be more open to structural reasoning than older children and adults. Rhodes and Gelman (2009) showed that young children are more flexible than older children about some social categories, such as race. In Seiver et al. (2013), it was older children, not younger children, who showed an overall bias for person over situation explanations. Moreover, young children may be less biased by prior assumptions than adults, and thus open to learning a broad range of causal relationships (Lucas, Bridgers, Griffiths, \& Gopnik, 2013). This body of work suggests that relative to older children and adults, young children could be more open to integrating external constraints in their representations of social categories and relying on structural relations in reasoning.

## Experiment

This study had three goals: to determine whether and when children can successfully engage in structural thinking in explaining the association between a category and a property; to determine whether a structural construal can be experimentally induced; and to evaluate the prediction that structural thinking can support formal explanations under a structural interpretation of the category.

To address these three goals, we adopted an approach mirroring Prasada and Dillingham (2006, 2009), who developed a set of tasks that can be used to identify whether people construe the connection between a feature and a category as principled (such as between "fighting crime" and being a police officer) or statistical (such as between "eating donuts" and being a police officer). They showed that only the principled connections between kinds and features supported judgments of feature immutability (a person who does not fight crime is not really a police officer), partial definitions (a police officer is a person who fights crime), and formal explanations ("this person fights crime because she is a police officer"). With the aim of detecting structural thinking and differentiating it from internalist thinking, we modified these three measures (described below). Vasilyeva and Lombrozo (in prep) found that with adults, responses across these judgments can successfully be used as a "profiling tool" to detect structural thinking, which generates a unique signature: relatively high mutability ratings, low partial definition ratings, and high formal explanation ratings. In contrast, the pattern for an internalist construal should be low - high - high. To further validate the profiling tool, we additionally included an open-ended explanation prompt and close-ended causal explanation evaluations.

## Method

Participants We recruited 41 3-4-year-olds (mean age 4.3 years, range 3.0-4.9; 23 females, 18 males) and 48 5-6-yearolds (mean age 5.6 years, range 5.0-6.9; 23 females, 25 males). Additionally, 67 adults (mean age 33 years, range 1971; 33 females, 64 males) were recruited via Amazon Mechanical Turk; participation was restricted to users with an IP address within the US and an approval rating of at least $95 \%$ based on at least 50 previous tasks. Children were tested in person using an illustrated storybook presented on a laptop; adults were tested online.

Materials, Design, and Procedure Participants were first introduced to a school where girls and boys study in separate classrooms, and presented with fictitious data about students playing different games during recess: girls predominantly played Yellow-Ball while boys predominantly played GreenBall. Participants were told that the game each child played was determined by tossing a pebble towards two buckets standing side by side: if the pebble fell into the yellow bucket, the child played Yellow-Ball that day, and if the pebble fell into the green bucket, that child played GreenBall that day (Figure 1a). The critical manipulation concerned the sizes of the buckets. In the internalist condition, both buckets were of the same size (Figure 1b), inviting participants to infer that the correlation between category membership and game choice was the product of inherent preferences (see Kushnir, Xu, \& Wellman, 2010, for evidence that even younger children can use statistical evidence to infer a preference). In the structural condition, one bucket was instead much larger than the other: in the girls' classroom the yellow bucket was larger than the green bucket, with the reverse in the boys' classroom (Figure 1c). The size difference imposed a stable structural constraint on the probability distribution over options available to members of each category, inviting a structural interpretation of the category-property connection.

After comprehension checks, all participants completed a series of measures designed to differentiate an internalist from a structural construal of the property. First, in the openended explanation task, participants were asked why girls in the girls' classroom play Yellow-Ball a lot at their school. Second, participants completed a causal explanation evaluation task and the three profiling tools measures: a mutability judgment, a partial definition, and formal explanation ratings.

In the causal explanation evaluation task, children evaluated three kinds of causal explanations offered by puppets that "sometimes say things that are smart, and sometimes say things that are silly." The puppets explained that girls tend to play Yellow-Ball "because girls like playing Yellow-Ball" (internalist); "because in the girls' classroom, it's easier to throw a pebble in the yellow bucket" (structural); or "because they got sprinkled with water" (an incidental explanation invoking an irrelevant fact from the cover story). Participants evaluated each explanation using a two-step, four-

Figure 1: Illustrations of the procedure determining which game each student played in the story (a) and of the different constraints on the probability of outcomes in the internalist (b) and structural conditions (c).
point thumb scale: they first chose one of two thumbs representing "good explanation" (up) and "bad explanation" (down), and they then chose between two subsequent options based on their choice: "kind of good/bad" (small thumb) or "really good/bad" (big thumb) - a scale previously shown to work well to measure children's agreement with explanations (Cimpian \& Steinberg, 2014; Hussak \& Cimpian, 2015).

For the mutability judgment, participants were told that after a change in the school's rules allowing children to attend any classroom, Suzy's parents transferred her to the boys' classroom. Participants were asked to guess which game Suzy would play after transferring, responding on a two-step, four-point scale ranging from "for sure YellowBall" to "for sure Green-Ball." This mutability judgment mirrors more familiar "switched at birth" tasks in the essentialism literature (Gelman \& Wellman, 1991), in which children are asked, e.g., whether a cow raised by pigs will moo or go oink. Similarly, our mutability judgment involves a change in environment (structural constraints), and participants are asked to infer whether a property will match the exemplar's category (the node occupier) or the new environment (the node). A shift in predictions from YellowBall to Green-Ball should track the causal influence of the node, and indicate structural thinking (as well as show that structural positions are seen as influencing behavior, rather than merely reflecting existing internal preferences).

For the partial definition task, participants rated whether an alien did a good job telling what a girl is to another alien who had never heard about girls: "A girl is a person who plays Yellow-Ball a lot." Participants used a two-step, four-point scale ("really bad job" - "really good job").

In the formal explanation task, participants met Suzy who "plays Yellow-Ball a lot at her school" and were asked to evaluate a formal explanation offered by a puppet - "Because Suzy is a girl" - using the two-step, four-point thumb scale ranging from "really bad" to "really good."

## Results and Discussion

Due to differing test formats and sample sizes, data from children and adults were analyzed separately. For the openended explanation task (see Figure 2), participants' explanations were coded as internalist ("maybe the girls just like it better, so they always aim to get their pebbles into the yellow ball bucket"), structural ("because the pebble went into the yellow bin, because the yellow one is bigger"), or miscellaneous, comprised of "I don't know," question restatements, and unclassifiable responses ("the yellow ball is brighter"). The distribution of explanations was affected by condition for each age group (3-4-year-olds: $\chi^{2}(N=41)=6.19$, $p=.045$; 5-6-year-olds: $\chi^{2}(N=48)=16.80, \quad p<.001$; adults: $\left.\chi^{2}(N=67)=42.86, \quad p<.001\right)$. Critically, in the structural condition some proportion of participants in each age group produced structural explanations (Figure 2, right panel, black bars). There was also evidence of developmental change: in the structural condition, the percentage of internalist explanations dropped as the percentage of structural explanations increased, so that the overall preference for internalist explanations in the younger age group flipped to a preference for structural explanations for older children.

Figure 2: Distribution of internalist and structural explanations generated in response to question about why girls play Yellow-Ball, as a function of condition and age group.

Children's evaluations of causal explanations (see Figure 3) were analyzed as a function of explanation type (internalist, structural, incidental), condition (internalist, structural), and age group (3-4, 5-6 year-olds) in a mixed ANOVA, with the key prediction concerning an interaction between explanation type and condition. The analysis revealed a main effect of explanation type, $F(2,170)=9.87, p<.001, \eta_{p}{ }^{2}=.104$, which was qualified by a significant interaction between explanation type and condition, $F(2,170)=6.00, p=.003, \eta_{p}^{2}=.066$ : only the structural explanation ratings were boosted by the structural framing. Most importantly, we observed the target three-way interaction: $F(2,170)=3.73, p=.026, \quad \eta_{p}{ }^{2}=.042$, driven by the selective effect of condition on 5-6-year-olds' evaluations of the structural explanation: older children, but not younger children, rated structural explanations higher in the structural condition than in the internalist condition ( $p_{\text {older }}<.001, p_{\text {younger }}=.390$ ). The interaction remained significant when restricting the analysis to internalist and structural explanations, $p=.012$. For adults, an explanation type (essentialist, structural, incidental) by condition (essentialist, structural) mixed ANOVA revealed a significant effect of explanation type, $F(2,126)=171.15, p<.001, \eta_{p}^{2}=.731$, and a marginal effect of condition, $F(1,63)=3.74, p=.058, \eta_{p}{ }^{2}=.056$, qualified by a significant interaction, $F(2,126)=117.83$, $p<.001, \eta_{p}{ }^{2}=.652$ : adults favored the internalist explanation over the structural in the internalist condition, with the reverse in the structural condition ( $p$ ' $s<.001$, see Figure 3).

Having succeeded in finding evidence of structural thinking in our open- and close-ended causal explanation tasks, we next turn to the profiling tool measures to see whether they reveal developmental differences mirroring these patterns. For adults, who exhibited high levels of structural thinking, we would predict the following for the structural condition relative to the internalist condition: more frequent predictions

Figure 3: Explanation evaluation as a function of explanation type, framing condition, and age group.

Figure 4: Mutability (a), partial definition (b), and formal explanation ratings (c) as a function of framing condition and age group.
that Suzy will play Green-Ball when switched to the boys' classroom, lower endorsement of the partial definition, and no difference in endorsement of the formal explanation. For children, we would predict the same patterns, with smaller effects for the younger children. This is what we found.

For the mutability judgment task (see Figure 4a), the predicted main effect of condition was marginal for the youngest group, $t(39)=1.96, p=.057, d=.42$, but significant for the older children, $t(46)=2.29, p=.027, d=.63$, and for adults, $t(65)=8.04, p<.001, d=2.00$. The age by condition interaction for children was not significant, $F(1.85)<.01$, $\mathrm{p}=.984$, but it appears that the property (playing Yellow-Ball for girls) was seen as more mutable in the structural condition than in the essentialist condition by age 5-6.

For the partial definition task (Figure 4b), we predicted that properties construed as internalist should support definitions better than properties construed as structural. Neither younger nor older children displayed such a pattern ( $p$ ' $\mathrm{s} \geq .687$ ), but adults did, $t(65)=2.11, p=.039, d=.52$.

Finally, as predicted, formal explanation ratings did not significantly differ across the essentialist and structural conditions for any age group, all $p$ 's $\geq .915$ (see Figure 4c), suggesting that these explanations support both internalist and structural construals.

These results show that even young children are capable of structural thinking, as reflected in their openended explanations. They also provide the first demonstration that across all age groups formal (categorical) explanations support two interpretations: essentialist and structural. Beyond these age-general effects, they reveal developmental changes in structural thinking, with older children and adults more readily engaged in structural thinking. (Notably, we have reasons to believe that the observed pattern of developmental change is not due to younger children simply not understanding the task or explanations: in the explanation generation task younger children produced predominantly internalist explanations regardless of the framing, and when asked to break ties in the explanation evaluation task, they ranked internalist explanations higher under the internalist framing.) Moreover, these results suggest that internalist versus structural construals can be effectively induced, though in reality, they likely coexist, and are triggered by different cues. Finally, our results show that the profiling tool can effectively track internalist versus structural thinking across development.

## General Discussion

Using novel tasks designed to assess structural thinking, we find evidence that even young children are able to reason about social categories in structural terms. By age 5-6, children preferentially generated and accepted structural explanations for a category-property association when a structural constraint was presented, with hints of an emerging sensitivity by ages 3-4.
Recognizing structural reasoning as a distinct cognitive phenomenon invites us to rethink some of the findings in the literature on psychological essentialism. For example, many discussions of essentialism emphasize its capacity to support predictions and promote generalizations across category members (Gelman, 2003). In fact, generalization tasks are often used to measure the extent to which a category representation is essence-based. However, a structural representation of a category can likewise support such generalizations: structural forces shape properties of the nodes within the structure, and the occupiers of the nodes, being subject to these forces qua occupiers, are likely to obtain the properties in spite of idiosyncrasies in their individual histories and predispositions. Haslanger (2015) correspondingly praises structural explanations for their stability and identification of broad patterns that hold across "inessential perturbations," suggesting that such explanations may be particularly good in supporting generalizations within stable structures. These features of structural thinking challenge the widespread assumption that the stability and generalizability of category properties imply internalist (essentialist) representations. More generally, our findings lay the groundwork for refining internalist claims and the evidence that is taken to support them, and for making more finegrained distinctions when it comes to externalist alternatives.
We have also demonstrated that formal explanations support both structural and internalist interpretations. Introducing structural connections as a new type of nonaccidental relationship between a property and a category raises new questions about generics (e.g., "Girls prefer pink"), which are implicated in perpetuating stereotypes. On most accounts, generics are interpreted as expressing something about the underlying nature of the category, reinforcing essentialist beliefs (Cimpian \& Markman, 2011; Leslie, 2014; Prasada \& Dillingham, 2009). For example, Leslie argues that generics are by default interpreted as expressing "generalizations that hold because of common, inherent features of the members of the kind" (p. 217), where the only alternative available to people is interpreting generics as describing statistical connections, along the lines of "police officers eat donuts," on the basis of "specific worldly knowledge." But if people can interpret generics structurally, by construing features of category members as products of structural constraints rather than inherent attributes of the kind, this potentially opens up a new way to mitigate harmful side-effects of generic language without purging it from everyday speech (or, equally implausibly, convincing people that many associations between properties and social categories are merely "accidental").

By introducing a structural alternative into the dichotomy of internal vs. vaguely and variably defined external (situational) factors in explanations of behavior, we have unmasked a gap in our understanding of categorical reasoning, and opened up new directions of study that may help account for some of the mixed evidence in research on the development of relational reasoning, essentialist beliefs about social categories, and reasoning about moral and conventional norms. The reported work already calls for revision of current accounts of generic language and formal explanation, and highlights the need to study categories embedded in relational structures. But of course, a lot more remains to be done.

# The statistical significance filter leads to overconfident expectations of replicability 

Shravan Vasishth (vasishth@uni-potsdam.de)<br>Department of Linguistics, University of Potsdam, Potsdam 14476, Germany.<br>Andrew Gelman (gelman@stat.columbia.edu)<br>Department of Statistics, Columbia University, New York, NY 10027, USA.

#### Abstract

We show that publishing results using the statistical significance filter-publishing only when the p-value is less than 0.05 -leads to a vicious cycle of overoptimistic expectation of the replicability of results. First, we show analytically that when true statistical power is relatively low, computing power based on statistically significant results will lead to overestimates of power. Then, we present a case study using 10 experimental comparisons drawn from a recently published metaanalysis in psycholinguistics (Jäger et al., 2017). We show that the statistically significant results yield an illusion of replicability. This illusion holds even if the researcher doesn't conduct any formal power analysis but just uses statistical significance to informally assess robustness (i.e., replicability) of results.

Keywords: Statistical significance; p-values; replicability
"‘. .. in [an]. . . academic environment that only publishes positive findings and rewards publication, an efficient way to succeed is to conduct low power studies. Why? Such studies are cheap and can be farmed for significant results, especially when hypotheses only predict differences from the null, rather than precise quantitative differences and trends." (Smaldino \& McElreath, 2016, p. 5)

## Introduction

The statistical significance filter tells us that significant results-those findings in which the p -value is less than 0.05 -are positively biased. The statistically significant estimate is, by definition, more than $t$ standard errors away from zero, where $t$ is some critical value determined by a statistical test (such as the t-test) and the pre-specified Type I error (the probability, under repeated sampling, of incorrectly rejecting the null hypothesis).

Statistical power is the probability, under repeated sampling, of correctly rejecting the null hypothesis assuming that the parameter of interest has some true point value $\mu .{ }^{1}$ It is well-known that when statistical power is low, the effect (the sample mean) will tend to be exaggerated. These are referred to as Type M errors by Gelman and Carlin (2014) (also see Gelman \& Tuerlinckx, 2000). This exaggeration of effects has been noticed in previous work (Hedges, 1984; Lane \& Dunlap, 1978), and most recently in neuroscience and epidemiology, where Button et al. (2013) refer to the exaggeration of effects in neuroscience as the "winner's curse" and "the vibration of effects." In related work, Ioannidis (2008)

[^223]discusses this exaggeration of effects in epidemiological studies in terms of the vibration ratio: the ratio of largest to smallest observed effects.

These overestimates get published and fill the literature. Now consider what happens when researchers design a new study. They read the literature and see all these big effects, then plan their next study. They do a power calculation based on these big effects and get an exaggerated estimate of power, and can easily convince themselves that they have a high powered study. Alternatively-and this is probably the more common route in many fields, such as psychology-they don't do a formal power analysis, but just rely on the informal observation that most of the previously published results had a significant effect and so the effect must be present.

A related observation about overestimation comes from the replication attempts reported by the Open Science Collaboration (2015). The authors report that the magnitude of the published p-values from the original studies were predictive of replication success. As they put it (p. 943): "...correlational evidence is consistent with the conclusion that variation in the strength of initial evidence (such as original P value) was ... predictive of replication success ..." From this, researchers might erroneously conclude that lower p-values are generally more predictive of replication success. In other words, an erroneous conclusion would be that a lower p-value suggests a higher probability that the effect can be detected in future repeated studies.

We show that if statistical significance is used as a filter for publishing a result, and the observed effect (or p-value) is used to determine replicability, this will lead the researcher to overestimate replicability. We demonstrate this point analytically, and then present a case study involving 10 reading studies in psycholinguistics that illustrates this illusion.

## The relationship between $p$-values and estimated power

Assume for simplicity the case that we carry out a one-sided statistical test where the null hypothesis is that the null hypothesis mean is $\mu_{0}=0$ and the alternative is that $\mu>0 .{ }^{2}$ Given some continuous data $x_{1}, \ldots, x_{n}$, we can compute the t -statistic and derive the p -value from it. For a large sample size $n$, a normal approximation allows us to use the $z$-statistic, $Z=\frac{\bar{X}-\mu_{0}}{\sigma_{X} / \sqrt{n}}$, to compute the p-value. Here, $\bar{X}$ is the mean, $\sigma_{X}$ the standard deviation, and $n$ the sample size.

[^224]The p-value is the probability of observing the z -statistic or a value more extreme assuming that the null hypothesis is true. The p-value is a random variable $P$ with the probability density function (Hung, O'Neill, Bauer, \& Kohne, 1997):

$$
\begin{equation*}
g_{\delta}(p)=\frac{\phi\left(Z_{p}-\delta\right)}{\phi\left(Z_{p}\right)}, \quad 0<p<1 \tag{1}
\end{equation*}
$$

where

- $\phi(\cdot)$ is the pdf of the standard normal distribution, Nor$\operatorname{mal}(0,1)$.
- $Z_{p}$, a random variable, is the (1-p)th percentile of the standard normal distribution.
- $\delta=\frac{\mu-\mu_{0}}{\sigma_{X} / \sqrt{n}}$ is the true point value expressed as a z-score. Here, $\mu$ is the true (unknown) point value of the parameter of interest.

Hung et al. (1997) further observe that the cumulative distribution function (cdf) of $P$ is:

$$
\begin{equation*}
G_{\delta}(p)=\int_{0}^{p} g_{\delta}(x) d x=1-\Phi\left(Z_{p}-\delta\right), \quad 0<p<1 \tag{2}
\end{equation*}
$$

where $\Phi(\cdot)$ is the cdf of the standard normal.
Once we have observed a particular z-statistic $z_{p}$, the cdf $G_{\delta}(p)$ allows us to estimate power based on the z -statistic (Hoenig \& Heisey, 2001). To estimate the p-value given that the null hypothesis is true, let the true value be $\mu=0$. It follows that $\delta=0$. Then:

$$
\begin{equation*}
p=1-\Phi\left(z_{p}\right) \tag{3}
\end{equation*}
$$

To estimate power from the observed $z_{p}$, set $\delta$ to be the observed statistic $z_{p}$, and let the critical z-score be $z_{\alpha}$, where $\alpha$ is the Type I error (typically 0.05 ). The power is therefore:

$$
\begin{equation*}
G_{z_{p}}(\alpha)=1-\Phi\left(z_{\alpha}-z_{p}\right) \tag{4}
\end{equation*}
$$

In other words, power estimated from the observed statistic is a monotonically increasing function of the observed z statistic: the larger the statistic, the higher the power estimate based on this statistic (Figure 1). Together with the common practice that only statistically significant results get published, and especially results with a large z-statistic, this leads to overestimates of power. As mentioned above, one doesn't need to actually estimate power in order to fall prey to the illusion; merely scanning the statistically significant z-scores gives an impression of consistency and invites the inference that the effect is replicable and robust. The word "reliable" is frequently used in psychology, presumably with the meaning that the result is replicable and represents the reality.

A direct consequence of Equation 4 is that overestimates of the z-statistic will lead to overestimates of power. For example, if we have 36 data points and the true effect is 0.1 on

Figure 1: The relationship between power and the observed zscore. The larger z-scores are easier to publish due to the statistical significance filter, and these published studies therefore give a mistaken impression of higher power.
some scale and standard deviation is 1 , then statistical power is $15 \%$. ${ }^{3}$

If we now re-run the same study, collecting 36 data points each time, and impose the condition that only statistically significant results with Type I error $\alpha=0.05$ are published, then only observed z-scores larger than 1.64 (for a one-sided test) would be published and the power estimate based on these z-scores must have a lower bound of

$$
\begin{equation*}
G_{Z_{\alpha}}(\alpha)=1-\Phi(1.64-1.64)=0.5 \tag{5}
\end{equation*}
$$

Thus, in a scenario where the real power is $15 \%$, and only z scores greater than or equal to $z_{\alpha}$ are published, power based on the z-score will be overestimated by at least a factor of $0.5 / 0.15=3.33$. Call this ratio the Power Inflation Index (PII).

Now, lower p-values are widely regarded as more "reliable" than $p$-values near the Type I error probability of 0.05. ${ }^{4}$ This incorrect belief, widely shared by editors, reviewers, and authors in areas like psychology and linguistics, has the effect that studies with lower p-values are more likely to be reported

[^225]and published, with the consequence that the PII will tend to be even higher than the lower bound discussed here.

We turn next to a case study involving psycholinguistic data that illustrates the illusion of replicability.

## Case study: Interference effects in reading studies

To illustrate the illusion of replicability, we consider the 10 experiments that were reviewed in the literature review and meta-analysis presented in Jäger, Engelmann, and Vasishth (2017). These were psycholinguistic studies in which the dependent measure was reading time in milliseconds of words. The experimental manipulation involved pairs of sentence types where one type was easier to read than the other; the empirical phenomenon of interest here is interference in working memory. Here, an appropriate statistical test is the two-sided paired t-test (one could do a one-sided t-test, although this is less common in psycholinguistics).

We had the raw data from these 10 studies and so were able to carry out the pairwise comparison. As discussed in detail in Jäger et al. (2017), theory predicts an effect with a negative sign. The original results as published were analyzed on the raw milliseconds scale, but here we analyze the data on the log milliseconds scale because the reading time data were log-normally distributed.

A summary of the pairwise t-test is shown in Table 1. From the table, it is clear that the studies consistently found negative values for the coefficient; this consistent result raises our confidence in the reproducibility of the result. A formal power analysis based on these studies, also shown in the last column of the table, leads to estimates of power ranging from 17 to $60 \%$.

|  |  |  | t | d | n | se | s |
| ---: | ---: | ---: | ---: | ---: | ---: | ---: | ---: |
| pval | power |  |  |  |  |  |  |
| 1 | -1.9 | -0.1 | 40 | 0.0 | 0.2 | 0.1 | 0.3 |
| 2 | -3.1 | -0.1 | 32 | 0.0 | 0.1 | 0.0 | 0.6 |
| 3 | -1.5 | -0.0 | 32 | 0.0 | 0.2 | 0.2 | 0.2 |
| 4 | -2.1 | -0.0 | 32 | 0.0 | 0.1 | 0.0 | 0.3 |
| 5 | -1.7 | -0.0 | 32 | 0.0 | 0.1 | 0.1 | 0.2 |
| 6 | -2.6 | -0.1 | 28 | 0.0 | 0.2 | 0.0 | 0.4 |
| 7 | -1.6 | -0.0 | 60 | 0.0 | 0.2 | 0.1 | 0.2 |
| 8 | -3.2 | -0.1 | 44 | 0.0 | 0.2 | 0.0 | 0.6 |
| 9 | -1.9 | -0.1 | 60 | 0.0 | 0.2 | 0.1 | 0.3 |
| 10 | -2.6 | -0.0 | 114 | 0.0 | 0.2 | 0.0 | 0.5 |

Table 1: Results from the paired $t$-tests for the 10 experimental comparisons. Shown are the $t$-score, the effect $d$ in $\log$ ms , the sample size n , the standard error se, the standard deviation $s$, and the $p$-value. The $t$-tests were done on the raw data from the original studies (the $t$-values reported here may deviate slightly from the published t -values). Also shown is the power estimated from each study.

## Using a Bayesian random-effects meta-analysis to estimate the power function

In Table 1, we calculated power based on the individual studies. As discussed above, these will tend to be overestimates because there is a preference to publish effects with low pvalues. How can we check this for the 10 studies? True power is unknown so we have no basis for comparing the power estimates from individual studies with a true value for power.

One way to arrive at a conservative estimate of the true power given these 10 studies is to carry out a Bayesian random-effects meta-analysis (Gelman et al., 2014). This hierarchical modelling approach allows us to determine the posterior distribution of the effect, which can then be used for computing an estimate of power. As discussed in Button et al. (2013), using estimates from a meta-analysis yields a more conservative estimate of power. In the random-effects meta-analysis, this conservativity arises due to the shrinkage property of hierarchical models: Larger sample studies receive a greater weighting in determining the posterior than smaller sample studies. Note, however, that even here the power may be an overestimate due to the fact that the studies that go into the meta-analysis are likely to have publication bias. But as we show below, the estimates of power from individual studies tend to be ever larger.

The random-effects meta-analysis model was set up as follows. Let $y_{i}$ be the effect size in log milliseconds in the $i$-th study, where $i$ ranges from 1 to $n$. Let $\mu$ be the true (unknown) effect in log ms, to be estimated by the model, and $\mu_{i}$ the true (unknown) effect in each study. Let $\sigma_{i} \log \mathrm{~ms}$ be the true standard deviation of the sampling distribution; each $\sigma_{i}$ is estimated from the sample standard error from study $i$. The standard deviation parameter $\tau$ represents between-study variability.

Then, our model for $n$ studies is as follows. The model assumes the i-th data point (the effect observed on the $\log \mathrm{ms}$ scale) $y_{i}$ is generated from a normal distribution with mean $\mu_{i}$ and some standard error $\sigma$, estimated from the sample's standard error. Each of the true underlying means $\mu_{i}$ are assumed to be generated from a normal distribution with true mean $\mu$ and between-study standard deviation $\tau$. We assign Cauchy $(0,2.5)$ priors to the parameters $\mu$ and $\mu_{i}$, and a truncated Cauchy $(0,2.5)$ prior for the between-study standard deviation $\tau$, truncated so that $\tau$ is greater than 0 . The model can be stated mathematically as follows:

## Likelihoods:

$$
\begin{align*}
& y_{i} \mid \mu_{i}, \sigma_{i}^{2} \sim \operatorname{Normal}\left(\mu_{i}, \sigma_{i}^{2}\right) \quad i=1, \ldots, n \\
& \mu_{i} \mid \theta, \tau^{2} \sim \operatorname{Normal}\left(\mu, \tau^{2}\right), \\
& \text { Priors: }  \tag{6}\\
& \mu \sim \operatorname{Cauchy}(0,2.5), \\
& \mu_{i} \sim \operatorname{Cauchy}(0,2.5), \\
& \tau \sim \operatorname{Cauchy}(0,2.5), \tau>0
\end{align*}
$$

Figure 2: Posterior distributions of the estimated effect ( $\hat{\mu}$ ), and the standard deviation of estimate of the between-study variability $(\hat{\tau})$ in the random-effects meta-analysis.

We fit the model using Stan 2.14.2 (Stan Development Team, 2016), running four chains with 4000 iterations (half of which were warm-ups). Convergence was successful, as diagnosed using the $\hat{R}$ diagnostic (Gelman et al., 2014). The posterior distributions of $\hat{\mu}$ and of the between-study standard deviation $\hat{\tau}$ are shown in Figure 2. The posterior mean of the effect is $-0.05 \log \mathrm{~ms}$, with $95 \%$ credible interval [-0.08,$0.03]$. Next, we use this estimate of the posterior distribution to compute a power distribution.
Computing the power distribution using the posterior distribution of the effect An analysis of reading studies, including the ones considered here, showed that the precisions (the inverse of the variance) in reading time studies have mean values 16.3 and standard deviation 7.07 (the unit for precision is $1 / \log \mathrm{ms}^{2}$ ). Since precision can be modelled as a Gamma distribution, we assumed that precisions are distributed as $\operatorname{Gamma}(\alpha=5.3, \beta=0.3)$. These parameters of the Gamma distribution were computed by taking the mean $\bar{x}$ and standard deviation $s$ of the precisions, and then deriving the parameters of the Gamma distribution by solving for $\alpha$ and $\beta$. We use the fact that for a random variable generated from a Gamma distribution with parameters $\alpha$ and $\beta$, the expectation $\mu$ and variance $\sigma^{2}$ are:

$$
\begin{equation*}
E(X)=\frac{\alpha}{\beta}=\mu \quad \text { and } \operatorname{Var}(X)=\frac{\alpha}{\beta^{2}}=\sigma^{2} \tag{7}
\end{equation*}
$$

Having obtained the estimate of the effect (through the meta-analysis) and the distribution of the precisions, we used these estimates to carry out 100,000 Monte Carlo simulations to derive a power distribution for different sample sizes ( $n=20, \ldots, 50$ ) in the following manner. For each sample size, we repeatedly computed power after obtaining:

- one sample for the effect by sampling from the distribution $\operatorname{Normal}(-0.05,0.01)$; this is the posterior distribution of the effect derived from the random-effects meta-analysis;
- one sample for the precision by sampling from the Gamma $(5.3,0.3)$, and then converting this to a standard deviation.

Such a Monte Carlo sampling procedure gives a probability distribution of power values and allows us to quantify our uncertainty about the estimated power by taking all sources of uncertainty into account-the uncertainty regarding the effect, and the uncertainty regarding the standard deviation.

Figure 3 shows the resulting power distributions for power given different sample sizes. These power distributions are of course only estimates, not the true power; and as Button et al. (2013) point out, are probably slight overestimates if the studies themselves have publication bias.

The power distributions illustrate two important points. First, the range of most likely power values is remarkably low for typical sample sizes used in psycholinguistic reading experiments relating to interference effects (see Table 1). As an aside, we note that our estimates are similar to those from a recent review of 44 meta-analyses of research in social and behavioural sciences published between 1960-2011; they report a mean power of 0.24 with most studies suggesting power to be below 0.4 (Smaldino \& McElreath, 2016, p. 6, Fig. 1). The second observation is that the power values computed from individual studies (the red dots) tend to be overestimates relative to the mean of each power distribution shown. The power from each study tends to be higher than the mean of each power distribution. Of course, if the statistical power of the original studies were very high (approximately $80 \%$ or higher), then the overestimation problem would disappear or at least be negligible.

We can quantify the overestimation of power by computing the Power Inflation Index: the ratio of the power computed from individual studies to the power distribution computed using Monte Carlo simulations. If power is overestimated, then the distribution of the PII will be such that the mean ratio will be greater than 1 . These distributions of PIIs are computed for a typical sample size used in psycholinguistic studies ( $\mathrm{n}=20,30,40$ ) in Table 2. Here, we can see that the PII can be as high as 12 .

## Discussion

We have shown that if statistical significance is used to decide whether to publish a result, overestimates of the effect will tend to be published, leading to an over-enthusiastic belief in the replicability of the effect.

Recently, the replication project reported by Open Science Collaboration (2015) showed that only $47 \%$ of the studies they investigated could be replicated. One factor causing these failures to replicate could have been low power in the original studies. Even before the replication project, Cohen $(1962,1988)$ and others have repeatedly warned against running low-powered studies. Despite these injunctions, many researchers do not believe that there is a problem of low power. For example, Gilbert, King, Pettigrew, and Wilson (2016) contested the $47 \%$ replication rate and argued that

Figure 3: Power distributions for different sample sizes (log reading times). The histogram shows the power distribution (generated through Monte Carlo sampling; see text for details). The red dots show power estimates from the 10 individual experimental comparisons considered in this case study. The white dot shows the mean of each power distribution.

| $\mathrm{n}=20$ |  |  |  | $\mathrm{n}=30$ |  | $\mathrm{n}=40$ |  |

| 10 | 1.02 | 3.47 | 0.73 | 2.96 | 0.57 | 2.59 |  |

Table 2: The 95\% credible intervals of the Power Inflation Index for each of the 10 experimental comparisons, for different sample sizes. The Power Inflation Index can be as large as 12.
the replication rate may be much higher, perhaps even "statistically indistinguishable from $100 \%$." The objections of Gilbert et al. (2016) were largely based on arguments about the lack of fidelity to the original design, but it is possible that, in addition to concerns about fidelity, Gilbert et al. are, like many researchers, generally overconfident about the replicability and robustness of their results. This overconfidence is also evident in reading research in psycholinguistics, where it is routine to run experiments with sample sizes ranging from 20 to 40 participants. Recent work has argued that sample sizes of 20-40 partipants may be too low for reading studies on interference (Jäger et al., 2017). We are hopeful that future work will take this finding into account when planning studies.

Currently, the replication problems in psycholinguistics are serious. For example, in recent work (Mertzen, Jäger, \& Vasishth, 2017) we carried out six replication attempts of two eyetracking experiments published in the Journal of Memory and Language. We were unable to replicate any of the claims in the paper. There is thus an urgent need to attempt to replicate published results, and not just in psycholinguistics. For example, Makel, Plucker, and Hegarty (2012) present a quantitative analysis of the low rate of successful replications in psychology ( $1 \%$ ). Other fields are also affected. For example, Button et al. (2013) have shown that in neuroscience studies, power may also be quite low, ranging from 8 to $31 \%$. Smaldino and McElreath (2016) have shown through a 50year meta-analysis in behavioural science that power has not improved (mean power: $24 \%$ ). In biomedical sciences, approximately $50 \%$ of studies have power in the $0-10 \%^{5}$ or 11$20 \%$ range (Dumas-Mallet, Button, Boraud, Gonon, \& Munafò, 2017).

Despite these indications, many researchers remain overconfident about the robustness of their results. This overconfidence is in part due to the statistical significance filter.

## Concluding remarks

We have shown that the statistical significance filter directly leads to over-optimistic expectations of replicability of published research. Even if the researcher doesn't conduct any formal power analyses, they can fall prey to this illusion because of the informal assessment of replicability afforded by the statistical significance filter. We illustrated the illusion of replicability through a case-study involving 10 published experimental comparisons.

Many psychology journals are beginning to require that power analyses be included in submitted manuscripts. But our results, echoing those of others who have studied this problem, suggest that such analyses, which invariably are based on previously published work, will tend to provide overestimates of power.

To resolve or at least reduce this problem, we offer two pieces of advice. First, we recommend entirely abandon-

[^226]ing the concept of power, which is based on the idea that " $p<.05$ " is a win, an attitude that fails miserably when effect sizes are small and measurements are noisy. Second, when performing design analysis, consider possible effect sizes based on subject-matter understanding; see Gelman and Carlin (2014) for further discussion of this point. It can make sense to consider a range of reasonable effect sizes.

## Appendix

Here, we review the well-known proof that for a point null hypothesis and a continuous dependent variable, the distribution of the p-value under the null is Uniform $(0,1)$.

When a random variable $Z$ comes from a $\operatorname{Uniform}(0,1)$ distribution, then the probability that $Z$ is less than (or equal to) some value $z$ is exactly $z: P(Z \leq z)=z$.

The p -value is a random variable, call it $Z$. The p -value is computed by calculating the probability of seeing a $t$-statistic or something more extreme under the null hypothesis. The t -statistic comes from a random variable $T$ that is a transformation of the random variable $\bar{X}: T=(\bar{X}-\mu) /(\sigma / \sqrt{n})$. This random variable T has a $\mathrm{CDF} F$.

We can establish that if a random variable $Z=F(T)$, then $Z \sim \operatorname{Uniform}(0,1)$, i.e., that the p-value's distribution under the null hypothesis is $\operatorname{Uniform}(0,1)$. This is proved next.

Let $Z=F(T)$. Then: $\quad P(Z \leq z)=P(F(T) \leq z)=$ $P\left(F^{-1} F(T) \leq F^{-1}(z)\right)=P\left(T \leq F^{-1}(z)\right)=F\left(F^{-1}(z)\right)=z$.

Since $P(Z \leq z)=z, \mathrm{Z}$ is uniformly distributed, that is, $\operatorname{Uniform}(0,1)$.

#### Abstract

We present a case-study demonstrating the usefulness of Bayesian hierarchical mixture modelling for investigating cognitive processes. In sentence comprehension, it is widely assumed that the distance between linguistic co-dependents affects the latency of dependency resolution: the longer the distance, the longer the retrieval time (the distance-based account). An alternative theory, direct-access, assumes that retrieval times are a mixture of two distributions: one distribution represents successful retrievals (these are independent of dependency distance) and the other represents an initial failure to retrieve the correct dependent, followed by a reanalysis that leads to successful retrieval. We implement both models as Bayesian hierarchical models and show that the direct-access model explains Chinese relative clause reading time data better than the distance account.

Keywords: Bayesian Hierarchical Finite Mixture Models; Psycholinguistics; Sentence Comprehension; Chinese Relative Clauses; Direct-Access Model; K-fold Cross-Validation

## Introduction

Bayesian cognitive modelling (Lee \& Wagenmakers, 2014), using probabilistic programming languages like JAGS (Plummer, 2012), is an important tool in cognitive science. We present a case study from sentence processing research showing how hierarchical mixture models can be profitably used to develop probabilistic models of cognitive processes. Although the case study concerns a specialized topic in psycholinguistics, the approach developed here will be of general interest to the cognitive science community.

In sentence comprehension research, dependency completion is assumed by many theories to be a key event. For example, consider a sentence such as (1):
(1) a. The man (on the bench) was sleeping

In order to understand who was doing what, the noun The man must be recognized to be the subject of the verb phrase was sleeping; this dependency is represented here as a directed arrow. One well-known proposal (Just \& Carpenter, 1992), which we will call the distance account, is that dependency distance between linguistically related elements partly
determines comprehension difficulty as measured by reading times or question-response accuracy. For example, the Dependency Locality Theory (DLT) by Gibson (2000) and the cue-based retrieval account of Lewis and Vasishth (2005) both assume that the longer the distance between two codependents such as a subject and a verb, the greater the retrieval difficulty at the moment of dependency completion. As shown in (1), the distance between co-dependents can increase if a phrase intervenes.

As another example, consider the self-paced reading study in Gibson and Wu (2013) in Chinese subject and object relative clauses. The dependent variable here was the reading time at the head noun (official). As shown in (2), the distance between the head noun and the gap it is coindexed with is larger in subject relatives compared to object relatives. ${ }^{1}$ Thus, the distance account predicts an object relative advantage. For simplicity, we operationalize distance here as the number of words intervening between the gap inside the relative clause and the head noun. In the DLT, distance is operationalized as the number of (new) discourse referents intervening between two co-dependents; and in the cue-based retrieval model, distance is operationalized in terms of decay in working memory (i.e., time passing by).

## a. Subject relative

[GAP $_{i}$ yaoqing fuhao de] guanyuan

'The official who invited the tycoon has bad intentions.
b. Object relative

[^227][fuhao yaoqing $\mathrm{GAP}_{i}$ de] guanyuan ${ }_{i}$
tycoon invite
 xinhuaibugui
have bad intentions
'The official who the tycoon invited has bad intentions.

In the Gibson and Wu study, reading times were recorded using self-paced reading in the two conditions, with 37 subjects and 15 items, presented in a standard Latin square design. The experiment originally had 16 items, but one item was removed in the published analysis due to a mistake in the item. We coded subject relatives as $-1 / 2$, and object relatives as $+1 / 2$; this implies that an overall object relative advantage would show a negative coefficient. In other words, an object relative advantage corresponds to a negative sign on the estimate.

The distance account's predictions can be evaluated by fitting the hierarchical linear model shown in (1). Assume that (i) $i$ indexes participants, $i=1, \ldots, I$ and $j$ indexes items, $j=1, \ldots, J$; (ii) $y_{i j}$ is the reading time in milliseconds for the $i$-th participant reading the $j$-th item; and (iii) the predictor $X$ is sum-coded $( \pm 1 / 2)$, as explained above. Then, the data $y_{i j}$ (reading times in milliseconds) are defined to be generated by the following model:

$$
\begin{equation*}
y_{i j}=\beta_{0}+\beta_{1} X_{i j}+u_{i}+w_{j}+\varepsilon_{i j} \tag{1}
\end{equation*}
$$

where $u_{i} \sim \operatorname{Normal}\left(0, \sigma_{u}^{2}\right), w_{j} \sim \operatorname{Normal}\left(0, \sigma_{w}^{2}\right)$ and $\varepsilon_{i j} \sim$ $\operatorname{Normal}\left(0, \sigma_{e}^{2}\right)$; all three sources of variance are assumed to be independent. The terms $u_{i}$ and $w_{j}$ are called varying intercepts for participants and items respectively; they represent by-subject and by-item adjustments to the fixed-effect intercept $\beta_{0}$. Their variances, $\sigma_{u}^{2}$ and $\sigma_{w}^{2}$ represent betweenparticipant (respectively item) variance.

This model is effectively a statement about the generative process that produced the data. If the distance account is correct, we would expect to find evidence that the slope $\beta_{1}$ is negative; specifically, reading times for object relatives are expected to be shorter than those for subject relatives. As shown in Table 1, this prediction appears, at first sight, to be borne out. Subject relatives are estimated to be read 120 ms slower than object relatives, apparently consistent with the predictions of the distance account.

|  | Estimate | Std. Error | t value |
| :--- | ---: | ---: | ---: |
| $\hat{\beta}_{0}$ | 548.43 | 51.56 | $10.64^{*}$ |
| $\hat{\beta}_{1}$ | -120.39 | 48.01 | $-2.51^{*}$ |

Table 1: A linear mixed model using raw reading times in milliseconds as dependent variable, corresponding to the reported results in Gibson and Wu 2013. Statistical significance is shown by an asterisk.

The object relative advantage shown in Table 1 was origi-
nally presented in Gibson and Wu (2013) as a repeated measures ANOVA.

To summarize, the conclusion from the above result would be that in Chinese, subject relatives are harder to process than object relatives because the gap inside the relative clause is more distant from the head noun in subject vs. object relatives. This makes it more difficult to complete the gap-head noun dependency in subject relatives. This distance-based explanation of processing difficulty is plausible given the considerable independent evidence from languages such as English, German, Hindi, Persian and Russian that dependency distance can affect reading time (see review in Safavi, Husain, and Vasishth (2016)).

Figure 1: Boxplots showing the distribution of reading times by condition of the Gibson and Wu (2013) data.

However, the distributions of the reading times for the two conditions show an interesting asymmetry that cannot be straightforwardly explained by the distance account. At the head noun, the reading times in subject relatives are much more spread out than in object relatives. This is shown in Figure 1, where reading times are shown on the log scale. Although this spread was ignored in the original analysis, a standard response to heterogeneous variances (heteroscedasticity) is to delete "outliers" based on some criterion; a common criterion is to delete all data lying beyond $\pm 2.5 S D$ in each condition. ${ }^{2}$ This procedure assumes that the data points identified as extreme are irrelevant to the question being investigated. An alternative approach is to not delete data but to downweight the extreme values by applying a variance stabilizing transform (Box \& Cox, 1964). Taking a log-transform

[^228]of the reading time data, or a reciprocal transform, can reduce the heterogeneity in variance; see Vasishth, Chen, Li, and Guo (2013) for analyses of the Gibson and Wu data using a transformation.

One might think that if subject and object relatives are generated by LogNormal distributions with different means, then modelling the data as being generated by LogNormals would adequately explain the data. Table 2 shows that if we assume such a model, there is no longer a statistically significant object relative advantage: the absolute $t$-value for the estimate of the $\beta_{1}$ parameter is smaller than the critical value of 2 (Bates, Maechler, Bolker, \& Walker, 2015). Thus, assuming that the data are generated by LogNormal distributions with different means for the subject and object relatives leads to the conclusion that there isn't much evidence for the distance account.

|  | Estimate | Std. Error | t value |
| :--- | ---: | ---: | ---: |
| $\hat{\beta}_{0}$ | 6.06 | 0.07 | $92.64^{*}$ |
| $\hat{\beta}_{1}$ | -0.07 | 0.04 | -1.61 |

Table 2: A linear mixed model using log reading times in milliseconds as dependent variable in the Gibson and Wu, 2013, data.

Consider next the possibility that the heteroscedasticity in subject and object relatives in the Gibson and Wu data reflects a systematic difference in the underlying generative processes of reading times in the two relative clause types. We investigate this question by modelling the extreme values as being generated from a mixture distribution.

Using the probabilistic programming language Stan (Stan Development Team, 2016), we show that a hierarchical mixture model provides a better fit to the data (in terms of predictive accuracy) than several simpler hierarchical models. As Nicenboim and Vasishth (2017) pointed out, the underlying generative process implied by a mixture model is consistent with the direct-access model of McElree, Foraker, and Dyer (2003). We therefore suggest that, at least for the Chinese relative clause data considered here, the direct-access model may be a better way to characterize the dependency resolution process than the distance account.

We can implement the direct-access model as a hierarchical mixture model with retrieval time assumed to be generated from one of two distributions, where the proportion of trials in which a retrieval failure occurs (the mixing proportion) is $p_{s r}$ in subject relatives, and $p_{o r}$ in object relatives. The expectation here is the extreme values that are seen in subject relatives are due to $p_{s r}$ being larger than $p_{o r}$.

Subject relatives

$$
\begin{align*}
y_{i j} & \sim p_{s r} \cdot \operatorname{LogNormal}\left(\beta+\delta+u_{i}+w_{j}, \sigma_{e^{\prime}}^{2}\right) \\
& +\left(1-p_{s r}\right) \cdot \operatorname{LogNormal}\left(\beta+u_{i}+w_{j}, \sigma_{e}^{2}\right) \tag{2}
\end{align*}
$$

Object relatives

$$
\begin{aligned}
y_{i j} & \sim p_{o r} \cdot \log N o r m a l \\
& \left(\beta+\delta+u_{i}+w_{j}, \sigma_{e^{\prime}}^{2}\right) \\
& +\left(1-p_{\text {or }}\right) \cdot \operatorname{LogNormal}\left(\beta+u_{i}+w_{j}, \sigma_{e}^{2}\right)
\end{aligned}
$$

Here, the terms $u_{i}$ and $w_{j}$ have the same interpretation as in equation 1.

## Model comparison

Bayesian model comparison can be carried out using different methods. Here, we use Bayesian k-fold cross-validation as discussed in Vehtari, Gelman, and Gabry (2016). This method evaluates the predictive performance of alternative models, and models with different numbers of parameters can be compared (Vehtari, Ojanen, et al., 2012; Gelman, Hwang, \& Vehtari, 2014).

The k-fold cross-validation algorithm is as follows:

1. Split data pseudo-randomly into $K$ held-out $\operatorname{sets} \mathbf{y}_{(k)}$, where $k=1, \ldots, K$ that are a fraction of the original data, and $K$ training sets, $\mathbf{y}_{(-k)}$. Here, we use $K=10$, and the length of the held-out data-vector $\mathbf{y}_{(k)}$ is approximately $1 / K$-th the size of the full data-set. We ensure that each participant's data appears in the training set and contains an approximately balanced number of data points for each condition.
2. Sample from the model using each of the $K$ training sets, and obtain posterior distributions $p_{\operatorname{post}(-\mathrm{k})}(\theta)=p(\theta \mid$ $\left.\mathbf{y}_{(-k)}\right)$, where $\theta$ is the vector of model parameters.
3. Each posterior distribution $p\left(\theta \mid \mathbf{y}_{(-k)}\right)$ is used to compute predictive accuracy for each held-out data-point $y_{i}$ :

$$
\begin{equation*}
\log p\left(y_{i} \mid \mathbf{y}_{(-k)}\right)=\log \int p\left(y_{i} \mid \theta\right) p\left(\theta \mid \mathbf{y}_{(-k)}\right) d \theta \tag{3}
\end{equation*}
$$

4. Given that the posterior distribution $p\left(\theta \mid \mathbf{y}_{(-k)}\right)$ is summarized by $s=1, \ldots, S$ simulations, i.e., $\theta^{k, s}$, $\log$ predictive density for each data point $y_{i}$ in subset $k$ is computed as

$$
\begin{equation*}
\widehat{e l p d}_{i}=\log \left(\frac{1}{S} \sum_{s=1}^{S} p\left(y_{i} \mid \theta^{k, s}\right)\right) \tag{4}
\end{equation*}
$$

5. Given that all the held-out data in the $K$ subsets are $y_{i}$, where $i=1, \ldots, n$, we obtain the $\widehat{\text { elpd }}$ for all the held-out data points by summing up the $\widehat{\text { elpd }}_{i}$ :

$$
\begin{equation*}
\widehat{e l p d}=\sum_{i=1}^{n} \widehat{e l p d}_{i} \tag{5}
\end{equation*}
$$

The difference between the $\widehat{\text { elpd}}$ 's of two competing models is a measure of relative predictive performance. We can also compute the standard deviation of the sampling distribution (the standard error) of the difference in $\widehat{\text { elpd }}$ using the formula discussed in Vehtari et al. (2016). Letting $\widehat{E L P D}$ be the vector $\widehat{e l p d}_{1}, \ldots, \widehat{e l p d}_{n}$, we can write:

$$
\begin{equation*}
\operatorname{se}\left(\widehat{e l p d}_{m 0}-\widehat{e l p d}_{m 1}\right)=\sqrt{n \operatorname{Var}(\widehat{E L P D})} \tag{6}
\end{equation*}
$$

When we compare the model (1) with (2), if (2) has a higher $\widehat{e l p d}$, then it has a better predictive performance compared to (1).

The quantity $\widehat{\text { elpd }}$ is a Bayesian alternative to the Akaike Information Criterion (Akaike, 1974). Note that the relative complexity of the models to be compared is not relevant: the sole criterion here is out-of-sample predictive performance. As we discuss below (Results section), increasing complexity will not automatically lead to better predictive performance. See Vehtari et al. (2012); Gelman, Hwang, and Vehtari (2014) for further details. ${ }^{3}$

## The data

The evaluation of these models was carried out using two separate data-sets. The first was the original study from Gibson and Wu (2013) that was discussed in the introduction. The second study was a replication of the Gibson and Wu study that was published in Vasishth et al. (2013). This second study served the purpose of validating whether independent evidence can be found for the mixture model selected using the original Gibson and Wu data.

## Results

In the models presented below, the dependent variable is reading time in milliseconds. Priors are defined for the model parameters as follows. All standard deviations are constrained to be greater than 0 and have priors Cauchy $(0,2.5)$ (Gelman, Carlin, et al., 2014); probabilities have priors $\operatorname{Beta}(1,1)$; and all coefficients ( $\beta$ parameters) have priors Cauchy $(0,2.5)$.

Fake-data simulation for validating model Before evaluating relative model fit, we first simulated data from a mixture distribution with known parameter values, and then sampled from the models representing the distance account and the direct-access model. The goal of fake-data simulation was to validate the models and the model comparison method: with reference to the simulated data, we asked (a) whether the $95 \%$ credible intervals of the posterior distributions of the parameters in the mixture model contain the true parameter values used to generate the data; and (b) whether k-fold cross validation can identify the mixture model as the correct one when the underlying generative process matches the mixture model.

[^229]The answer to both questions was "yes". This raises our confidence that the models can identify the underlying parameters with real data. The fake-data simulation also showed that when the true underlying generative process was consistent with the distance account but not the direct access model, the hierarchical linear model and the mixture model had comparable predictive performance. In other words, the mixture model furnished a superior fit only when the true underlying generative process for the data was in fact a mixture process. Further details are omitted here due to lack of space.
The original Gibson and Wu study The estimates from the hierarchical linear model (equation 1) and the mixture model (equation 2) are shown in Tables 3 and 4. Note that in Bayesian modelling we are not interested in "statistical significance" here; rather, the goal is inference and comparing predictive performance of two competing models.

|  | mean | lower | upper |
| :--- | ---: | ---: | ---: |
| $\hat{\beta}_{1}$ | 6.06 | 5.91 | 6.20 |
| $\hat{\beta}_{2}$ | -0.07 | -0.16 | 0.02 |
| $\hat{\sigma}_{e}$ | 0.52 | 0.49 | 0.55 |
| $\hat{\sigma}_{u}$ | 0.25 | 0.18 | 0.34 |
| $\hat{\sigma}_{w}$ | 0.20 | 0.12 | 0.33 |

Table 3: Posterior parameter estimates from the hierarchical linear model (equation 1) corresponding to the distance account. The data are from Gibson and $\mathrm{Wu}, 2013$. Shown are the mean and $95 \%$ credible intervals for each parameter.

|  | mean | lower | upper |
| ---: | ---: | ---: | ---: |
| $\hat{\boldsymbol{\beta}}_{0}$ | 5.85 | 5.76 | 5.95 |
| $\hat{\delta}$ | 0.93 | 0.73 | 1.14 |
| $\hat{p}_{s r}-\hat{p}_{o r}$ | 0.04 | -0.04 | 0.13 |
| $\hat{p}_{s r}$ | 0.25 | 0.17 | 0.34 |
| $\hat{p}_{o r}$ | 0.21 | 0.14 | 0.29 |
| $\hat{\sigma}_{e^{\prime}}$ | 0.64 | 0.54 | 0.74 |
| $\hat{\boldsymbol{\sigma}}_{e}$ | 0.22 | 0.20 | 0.25 |
| $\hat{\boldsymbol{\sigma}}_{u}$ | 0.24 | 0.18 | 0.31 |
| $\hat{\sigma}_{w}$ | 0.09 | 0.05 | 0.16 |

Table 4: Posterior parameter estimates from the hierarchical mixture model (equation 2) corresponding to the directaccess model. The data are from Gibson and Wu, 2013. Shown are the mean and $95 \%$ credible intervals for each parameter.

Table 4 shows that the mean difference between the probability $p_{s r}$ and $p_{o r}$ is $4 \%$; the posterior probability of this difference being greater than zero is $82 \%$. K-fold crossvalidation shows that $\widehat{e l p d}$ for the hierarchical model is -3761 (SE: 38) and for the mixture model is -3614 (35). The difference between the two $\widehat{\text { elpds }}$ is 148 (18). The larger $\widehat{e l p d}$ in the hierarchical mixture model suggests that it has better predictive performance than the hierarchical lin-
ear model. In other words, the direct-access model has better predictive performance than the distance model.
The replication of the Gibson and Wu study This dataset, originally reported by Vasishth et al. (2013), had 40 participants and the same 15 items as in Gibson and Wu's data. Figure 2 shows the distribution of the data by condition; there seems to a similar skew as in the original study, although the spread is not as dramatic as in the original study.

Figure 2: Boxplots showing the distribution of reading times by condition of the replication of the Gibson and Wu data.

Tables 5 and 6 show the estimates of the posterior distributions from the two models. Table 4 shows that the mean difference between the probability $p_{s r}$ and $p_{o r}$ is $7 \%$; the posterior probability of this difference being greater than zero is $96 \%$.

The $\widehat{\text { elpd }}$ for the hierarchical model is -3959 (53), and for the hierarchical mixture model, -3801 (38). The difference in $\widehat{e l p d}$ is 158 (29). Thus, in the replication data as well, the predictive performance of the mixture model is better than the hierarchical linear model.

|  | mean | lower | upper |
| :--- | ---: | ---: | ---: |
| $\hat{\beta}_{0}$ | 6.00 | 5.88 | 6.12 |
| $\hat{\beta}_{1}$ | -0.09 | -0.16 | -0.01 |
| $\hat{\sigma}_{e}$ | 0.44 | 0.41 | 0.47 |
| $\hat{\sigma}_{u}$ | 0.25 | 0.19 | 0.33 |
| $\hat{\sigma}_{w}$ | 0.16 | 0.10 | 0.26 |

Table 5: Posterior parameter estimates from the hierarchical linear model (equation 1) corresponding to the distance account. The data are from the replication of Gibson and Wu, 2013 reported in Vasishth et al., 2013. Shown are the mean and $95 \%$ credible intervals for each parameter.

|  | mean | lower | upper |
| ---: | ---: | ---: | ---: |
| $\hat{\boldsymbol{\beta}}_{0}$ | 5.86 | 5.78 | 5.95 |
| $\hat{\delta}^{\delta}$ | 0.75 | 0.56 | 0.97 |
| $\hat{p}_{s r}-\hat{p}_{o r}$ | 0.07 | -0.01 | 0.15 |
| $\hat{p}_{s r}$ | 0.23 | 0.15 | 0.33 |
| $\hat{p}_{o r}$ | 0.16 | 0.09 | 0.25 |
| $\hat{\sigma}_{e^{\prime}}$ | 0.69 | 0.59 | 0.81 |
| $\hat{\sigma}_{e}$ | 0.21 | 0.18 | 0.23 |
| $\hat{\sigma}_{u}$ | 0.22 | 0.17 | 0.29 |
| $\hat{\sigma}_{w}$ | 0.07 | 0.04 | 0.12 |

Table 6: Posterior parameter estimates from the hierarchical linear model (equation 2) corresponding to the direct-access model. The data are from the replication of Gibson and Wu, 2013 reported in Vasishth et al., 2013. Shown are the mean and $95 \%$ credible intervals for each parameter.

## Discussion

The model comparison and parameter estimates presented above suggest that, at least as far as the Chinese relative clause data are concerned, a better way to characterize the dependency completion process is in terms of the direct-access model and not the distance account implied by Gibson and Wu (2013) and Lewis and Vasishth (2005). Specifically, there is suggestive evidence in the Gibson and Wu (2013) data that a higher proportion of retrieval failures occurred in subject relatives compared to object relatives. In other words, increased dependency distance may have the effect that it increases the proportion of retrieval failures (followed by reanalysis). ${ }^{4}$

There is one potential objection to the conclusion above. It would be important to obtain independent evidence as to which dependency was eventually created in each trial. This could be achieved by asking participants multiple-choice questions to find out which dependency they built in each trial. Although such data is not available for the present study, in other work (on number interference) (Nicenboim, Engelmann, Suckow, \& Vasishth, 2016) did collect this information. There, too, we found that the direct-access model best explains the data (Nicenboim \& Vasishth, 2017). In future work on Chinese relatives, it would be helpful to carry out a similar study to determine which dependency was completed in each trial. In the present work, the modelling at least shows how the extreme values in subject relatives can be accounted for by assuming a two-mixture process.

## Conclusion

The mixture models suggest that, in the specific case of Chinese relative clauses, increased processing difficulty in subject relatives is not due to dependency distance leading to longer reading times, as suggested by Gibson and Wu (2013).

[^230]Rather, a more plausible explanation for these data is in terms of the direct-access model of McElree et al. (2003). Under this view, retrieval times are not affected by the distance between co-dependents, but a higher proportion of retrieval failures occur in subject relatives compared to object relatives. This leads to a mixture distribution in both subject and object relatives, but the proportion of the failure distribution is higher in subject relatives.

In conclusion, this paper serves as a case study demonstrating the flexibility of Bayesian cognitive modelling using finite mixture models. This kind of modelling approach can be used flexibly in many different research problems in cognitive science. One example is the above-mentioned work by Nicenboim and Vasishth (2017). Another example, also from sentence comprehension, is the evidence for feature overwriting (Nairne, 1990) in parsing (Vasishth, Jäger, \& Nicenboim, 2017).

## Acknowledgments

We are very grateful to Ted Gibson for generously providing the raw data and the experimental items from Gibson and Wu (2013). Thanks also go to Lena Jäger for many insightful comments. Helpful observations by Aki Vehtari are also gratefully acknowledged. For partial support of this research, we thank the Volkswagen Foundation through grant 89953.

#### Abstract

We cannot see others' mental states, so we infer them by watching how people behave. Bayesian inference in a model of rational action - called inverse planning - captures how humans infer desires from observable actions. These models represent desires as simple associations between agents and world states. In this paper we show that by representing desires as probabilistic programs, an inverse planning model can infer complex desires underlying complex behaviors-desires with temporal and logical structure, which can be fulfilled in different ways. Our model, which combines basic desires via logical primitives, is inspired by recent probabilistic grammarbased models of concept learning. Through an experiment where we vary behaviors parametrically, we show that our model predicts with high accuracy how people infer complex desires. Our work sheds light on the representations underlying mental states, and paves the way towards algorithms that can reason about others' minds as we do.

Keywords: social cognition; theory of mind; computational modeling; Bayesian inference.

## Introduction

As social creatures, humans routinely have to make sense of what other people are doing, and we do so by appealing to mental states such as beliefs, desires, and intentions. Because we cannot see these internal mental states we need to infer them by watching how people act.

Research into this capacity, called a Theory of Mind (Gopnik \& Meltzoff, 1997; Dennett, 1989), suggests that mental state inferences are driven by the assumption that agents act efficiently, subject to constraints imposed by their environment (Gergely \& Csibra, 2003). If, for instance, an agent takes a straight path towards a cookie jar, we can guess that her goal is to get a cookie, even before she has reached it. By contrast, if she gets there after wandering around for a while, we may infer that she found it without having deliberately searched.

In such scenarios, it makes sense to equate goals with desires. But in more complex scenarios it is important to distinguish between the two: a one-to-one correspondence between desires and goals is rare. Consider, for instance, if Bob wants to have breakfast. He can do this in several different ways that each require a different plan: he can stay home and prepare breakfast; he could go to the local café near his house; or he could go to a coffee shop that is out of the way. If he chooses to eat at the local café, he can show up and request food. By contrast, if he chooses to cook, he may have to go to the grocery store first and then go to his kitchen, in that order. While Bob is at the grocery store, he may need to
buy coffee and milk, but the order in which he buys them does not matter. Finally, before Bob has had breakfast, many states of the world are rewarding (eating at the café or having a scone at home, for example), but once he eats something, all rewards associated with breakfast disappear.

These examples reveal three key properties of desires. First, desires can often be fulfilled in more than one way. So from an observer's standpoint, goals cannot be equated with desires. Second, desires can have logical and temporal structure: they can be fulfilled in different ways (get tea or coffee), they can break into subgoals (get coffee and milk), and they can have temporal structure (go to the café and then buy a scone). Finally, the logical and temporal structure of desires interacts with the underlying rewards. If Bob is thirsty, then both soda and water are rewarding. But once he's had one of them, the other loses its immediate appeal. If Bob wants to exercise and then bathe before work, he has to do them in that specific order; doing them in the wrong order does not suffice. In other cases, the order does not matter, but the reward is only achieved once all the necessary prerequisites are fulfilled. If Bob likes his coffee with milk, then having coffee and milk together is rewarding, but having only one of them is not.

Computational models of mental-state attribution that successfully explain human mental-state inferences assume a relatively simplistic representation of desires: each desire can only be fulfilled in one way, and it is fulfilled by reaching one and only one physical state of the world (e.g. Baker et al., 2017; Baker et al., 2012). This assumption implicitly blurs together desires, intentions, goals, and physical states of the world. As our examples show, this is overly limiting; people may require conjunctions ( A and B ) or disjunctions of goals (A or B), with temporal properties (A then B).

In this paper we develop a richer representation of desires, and clarify the multiple computational levels that transform desires into actions. To solve the representational challenges, we draw on advances in concept learning that support concepts of unbounded complexity (Piantadosi et al., 2012; Goodman et al., 2008, 2014). To solve the inferential challenges that arise with more sophisticated representations, we draw on advances in mental-state attribution beyond goal inference (Lucas et al., 2014; Jara-Ettinger et al., 2016, under review). In the remainder of the paper, we sketch out the computational framework and we present an experiment testing quantitative predictions of our model.

Figure 1. (a) schematic of the generative model. (b) example of how an expression combines primitives and objects to determine how to satisfy a desire. This expression corresponds to an agent who first wants either coffee and milk, or just tea, and then a scone afterwards. The tree below shows the space of possible intentions that can fulfill the desire.

## Computational model

We take as a starting point the idea that social cognition is supported by a probabilistic generative model that determines how mental states lead to actions (Baker, et al., 2017). We expand on this approach by building a more powerful representation of desires, and how they relate to behavior.

Figure 1a shows the overall schematic of our model. We argued that a realistic model of commonsense psychology should distinguish between desires, goals, intentions, and actions, and our model attempts to do so.

At the top level we place desires, which combine logical (and/or) and temporal (then) primitives with simple goals (such as arriving to certain physical locations). This approach enables us to represent desires that directly map onto a single goal (e.g. "go to get coffee") as well as desires that can be fulfilled in different ways (e.g. "eat breakfast first, and then either get coffee and milk, or alternatively get tea"). This representation is inspired and based on computational models that combine logical primitives with unitary concepts to explain the productivity and compositionality of conceptual knowledge (Piantadosi et al., 2012; Goodman et al., 2008, 2014).

Following Goodman et al. (2008), we model the space of desires with a probabilistic grammar, which builds arbitrarily complex desires by composing simple ones. The grammar implements production rules that recursively conjoin primitives and units to yield desire expressions. We endow the grammar with several primitives - And, Or, and Then but the framework is general. These primitives are motivated by common-sense intuitions, but our primary goal is to develop a framework for compositional desires, not to identify the exact primitives that underlie goal-directed behavior.

To connect desires to actions, we rely on an intermediate representation of intentions (see Jara-Ettinger et al., under review). Given a composite desire, our model derives the space of intentions as the set of all ordered sequences of subgoals that satisfy it. For instance, if an agent desires to get either coffee and milk, or just tea, and then a scone afterwards
(Fig 1b), her space of intentions is \{get tea and then a scone; get milk, coffee, and then a scone; and get coffee, milk, and then a scone $\}$.

To model how the agent selects an intention and transforms it into an action plan, we rely on advances in commonsense psychology that suggest that we interpret other people's behavior through the assumption that they act to maximize their subjective utilities - the difference between the rewards they obtain and the costs they incur (Jara-Ettinger et al., 2016, under review; Lucas et al., 2014). This assumption operates at two levels: given a space of intentions, the agent will choose the one that maximizes her subjective utilities, and given an intention, the agent will attempt to complete it as efficiently as possible (for an agent to maximize utilities, they must also minimize costs).

Figure 2: Examples of the experimental stimuli. (a-b) examples of stimuli that consist of a single event. (c) example of stimuli that consists of two events.

To compute each intention's utility, we rely on planning algorithms developed in the robotics literature (Puterman, 2014) that have been successfully applied to model mentalstate attribution (Baker et al., 2009; 2017): Markov Decision Processes (MDPs). Given a set of states, a set of actions, and an underlying reward function, MDPs allow us to determine the sequence of actions that an agent should take to fulfill her goal as efficiently as possible. By using MDPs, we can compute the expected cost of achieving each goal, and define an intention's utility as the reward gained by fulfilling the desire minus the sum of the costs for achieving each goal in the intention. Given each intention's utility, we assume that agents probabilistically select an intention:

$$
\begin{equation*}
p(I) \propto \exp \left(\frac{U(I)}{\tau}\right) \tag{1}
\end{equation*}
$$

Hypothesis
Figure 3: Detailed results from the experiment. Each plot represents one trial from the experiment. The x-axis shows the model's top three hypotheses and the y-axis shows the z -scored prediction with participant judgments. Blue lines and dots show model predictions and red lines and dots show participant judgments. Vertical bars show $95 \%$ confidence intervals. In each plot, the schematic represents the paths the agent took in the event (see Figure 2 for examples of the actual stimuli).
where $\tau$ is a parameter that captures expectations about the agent's rationality. When $\tau$ is low, the agent invariably selects the intention with the highest utility; as $\tau$ increases, the agent is more likely to choose a suboptimal intention.

Finally, once the agent has selected an intention, we define the action plan as the ordered sequence of goals along with the motor programs that complete each goal (computed through MDPs).

## Inference in the generative model

We have specified a generative model for compositional desires, intentions, and action plans. To recover a desire
given some observed actions, we use Bayesian inference to invert the generative model. Given an observable set of actions $A$, the posterior belief for each underlying desire $D$ is given by:

$$
\begin{equation*}
p(D \mid A) \propto l(A \mid D) p(D) \tag{2}
\end{equation*}
$$

where the prior $p(D)$ is set to favor simpler explanations using a simple penalization for the length of the expression (as in Goodman et al., 2008).

To compute the likelihood, $l(A \mid D)$, we integrate over the space of all possible intentions the agent could have:

$$
\begin{equation*}
l(A \mid D)=\sum_{I \in \text { Intentions }} p(A \mid I) p(I \mid D) \tag{3}
\end{equation*}
$$

Both the probability of the intention given the desire $(p(I \mid D))$, and the probability of the action, given the intention $(p(A \mid I))$ are computed through the assumption that agents act to maximize their utilities-the difference between the subjective reward for fulfilling their desires minus the cost for fulfilling it. This expectation implies that agents are more likely to act efficiently given their intention, but that they are also more likely to select the intention that can fulfill the desires with the overall lowest cost. We enumerate a set of desires using breadth-first-search over the grammar, and then approximate the posterior over that space using Bayesian inference.

## Simplicity prior alternative model

To better understand our model, we developed a simple alternative that uses a deterministic likelihood function, where the probability of a desire generating an action $(p(A \mid D))$ is 1 if the action satisfies the desire and 0 otherwise. This model continues to have much of the power of the full model: it has access to rich representations of desires and the prior over hypotheses creates a preference for simpler explanations. Unlike the main model, this model is insensitive to the intermediate representations of intentions, as it does not account for how the agent chooses the intention that will fulfill their desires.

## Experiment

## Design

To evaluate our model, we designed a simple task where participants watched an agent's behavior across one or two days and were asked to determine their belief that the agent had certain desires (see Figure 2).

## Methods

Participants 33 participants, mean age $(S D)=32.13$ years ( 9.38 years), range $=20-61$ years from the US (as determined by their IP address) were recruited using Amazon's Mechanical Turk Framework.

## Stimuli

Figure 2 shows an example of the stimuli. Stimuli consisted of 19 two-dimensional images of an agent traveling to one or more of three potential static locations. Eight of these trials consisted of a single event and the remaining 11 consisted of two events. The one event trials were built by designing all possible efficient paths agents could take to reach between 1 and 3 of the locations and removing equivalent paths (i.e. identical under a rotation or reflection of the map).

Trials with two events were built by first creating a set including possible efficient paths between 1 and 2 of the

Figure 4. Comparison between our model (simplicity \& efficiency) and the alternative model (prior only). Each dot represents a judgment of a hypothesis for a given trial. The x -axis shows the model's prediction and the y -axis shows participant judgments.
locations, omitting paths between 3 locations to prevent the stimuli set from growing too large. In contrast to the single event set, we keep the equivalent paths, as they become necessary to construct the most primitive desires occurring over two events e.g. (A or B). This creates a base set of 9 paths. To generate the trials with two events, we first split the 9 paths into two classes, one for paths that go to only one location (3 paths) and another for paths that go to two locations ( 6 paths). For each class we compute the cartesian product of itself, and after removing duplicate pairs of stimuli in each class, (e.g. $A, B=B, A$ ), this provided a set of 27 two event trials. From that set, events that violated the principle of rational action were removed ( 10 trials). Additionally, if a trial with repeated events was the reflection or rotation of another trial with two events, it was removed ( 5 trials); e.g. between (A,A) and (C,C), we kept (A,A). Last, trials with two events were removed if only one possible hypothesis could explain the trials ( 2 trials), these trials trials impact our ability to get graded responses on alternative plausible hypotheses (an ideal trial would have more than one plausible explanation, to determine if the model captures the same graded measure humans have for alternatives). For example, if the agent only goes to the farthest location on event 1 and 2 , it's clear the only compatible hypothesis is that the agent wants to go that location. As an exception, we included one of these cases in the final set, just to show that the model was capable of inferring the only plausible hypothesis. After filtering the original 27 two event stimuli, 11 remained. These 11 plus the 8 one event trials result in the 19 stimuli used in the experiment.

## Procedure

Participants first read a tutorial that explained the logic of the task. Participants then completed a short survey that ensured they had read the instructions, and the test phase followed immediately after.

During the test phase, participants completed 19 trials. In each trial participants saw the stimuli on the left side, and they were asked to rate their belief that the agent had each of three different desires. Each desire was rated on a scale from $0-10$ for each, with 0 indicating "Definitely not"; 5 "Maybe";
and 10 "Definitely." The three desires were obtained by selecting the three hypotheses with the highest posterior distribution according to the model. In order to present these hypotheses to participants, we translated the description from the model into descriptions in English. To ensure their accuracy, two coders blind to the original hypotheses backtranslated the descriptions into the model's original representations. The two coders showed $100 \%$ agreement and recovered the correct model hypothesis in all trials.

Figure 5. Detailed results one of the trials. The top left plot shows the schematic of the stimuli we used. The top right plot shows participant judgments (z-scored); the bottom two plots show the predictions of the full model and the alternative model (z-scored). This example illustrates how, by removing the probabilistic nature of the likelihood function, the model loses sensitivity to variability in participant judgments.

## Results

Figure 3 shows the results from the experiment. Qualitatively, our model fit participant judgments well. Our model predictions showed a correlation of $\mathrm{r}=0.92$ with participant judgments ( $95 \%$ CI: 0.86-0.95). See Figure 4. By contrast, the alternative model (prior only) showed a weaker correlation ( $\mathrm{r}=0.80 ; 95 \% \mathrm{CI}: 0.69-0.88$ ). A bootstrap over the correlation difference showed that the full model performed reliably better than the alternative model (correlation difference $=0.11 ; 95 \% \mathrm{CI}: 0.009-0.18$ ).

Figure 5 shows the detailed results of a single trial that illustrates how the alternative model with a deterministic likelihood function fails to capture participant judgments. In this trial the agent begins by going to the top left location (which is one of the closest ones, together with the bottom
right location), and then travels diagonally to the bottom right location. Our full model gives a high probability to the desire that the agent wanted to visit those two locations in that specific order (A then C ), an average probability to the desire that she could have wanted to visit the locations in any order ( A and C ), and a low probability to the desire that the agent wanted to visit either A or B first, then C ((A or B) then C). Although all hypotheses explain the actions, our model is sensitive to the probability that each desire would generate the observed actions relative to competing ways to fulfill the same desire (driving the difference between the first and second hypotheses) and to the baseline complexity of the desires (driving the difference between the second and third hypotheses). That is, our model recognizes that there are two equally good intentions that fulfill the desire "A and C" (A and then C , or C and then A ), but only one that fulfills the ordered desire "A then C " (A and then C ). This makes our model favor the ordered explanation, as participants do (see Figure 5). This is not captured in the prior only model, as it is only sensitive to expression complexity. These results show how people are both sensitive to the likelihood that a desire would generate the observed actions, and to the complexity of the ascribed desire. Figure 6 shows how this failure becomes even stronger in the case where participants watch the agent behave identically across two events.

## Discussion

Here we presented a formal model of action understanding that represents desires as composite entities sampled from a probabilistic context free grammar. Desires get transformed into intentions and then into action plans by the assumption that agents act to maximize their utilities. By performing Bayesian inference over this generative model, we showed how we can capture desires that have rich logical and temporal structure, as well as enabling us to represent desires that can be fulfilled in more than one way. We tested our model by comparing its inferences with those made by human participants, finding that it closely mirrors their judgments, and that an alternative model is less successful.

Our model shows that combinations of primitives and objects using a probabilistic context free grammar supports rich representations of desires in Theory of Mind. The primitives, composing over objects, generate structured desires that capture temporal and logical structure.

Our goal was to develop a more nuanced representation of desires, and the framework we propose works for any arbitrary set of primitives and objects. To test our model, we focused on three specific primitives: And, Or, and Then. Our results do not imply that these are the only primitives people use when they reason about others' desires, or even that they are central in action-understanding. Other primitives such as If, Any, and Not, are likely also at play when we reason about other people's behavior. More research is needed to characterize the primitives we use in action-understanding, and their developmental origins.

To characterize desire complexity, we used a simple prior
that penalized the length of the expression (based on Goodman et al., 2008). Although this is a useful approximation, different primitives may have different priors which capture both their conceptual complexity and the extent to which they are useful in explaining behavior. Future work may attempt to uncover primitive-specific priors and the forces that shape these priors.

Figure 6. Results from the trial where participants watch two repeated events. While the prior only model continues to make the same predictions, both participants and our model have a stronger belief that the order mattered, in comparison to the trial with a single event (Figure 5)

In our current work, we focused specifically on desires and we assumed that the agents had full knowledge about the environment. In more realistic cases, agents can be uncertain, ignorant, or wrong about the world, and people's reasoning about others is sensitive to this fact (Baker et al., 2017; Kovács, Téglás, \& Endress, 2010). Our grammatical approach to desires may also support more structured representations about beliefs. Intuitively, people's beliefs are often structured logically (e.g. my laptop is in my backpack or at home; she thinks he is hungry and tired). In future work we will investigate the power and limitations of applying this approach to the representations of beliefs, and to the interaction of beliefs and desires.

Although in our work we focused on these representations as applying to desires, these desires often inherit their structure from how the world works. If Bob wants to shoot a water gun, he needs to pour water into the tank first, then pump air into valve, and then press the trigger, in that order. The fact that Bob's desire takes this structure is a reflection of how water guns work. This opens the possibility that, through the ability to reason about other people's desires, we may simultaneously learn procedural knowledge about how to make changes to the world. As such, our model may shed
light on how we learn about the world by watching more competent agents (see also Jara-Ettinger, Baker \& Tenenbaum, 2012).

#### Abstract

English-speakers whose access to number language is artificially compromised by verbal interference and the Pirahã (an Amazonian tribe without exact number words) appear to rely on analog magnitude estimation for representing nonsymbolic exact quantities greater than 3 . Here, 16 participants with aphasia performed the 5 counting tasks from these previous studies. Performance was poorest when targets were not visible during response ( $70 \%$ correct, task $4 ; 71 \%$ correct, task 5) and best when targets were presented as subitizable groups of 2 and 3 ( $98 \%$ correct, task 2). Western Aphasia Battery-Revised subtest scores correlated with task performance, suggesting diverse forms of language impairment may contribute to errors. Coefficients of variation for tasks and significant correlations of target magnitude with error rate ( $r^{2}=.88$ ) and error size ( $r^{2}=.87$ ) across tasks suggest participant use of analog magnitude estimation. Experiments involving people with aphasia may further refine our understanding of how language and thought interact.

Keywords: aphasia, language, number

## Introduction

"Linguistic relativity" occupies the broad theoretical middle ground where language and cognition interact, where the grammatical structures and lexicons of a language are believed to influence thought to a greater or lesser degree. While the idea that language can influence thought, perception, and action has a long history in Western philosophy, Whorf (1956) provided the first and clearest articulation of a strong version of this position. According to linguistic relativity, words aren't just names for pre-existing concepts; thought is influenced by the way particular languages are structured, what languages have words for, and what they don't. When a language is transmitted from one generation to the next, so are particular ways of "cutting up" the world that come with speaking that language.

Everett (2013) compiles a diverse array of recent research that explores domains like space, time, quantity, gender, and color and draws positive conclusions about the effects of language on thought. Similarly, Frank, Fedorenko, Lai,

Saxe, and Gibson (2012), review several studies that find "meaningful cognitive differences" ( p .75 ) between speakers of languages that have words for particular concepts and those that don't. Such cognitive differences appear to exist both across cultures and across development. At the same time, experimentally manipulated verbal interference can temporarily remove differences otherwise present.

The domain of number is a good entry point for testing the linguistic relativity hypothesis. Numeracy develops alongside language in humans, and there are clear differences between the ways adult speakers of different languages perform number-related tasks. The Pirahã, an indigenous Amazonian tribe, are of particular interest here, as their language lacks words for exact number. Gordon (2004) engaged seven Pirahã tribe members in a series of nonverbal matching tasks where participants were asked to reproduce a visual array that matched a model. The Pirahã struggled to accurately reproduce any set of objects containing more than three items, even when the model was visible to copy. Gordon (2004) also noted Pirahã responses produced a coefficient of variation (CoV) of approximately 0.15 , congruent with evidence that without access to number language and counting, people use less accurate but inborn abilities to estimate quantities larger than three ${ }^{1}$.

Frank, Everett, Fedorenko, and Gibson (2008) replicated the tasks from Gordon (2004) with fourteen participants in a different Pirahã village. The authors found similar results for each task with the exception of the one-to-one matching task, where results were near ceiling. Consequently, Frank et al. (2008) concluded that some of the startling results of Gordon (2004) might be the product of participants not understanding the task or inconsistencies in the experiment.

Everett and Madora (2012) sought to resolve the conflicting results of Gordon (2004) and Frank et al. (2008). The authors recreated the three tasks from Frank et al.

[^231](2008) with fourteen participants in a third Pirahã village. With one exception, Everett and Madora (2012) found no significant differences when making intra- or inter-study task comparisons. The exception was the one-to-one matching task from Frank et al. (2008), which was significantly different from control tasks and the Everett and Madora (2012) one-to-one matching task. The CoVs for all tasks in Everett and Madora (2012) were 0.15, consistent with Gordon (2004) and the hypothesis that the Pirahã were employing analog estimation strategies.

Frank et al. (2012) extends the experimental tasks performed with the Pirahã to a numerate population by using verbal interference in an attempt to force participants to resort to analog magnitude estimation (Whalen et al., 1999). The authors hypothesized that if language is not crucial to establishing exact number, then participants should successfully perform non-verbal number tasks under verbal interference. Should language be necessary for exact numeracy, however, these same participants should fall back on analog magnitude estimation under verbal interference revealing a constant CoV , as seen in other studies. To test this, Frank et al. (2012) had thirty-five MIT students attempt the matching tasks performed with the Pirahã while simultaneously repeating radio news broadcasts aloud. The results of these experiments were then compared to each other and to the results of the same experiments with the Pirahã from Frank et al. (2008).

While the English-speakers were found to be more accurate than the Pirahã, both groups made "significant and systematic errors" (p. 79) on the "nuts-in-a-can" task (see Figure 1 below), where participants have no access to a direct or remembered visual representation of the array. Here, college students under verbal interference, like the Pirahã, produced a flat CoV of 0.15 across targets, suggesting the use of analog magnitude estimation. Frank et al. (2012) drew the conclusion that the concept of "exact match" does not require language, but that language is crucial to storing and manipulating exact quantities greater than three. This conclusion is in line with the language as a technology or tool-kit version of the linguistic relativity hypothesis, wherein language allows us to transcend our pre-linguistic cognitive capacities (Gentner \& GoldinMeadow, 2003).

The evidence to date strongly suggests that language for number has a significant influence on how quickly and accurately we comprehend and process quantities larger than three. At the same time, there is room for debate as to how fundamental number language is to the correct apprehension of exact quantity. One largely unexplored route to an understanding of the relationship between language and counting (and more generally, questions regarding linguistic relativity) involves studying people with organic language impairments. People with focal brain lesions-either as a result of infarcts, tumor resections or other restricted lesions-may acquire aphasia, an impairment of a person's ability to comprehend and formulate language across multiple modalities, including
speaking, reading, writing, and listening (Rosenbek, LaPointe, \& Wertz, 1989). Consequently, people with aphasia may experience difficulty in the use of language for number and calculation (Dragoy, Akinina, \& Dronkers, 2016). McNeil and Pratt (2001) specify that aphasia is a processing or performance disorder-that is, a problem in using language for a known concept. By this reasoning, if aphasia were to affect a person's ability to represent exact quantity on a non-symbolic task such as the one employed in the current study, it may work in a similar fashion to verbal interference-by disrupting access to a number concept and consequently impairing comprehension or speech in relation to that concept. However, it is conceivable that aphasia may impair some individuals' ability to represent exact quantity in a manner more like the Pirahã, who have no exact number language to employ. In such a scenario, a person with aphasia may be impaired because they have no stored verbal label for exact quantity available for access. While the current study cannot adjudicate between these possibilities, we hope the diversity of impairment within the present aphasia population may provide a window into qualitative differences that account for errors across the kinds of tasks used with the Pirahã. We also hope to suggest ways that aphasia populations may generally contribute to investigations of the linguistic relativity hypothesis.

While several case studies have examined the impact of aphasia on calculation-e.g., Dragoy et al. (2016), where 7 of 10 participants with aphasia struggled with basic arithmetic and when comparing Arabic representations of quantities-little research to date has examined the impact of language impairment on non-symbolic representation of quantity. Lemer, Dehaene, Spelke, and Cohen (2003) examined a person with acalculia due to a focal lesion of the left parietal lobe and another person with semantic dementia from predominantly left temporal hypometabolism to demonstrate dissociations between tasks associated with counting and those associated with innate quantity systems of number processing. As predicted by a lesion in the parietal lobe, the patient with acalculia showed a severe slowness in approximation, and exhibited impairments in subitizing and numerical comparison tasks. Meanwhile, the patient with semantic dementia had intact approximation abilities and showed preserved processing of non-symbolic small numbers-that is, her "quantity processing" systems were functioning as expected-but struggled with tasks that required intact verbal processing and counting. Given these findings and related results with other populations, language impairment in the form of aphasia may be predicted to negatively affect the individual's ability to produce nonverbal and non-symbolic representations of exact quantity.

In the current study, participants with aphasia performed the same set of five, increasingly complex matching tasks used with the Pirahã and English-speakers whose access to language was artificially compromised by verbal interference (Frank et al., 2012). It bears noting that unlike the previously studied groups, a clinical aphasia population
consists of individuals with a diversity of verbal and nonverbal impairments. Regardless, we hypothesize that participants will make more frequent and larger errors (1) in proportion to target size; (2) on each subsequent, more difficult, task; and (3) produce a flat coefficient of variation (CoV) on each task and across target quantities, suggesting reliance on the analog magnitude system to estimate quantity. Such results would lend further support to the hypothesis that access to language for exact number is necessary for the recognition and representation of exact quantities. While general severity of language impairment is predicted to correlate with performance across tasks, we are also interested in whether particular aspects of language impairment point to specific qualities of language involved in counting and exact quantity representation.

Results suggesting that aphasia limits a person's ability to represent non-symbolic exact quantities would complement the body of evidence demonstrating a relationship between exact number language and the ability to perform nonsymbolic exact quantity tasks. When taken alongside similar evidence from previous studies with different human populations-i.e. children raised in numerate cultures but who have yet to develop number-language skills (e.g., Condry \& Spelke, 2008), adults in numerate cultures under verbal interference, and adults in an anumeric culture-it would seem difficult not to conclude that access to exact number language has an effect on the way that humans think about numbers. More broadly, these findings may refine hypotheses generated by linguistic relativity with regard to the necessity and/or effective use of language in representing basic number concepts. The linguistic diversity present within the present clinical aphasia population may provide deeper insight into relations between particular aspects of language function and the representation of exact quantity.

## Methods

Sixteen participants (3 female) completed aphasia assessments and the set of five non-verbal and non-symbolic exact quantity representation tasks from Everett and Madora (2012) and Frank et al. (2012). Thirteen participants also completed a numeral elicitation task, confrontation naming task, and free counting task. Eight completed tests of nonverbal semantic processing and short-term memory-the Semantic Category Probe (Freedman \& Martin, 2001), and Pyramids and Palm Trees tests (Howard \& Patterson, 1992). All participants had aphasia resulting from a lefthemisphere stroke as determined by their score on the Aphasia Quotient (AQ) portion of the Western Aphasia Battery-Revised (WAB-R) (Kertesz, 2006) and a speechlanguage pathologist. Within this framework, 5 participants are considered to have Broca's aphasia, 6 Anomic aphasia, 2 Wernicke's aphasia, 2 conduction aphasia, and 1 global aphasia. Eligible participants were a minimum of six months post onset of aphasia ( $M=73$ months, $R=9-159$ months), between the ages of eighteen and eighty-five years ( $\mathrm{M}=61, \mathrm{R}=43-75$ ) and native English speakers.

Aphasia assessment. Participants completed the AQ portion of the WAB-R (Kertesz, 2006). This formal assessment includes tasks such as answering simple questions, describing pictures, manipulating and naming common objects, following directions, repeating words, and matching pictures to printed words and sentences.

Matching tasks (Everett \& Madora, 2012; Frank et al., 2012). Participants completed five non-verbal and nonsymbolic exact quantity representation tasks in the following order: a one-to-one matching task, an uneven matching task, an orthogonal matching task, a hidden matching task, and a "nuts-in-a-can" task (see Figure 1). In every task, the experimenter presented a quantity of spools of thread (approximately 1 " tall, $3 / 4$ " in diameter) and asked the participant to construct a row of un-inflated balloons (approximately $4 "$ long and $2 "$ wide) that matches the number of spools of thread. In the one-to-one task, the experimenter placed the spools one at a time in an evenly spaced line from left to right. In the uneven task, the spools were presented in the same manner as in the one-to-one task, but broken randomly into smaller groups of two and three. The orthogonal task is identical to the one-to-one task except that the row of spools is presented in a line perpendicular to the participant. The hidden matching task is identical to the one-to-one task except that the row of spools is hidden from the participant after being presented. In the "nuts-in-a-can" task, the experimenter places spools one by one into an opaque cup. Participants were tested once per task on each quantity from four to twelve in one of two random orders, totaling forty-five trials per participant.

Figure 1: Schematic of each matching task. From left to right: one-to-one match (task 1), uneven match (task 2), orthogonal match (task 3), hidden match (task 4), "nuts-in-a-can" (task 5). Image is from Frank et al. (2012).

Numeral elicitation task. Participants were asked to name the number of spools of thread presented, increasing from one to twelve and then decreasing from twelve to one. In each case, participants were asked, "How many spools of thread are there?" by the researcher. Divergence between performance on this task and on the matching tasks might illuminate whether the participant is having difficulty recognizing, articulating, or representing the target quantity.

Confrontation naming task. Participants were asked to name the Arabic numerals one through twenty as presented individually on flashcards. In each case, participants were asked, "What number is this?" This task assessed the participant's ability to recognize and name Arabic numerals. Confluent or divergent performance on this task when
compared to the matching and counting tasks might help differentiate the participant's ability to recognize and name symbolic and non-symbolic numbers.

Free counting task. Participants were asked to count up from one to twenty and down from twenty to one. The researcher says, "Please count from one up to twenty" and "Please count from twenty down to one." Participants were allowed five minutes to recite each count list. Performance on this task indicates the participant's capacity to access and articulate counting numbers in order, a factor in the participant's performance on the matching tasks.

Semantic Category Probe Test (Freedman \& Martin, 2001). Participants listened to a list of three or more words and determined whether the final word is from the same category as any of the preceding words by saying or pointing to "Yes" or "No." This task assesses the participant's capacity to retain semantic information in their short-term memory, where impairment might be a potential reason for poorer performance on the matching tasks.

Pyramids and Palm Trees Test (Howard \& Patterson, 1992). Participants matched a pictured item to the closest associate among a set of two pictured choices (e.g., fish matched to: cat, table). This task assessed the participant's capacity to process non-verbal semantic information. Distinguishing between semantic and verbal impairments may help explain performance on the matching tasks.

## Results

There was notable variation across participants and tasks. Percent correct scores for all tasks ranged from $53 \%$ to $98 \%$ (Table 1). Participants responded correctly on $83 \%$ of task 1 trials, $98 \%$ of task 2 trials, $90 \%$ of task 3 trials, $70 \%$ of task 4 trials, and $71 \%$ of task 5 trials (Fig. 2, far left).

Participants' accuracy descreased as the target quantity increased across all tasks ( $r^{2}=0.87$ ) (Fig. 2, center left) and for each individual task (Fig. 3, top row). Similarly, error magnitude increased as target quantity increased ( $r^{2}=0.88$ ) (Fig. 2, center right). CoV was similar across target
quantities and tasks (Fig. 2, far right), but higher on task 4 (0.10) and task 5 (0.11) (Fig. 3, bottom row). Across analyses, aphasia participants' performance was remarkably similar to the performance of English speakers under verbal interference from Frank et al. (2012) (Figs. 2 and 3). Compared to the Pirahã (Figs. 2 and 3, aggregated from Everett \& Madora, 2012; Frank et al., 2008; and Gordon, 2004), participants with aphasia and English speakers under verbal interference were generally more accurate and made smaller errors, but all three groups showed similar patterns of responding across tasks.

Table 1: Participant errors across tasks. The maximum number of errors on each task is nine. Darker colors indicate more errors.

WAB-R AQ and subtest scores were reliably correlated with task performance on tasks 4 and 5. AQ and subtest scores were most predictive of performance on task 5, the "nuts-in-a-can" task (Table 2).

Thirteen participants completed additional number tasks. While, generally speaking, participants with higher AQ scores who had made fewer errors on the nonverbal matching tasks also performed better on the additional

Figure 2: Matching task summary data for participants with aphasia, Pirahã, and adults under verbal interference. Far left: For participants with aphasia, performance was poorest when targets were not visible during response ( $70 \%$ correct, task $4 ; 71 \%$ correct, task 5 ) and best when targets were presented as subitizable groups of 2 and 3 ( $98 \%$ correct, task 2 ). Center left: Significant correlations were found between target magnitude with both error rate ( $r^{2}=.87$ ) and error size ( $r^{2}=.88$ ) (Center right) across tasks. Far right: Coefficients of variation for participants with aphasia mirrored those of adults under verbal interference. "Pirahã" data is from Everett and Madora (2012); Frank et al. (2008); and Gordon (2004). "Verbal Interference" data is from Frank et al. (2012).
counting tasks, there were exceptions. Participant 13, who has a high AQ score and made no errors on the additional number tasks made seven errors across matching tasks. Participant 11 made as many matching task errors as Participant 13 (refer to Table 1), but scored only 4 of 12 on the numeral elicitation task. Additionally, Participant 11, despite correctly reciting 18 of 20 numbers on the ascending free counting task, could not count backwards from 20 to 1 , receiving a score of zero on the descending free counting task. Across all 8 participants who completed the nonverbal semantic processing and short-term memory tasks, higher AQ scores predicted better performance on the Pyramids and Palm Trees and Semantic Category Probe tests.

## Discussion

Generally, participants (1) made more errors for larger target quantities, (2) made errors of greater magnitude for larger target quantities, and (3) had more difficulty with tasks where targets were not visible during response. There was consistency among those participants with the greatest overall task impairments. Participants who made ten or more incorrect responses also made errors across tasks 1, 3, 4, and 5. Eight different participants responded incorrectly
to at least one trial of task 1, where the target remained visible and did not require conservation in space or time, nor, presumably, counting: correct responding only required participants to match one object to another. The results of task 1 stand in stark contrast to near-ceiling results on task 2. In task 2, targets were presented in groups of 2 and 3. This is the only difference between tasks 1 and 2 , suggesting that many participants were able to subitize the visible targets on task 2 in order to answer accurately, but were unable to do so consistently on task 1 . Near-ceiling performance on task 2 also suggests that perceptual and/or attentional impairments (e.g., field cuts, neglect) do not explain poor performance on tasks $1,3,4$, and 5 ; this represents an important control condition in a stroke population with expected neurological and behavioral heterogeneity. Surprisingly, performance on task 3 was superior to performance on task 1, despite the required spatial translation between the perpendicular target array and horizontal response. Participants responded incorrectly on $10 \%$ of task 1,2 , and 3 trials, where the target remained visible for comparison, matching, and recounting. Performance on tasks 4 and 5 was poorer, as expected: both involve responding without the target array still visible.

These results mirror those of previous studies with the Pirahã and adults under verbal interference, although the Pirahã made more frequent and larger errors, more clearly suggesting a reliance on analog magnitude estimation in attempting to represent target quantities. Of all the research of this kind conducted with the Pirahã, only the one-to-one matching task in Frank et al. (2008) produced a CoV markedly different from 0.15 . Everett and Madora (2012) offered a speculative explanation: unlike the others, the village tested in Frank et al. (2008) had been exposed to math tutoring that included neologisms for number words. It is the neologisms for number words that are exceptionalall the villages had been exposed to the one-to-one matching
Accuracy: one-to-one

Figure 3: Task accuracy and CoV for participants with aphasia, Pirahã, and adults under verbal interference. Accuracy (Top row) and CoV (Bottom row) for participants with aphasia mirrored those of adults under verbal interference. "Pirahã" data is from Everett and Madora (2012); Frank et al. (2008); and Gordon (2004). "Verbal Interference" data is from Frank et al. (2012).
task and other attempts at basic math training by the Brazilian government, but only the site of Frank et al. (2008) had been exposed to number word neologisms. The authors are clear that this is speculation on their part, but it dovetails with a possible explanation as to the task performance differences between the Pirahã on the one hand and the verbal interference and aphasia participants on the other. In attempting to account for the lower CoVs and greater accuracy of the verbal interference participants, Frank et al. (2012) suggests that participants' "differential cultural experience with mathematics and other uses of exact numerosity led to their relatively more precise representation of analog magnitude" (p. 82). The same could be suggested of the aphasia participants in this study.

Certainly there are differences between the current population of people with aphasia, people of an anumeric culture, and English-speakers under verbal interference. What separates the Pirahã from other populations under discussion here is that they exist in a world without exactquantity language and may not have a concept of number to access. English speakers under verbal interference, meanwhile, are members of a numeric culture who have had their ability to use language temporarily disrupted, and people who have aphasia are members of the same culture with a more permanent disruption. Also, an aphasia population consists of individuals with distinct lesions, resulting in a range of verbal and nonverbal impairments and significant heterogeneity is to be expected, compared to a population of English speakers undergoing experimental manipulation via verbal interference. While diversity within the current aphasia population is viewed as a potentially rich source for identifying particular aspects of language (e.g., comprehension, speech) that may uniquely affect particular aspects of number use (e.g., mental representation of exact quantity, counting), it also suggests caution before drawing definitive conclusions based on group performance.

That several studies have repeatedly found similar results despite population differences lends support to established ways of thinking about number, thought, and language. According to the model put forth by Feigenson, Dehaene, and Spelke (2004), we are born with two systems for the cognitive representation of number-a parallelindividuation system that can track up to three or four discrete objects and an analog magnitude estimation system we use to approximate large quantities. While these cognitive systems are also found in other animals, humans appear to use exact number words as tools that enhance our capacity to do things with quantities by bridging these systems. The results of the present and previous studies fit this model: language impairment, like verbal interference and living in a culture without exact number words, makes it difficult, if not impossible, for individuals to bridge the two systems for cognitively representing quantities. The present study also suggests that experiments involving people with aphasia may serve to further refine our understanding of how language and thought interact.

## Acknowledgments

The authors would like to thank Michael C. Frank and Peter Gordon for sharing raw data from Frank et al. (2008), Frank et al. (2012), and Gordon (2004), respectively.

#### Abstract

Humans constantly receive sensory input from several sensory modalities. Via the process of multisensory integration, this input is often integrated into a unitary percept. Researchers have investigated several factors that could affect the process of multisensory integration. However, in this field of research, social factors (i.e., whether a task is performed alone or jointly) have been widely neglected. Using an audiovisual crossmodal congruency task we investigated whether social factors affect audiovisual integration. Pairs of participants received congruent or incongruent audiovisual stimuli and were required to indicate the elevation of these stimuli. We found that the reaction time cost of responding to incongruent stimuli (relative to congruent stimuli) was reduced significantly when participants performed the task jointly compared to when they performed the task alone. These results extend earlier findings on visuotactile integration by showing that audiovisual integration is also affected by social factors.

Keywords: multisensory integration; joint action; task distribution; social cognition.

## Introduction

In everyday life, humans constantly process sensory input from several sensory modalities. If sensory input from multiple sensory modalities coincides in space and/or time, it is frequently integrated into a unitary percept (Alais \& Burr, 2004; Ernst \& Banks, 2002; Körding et al. 2007; Rohe \& Noppeney, 2015; for a review, see: Spence, 2007) - a process referred to as "multisensory integration". Multisensory integration can result in perceptual benefits as
well as costs. In particular, if the multisensory inputs contain redundant information (e.g., visual and auditory stimuli originate from the same spatial location), human localization performance is faster and more accurate (e.g., Körding et al. 2007; Rohe \& Noppeney, 2015; Wahn \& König 2015a,b; 2016). Yet, if the sensory inputs provide conflicting information (e.g., visual and auditory stimuli originate from different spatial locations but still coincide in time), human localization performance is slowed down and less accurate (Heed, Boukje, Sebanz, \& Knoblich, 2010; Plöchl et al., 2016; Rohe \& Noppeney, 2015; Spence, Pavani, \& Driver, 2004). In the past, researchers have explored how attentional processes influence the multisensory integration process, and more generally, how attentional processing is distributed across the sensory modalities (e.g., Alais, Morrone, \& Burr, 2006; Alsius, Navarra, Campbell, \& Soto-Faraco, 2005; Helbig \& Ernst, 2008; Wahn \& König, 2015a,b, 2016; Wahn, Murali, Sinnett, \& König, 2017; for recent reviews, see Talsma, 2015; Wahn \& König, 2017). However, to date, researchers have largely neglected how social factors could affect the integration process. Thus we know relatively little about how the social presence of another person, and/or how performing a task with another person, influences the process of multisensory integration.

To date, to the best of our knowledge, only two studies (Heed et al., 2010; Teneggi, Canzoneri, di Pellegrino, \& Serino, 2013) have addressed the extent to which social factors can modulate multisensory integration. In Heed et al.'s experiment participants performed a visuotactile congruency task that was either performed alone, or jointly
with another person. When the task was performed alone, participants were required to hold two foam cubes, one in each hand, and indicate with foot pedal presses the spatial elevation of a tactile stimulus that could either appear at the top of the cube (i.e., felt at the index finger) or at the bottom of the cube (i.e., felt at the thumb). The participants also simultaneously received irrelevant visual stimuli that either appeared at the same spatial location as the tactile stimulus or not (i.e., stimuli were presented either in congruent or incongruent positions). Thus, the visual stimuli provided either conflicting or redundant spatial information, resulting in costs or benefits of multisensory integration, respectively. Heed et al. (2010) replicated earlier results (Spence, Pavani, \& Driver, 1998; 2004) by finding that reaction times were faster when indicating the location of the tactile target if the visual stimulus appeared in a congruent position compared to an incongruent position. This effect is referred to as the "crossmodal congruency effect" (CCE). That is, when the tactile and visual stimuli provide redundant information (i.e., are presented in the same (congruent) position), localization performance is faster compared to when conflicting information is provided (i.e., stimuli are presented in different, i.e. incongruent positions). When participants performed the task in pairs, one of them indicated the elevation of the tactile stimuli (as before) while the second participant indicated the elevation of the visual stimuli. But note, the person detecting tactile stimuli was still exposed to the congruent or incongruent visual stimuli. Heed et al. found that the magnitude of the CCE was reduced when performing the crossmodal congruency task jointly compared to performing it alone. In particular, when participants performed the task jointly, incongruent presentations had less of an effect on reaction times when compared to performing the task alone. This observation suggests that the cost of incongruent presentations on multisensory integration is reduced when the task is performed jointly.

To date, the modulation of the CCE by social factors as found by Heed et al. (2010) has not been investigated with other sensory modalities. In particular, it is an open question whether audiovisual integration is similarly affected by social factors. Given that the tactile sensory modality processes events in close proximity while the auditory sensory modality is also able to sense more distal events, it is not clear whether audiovisual integration would be similarly affected by social factors as visuotactile integration. Thus rather than the visuotactile congruency task as used in Heed et al. the present study required participants to perform an audiovisual congruency task, either alone or jointly. If social factors modulate the CCE for audiovisual stimuli, we predict that the CCE will be reduced when performing the audiovisual congruency task jointly as compared to performing the task alone. Conversely, if social factors do not affect the CCE, then the CCE should not be modulated regardless of whether the task is performed jointly or alone.

## Methods

## Participants

Twelve pairs of individuals ( 15 female, $M=21.92$ years, $S D=3.35$ years) participated in the study at the University of Osnabrück. Prior to the experiment, participants signed informed written consent. The study was approved by the ethics committee of the University of Osnabrück. After the experiment had been completed, participants were debriefed and received monetary compensation or participation hours.

## Experimental setup

Participants sat in a dark room in front of a computer screen (Apple 30" LCD screen, resolution $2560 \times 1600$ pixels, $77.53 \times 48.46$ visual degrees) at a distance of 50 cm . Four USB speakers (Mini HiFi USB 2.0 mini speaker), which were connected via a USB hub (Orico HF9US-2P USB 9-Port HUB) were arranged in a $2 \times 2$ grid above and below the monitor (vertically and horizontally 1600 pixels, equivalent to 48.45 visual degrees, apart) in front of the participants (Figure 1). The positions of the visual flashes ( 80 x 80 pixels, 2.42 visual degrees wide, 100 ms ) were arranged in the same $2 \times 2$ grid, such that the visual flashes were observed from approximately the same spatial locations as the auditory stimuli (sine wave tone, 4800 Hz , 100 ms ) - they were vertically displaced by 2.4 cm .

Participants sat in two chairs placed in front of the computer screen (left and right of the fixation cross, respectively) with keyboards on their laps.

Figure 1: Experimental Setup.

## Experimental conditions and procedure

In the experiment, participants performed an audiovisual congruency task either alone or jointly. In this task, participants received visual flashes and auditory tones, originating either from the same (i.e., congruent) or a different (i.e., incongruent) spatial elevation. In addition, stimuli could originate either from the same or opposite side. For example, either both stimuli could originate from the left side or one could originate from the left and one from the right side. The task was to indicate the elevation of one of these stimuli using the keyboard with the mapping of keys $\mathrm{F} / \mathrm{up} \& \mathrm{C} /$ down for the visual stimuli; keys $\mathrm{K} / \mathrm{up}$ \&
$\mathrm{M} /$ down for the auditory stimuli. We set the time limit for responses to 2 seconds (see Figure 2, for a trial overview).

When participants performed the task jointly, they sat next to each other in front of the computer screen in close proximity ( $\sim 10 \mathrm{~cm}$ ) to ensure that they shared peripersonal space (Heed et al., 2010). In this condition, one participant would indicate the elevation of the auditory stimuli while the other participant would indicate the elevation of the visual stimuli. When participants performed the task alone, one participant was asked to wait outside the experiment room while the other participant performed the task, indicating the stimulus elevation for their assigned modality. Note, regardless of whether participants performed the task alone or jointly, the seating positions of participants remained constant in all conditions within a pair and were counterbalanced across pairs (i.e., in half of the pairs, the participant responding to the auditory stimuli was sitting on the right side).

100 ms

Figure 2: Trial overview. (A) Participants simultaneously received a visual and auditory stimulus. (B) Participants were required to indicate the elevation of one of the stimuli using the keyboard. In this example trial, the auditory stimulus would be in the upper location on the right side, the visual stimulus in the bottom location on the left side (i.e., an incongruent opposite side trial). After two seconds passed, the next trial started automatically.

In sum, the experiment consisted of a $2 \times 2 \times 2$ factorial design with Congruency (Congruent, Incongruent), Side (Same, Opposite), and Condition (Individual, Joint) as factors.

The experiment consisted of six blocks, each composed of 144 trials. In these trials, each combination of the factor levels for the factors Congruency and Side occurred equally often in a randomized order. The factor Condition was varied across blocks. That is, there were three types of blocks: 1) The participant responding to the visual stimuli performing the task alone, 2) the participant responding to the auditory stimuli performing the task alone, 3) both participants performing the task jointly. Participants performed a pseudorandomized sequence of these three types of blocks twice. We avoided repetitions of the same block type in consecutive blocks.
The experiment took approximately 40 minutes. It was programmed in Python 2.7.3.

## Data preparation and analysis

In line with Heed et al. (2010), we restricted our analysis to the participant in a pair responding to the auditory stimuli. That is, given that visual stimuli are considerably
easier to localize than auditory stimuli, CCE effects are only observed for the participants responding to the auditory stimuli. Prior to performing inferential statistical tests, we tested whether the normality assumption was given with a Shapiro-Wilk test. In the case of a violation, we transformed the data using a log transformation.

## Results

On a descriptive level (see Figure 3A \& B), when examining the reaction times of correctly localized auditory cues, participants were slower to localize the cues in the incongruent condition compared to the congruent condition. This observation establishes the well-known CCE effect. Furthermore, in line with earlier studies (Heed et al., 2010), the CCE was more pronounced for stimuli that were shown on the same side compared to the opposite side. Importantly, for same side stimuli, the CCE was reduced profoundly in the joint condition relative to the individual condition.

Figure 3: Mean reaction time (in seconds) as a function of the factors Condition (Individual, Joint) and Congruency (congruent, incongruent), separately for same side (A) and opposite side stimuli (B). Error bars in both panels are standard error of the mean.

We tested whether these observations were statistically reliable by performing a $2 \times 2 \times 2$ repeated measures ANOVA with the factors Congruency (Congruent, Incongruent), Side (Same, Opposite), and Condition (Individual, Joint). As the assumption of normality was violated, we applied a log transformation to the reaction times prior to entering them to the ANOVA.

We found a significant main effect for the factor Congruency $(F(1,11)=19.73, p<.001)$. We found significant two-way interactions between the factors Side and Congruency $(F(1,11)=38.42, p<.001)$ and the factors Condition and Congruency $(F(1,11)=6.00, p=.032)$. The former interaction effect suggests that the magnitude of the CCE is reduced for opposite side stimuli compared to same side stimuli. Importantly, the latter interaction effect suggests that the CCE is reduced for the joint condition compared to the individual condition. In addition, we also observed a three-way interaction $(F(1,11)=6.61, p=.026)$, suggesting that the reduced CCE for the joint condition compared to the individual condition depends on whether stimuli appear on the same side or opposite sides. To further investigate the three-way interaction effect, we performed two $2 \times 2$ repeated measures ANOVAs (Condition $x$ Congruency), restricting the data either to only same side or opposite side stimuli. For same side stimuli, we found a significant main effect of Congruency $(F(1,11)=27.29, p<$ .001 ) and a significant interaction between the factors Condition and Congruency $(F(1,11)=9.62, p=.01)$. This demonstrates that for same side stimuli, performing a task jointly indeed reduced the CCE. However, for opposite side stimuli, we only found a significant main effect of Congruency $(F(1,11)=5.58, p=.038)$ but no interaction effect between the factors Condition and Congruency $(F(1,11)=0.07, p=.801)$. Both of these results are in line with the findings by Heed et al. (2010). That is, when investigating visuotactile integration, Heed et al. (2010) similarly found that the CCE effect was reduced in the joint condition relative to the individual condition for same side stimuli but not for opposite side stimuli.

We also tested an alternative explanation of these results by a speed-accuracy tradeoff. That is, in the joint condition, participants potentially could have localized the incongruent cues faster at the expense of being less accurate in their responses. To investigate this, we repeated the $2 \times 2 \times 2$ repeated measures ANOVA with the dependent variable fraction correct (for a descriptive overview, see Figure 4A \& B). We found significant main effects for the factors Side $(F(1,11)=73.32, p<.001)$ and Congruency $(F(1,11)=$ 29.87, $p<.001$ ) and a significant interaction effect between these two factors $(F(1,11)=66.14, p<.001)$. Importantly, we did not find a significant main effect or interaction
involving the factor Condition (Condition: $F(1,11)=0.31, p$ $=.588$; Condition x Congruency: $F(1,11)=0.02, p=.881$; Condition x Congruency x Side: $F(1,11)=0.003, p=.954$ ). These results indicate that a speed-accuracy tradeoff does not explain the reduced CCE for the joint condition relative to the individual condition reported above because the accuracy did not vary as a function of whether the task was performed in pairs or alone. Thus the latency benefit of the joint condition relative to the alone condition was not acquired at the expense of committing more errors.

In sum, the results for same side stimuli indicate that the CCE is reduced significantly when participants perform an audiovisual crossmodal congruency task jointly compared to when they perform it alone.

Figure 4: Mean fraction correct as a function of the factors Condition (individual, joint) and Congruency (Congruent, Incongruent), separately for same side (A) and opposite side stimuli (B). Error bars in both panels are standard error of the mean.

## Discussion

The present study investigated whether the modulation of the CCE by social factors found in earlier studies investigating visuotactile integration (Heed et al. 2010) can also be observed for audiovisual presentations. In line with Heed et al., we found that the CCE is indeed reduced for same side stimuli when participants perform an audiovisual crossmodal congruency task jointly compared to performing it alone. Furthermore, we found that the data are not explained by a speed-accuracy tradeoff. Collectively, the present results extend Heed et al.'s earlier findings of a modulation of the CCE for a visuotactile crossmodal congruency task, and indicate that this social effect generalizes to audiovisual integration.

A possible "mechanism" for our present social effect could be a co-representation process (Sebanz, Knoblich, \& Prinz, 2003; for reviews see: Sebanz, Bekkering, \& Knoblich, 2006; Vesper et al., 2017). That is, when participants perform the task jointly, participants corepresent the task of their partner (e.g., that the partner responds to the visual stimuli) which could lead to a reduced processing of the stimuli relevant for the partner but irrelevant for the own task. As a consequence, the irrelevant stimuli could be perceived as less distracting for incongruent stimulus presentation but still sufficiently processed for congruent presentations, yielding faster reaction times. Alternatively, the effects in the present study could be explained by a dynamic modulation of the coactor's peripersonal space as found in an earlier study (Teneggi et al., 2013) or by a general withdrawal of attention to the stimuli to which the co-actor responds (Szpak et al., 2015).

Future studies could discern further how social factors contribute to the modulation of the CCE. In the present study, pairs of participants performed the crossmodal congruency task in the same peripersonal space and both participants performed the task. Earlier findings (Heed et al., 2010) showed that the CCE for visuotactile stimuli is only affected by social factors if both participants perform the task and are located in their respective peripersonal spaces. It is an open question whether a reduction of the CCE for audiovisual stimuli would be observed when only one of these factors is manipulated. For instance, when participants are in the same peripersonal space but only one of them performs the task, or when both of them perform the task but from separate peripersonal spaces. In contrast to the tactile modality, both the visual and the auditory modality investigated here sample distant events. Thus, it is quite conceivable that visuotactile integration is dependent on jointly executing the task in peripersonal space while this might not be the case for audiovisual integration.

As another point of note, our finding that performing the crossmodal congruency task jointly affects the CCE for same side stimuli but not for opposite side stimuli could be explained by the observation that for opposite side stimuli the CCE was already greatly reduced in the individual
condition. That is, an already lower CCE may not allow for any additional modulations by social factors.

Future studies could also test whether the social effects found in this study can alternatively be explained by other factors (Stenzel \& Liepelt, 2016). For instance, it could be investigated whether a non-human co-actor (e.g., a robot) responding to the distractors is sufficient to find the effects in the present study (Stenzel et al., 2012).

More generally, the present findings are relevant to, and may benefit, real-world situations in which humans perform tasks jointly while processing multisensory information. That is, our data and the earlier findings of Heed et al., (2010) suggest that the benefits of multisensory integration are preserved when performing a task jointly (i.e., participants respond faster to congruent multisensory stimuli) while the costs of multisensory integration are reduced (i.e., participants are slowed down less by incongruent stimuli). Future studies could investigate further how the benefits of multisensory processing (e.g., due to multisensory integration (Alais \& Burr, 2004; Ernst \& Banks, 2002; Körding et al. 2007; Rohe \& Noppeney, 2015), sensory augmentation (König et al., 2016; Goeke, Planera, Finger, \& König, 2016), or circumventing limited attentional resources (Alais \& Burr, 2004; Arrighi, Lunardi, \& Burr, 2011; Wahn, et al. 2016; for a review, see: Wahn \& König, 2017)) may facilitate human performance in other joint settings.

#### Abstract

The ability to represent same-different relations is a condition for abstract thought. However, there is mixed evidence for when this ability develops, both ontogenetically and phylogenetically. Apparent success in relational reasoning may be evidence for conceptual understanding or may be due to low-level, perceptual strategies. We introduce a method to discriminate these possibilities by pitting two conditions that are perceptually matched but conceptually different: in a "fused" condition, same and different objects are joined, creating single objects that have the same perceptual features as the pairs in the "relational" condition. However, the "fused" objects do not provide evidence for the relation. Using this method in a causal task provides evidence for genuine conceptual understanding. This novel technique offers a simple manipulation that may be applied to a variety of existing match-to-sample procedures used to assess same-different reasoning to include in future research with non-human animals, as well as human infants.

Keywords: cognitive development; causal inference; relational reasoning; perceptual processes

The ability to represent relations between objects and events is an essential condition for abstract thought; some have suggested that relational abilities may be the key to the cognitive differences between humans and other animals (Penn, Holyoak, \& Povinelli, 2008). However, there is mixed evidence about when this ability develops, both ontogenetically and phylogenetically. Traditionally, there was little evidence for relational reasoning in either young children or non-human animals. More recent results, particularly involving the foundational relations "same" and "different" challenge that conclusion. Ducklings can generalize these relations in an imprinting paradigm (Martinho \& Kacelnik, 2016). Human infants are able to generalize these relations in looking-time experiments. In particular, pre-verbal infants can be habituated to pairs of same and different objects (Addyman \& Mareschal, 2010; Ferry, Hespos, \& Gentner, 2015; Hochman, Mody, \& Carey, 2016; Tyrell et al., 1991), discriminate and generalize patterns of repeated visual or auditory elements (ABA/AAB/ABB) (Dawson \& Gerken, 2009; Johnson et al., 2009; Marcus et al., 1999; Saffran et al., 2007), and provide
a conditioned response to pairs of identical stimuli (Kovács, 2014; Hochmann, 2010). Moreover, very young toddlers can apparently use same-different relations in an active causal learning paradigm (Walker \& Gopnik, 2014), although this ability declines in the preschool period (Walker, Bridgers, \& Gopnik, 2016). In these studies, toddlers, aged 18-30-months, were able to infer same-different relations in a causal version of a match to sample task (i.e., matching AA' with $\mathrm{BB}^{\prime}$, not CD, and matching EF with CD, not BB').

On the other hand, it is possible that these successes may be mediated by perceptual factors that are quite separate from the abstract same-different concepts that these tasks are intended to assess (see Addyman \& Mareschal, 2010 for a review). It is clear that both human and non-human animals are able to perceive the similarity of objects, agents, and events in their environment; these abilities are necessary for basic cognitive functions (Martinho \& Kacelnik, 2016; Hochman, Mody, \& Carey, 2016). However, noticing similarity does not necessarily imply the existence of the conceptual representation, same. This distinction is difficult to make, and this point has been widely debated in the comparative literature (Penn, Holyoak, \& Povinelli, 2008; Thompson \& Oden, 1996).

For example, non-human primates (Wasserman, Fagot, \& Young, 2001) and several species of birds (Smirnova et al., 2015; Pepperberg, 1987) have succeeded in solving similar relational problems, in the context of multiple trials in reinforcement learning paradigms (Wasserman, Fagot, \& Young, 2001; Smirnova et al., 2015; Pepperberg, 1987), suggesting that these species, like humans, may possess the ability to learn abstract relational properties (Cook \& Wasserman, 2007). However, there is also growing evidence indicating that these trained abilities may be grounded in perceptual expertise, reflecting learned sensitivity to surface cues, rather than higher-order reasoning, per se (Thompson \& Oden, 2000).

This suggests that the match to sample tasks that have historically served as the standard for assessing samedifferent understanding across species may be passed in the absence of genuine conceptual representations. In particular, lower-level, perceptual strategies, like attention to the symmetry, contrast, and the variance of the stimuli could contribute to success (Young \& Wasserman, 2001; Smith et
al. 2008; Blaisdell \& Cook, 2005). Might infants, toddlers, and non-human animals in an imprinting paradigm, like nonhuman animals in reinforcement training, be responding to a perceptual analysis of the stimuli pairs rather than a samedifferent strategy?

One candidate for such a strategy is a low-level heuristic, called "perceptual entropy," that has been proposed to facilitate relational recognition in non-human animals (Penn, Holyoak, \& Povinelli, 2008; Wasserman, Fagot, \& Young, 2001; Fagot, Wasserman, \& Young, 2001; Young \& Wasserman, 1997; Wasserman, Young, \& Cook, 2004; Wasserman \& Young, 2010; Zentall et al., 2008). In particular, any visual display can be reduced to "a continuous analog estimate of the degree of perceptual variability between the elements" (Penn, Holyoak, \& Povinelli, 2008, pg. 112), a strategy similar to a process of conceptual chunking (Halford, Wilson, \& Phillips, 1998). In other words, because there is a lower amount of perceptual variation among the elements for 'same' displays (AA') than for 'different' displays (AB), toddlers (as well as human infants and non-human animals) may succeed by learning and applying the following rule: If the variability of the effective training sample is low, select the test pair that also has low variability.

This attention to variance would also subsume a range of other perceptual cues including symmetry, oddity, and spatial orientation, among others (Cook \& Wasserman, 2007). Adult humans show some sensitivity to the amount of perceptual variance in a display, but this evidence is not sufficient to prove that it is responsible for their performance. In fact, previous findings suggest that additional processes of categorization likely play $a$ role in the human conceptualization of "same-different" relations (Smith et al., 2008; Fagot, Wasserman, \& Young, 2001). Interestingly, similar findings have been recently found with baboons (Flemming, Thompson, \& Fagot, 2013).

Discriminating between conceptual and perceptual learning strategies in non-verbal relational reasoning tasks is a notoriously difficult problem to solve in both developmental and comparative contexts. In the current study, we introduce a novel method designed to directly pit the perceptual and conceptual accounts against one another. The method involves a contrast between one condition relying upon a traditional match to sample task involving same-different relations (i.e., matching AA' with BB', not CD, and matching EF with CD, not BB') and a "fused" object condition. Exactly the same objects are used in the two conditions, but in the "fused" condition the objects are physically joined to create a single compound object. Importantly, the amount of perceptual entropy, or variance, as well as other perceptual features such as symmetry is matched between the two conditions. However, only the unfused/relational condition also provides evidence for the higher-order relation 'same.' In the fused/single object case, there is no relation between objects to learn - there is only one object present.

As a proof of concept, we applied this method to assess human toddlers in a causal match to sample task originally developed by Walker and colleagues (Walker \& Gopnik, 2014; Walker, Bridgers, \& Gopnik, 2016). In the current study, children observed two trials in which a pair of "same" objects, or a fusion of those objects, activated a machine, but a pair or fusion of two "different" objects did not. Then, children had to select a novel pair of objects or a novel fused object to activate the machine (see Figure 1). If children are indeed relying upon a low-level perceptual heuristic, they should select the lower entropy pair (i.e., the pair with less variance among its features) consistently across both conditions, whether they are fused or not. On the other hand, if children learn the abstract relation 'same' during the training trials, they should privilege this test pair only in the unfused/relational condition, where there is a relation between objects to learn.

Although the current study applies this method to assess human reasoning in a previously published causal reasoning paradigm, this same technique is intended to be used for discriminating perceptual strategies from genuine relational reasoning in a variety of existing paradigms, across species.

## Method

## Participants

A total of 80 18-30-month-olds participated $(M=24.3$ months; $S D=3.6$ months; range $=17.9-31.1$ months; 40 girls), with 40 toddlers randomly assigned to one of two conditions (fused/single object or unfused/relational). There was no difference in age between conditions, $t(1)=1.21, p=$ .23, and approximately equal numbers of males and females were assigned to each. Sixteen additional children were tested but excluded for failure to complete the study (11) or due to experimenter error (5). Children were recruited from a local museum.

## Materials

The toy was a 10 " $\times 6$ " $\times 4$ " opaque cardboard box containing a wireless doorbell. When a block or pair of blocks "activated" the toy, the doorbell played a novel melody. In fact, the toy was surrepticiously activated by a remote control. Eight painted wooden blocks in assorted colors and shapes (2 pairs of 'same' blocks and 2 pairs of 'different' blocks) were placed on the toy in pairs during the unfused/relational condition training. The 'same/low entropy' blocks were identical in color and shape, and the 'different/high entropy' blocks were distinct in color and shape. An identical set of these eight painted blocks were used to create the "fused" objects to be placed on the toy as single objects in the fused/single object condition training. In this condition, each pair of training blocks were glued together to create a single, larger block. Four additional blocks were used during the test phase of each condition, including 1 novel pair of 'same' and 1 novel pair of 'different' blocks. The test blocks either appeared as two pairs of blocks or as two fused, single objects, depending
upon condition (see Figure 1). The pairs of test blocks in each condition were placed on 4 " $\times 4$ " plastic trays.

Two different complete sets of blocks were constructed for each condition. In the simple set, all blocks were composed of simple, symmetrical geometric shapes (e.g., cubes, spheres, cylinders) with a single color and no pattern. In the complex set, all blocks were composed of asymmetrical, irregular polygons. Half of the children in each condition were randomly assigned to receive each stimuli set.

## Procedure

All children were tested one-on-one, seated at a table across from the experimenter. Following a brief warm-up, the experiementer introduced a toy that was placed on the table. The experimenter said, "This is my toy. Some things make my toy play music and some things do not. Let's try some things on my toy and find out how it works."

In the unfused/relational condition, children observed as the experimenter placed a pair of 'same' blocks (AA') on the toy, causing it to activate and play music (twice). They then observed that a pair of 'different' blocks (BC) failed to activate the toy (twice). This procedure was repeated for two additional pairs, one pair of 'same' (DD') and one pair of 'different' blocks (EF) (see Figure 1). The 'same' pairs (AA', DD') were composed of individual blocks that were identical in both color and shape, and the 'different' pairs (BC, EF) were composed of individual blocks distinct in both color and shape. In the fused/single object condition, children observed an identical presentation with one critical exception: each pair of blocks were glued together to form single objects (Alow entropy, B-high entropy, C-low entropy, D-high entropy) (see Figure 1).

In detail, the experimenter selected the first pair [block], saying, "Let's try!" and placed them [it] on the toy. Children in both conditions observed the 'same' pair ['low entropy' block'] activate the toy. The experimenter said, "Music! Let's try again!", picked up the pair [block], and placed them [it] back on the toy a second time, and children observed the outcome. The experimenter said, "Music! These ones [this one] made my toy play music." After this second demonstration, the experimenter removed the pair [block], selected another - a 'different' pair or a 'high entropy' block - and placed it on the toy. This time, children in both conditions observed no effect. The experimenter said, "No music. Let's try again!" As with the first pair [block], this was demonstrated a second time. The experimenter concluded, "No music. These ones [this one] did not make my toy play music."

This procedure was repeated for all 4 pairs [blocks]: 2 pairs [blocks] of 'same' ['low entropy'] objects and 2 pairs [blocks] of 'different' ['high entropy'] objects. All pairs were placed on the toy twice. Therefore, children observed a total of 8 outcomes (4 positive and 4 negative). The order that the individual pairs [blocks] were presented was randomized, however, the order of the presentation pairs was fixed, beginning with a causal pair, and alternating between causal and inert pairs. In all cases, the experimenter placed all pairs
of objects on the toy in the same orientation as the objects that formed the fused blocks, so that they were perceptually identical. Except for the particular objects used in the training trials (fused or unfused), there were no other differences in procedure between conditions.

Figure 1: Schematic of study design (simple set). On training trials, pairs of blocks were placed on the toy. In the fused/single object condition, fused, identical/low entropy objects activated the toy, while fused, distinct/high entropy objects did not. In the unfused/relational condition, pairs of identical/low entropy objects activated the toy while pairs of distinct/high entropy objects did not. Participants observed 4 pairs (2 causal, 2 inert). On each test trial, the child selected between 2 novel pairs ("low entropy [same]" or "high entropy [different]").

Following the training phrase in both conditions, the experimenter said, "Now it is your turn. Can you help me pick the thing[s] that will make my toy play music?" The experimenter produced 2 pairs of test blocks (1 novel 'same' pair ['low entropy' block], 1 novel 'different' pair ['high entropy' block]). In order to avoid a novelty preference, both test pairs were composed of novel objects. The pairs were presented to the child on trays. The experimenter held up the two trays, saying, "I have these [this] and I have these [this]. Only one of these trays has the thing[s] that will make my toy
play music." She then lowered the trays and placed them on opposite sides of the table in front of the child, saying, "Can you point to the one[s] that will make my toy play music?" The side on which the correct pair was placed was randomized between subjects.

Coding The first tray that the child selected (pointing, reaching, picking up objects) was recorded. Children received 1 point for selecting the low entropy pair/object that was consistent with their training and 0 points for selecting the high entropy pair/object. Children's responses were recorded by a second researcher during the testing session, and all sessions were video recorded for independent coding by a third researcher who was naïve to the the hypotheses of the experiment. Interrater reliability was very high; the two coders agreed on $99 \%$ of the children's responses to the test questions.

## Results

Results show no difference between the complex objects and simple objects, in either condition, $\chi^{2}(1)=0, \mathrm{p}=1, \varphi=0$ (fused/single object); $\chi^{2}(1)=.13, \mathrm{p}=.72, \varphi=-.06$ (unfused/relational). We therefore combined data from the two stimuli sets within each condition for all subsequent analyses. Children in the unfused/relational condition selected the 'same' test pair more often than chance (73\%), $p$ $=.006$ (two-tailed, exact binomial). These results replicate previous findings with 18-30-month-olds (Walker \& Gopnik, 2014; Walker et al., 2016). However, in contrast with the perceptual account, children of the same age in the fused/single object condition selected at chance (40\%), $p=$ .27 (two-tailed, exact binomial). There was a significant difference between conditions, $\chi^{2}(1)=8.58, \quad p=.004, \varphi=$ . 33.

## Discussion

Results demonstrate that when perceptual cues are matched, but no relation is present, toddlers do not appear to learn and generalize an abstract concept of 'same' to a novel set of objects. These findings therefore suggest that early relational competence in humans found here and elsewhere is unlikely to be the result of reliance on a perceptual heuristic, and provide evidence for genuine conceptual understanding of 'same' at this young age.

This novel method offers a simple, non-verbal manipulation that may be applied to a variety of existing match-to-sample procedures used to assess same-different reasoning to include in future research with non-human animals across species, as well as human infants. If infants or animals show the discriminative pattern of the toddlers in this experiment - generalizing the unfused/relational but not the fused/single objects - that suggests that they genuinely understand the relations. On the other hand, if they respond in the same manner to both conditions, the perceptual hypothesis would gain more weight. The latter pattern would not eliminate the possibility that relational reasoning was in play - perhaps children or animals are using different kinds
of reasoning in the two conditions. But it would place the burden of proof on the relational claim.

Whatever the results of non-human animals or infants might turn out to be, the present results are consistent with previous claims that, from a very early age, as young as 18 months, humans posess cognitive tools for genuine conceptual understanding of same-different relations. These findings are also consistent with the idea that humans may possess a qualitatively different system for abstracting relations.

## Acknowledgments

Research for this project was funded by the American Psychological Foundation to C. Walker (Elizabeth Munsterberg Koppitz Child Psychology Graduate Fellowship) and the National Science Foundation to A. Gopnik. We thank all of the parents and children who participated in this research, as well as the Childhood Creativity Center at the Bay Area Discovery Museum for facilitating recruitment. Finally, we thank Rosie Aboody, Hannah Broidy, and Gillian Rush for their efforts towards data collection.

#### Abstract

Learning syntax requires determining relations between the grammatical categories of words in the language, but learning those categories requires understanding the role of words in the syntax. In this study, we examined how this chicken and egg problem is resolved by learners of an artificial language comprising nouns, verbs, adjectives and case markers following syntactic rules. We found that the language could be acquired through cross-situational statistical correspondences with complex scenes and without explicit feedback, and that knowledge was maintained after 24 hours. Results also showed that verbs and word order were the first to be acquired, followed by nouns, adjectives and finally case markers. Interdependencies in learning were found for word order and verbs, and also for nouns, adjectives and case markers. Grammar and vocabulary can be acquired simultaneously, but with distinctive patterns of acquisition grammar and the role of verbs first, then the vocabulary of other lexical categories.

Keywords: language acquisition; grammar; vocabulary; artificial language learning; statistical learning.

## Introduction

The early stages of language learning involve a great deal of ambiguity as learners must make sense of the stream of input they hear by noticing words boundaries, decoding the meanings of words, identifying lexical categories and understanding the relations between categories defined by the syntax. How this is achieved and the order in which vocabulary and grammatical knowledge is acquired has been a critical question in the cognitive sciences (Marcus, 1996).

## Cross-situational learning

Recent research has shown that it is possible for children and adults to learn vocabulary within basic categories of words when they are presented across numerous ambiguous learning situations without any feedback, a mechanism
known as cross-situational learning. Smith and Yu (2008) showed that 12 to 14 -month old infants could learn the meanings of novel nouns by keeping track of cross-trial statistics. Scott and Fisher (2012) also demonstrated that it is possible for 2.5 year-old toddlers to learn novel verbs, utilising syntactic cues, knowledge of nouns and other situational referents. Monaghan et al. (2015) found that nouns and verbs could be learned simultaneously without any syntactic cues, although nouns were learned slightly more quickly. They suggested that this prioritisation of nouns could be explained by the greater saliency and stability of object versus action referents.

However, these studies on the cross-situational learning of nouns and verbs are a substantial abstraction from the complexity of natural language acquisition. In child-directed speech, children are generally exposed to multi-word utterances containing many word categories (Mintz, 2006). With every new word category or syntactic phrase added, the number of possible referents for any given word increases, making the tracking of statistical probabilities more complex.

On the other hand, with greater complexity comes greater interdependency between content words, function words and word order. And so conversely, this extra complexity may also provide additional cues from which to constrain learning. Monaghan and Mattock (2012), for example, found that function words could aid the learning of nouns in a cross-situational learning paradigm.

A key question is, therefore, how learners can break into this complex stream, given the difficulty of attempting to acquire the syntax to indicate the role of grammatical categories, and learning the vocabulary to populate those categories. This chicken and egg problem has proven difficult to resolve, and has led to proposals either for independence of learning grammar and vocabulary (e.g., Marcus, 1996), or their inter-relatedness (Bates \& Goodman, 1997). Under these latter accounts, learning a
few words can give rise to syntactic bootstrapping (Gleitman, 1990), which can then be used to promote further vocabulary acquisition, predicting correlations in children's performance for vocabulary and grammatical processing tasks. However, evidence from actual language learning tasks in which both vocabulary and grammar must be acquired has not been extensively explored. Many previous studies of artificial language learning have trained participants on vocabulary before testing them on a language structure.

In the current study, we investigated whether it is possible to learn more complex artificial languages that combine content words, function words and syntactic structures under cross-situational learning conditions without any feedback.

## The acquisition order of linguistic categories

The second question this study addressed was that of acquisition order: When are nouns, verbs, adjectives, case markers, and syntactic constraints on word order acquired and are some aspects learned before others? The vast majority of studies into early childhood language learning support Gentner's (1982) claim that across all languages children learn nouns before verbs and adjectives (e.g, Bornstein et al., 2004). One reason might be that predicates are more semantically complex as they modify and depend on nouns (Dixon, 1982), whether that be adjectives (the black dog) or verbs (the cat pounced on the mouse). Therefore, in order to learn the verb or adjective, learners need to also encode information about the noun (Gleitman et al., 2005).

However, there is some evidence that in languages such as Korean and Japanese, where the verb is found in a highly-salient sentence-final position and subjects and objects are often left out of utterances by caregivers, verbs may be learned earlier than in SVO languages such as English (Choi \& Gopnik, 1995). There is, however, a lack of consensus as to whether verbs in these languages are learned at the same time as nouns (see Bornstein et al., 2004).

Regarding adjectives, Booth and Waxman (2003) demonstrated that 14 -month-old children could extract the meaning from nouns but not adjectives when presented with basic syntactic and visual frames. In a large corpus-based study, Behrens (2006) found that German children aged 1 year 11 months produced more verbs than adjectives.

Finally, case markers which indicate the agent and patient of a sentence have been shown to be understood by children as young as two years old (Göksun et al., 2008). However, in this and other studies, a small vocabulary of nouns and verbs had been acquired before comprehension of case markers was demonstrated.

The participants in the current study were adults who have already mastered their first language, and so it is arguable that the acquisition order observed in child language development may not apply to these learners. An alternative strand of research comes from first exposure
studies of adults learning a second language (L2; for an overview, see Indefrey \& Gullberg, 2010). In a study into the initial stages of learning an L2 by adults in a classroom setting, Shoemaker and Rast (2013) found that it was the words in sentence-initial and sentence-final positions that were most easily recognised in a stream of speech. They argued that this was due to not only silence bordering the initial and final words, but that working memory is less burdened for the final word of the utterance.

Another factor that influences whether a word can be picked out of a stream of speech is the number of syllables it contains (Gullberg et al., 2012). With many function words monosyllabic, this could render them less easily noticed than highly salient content words, despite the frequency with which they occur in utterances.

Overall, if the learning of nouns and verbs follows the findings of child language research, then we can expect nouns to be learned before verbs. Alternatively, if sentence position is a more important factor, we could expect verbs, which in our current study occupy the sentence-final position, to be learned before nouns, which are mostly in medial position. We then predict that adjectives will be learned next, followed by case markers, although given the short duration of the learning paradigm, it is possible that the latter may not be learned at all (e.g., DeKeyser, 2005).

## The learning mechanisms of vocabulary and syntax

A final aim of this study was to investigate how the different types of language structure cohere. Is the meaning of vocabulary items (nouns, verbs, adjectives) learned in the same way as grammatical items (word order, case markers) or do they depend on different mechanisms? Research from models of learning data (Frost \& Monaghan, 2016), neuropsychology patient studies (Alario \& Cohen, 2004), theoretical models (Bock \& Levelt, 1994), and memory models (Ullman, 2004) treat vocabulary and syntax as distinct. If this were the case, we might expect word order and case markers to be interdependent, with nouns, verbs and adjectives also grouped together. Alternatively, if syntax and vocabulary share the same learning mechanism, as is postulated in single-system models (MacWhinney, 1987), we might expect to see no interdependency of word order and case markers. Instead, as word order is determined by the position of the verb, it is possible that learning which word is the verb and the word order will be linked.

## Method

## Participants

Sixty-four native speakers of English (47 women) were randomly assigned to two conditions (massed vs distributed, each $n=32$ ) which varied in terms of whether there were pauses between blocks of training on an artificial language learning task. Participants were students or graduates of universities in the North West of England. The mean age was 26.0 years $(S D=7.1)$. None of the participants had previously studied any verb-final languages. Participants in
the massed group received 20 GBP and participants in the distributed group received 28 GBP . The difference was due to the extra time involved in the distributed condition.

Figure 1: Screenshot of the cross-situational learning task. Participants see two dynamic scenes and hear a sentence and decide which scene the sentence refers to.

## Materials

A novel artificial language was created for this experiment. The lexicon consists of 16 pseudowords, taken from Monaghan and Mattock (2012). Fourteen bisyllabic pseudowords were content words: Eight nouns, four verbs, and two adjectives. Two monosyllabic pseudowords served as function words that reliably indicated if the preceding noun referred to the subject or the object of the sentence. The words were recorded by a female native speaker of British English who was instructed to produce the words in a monotone.

In terms of syntax, the artificial language was based on Japanese. Sentences could either be SOV or OSV, i.e. verbs had to be placed in final position but the order of subject and object noun phrases (NPs) was free. NPs had to contain a noun as its head and a post-nominal case marker that indicated if the preceding noun was the agent or the patient of the action. Adjectives were optional and only occurred in half the NPs. Adjectives occurred pre-nominally.

Eight alien cartoon characters served as referents for the language (see Figure 1). The aliens could either appear in red or blue and were depicted performing one of four actions (hiding, jumping, lifting, pushing) in dynamic scenes generated by E-Prime (version 2.0). Figure 1 shows a sample screen shot, containing the target scene and a distractor scene. Each noun referred to one alien, the adjectives referred to the colours of aliens, and the verbs referred to the actions. Word-referent mappings were randomly generated for each participant to control for preferences in associating certain sounds to objects, motions or colours.
For training, there were 12 blocks of 16 trials each. In each trial, two scenes were presented and an artificial language sentence played. The sentence described only one of the scenes and the participants had to match the sentence to the correct scene. Within each block, each alien and action occurred an equal number of times; half the
utterances in each block were SOV, the other half OSV. In the distractor scene, no actions were the same and the aliens and their colours were randomly selected. The locations of the target scene were counterbalanced.
For testing, each type of information in the language was assessed by presenting an utterance and varying the target and distractor scenes by one piece of information: For testing nouns, target and distractor scenes were identical except for one of the aliens; for testing verbs, only the scenes' actions differed; for testing adjectives, one of the colours of an alien was changed; and for testing marker words, the two scenes depicted the same aliens performing the same actions but with opposite agent-patient assignment. Testing trials were intermingled with every third training block. The purpose of this was to make it less likely that participants would know they were being tested. For testing word order, grammatical and ungrammatical sentences were presented: Half the trials followed the licensed SOV or OSV order in sentences that had not been presented in the crosssituational learning trials, whereas the other half contained syntactic violations (*VSO, *VOS, *OVS, *SVO).

## Procedure

Participants were trained and tested on the artificial language on two days. Participants first completed 16 training and testing blocks. Twenty-four hours later, they returned to the lab to complete a delayed post-test. There were eight pure training blocks, four mixed training and testing blocks, and four grammaticality judgment test (GJT) blocks. In the cross-situational learning task, participants were instructed to observe the two scenes on the screen and listen to the sentence played over headphones. Their task was to decide, as quickly and accurately as possible, which scene the sentence referred to. Participants received no feedback regarding the accuracy of their choice. For the word order trials, participants were told that they would see only one scene and hear a sentence spoken by another alien from a very different planet who was also learning the new language. Their task was to listen carefully and decide if the sentence sounded "good" or "funny".
Presentation order of trials within each block was randomized but all participants completed blocks in the same sequence. There were two training blocks, then one mixed training and vocabulary testing block, then a word order test block. This sequence was then repeated four times.
The massed group completed the first 16 blocks consecutively while the distributed group had three 20minute breaks after every four blocks, in which they watched a natural history documentary on mute. Training and testing on day 1 took between 70 and 90 minutes for the massed group and between 130 and 150 minutes for the distributed group. The delayed test on day 2 comprised a final block of vocabulary testing trials and then a block of word order testing, and five cognitive tests (not reported here), and lasted approximately 90 minutes.

## Results

## Performance on training trials

We first performed a mixed analysis of variance on accuracy within each block, with training block as within subjects factor and the two training conditions (massed and distributed) as between subjects factor. There was a significant main effect for block, using the GreenhouseGeisser correction, $F(4.55,282)=42.0, p<.001, \eta_{\mathrm{p}}{ }^{2}=.40$. This indicates that subjects improved with more training. However, there was no significant main effect for group, nor was there a significant interaction between time and group, both $F<1$. We therefore pooled the data from the two training conditions for the remaining analyses.

In order to ascertain when learning had taken place during the training blocks, a one-sample t-test was conducted to compare the mean scores for each block to a chance score of .5. Participants performed significantly above chance from block two ( $M=.57, S D=.18$ ) onwards, $95 \%$ CI $[.028$ to .12], $t(63)=3.27, p=.002$. In other words, 32 trials of exposure (without feedback) were enough to lead to abovechance performance in the cross-situational learning task.

## Performance on test trials

In order to determine performance for each type of information in the language, we performed one sample ttests to establish the first test block at which accuracy was above chance (at .5). We then carried out a series of repeated measures ANOVAs in order to determine the effects of test block on the scores for word order, nouns, verbs, adjectives and markers. Finally, we conducted further repeated measures ANOVAs for test blocks 4 (immediate post-test) and 5 (delayed post-test) for each word type and word order to assess the role of the 24-hour delay. The results are displayed in Figure 2 and Table 1 and Table 2.

Table 1: Summary of repeated measures ANOVA over test blocks 1 to 4 showing effect for block.

| Test | F | p | $\mathrm{h}_{\mathrm{p}}{ }^{2}$ |
| :--- | :--- | :--- | :--- |
| Word order | 7.82 | $<.001$ | 11 |
| Noun | 14.5 | $<.001$ | .19 |
| Verb | 2.46 | .064 | .038 |
| Adjective | 2.76 | .043 | .043 |
| Case marker | .63 | .60 | .010 |

Table 2: Summary of repeated measures ANOVA over blocks 4 to delayed test block 5 showing effect for block.

| Test | F | P | $\mathrm{h}_{\mathrm{p}}{ }^{2}$ |
| :--- | :--- | :--- | :--- |
| Word order | .025 | .88 | .00 |
| Noun | 2.90 | .59 | .005 |
| Verb | 4.61 | .036 | .069 |
| Adjective | 2.50 | .12 | .040 |
| Case marker | 2.63 | .11 | .041 |

Figure 2: Proportion of correct trials across the five test blocks. Test blocks 1 to 4 were completed on day 1 . Test block 5 was administered with a 24 -hr delay.

Participants performed significantly above chance from test block 1 onwards for both the word order tests, ( $M=.76$, $S D=.19), 95 \%$ CI $[.22$ to .31$], t(63)=10.9, p=<.001$ and also verb tests, $(M=.70, S D=.25,95 \%$ CI [. 13 to .26$]$, $t(63)=6.16, p<.001)$. For noun tests, participants performed significantly better than chance from test block 2 onwards, $(M=.60, S D=.19,95 \%$ CI [.052 to .15$], t(63)=$ 4.16, $p<.001$ ). Adjective test results were significantly above chance from test block 4 onwards, ( $M=.64, S D=$ .27), $95 \%$ CI [.076 to .21$], t(63)=4.22, p<.001)$. Finally, case markers only reached significantly above chance on test block 5, ( $M=.54, S D=.16$ ), $95 \%$ CI [.001 to .079$]$, $t(63)=2.06, p=.043$.

## Determining relations between learning different information types

In order to determine the factors driving performance in the task - whether learning was independent or interdependent for different types of information, we conducted a principal components analysis on test performance for the final test block for word order, nouns, verbs, adjectives, and marker words. There were two components with eigenvalues greater than 1 , and the loadings of the individual tests on these components, with varimax rotation, showed a simple solution (i.e., each test loaded $>0.4$ on only one component). The components and their loadings are shown in Table 3.
The first component related to learning nouns, adjectives, and marker words, and the second component related to learning word order and verbs. This indicated that performance across the five information types was effectively explained by two aspects of the data: The first relates to learning the vocabulary items of nouns and

Table 3: Loadings of the five delayed tests on the two principal components.

| Test | First component | Second component |
| :--- | :--- | :--- |
| Noun | $\mathbf{. 7 7 8}$ | .104 |
| Adjective | .769 | .034 |
| Marker words | $\mathbf{. 6 0 4}$ | .081 |
| Verb | .322 | .718 |
| Word order | -.090 | $\mathbf{. 8 7 3}$ |

adjectives and how the marker words affected the role of the adjective-noun phrases, and the second indicated a close relation between learning the identities of verbs and learning that the word order of sentences was verb-final.

## Discussion

In this study we investigated whether adult learners could acquire the syntax and vocabulary of a novel language by keeping track of cross-trial statistics, without feedback and without any explicit instruction about the structure of the language or its vocabulary. We also provided a delayed post-test after 24 hours to determine whether any acquired knowledge had been maintained. Furthermore, we examined the order of acquisition and investigated how learning of syntax and of vocabulary cohered.

## Simultaneous learning of words and syntax

Our results indicated that adult learners can rapidly acquire both syntax and vocabulary of the language simultaneously. Previous cross-situational learning studies only investigated nouns (Smith \& Yu, 2008) or verbs (Scott \& Fisher, 2012) or nouns and verbs simultaneously (Monaghan et al., 2015). Our results extend these findings to demonstrate that it is possible for adults to acquire a wider range of information, including adjectives and case markers. We cannot rule out, however, that this occurred because of the nature of the lexical test design, in which the two scenes presented differed only in terms of the lexical item being tested, artificially making these word categories more salient. It also remains to be seen whether children can also learn such a complex system via cross-situational learning, and this is an important question that we are currently addressing. The results also show that the learning effects can be retained overnight. This is an important methodological observation as the majority of studies in statistical learning do not have a delayed post-test, which means that it is unclear whether the learning is robust. By including a $24-\mathrm{hr}$ delayed post-test, we show that learning is indeed robust and that this applies to words and syntax.

For the case markers, it was only after 24 hours that test scores were significantly above chance. This corresponds with Grey, Williams and Rebuschat's (2015) study that found no learning effect for Japanese morphology on an immediate post-test, but a significant effect after a two-week delay. These findings suggest that consolidation may be valuable, particularly for the function words' role in the language. Indeed, there is evidence that sleep aids in the
generalization of grammatical rules (Walker \& Stickgold, 2010). The case marker results also raise another important methodological consideration. Without the delayed test, we would have underestimated the amount of learning that had taken place and would have concluded that case markers had not been learned at all. Whereas, with the delayed test, there is evidence, albeit a small effect, that learning of case markers does in fact take place. It is recommended, therefore, that future studies into cross-situational learning include delayed post-tests to show that learning is robust and to catch any learning effects brought on through consolidation.

## Order of acquisition

Although learners were exposed to both vocabulary and syntax simultaneously, they performed above chance on different aspects of the language at distinct stages: First, verbs and word order were acquired, then nouns, then adjectives, and finally case markers (see Figure 2). It is interesting to note that verbs were learned before nouns in this artificial language and thus differed from the majority of first language acquisition studies. One possible reason for this is the saliency of the final-position verb compared to the mostly medial-position nouns (Shoemaker \& Rast, 2013). Another possibility is that adult learners already possess syntactic and lexical knowledge of word categories in their L1 and so can transfer them to their L2. This would then allow the learner to concentrate on deciding which words map onto the different lexical categories, rather than also working out the lexical categories as infants do.

## The coherence of vocabulary and syntax

Regarding the coherence of learning of syntax and vocabulary, we found that acquisition of word order and verb learning were interdependent. Upon learning that the final word in the sentence was a verb, participants were able to gain an understanding of the basic word order of the sentence. It is conceivable that such an understanding could be gained by breaking into the stream of input through any word category, with the greater salience of verbs due to final utterance position promoting this acquisition. In addition, we found that nouns, adjectives and case markers were also interdependent but acquired somewhat independently of verbs and word order. This result supports an emergentist view that syntactic knowledge associated with case markers develops only after a core vocabulary of content words has been learned (Bannard et al., 2009).

These results demonstrate that the chicken and egg problem of acquiring grammar and vocabulary can be resolved by the learner through using cross-situational statistics with events in the environment. An alternative explanation is that once verbs are learned, this knowledge is then bootstrapped to aid the acquisition of the other lexical categories. The patterns of results we found for this verbfinal language in our experimental paradigm did not neatly correspond with a distinction between grammar and vocabulary learning (e.g., Ullman, 2004), with word order
being related to verb acquisition, and case marking being related to noun and adjective learning. Complex interactions between grammatical categories and grammar do not appear to lend themselves to a neat distinction in acquisition of these sources of linguistic knowledge.

# Please Explain: Radical Enactivism and its Explanatory Debt 

Lachlan Douglas Walmsley (lachlan.walmsley@anu.edu.au)<br>School of Philosophy, 9 Fellows Road<br>Canberra, ACT 2602 Australia

#### Abstract

Radical Enactivism is a position in the philosophy of cognitive science that aims to displace representationalism, the dominant position in cognitive science for the last 50-60 years. To accomplish this aim, radical enactivism must provide an alternative explanation of cognition. Radical enactivism offers two alternative explanations of cognition. The first I call the dynamical explanation and the second I call the historical explanation. The mechanists have given us reasons for doubting that the first alternative makes for a good explanation. The historical explanation does not hit the right explanatory target without the introduction of a proximate mechanism, but the proximate mechanisms suggested by radical enactivism are associationist mechanisms, the limitations of which led to the initial widespread endorsement of representationalism. Therefore, radical enactivism cannot displace representationalism in cognitive science.

Keywords: radical enactivism, representation, dynamical explanation, computationalism, explanation

## 1 Introduction

Radically enactive cognition (REC) is a position in the philosophy of cognitive science aiming to displace representationalism (Hutto \& Myin 2013), the dominant position in cognitive science for the last $50-60$ years. ${ }^{1}$ To accomplish this aim, proponents of REC-or RECersmust settle their explanatory debt by providing us with an alternative explanation of cognition. Cognition, here, is understood in a non-question begging biological sense as that system functioning to coordinate behaviour intelligently (Godfrey-Smith 1996). ${ }^{2}$ It's a familiar phenomenon. It's what happened when you wrote your last paper or organised your last workshop. It's probably what happened when you performed some less sophisticated tasks too. The RECers owes us an explanation of that. For half a century, the representational explanation of cognition has been the defining explanation of cognitive science-"the only game in town" (Fodor 1975). But the RECers argue that the representational explanation is bad. If we can't play the representation game anymore what game shall we play?

REC is committed to two alternative explanations of cognition. The first, I call the dynamical explanation. Here, RECers presuppose that all dynamical models make for good explanations, and David Kaplan and William Bechtel

[^232]have given us good reasons to think otherwise (Kaplan 2015; Kaplan \& Bechtel 2011). Although many of the dynamical models appealed to by the RECers provide elegant and predictive descriptions of phenomena, they do not explain those phenomena. Their second alternative, I call the historical explanation. Although this is a good explanation, it is, by itself, not the right kind of explanation to compete with the representational explanation. Even with the addition of associationist mechanisms, the explanation still fails to explain certain intelligent behaviour, a limitation that led to the initial widespread endorsement of the representational explanation in cognitive science. Therefore, RECers owe us an explanation of cognition that can displace the representational explanation. ${ }^{3}$

## 2 The Representational Explanation

According to the representational explanation, intelligent behaviour is coordinated through the manipulation and transformation of information-bearing structures called representations. There are a number of versions of the explanation, however, owing to the different ways in which the term "representation" has been used. William Ramsey identifies four ways in which the term has been used (Ramsey 2007). Here, I defend only the representational explanation of the classical computational theory of cognition (CCTC), so only two of the four notions of representation Ramsey identifies are relevant: the $I O$-notion and $S$-representation. For brevity's sake, I will discuss only the IO-notion (Ramsey 2007: 68-77). ${ }^{4}$

The IO-notion of representation is used to describe those situations in which some structure standing in for another is taken as a system's input (hence the "I") and transformed into another structure (again standing in for yet another structure), which is its output (hence the "O"). If this is a little abstract, imagine a calculator taking as input some structures standing in for numbers and mathematical operators-say, " 2 ," " 3 ," " + ," and " $=$." All going well, the calculator transforms its input into another structure, "5," which stands in for the number five, and which the

[^233]calculator gives as its output. Here's another example. Imagine a face recognising computer. Again, its input is a structure standing in for another structure, a face in this case. Let's say its input is a portrait of Charles Darwin. All going well, the computer transforms its input and gives as output a different structure that stands in for the individual to whom the face belongs. Something like "Charles Darwin." CCTC models the transformation of a structure from input to output as a series of operations carried out by component sub-systems. Each sub-system also takes as its input structures standing in for other structures and gives as its output yet more such structures. It is due to this on-going replacement and its role in the transformation of system input to system output that CCTC takes such systems to manipulate and transform structures standing in for other structures-that is, representations. ${ }^{5}$

If you are sceptical of CCTC's representational explanation then consider the digital computer. The digital computer can perform calculation and facial recognition as in the examples above and does so in the way I've described. The digital computer is a paradigm case of a physical system for which the representational explanation is good. It is, in effect, an existence proof for good representational explanations. No matter what position you occupy in the philosophy of cognitive science, if it follows from your argument that the representational explanation of a digital computer is bad, then that is a reductio against your argument. Whether or not the representational explanation is good for human cognition is an empirical question. But RECers argues that the representational explanation of human cognition is bad on theoretical grounds.

### 2.1 The Cost of the Representational Explanation

RECers claim that we should reject the representational explanation because it is too metaphysically demanding to be naturalised. ${ }^{6}$ A naturalistic explanation, here, is understood as one that can be squared with our current scientific knowledge-no spooky stuff. The representational explanation is too metaphysically demanding, REC claims, because it posits the existence of content, which determines what a structure stands for: the structure " 5 " stands in for the number five because of its content. According to REC, no naturalistic account of content has succeeded in explaining the "special properties," such as "truth, reference, implication," attributed to content (Hutto \& Myin 2013: 67). These properties make content, and hence the

[^234]representational explanation, "too metaphysically extravagant to be accepted by hard- nosed naturalists" (21).

As a naturalist, I shy away from metaphysical extravagance, and I agree that no naturalistic account of representation has explained content as REC understands it. But I resist the assumption that content must have such metaphysically demanding properties, such as truth and reference. One reason why REC might make this assumption is because their emphasis is partly on mentality and the mind: "Enactivism is inspired by the insight that the embedded and embodied activity of living beings provides the right model of understanding minds" (Hutto \& Myin 2013: 4, my emphasis). The focus of the representational explanation radical enactivists hope to displace, however, is not on the mind but on cognition. It may prove difficult to give good naturalistic explanations of the mind's features because the mind simply doesn't lend itself to good naturalistic explanation. But I will leave that to the philosophers of mind.

Can we make do with less metaphysically demanding accounts of representational in cognitive science? I think we can. Furthermore, I think REC must also make do with less metaphysically demanding accounts of representation because they are committed to the existence of public representational systems, such as public language. How does " 5 " come to stand in for (at least in most instances) the number five in our public language? Radical enactivists cannot answer that " 5 " stands for the number five because of representations internal to the language users. The meaning of public representations can't be due to something metaphysically extravagant in your head or in mine. Such an answer is anathema to RECers. Instead, public structures like " 5 " come to stand in for what they do in virtue of the interactions between public language users (Hutto 2008). This was, roughly, Wittgenstein's view of language in his Philosophical Investigations. According to this view, "5" stands in for the number five because we use that structure, either as a written symbol or as an utterance, in those situations involving five-type things, such as when we ask someone to fetch five stones or to wait five days. Over time, language users become expert at recognising situations like these and can use " 5 " in situations involving much more complicated or abstract entities, like dollars and electrons. For Wittgenstein, structures stand in for other structures (in most cases) in virtue of their functional role in a system of public language users. In slogan form: "the meaning of a word is its use in the language" (Wittgenstein 2009/1953: $\S 43)$. So " 5 " or "five" means (has as its content) the number five because of the way in which " 5 " is used in a community of language users. ${ }^{7}$

REC is committed to something like Wittgenstein's meaning-as-use account. A metaphysically undemanding explanation of representation such as this can generalise to cognitive systems. Just as utterances can be said to stand in for other structures in virtue of their functional role in a

[^235]public system, so can structures in a computational system. These structures can be said to stand in for others in virtue of how they are passed between the different sub-systems of the computational system and how they are transformed by each sub-system-that is, how they are used within and by the system. You might be sceptical of a Wittgensteinflavoured meaning-as-use account of representation. And it's fine if you are. All that's important here is that REC is committed to an explanation of interactions between organisms-that is, human public practices-that involves representation and avoids metaphysical extravagance. If public practice can be given a metaphysically undemanding representational explanation then so can cognition. There is no reason to suppose that representational explanations of intraorganism processes will be any more metaphysically extravagant than those for interorganism processes.

Advancing the representational explanation, at least as it is understood in CCTC, does not entail positing anything as problematic as REC suggests it does. As I outlined above, within CCTC we can posit representations and explain representational content in virtue of a structure's function within the computational system. A structure stands in for what it does because of the role that structure plays in the computational system. Furthermore, this way of grounding content is analogous to REC's strategy for grounding the content of public representations. So, if REC remains sceptical of CCTC's representational explanation, as I have outlined it in this section, then they must rethink their own commitments to the existence of public representational systems.

Furthermore, according to CCTC's representational explanation, structures in a computational system are not causally efficacious because of their content. They are causally efficacious because of how their formal properties map onto physical parts of the target system, such as transistors or neurons (Fodor 1981; Pylyshyn 1984; Gallistel and King 2009). If the RECers suppose the representational explanation requires that structures be causally efficacious because of their content then they are setting up a straw person. Hence, I take it this is not their position. If the RECers accept CCTC's representational explanation but reject other versions of the representational explanation, such as those according to which structures are causally efficacious in virtue of their content, then they are conservatives, classical computationalists rather than radicals. Hence, I take it this is not their position. Instead, I take it that REC is a position according to which CCTC's representational explanation is unnecessary for explaining any intelligent behaviour. This is an empirical question. And we have good reasons to answer it in favour of the representational explanation (see $\S 4.1$ especially). From here on, I argue that REC's candidate replacement explanations are not genuine alternatives to the representational explanation of CCTC or, where they are genuine alternatives, they fail to explain some intelligent behaviour that the representational explanation can.

## 3 The Dynamical Explanation

The first alternative to the representational explanation offered by REC is the dynamical explanation: "the vast sea of what humans do and experience is best understood by appealing to dynamically unfolding, situated embodied interactions and engagements with worldly offerings" (Hutto \& Myin 2013: ix). Dynamical explanations are constructed with the language of dynamical systems theory, which models how physical systems change over time with differential and difference equations. These equations quickly become analytically intractable as structures or details are added but their solutions can be satisfactorily approximated using numerical methods and computer simulation. From the approximate solutions, modellers create geometric visualisations of the different ways in which the system can change over time as transitions through a state space. The explanation's language is complex, but it need not concern us here. The problem with dynamical explanations is not the language in which they are described.

A paradigm case of a dynamical model is the Haken-Kelso-Bunz (HKB) model of human hand movements (Haken et al. 1985). The model captures "voluntary oscillatory motions of the two index fingers"-that is, the movement of your index fingers when you move them back and forth in a coordinated fashion, either symmetrically or asymmetrically. In particular, it captures the abrupt change from asymmetrical and symmetrical coordination when the oscillations reach a certain frequency. HKB is a phenomenological model, built to have a close qualitative fit with the system's behaviour: the "first step in the development of the model is to provide a mathematically accurate description of the main qualitative features of the data" (349).

HKB has received much attention because it is a minimal model of a "relatively simple two-component system" (Bressler \& Kelso 2001: 28) with predictive power, capturing the dynamics of a wide range of interactions including those between an agent and their environment (Kelso 1994) and between two agents (Schmidt et al. 1990). For RECers and similarly inclined anti-representationalists, models like this provide good alternative explanations because they make simple and generalisable predictions (without positing content): "If models are accurate enough to describe observed phenomena and to predict what would have happened had circumstances been different, they are sufficient as explanations" (Chemero \& Silberstein 2008: 12). Although accurately describing the behaviour of a large class of systems is a virtue of these models, good descriptions and predictions are not sufficient for explanation.

Dynamical explanations of the intelligent coordination of behaviour can only be genuine alternatives to the representational explanation if they are genuine explanations. Dynamical explanations are only genuine explanations if the predictions and descriptions of behaviour offered by models like HKB are also explanatory.

Description and prediction are certainly similar to explanations. The covering law account of explanation, for example, treats them as having the "same logical character" as each other (Hempel 1958: 37; 1965). But they are importantly different from explanation (Kaplan 2015; Kaplan \& Bechtel 2011). The difference between description and explanation is obvious: a description of a phenomenon is simply a statement of the explanandum. The difference between prediction and explanation is not so obvious but just as real.

To see the difference between prediction and explanation, imagine a flagpole, which casts a shadow as the sun rises and sets. As the position of the sun changes, so does the shape and size of the shadow. The two change together with law-like regularity. Hence, we can use the height of the flagpole along with the position of the sun and some mathematics to predict the shape and size of the shadow. We can also use the shape and size of the shadow along with the position of the sun and some mathematics to predict the height of the flagpole, but we cannot explain the height of the flagpole in virtue of the shadow's shape and size. Although predictions can run either way, from flagpole to shadow and from shadow to flagpole, explanations run in only one direction - in this case, from flagpole to shadow (Bromberg 1966; also Kaplan \& Bechtel 2011: 440-441). Explanations must inform us of that which gives rise to a phenomenon, so an explanation of the height of the flagpole would appeal to the factory in which it was made, but not to its shadow.

Precise mathematical models of behaviour like HKB are not the explanans. ${ }^{8}$ They are the explanandum. This is not especially controversial; dynamical modellers themselves are aware of this. Haken et al., for example, admit of their model that it describes the coupling between the two hands but says nothing about what gave rise to that coupling and leave this for "further theoretical and experimental research" (Haken et al. 1985: 355). Short an actual explanation of the phenomena described by HKB, Haken et al. provide a howpossible explanation, describing a mechanism that might be responsible for causing the phenomena: "one coupling might be established via the corpus callosum, the wellknown band of fibres that joins the two hemispheres of the brain" (ibid.). Another explanation of the regularities described by dynamical models like HKB may involve the manipulation and transformation of information-bearing structures. The behaviour of digital computers, for example, can be modelled using the tools of dynamical systems theory, but, as I said above, it is a paradigm case of a system for which the representational explanation is good. Hence, dynamical models of cognition-explanatory or not-are compatible with representational explanations. Even if

[^236]REC's dynamical explanation were genuinely explanatory it would be compatible with representational explanation.

## 4 The Historical Explanation

REC's second alternative to the representational explanation is the historical explanation. In this case, cognition is explained in virtue of an agent's "history of previous engagements and not in some set of internally stored mental rules and representations" (Hutto \& Myin 2013: 9). To make this concrete, imagine some behaviour:
"Someone is living in a house with a kitchen in the hallway, such that she has to walk around a sideboard to get to the other side. Suppose that at some point the sideboard gets removed, but that the person still takes the same curve to get to the other side of the hall." (Degenaar \& Myin 2014: 3642)

Here is the historical explanation of that behaviour:
"In the new situation, the person is going through the same old motions in absence of the environmental basis for these motions. Over the years, a behavioural pattern has emerged: the person tends to take a particular trajectory when walking through the hallway." (Degenaar \& Myin 2014: 3642)

The historical explanation is neither mere prediction nor description. Unlike REC's first alternative explanation, its second is genuinely explanatory. However, it is still not a genuine alternative to the representational explanation. Rather, it is compatible with the representational explanation. As Jan Degenaar and Erik Myin say of the above example, "This might involve representations or it might not" (Degenaar \& Myin 2014: 3642).

The historical explanation is not the right kind of explanation to be an alternative to the representational explanation because the historical explanation is an ultimate explanation, while CCTC's representational explanation is a proximate explanation. Niko Tinbergen (1963) first made the distinction between proximate and ultimate explanations. An example will help illustrate the distinction: humans regularly help needy others at a cost to themselves. One explanation of this behaviour is that empathising with needy others motivates us to help them (Batson 2011). This is a proximate explanation. It tells you about the mechanism here and now-empathy-that produces the helping behaviour. But why this sort of mechanism? Why are we empathetic? This question calls for an ultimate explanation, which might explain the helping behaviour as the result of selection for a particular behavioural disposition in terms of benefits to an organism or group's fitness. For example, perhaps our empathetic ancestors were better carers for their and their kin's young, so our empathetic ancestors did better than our nonempathetic ones and empathy spread through the population (De Waal 2008). Importantly, ultimate explanations need not refer to evolution. They can also refer to an agent's developmental history (Baum 1994). For example, an ultimate explanation of an agent without the
disposition to help may be that their helping was rewarded materially early in their developmental history such that the agent came to expect material rewards to follow from helping (Warnaken \& Tomasello 2014). Hence, when there are no material rewards on the horizon, the agent doesn't help. Here, our ultimate explanation refers to a learning process rather than an evolutionary one.

Proximate and ultimate explanations are natural partners, with one explaining the mechanism producing the behaviour here and now and the other explaining why that kind of mechanism exists instead of another. Since REC's historical explanation is compatible with the representational explanation it is no real alternative at all.

### 4.1 The Proximate Explanation

RECers might respond that their historical explanation does involve a proximate mechanism, which is something akin to what Kim Sterelny (2003) calls a detection system. Detection systems link certain environmental stimuli with certain behavioural responses and do not involve the manipulation and transformation of information-bearing structures. ${ }^{9}$ In the example above, entering the hallway has been linked with the response of taking a particular trajectory. This connection has been wired up through something like simple association-based learning-the hallway becomes associated with taking the trajectory in virtue of certain rewards, such as not bumping into the sideboard. But detection systems can also be wired up through evolutionary processes. Organisms can be born responding to particular stimuli with particular responses because such organisms have had greater reproductive success. The infamous male Photuris firefly, for example, is born with such a detection system, which links a certain series of flashes with the response of flying toward the source of the flashes. Female Photuris fireflies produce these flashes and males find them, so the two can mate.

Although often effective, detection systems are fragile. The Photinus firefly's detection system is exploited by the Photuris firefly. They produce the flashing just like the Photinus females, catching and eating a fair number of unfortunate males (Lloyd 1965). Sterelny's robust systems are, as the name suggests, less fragile than detection systems. These link a number of environmental stimuli with a particular response. But even these have their limits. Once the causal chain through which a relevant aspect of an environment and an appropriate behavioural response are linked becomes sufficiently complex and rare, it becomes invisible to whatever processes build detection and robust systems, such as associationist learning or evolution by selection. Sterelny argues that this is the case in complex social environments in which deception is common and multi-place relations between group members matter, and from which language can emerge as it has in the case of human lineage. Explaining human cognition, then, will

[^237]require a proximate explanation appealing to more than detection systems and associationist learning.

If the only good proximate explanation RECers have up their sleeves is one involving associationist mechanisms linking a stimulus with response in virtue of a history of interaction then that's a problem. As Sterelny argues, the complexities of social life are such that stimulus-response systems like Photinus's just won't do. But REC needs more than a good proximate explanation for human social behaviour (here, RECers will argue is richly scaffolded by shared practices and hence not as computationally demanding as it seems). REC also needs one for the behaviour of much simpler organisms, such as insects (Gallistel 1990, Gallistel \& King 2009). Desert ants, among other insects, often trace winding paths away from their nests as they forage. Upon returning to their nests, they don't retrace their steps, but take an almost direct route. This is known as path integration or dead reckoning. It requires integrating information both about the distance and direction travelled from the nest. This ability has been experimentally demonstrated (Wehner \& Srinivasan 1981). In Wehner and Srinivasan's experiment, ants forage from their nest to a feeder station 20 m away. Upon reaching the feeder station, the ants are transferred to a test area several hundred meters away with a replica feeder station. From this replica, the ants take a direct path to where their nest should be. When they reach this point they begin searching for their nest in different directions. In these experiments, the ants are clearly not using environmental cues. If they were, they would find their actual nest, not where their nest should be. Their destination is a novel location, so they cannot be navigating by anything like habit. In this instance, there is no history of on-going interactions to appeal to and no stable environmental stimuli with which behaviour can be associated. A good explanation is one positing a computational process involving representations of the ants' location relative to the nest and feeder station.

## 5 Revolution?

The radical enactivists owe me an explanation. They owe you one too. They owe us all an explanation of how biological systems like you and I behave in the complicated ways we do. They owe us an explanation of cognition. Importantly, the explanation cannot one of those advanced before the cognitive revolution. You cannot displace the representational explanation with stimulus-response mechanisms because the representational explanation initially gained traction in virtue of the limitations of such mechanisms.

So what new explanations are on offer? There is the dynamical explanation, according to which our actions are the results of dynamically unfolding interactions with our environments. But what explains why these dynamics obtain instead of others? When I become reciprocally coupled with my environment, what initiates and maintains that coupling such that my behaviour can be predicted with a set of elegant differential equations? Although the models of the
dynamical explanation can offer mathematically precise descriptions of behaviour, they don't explain why those descriptions hold. If those in the radical camp want an antirepresentational revolution, they must fill the explanatory gap left by the representational explanation. So far, they have failed to do this.

# Learning to reinforcement learn 

Jane Wang<br>DeepMind<br>Zeb Kurth-Nelson<br>DeepMind, Max Planck-UCL Centre for Computational Psychiatry<br>Hubert Soyer<br>DeepMind<br>Joel Leibo<br>DeepMind<br>Dhruva Tirumala<br>DeepMind<br>Remi Munos<br>DeepMind<br>\section*{Charles Blundell}<br>DeepMind<br>Dharshan Kumaran<br>DeepMind, Institute of Cognitive Neuroscience, UCL<br>Matt Botvinick<br>DeepMind, Gatsby Computational Neuroscience Unit, UCL

#### Abstract

In recent years deep reinforcement learning (RL) systems have attained superhuman performance in a number of challenging task domains, but are constrained by a demand for large training sets. A critical present objective is thus to develop deep RL methods that can adapt rapidly to new tasks. In the present work we introduce a novel approach to this challenge, which we refer to as deep meta-reinforcement learning. Previous work has shown that recurrent networks can support metalearning in a fully supervised context. We extend this approach to the RL setting. What emerges is a system that is trained using one RL algorithm, but whose recurrent dynamics implement a second, quite separate RL procedure. This second, learned RL algorithm can differ from the original one in arbitrary ways and exploit structure in the training domain. We unpack these points in five proof-of-concept experiments to examine key aspects of deep meta-RL.

# The Learning of Subordinate Word Meanings 

Hao Wang<br>University of Pennsylvania<br>Lila Gleitman<br>University of Pennsylvania<br>John Trueswell<br>University of Pennsylvania

#### Abstract

In three experiments, adults attempted to learn words with subordinate-level meanings (dalmatian) by sampling the referent world cross-situationally. Xu \& Tenenbaum, 2007 predicted that encountering three uses of a word, each referring to a dalmatian would evoke "suspicious coincidence" inferencing, leading to the subordinate meaning (dalmatian). Exp. 1 found little evidence for this; cross-situational exposure led to a basic-level bias. This bias was unchanged even when the sample was increased to five subordinate exemplars (Exp. 2). Exp. 3 encouraged semantic contrast by simultaneously teaching each subject a word for the subordinate-level and the basic-level category within the same semantic domain (dap=dalmatian; blit=dog). Participants now showed non-basic level learning, but more in line with mutual exclusivity: they may think "dap" means dalmatian but "blit" means all-dogs-except-dalmatians. We conclude that the basic-level interpretation is powerful and cannot be removed by the mere observation of exemplar items over multiple word instances.

#### Abstract

By integrating theories and methodologies from a diverse range of scientific disciplines (e.g., physics, neuroscience, cognitive science, psychology and robotics engineering) the present work is aimed at harnessing self-organized anticipatory synchronization in order to advance humanrobotic interaction (HRI). This phenomenon is characterized by the emergence of anticipatory behavior by one system coupled to the chaotic behavior of another, following the introduction of short self-referential delays in the coordinating system. The current set of studies involved the creation of an artificial agent based on a time-delayed, low-dimensional dynamical model capable of behaving prospectively during an interaction with a human actor performing complex, unpredictable behaviors. By achieving characteristics similar to those observed during natural human interaction and coordination, the time-delayed modeling approached advocated here provides the potential for considerable future advancements in HRI.

Key words: human-robotic interaction; artificial agents; dynamical modeling; virtual reality; anticipatory synchronization; interpersonal coordination; chaos

Rapid advances in cyber-technologies and robotics present increasing opportunities for the implementation of interactive, artificial agents within contexts of human behavior. This includes, but is not limited to, assistance during the performance of everyday tasks and the development of new skills. Work has already been done, for example, on the development of virtual agents able to assist elderly individuals with the organization of their daily activities (Yaghoubzadeh et al., 2013), and to create a robot whose structured interaction may help to improve interpersonal coordination in children with autism spectrum disorders (Palatinus, 2014). However, Lorenz and Hirche (2014) have recently drawn attention to the fact that engineers working to design virtual and robotic agents do not always prioritize those aspects which will allow for
smooth, effortless human interaction, while psychologists studying interpersonal or joint-action do not always take into account technical realizability in describing what they see as the fundamental elements of successful multi-agent coordination.

One potential solution to this issue is to identify and model the behavioral dynamics (Warren, 2006) of natural human-human interaction using low-dimensional differential equations that can be easily implemented within interactive robotic or machine systems. Recent work by Dumas et al. (2014) and Zhai et al. (2014) has already provided support for the idea that relatively simple selfsustaining, nonlinear dynamical systems can be used to construct virtual interaction partners capable of successful, flexible coordination with human actors. Both groups of researchers used long-standing oscillator models of biological coordination to develop virtual agent systems capable of synchronizing with a selection of behaviors exhibited by a human actor. For instance, Dumas et al. (2014) have developed variations of their Human Dynamic Clamp (HDC) system that can coordinate with continuous and discrete finger movements of a human actor. Zhai et al. (2014) have designed a similarly adaptive virtual agent that is capable of coordinating with an individual during a continuous, one-dimensional movement-mirroring task.

The development of these dynamical, artificial agents has primarily focused on their ability to exhibit coordination with periodic behaviors, or synchronize with fluctuating movement speeds using a velocity estimation algorithm. However, one only has to consider a pedestrian navigating a busy city sidewalk to be reminded that people are often capable of prospectively coordinating their behavior with highly variable, seemingly unforeseeable events in an effortless manner. Recent research in human motor control and joint-action has demonstrated that small perceptualmotor feedback delays, such as those known to exist within the human nervous system, may actually facilitate the ability
to achieve anticipation of such continuous chaotic events (Stepp, 2009; Washburn et al., 2015). This phenomenon, referred to as strong anticipation or self-organized anticipatory synchronization, has been found to emerge when a unidirectional coupling exists between a "slave" system and a chaotically behaving "master" system (e.g., Masoller, 2001; Stepp \& Turvey, 2015; Voss, 2000). Surprisingly, as the slave system begins to synchronize with the chaotic behavior of the master system, the introduction of small temporal feedback delays results in the slave system anticipating the ongoing behavior exhibited by the chaotic master system.

Of particular significance here, is that the dynamics of chaotic anticipation during interpersonal coordination can be captured using a low-dimensional dynamical model and can be easily implemented in artificial agents. Such models of self-organized anticipatory synchronization could therefore provide an opportunity for significant advancement in HCI and HRI through the development of artificial systems capable of anticipating chaotic human behavior during real-time interaction. In the current study, two experiments were conducted to examine whether a virtual, artificial agent, whose arm movements were controlled by a time-delayed dynamical model, could not only coordinate with the chaotic movements of human actors in real time, but could do so in a self-organized anticipatory manner akin to human-human perceptual-motor coordination.

## Method

## Participants

Twelve students were recruited from the University of Cincinnati to take part in Experiment 1 along with four individuals from the greater Cincinnati area, for a total of 16 participants. Participants ranged in age from 19 to 31 years.

Seventeen University of Cincinnati undergraduate students participated in Experiment 2 (eight in the 1.5 coupling strength condition and nine in the 2.0 coupling strength condition). Participants ranged in age from 18 to 31 years.

## Procedure and Design

A virtual reality (VR) interface was employed in both experiments as it afforded the opportunity to examine the phenomenon of human-human and human-machine anticipatory synchronization within a realistic, yet highly controllable setting. A seated participant interacted with a simple virtual environment created using Unity 3D and viewed via a head-mounted Oculus Rift. Within the virtual environment participants saw a robot avatar sitting directly in front of them, and an additional avatar arm that moved along with their own right arm movements. The movements of this virtual participant arm were generated through the inverse kinematics function available within Unity 3D by coupling the pointer finger of the virtual arm to the real time
position of a wired motion sensor attached to the first two fingers of a participant's right hand. A Polhemus Liberty electro-magnetic motion capture system $(\sim 0.1 \mathrm{~mm}$ accuracy) (Polhemus Liberty, Polhemus Corporation, Colchester, VT) was used to record and track participants' movements at 120 Hz . The horizontal and vertical coordinates of participant movement were also recorded from the magnetic tracking system at a sampling rate of 75 Hz for later analysis. The receiver for this system was positioned approximately 10 cm in front of the fingers of a participant's right arm outstretched directly in front of their body.

Experiment 1: Human (slave) - Avatar (master) Experiment 1 was designed to establish the coordinative dynamics exhibited by human actors coordinating with an artificial agent via a novel VR setup. That is, we examined whether small perceptual-motor feedback delays could enhance a human actor's ability to anticipate the chaotic movements of the artificial agent system. Experiment 1 was also conducted to assess the degree to which bidirectional coupling (from master to slave) might influence the emergence of anticipatory synchronization. At the beginning of each experimental trial, the robot avatar began to move its left arm with the index finger pointed in a continuous trajectory. The participants' task was to synchronize their own arm movements with those of the moving stimulus (in this case the robot avatar's arm). The movements of the robot avatar (master system) were defined online by means of a chaotic spring system,

$$
\begin{aligned}
& \dot{x}_{1}=x_{2}+C\left(p_{1}-x_{1}\right) \\
& \dot{x}_{2}=-\left(\omega \pi\left(\frac{x_{3}}{\alpha}+\beta\right)\right)^{2} x_{1}+C\left(p_{2}-x_{2}\right) \\
& \dot{x}_{3}=-x_{4}-x_{5} \\
& \dot{x}_{4}=x_{3}+\alpha x_{4} \\
& \dot{x}_{5}=b+x_{5}\left(x_{3}-c\right)
\end{aligned}
$$

with the $x_{3}, x_{4}$ and $x_{5}$ dimensions defining a standard Rössler attractor (Stepp, 2009). This attractor generates the chaotic dynamics used to define position of the ' $x$ ' and ' $y$ ' dimensions for a simple harmonic oscillator specified in $x_{I}$ and $x_{2}$. The resulting system maintains an elliptical trajectory over time while exhibiting chaotic fluctuations in amplitude and frequency. Nine sets of system parameters $a$, $b, c, \alpha, \beta, \omega$ and initial conditions $x_{1}, x_{2}, x_{3}, x_{4}$, and $x_{5}$ were selected for use based on support of the evolution of bounded chaotic behavior.

Generating this behavior online allowed us to introduce a coupling term, $C$, between the virtual robot avatar and the behavior of the human participant. This system included an influence of the ' $x$ ' coordinates of a participant's arm
movements, $p_{1}$, on the ' $x$ ' coordinates of robot avatar arm movements, $x_{I}$, as well as a symmetrical influence of the ' $y$ ' coordinates of participant arm movements, $p_{2}$, on the ' $y$ ' coordinates of the robot avatar arm movements, $x_{2}$. The weight of avatar-participant coupling was manipulated to allow for more or less influence of the movement of the participant on that of the robot avatar, resulting in three total coupling strength conditions ( $0, .025$, and .05 ). Feedback delays of $26.67^{1}, 200$, and 400 ms were introduced between the participant's movements and the movement of their virtual arm. The average movement frequency exhibited by the robot avatar for a given trial in this study was between .23 and $.30 \mathrm{~Hz}^{2}$. Trials lasted 60 s . The first 10 s and last 5 s of each time series were discarded to remove transients.

Experiment 2: Human (master) - Avatar (slave) Experiment 2 examined whether an artificial agent, as a slave system, could anticipate the chaotic movements of a human master system. Participants were initially asked to complete two training trials in which they were to synchronize with robot avatar movement defined by fully chaotic, 2-D movement sequences generated ahead of time (i.e., there was no influence of participant movements on robot avatar master system behavior). The same two chaotic robot avatar movement sequences ${ }^{3}$ were provided to all individuals. During these trials participants saw their own virtual arm within the environment at the minimum delay possible (i.e., 26.67 ms ). Each sequence lasted 100 s . For the remainder of the experiment participants were asked to continue making the same kinds of movements they had been making during the training period: "generally circular and always in the same direction, but somewhat unpredictable in terms of the speed and size of movements". They were also informed that they would be switching roles with the robot avatar, so that they were now the leader and the avatar would be coordinating with their movements. For these test trials the system of equations specifying the baseline slave behavior of the robot avatar consisted of a harmonic spring oscillator ${ }^{4}$

[^238]\[

$$
\begin{aligned}
& \dot{x}_{1}=x_{3}+C\left(m_{1}-x_{1 d}\right) \\
& \dot{x}_{2}=x_{4}+C\left(m_{2}-x_{2 d}\right) \\
& \dot{x}_{3}=-\omega x_{1} \\
& \dot{x}_{4}=-\omega x_{2}
\end{aligned}
$$
\]

As in the harmonic spring system used in the previous experiment, this system includes a coupling term, $C$, here to modulate the strength of coupling between the robot avatar and the ' x ', $m_{1}$, and ' y ', $m_{2}$, dimensions of a 2-D master system (i.e., human participant) behavior. This method of delay-coupling results in a function that incorporates the ' x ' and ' y ' dimensions of its' past behavior, $x_{I d}$ and $x_{2 d}$, into the terms that reference the velocity of movement in each of the ' $x$ ' and ' $y$ ' dimensions, $x_{3}$ and $x_{4}$, effectively constituting a feedback delay within the system (see Stepp \& Turvey, 2015; Voss, 2000). Here the past behavior being referenced, $x_{d}$, is always that which occurred at a constant, set length of time, $\tau$, prior to the current time point, $t$,

$$
x_{d}=x(t-\tau)
$$

The remaining terms in the system of equations responsible for robot avatar movement include the variable specifying spring stiffness, $\omega$, through interaction with the ' $x$ ' and ' $y$ ' position variables, $x_{1}$ and $x_{2}$. Two different values for the slave-master coupling term, $C$, were introduced within this system (1.5 and 2), and were treated as a between subjects variable such that participants either interacted with the avatar system coupled to them with the lower or higher strength. Five different delay latencies were also introduced within the robot avatar system as $\tau(26.67,106.64,199.95$, 306.59 , and 399.90 ms ). These coupling strengths and delay latencies were chosen based on preliminary simulations using a chaotic spring master system and the current harmonic spring oscillator slave system. Each delay latency was instituted once per participant, with the order of presentation randomized over the five test trials experienced by each participant. Each trial lasted a total of 60 s . As in Experiment 1, the first 10 s and last 5 s of each time series were discarded for analysis.

## Data Analysis \& Results

## Largest Lyapunov Exponent

Calculation of the largest Lyapunov exponent (LLE) provided an initial measure of the chaotic dynamics within master system movement time series (see Washburn et al., 2015 for details). Average LLE values of robot avatar movement sequences from Experiment 1 were all positive ( $\mathrm{M}=0.024, \mathrm{SD}=0.008$ ), indicating that the robot avatar exhibited consistent chaotic movement dynamics even when it was coupled to the coordinating behavior of the human participant. LLE values associated with human participant
behavior in Experiment 2 were also positive for all combinations of feedback delay latency and slave-master coupling conditions except one (feedback delay: 26.67 ms , avatar-actor coupling: 2.0 ) (overall $\mathrm{M}=0.034, \mathrm{SD}=0.046$ ), indicating that the participants produced reasonably consistent chaotic movement dynamics when acting as the master system.

## Cross-Correlation and Phase Lead

To evaluate whether anticipatory synchronization occurred between the slave and master systems in Experiments 1 and 2, we first performed a cross-correlation analysis. This analysis indexes the degree of synchrony between two behavioral time series across a range of possible temporal relationships (Stepp, 2009). Of relevance for identifying anticipatory synchronization is the maximum degree of synchrony that occurred (indexed by the maximum observed cross-correlation coefficient) and the corresponding time lag (or lead) at which the synchrony occurred.

Figure 1: Average maximum cross-correlation (left) and temporal lead/lag (right) between artificial agent and human participant movements for Exp. 1 (top) and 2 (bottom). Line graphs in this figure are presented as means $\pm$ SEM. $* p<$ .05; two-way analysis of variance (ANOVA), using Bonferroni post hoc comparisons.

The results of this analysis for Experiment 1 were very similar to those found in previous studies of human anticipatory synchronization (Stepp, 2009; Washburn et al., 2015). Namely, that although overall coordination decreased slightly with increases in perceptual-motor feedback delay, anticipatory synchronization was observed for delays
between 200-400 ms (Fig. 1, top). Interestingly, no significant differences in anticipation were observed for the different coupling strengths employed. This is also consistent with existing studies in agent-environment and interpersonal human coordination, indicating that the VR paradigm employed here is suitable for the continued investigation of human anticipatory synchronization during uni-directional and bi-directional slave-to-master coupling situations.

In Exp. 2, maximum cross-correlation analysis also revealed a decrease in coordination with increases in timedelay, here implemented within the artificial agent slave system (Fig. 1, bottom left). More importantly, increases in time-delay were associated with a progressive decrease in lag latency between the artificial agent and human participant, with the artificial agent achieving temporal synchrony with the human participant for the 399.90 ms delay latency (Fig. 1, bottom right).

## Instantaneous Relative Phase

To gain further information about the anticipatory coordination that occurred between the human and artificial agent, an analysis of the relative phase between the movements of the slave and master systems in each experiment was conducted. Relative phase captures the spatial-temporal patterning of the coordination that occurs between two movement time-series. Of particular relevance for the current study was the distribution of relative phase angles that occurred for each feedback delay condition (i.e., how often a particular relative phase relationship was observed between the coordinator and producer over the course of a behavioral trial), with peaks in the distribution indicative of the stability of the coordination (higher peaks $=$ higher stability) and the degree to which the slave system led or lagged behind the movements of the master system (Schmidt \& O'Brien, 1997).

IRP distributions for participant with respect to avatar movements in Experiment 1 consistently indicated the occurrence of intermittent leading and lagging behavior, with more frequent leading than lagging in all combinations of coupling strength and feedback delay conditions (see Fig. 2). This kind of intermittent, or relative, coordination is consistent with the coordinative dynamics exhibited during interpersonal anticipatory synchronization (Washburn et al., 2015), and characterizes weakly coupled physical or biological limit-cycle oscillators (see Kelso \& Ding, 1993), including visually coupled rhythmic limb movements of coacting individuals (Schmidt \& O’Brien, 1997). These distributions look similar across conditions with some decreased stability apparent in the 400 ms delay condition, especially when there was no coupling from robot avatar to participant. There also seemed to be less relative difference in the frequency of leading to lagging in both of the bidirectional coupling conditions as compared to the no coupling condition at the 26.67 ms feedback delay. There
were very few differences in these distributions between the low and high coupling strengths conditions examined.

Figure 2: Distribution of average instantaneous relative phase (IRP) values between artificial agent and human actor as a function of the coupling strengths and delay conditions examined in Experiment 1.

Consistent with the maximum cross-correlation results above, when the artificial agent slave system was coupled to the live human actor master system in Experiment 2, most combinations of feedback delays and coupling strengths were associated with the artificial agent lagging behind the human actor (see Fig. 3). There was in fact relatively more anticipation than lagging at the longest feedback delay in Experiment 2 (i.e., 399.90 ms ), but the overall stability the phase relationships at this delay was reduced in comparison to the shorter delays. It is important to keep in mind that both the IRP frequency distributions and the maximum cross-correlation analysis represent average phase and temporal relationships between the artificial agent and the master system to which it is coupled. Furthermore, a participant-wise examination revealed that the artificial agent achieved anticipation for three of the eight participants in the 1.5 coupling strength condition, and five of the nine participants in the 2.0 coupling strength condition. This provides strong support for the idea that the kind of artificial agent developed and tested here can produce adaptive, prospectively coordinated behavior during ongoing, bi-directionally coupled interaction with a human actor.

## Discussion

The current project extends a rapidly emerging line of work investigating the process of coordination and self-organized
anticipatory synchronization during human-human and human-machine interaction. The findings of Experiment 1, demonstrated that anticipation similar to that observed during interpersonal interaction is also exhibited by human actors with respect to a chaotically behaving virtual coactor. Experiment 2 used the same novel VR paradigm to evaluate the anticipatory abilities of time-delayed artificial agent during interaction with a human co-actor. The movements of this artificial agent were defined by a low dimensional, harmonic oscillator system, coupled to the real-time behavior of the human co-actor. The results of this experiment revealed that the addition of feedback delays reduced the degree to which the avatar lagged behind the human actor.

Figure 3: Distribution of average instantaneous relative phase (IRP) values between human participant and robot avatar for coupling strengths of 1.5 (left) and 2.0 (right) and in each feedback delay condition examined in Experiment 2.

It is important to appreciate that while the addition of feedback delays in the artificial agent only, on average, reduced the lag between artificial agent and the human coactor, this should not be taken to indicate that the current agent is ill-suited to achieving self-organized anticipatory synchronization during human-machine interaction. The fact that human actors are intentional agents means they likely exhibited some adaptation to the artificial agent during interaction even though they were instructed to focus on producing their own movements and simply allow the avatar to follow them. This could account for the finding that the artificial agent only consistently achieved more anticipation than lagging of the human co-actor in the context of the longest time-delay. Furthermore, the patterns of intermittent anticipatory coordination observed in Experiment 2 were still quite similar to those seen in instances of interpersonal anticipatory synchronization, suggesting that small feedback delays in artificial agents induce a coordinative dynamic analogous to natural to human-human interaction.

Indeed, overall the current findings present a potentially transformative advance in the development of artificial agents and HRI. An agent defined by a low-dimensional dynamical model was able to display adaptive, anticipatory coordination during real time interaction with a human actor performing complex, seemingly unpredictable movements. The coordinative patterns exhibited by this agent were analogous to those observed during the occurrence of visual-motor agent-environment and interpersonal anticipatory synchronization in humans. This supports the idea that the dynamical models employed in the current research capture universal properties intrinsic to many physical systems, including complex biological behaviors like the human neural and movement processes that exhibit the kind of unpredictable determinism characteristic of chaos (e.g., Mitra et al., 1997). In displaying behavior that is qualitatively similar to human individuals the artificial agent developed here is likely capable of not only participating in the kind of interpersonal coordination known to support the successful completion of many everyday human tasks, but also engendering some of the associated increases interpersonal rapport and the facilitation of social awareness found following behavioral coordination between individuals (e.g., Miles et al., 2011). The current outcomes therefore suggest that engaging in coordinated interaction with such agents in the process of some higher order task goal will not only allow for more successful and efficient interactions during a wide variety of tasks, but may also result in the kinds of positive social outcomes associated with naturally occurring human interaction.

# Structure Learning in Motor Control: A Deep Reinforcement Learning Model 

Ari Weinstein (ariweinstein@google.com)<br>Deepmind, London, UK<br>Matthew M. Botvinick (botvinick@google.com)<br>Deepmind, London, UK<br>Gatsby Computational Neuroscience Unit, University College London

#### Abstract

Motor adaptation displays a structure-learning effect: adaptation to a new perturbation occurs more quickly when the subject has prior exposure to perturbations with related structure. Although this 'learning-to-learn' effect is well documented, its underlying computational mechanisms are poorly understood. We present a new model of motor structure learning, approaching it from the point of view of deep reinforcement learning. Previous work outside of motor control has shown how recurrent neural networks can account for learning-to-learn effects. We leverage this insight to address motor learning, by importing it into the setting of model-based reinforcement learning. We apply the resulting processing architecture to empirical findings from a landmark study of structure learning in targetdirected reaching (Braun et al., 2009), and discuss its implications for a wider range of learning-to-learn phenomena.

Keywords: motor adaptation; reinforcement learning; learning to learn; structure learning; system identification

## Introduction

Learning can be defined as a process that improves performance as exposure to a task increases. However, research on human and animal learning makes clear that this simple definition is not quite enough to explain the observed relationship between experience and performance. The full picture must also include 'learning-to-learn,' a process whereby growing experience causes learning itself to become more efficient (Harlow, 1949). More specifically, learning-to-learn (also referred to as meta-learning and structure learning) occurs in settings where the learner encounters a series of tasks that share some underlying structure, and gains from these an ability to quickly adapt to a new task that displays the same general form (Thrun \& Pratt, 1998).

A vivid example of learning-to-learn, which provides a concrete focus for the present research, comes from research on motor adaptation. Many studies have documented the ability of human subjects to adapt to perturbations of motor dynamics or kinematics, as for example in prism adaptation (Harris, 1963). However, a series of studies by Braun and colleagues (Braun et al., 2009, 2010; Braun \& Wolpert, 2012) went beyond this to show that adaptation can occur faster when the subject has prior exposure to perturbations that share structure with the final test conditions. In one specific experiment, upon which we will continue to focus, Braun and colleagues (2009) studied reaching under visuomotor rotation. They examined the speed with which targetdirected reaching adapted to a 60-degree rotation, manipulating between subjects the content of a preceding set of training
trials. In one condition, which we will refer to as Rot, subjects dealt with a series of rotations (though never the one presented at test). In a comparison condition Rot+, subjects dealt with a more diverse set of transformations, each made up of a rotation along with shear and scale components. Results showed that subjects in the Rot group adapted faster to the probe rotation problem (Figure 1). Braun et al. (2009) interpreted this as learning-to-learn effect, which they referred to as "motor structure learning": Subjects in the Rot group evidently learned that the transformations being presented were restricted to a particular structurally coherent set (rotations), and this allowed them to infer and adapt rapidly to the probe transformation. This structure learning was less feasible in the Rot+ condition because the structure underlying the training set was more complex, thus offering weaker constraint on inference when facing a new transformation.

In the present study, we consider the computational mechanisms underlying motor structure learning, treating it as a case study in learning-to-learn. Despite widespread agreement that learning-to-learn effects are both real and important, the precise computational processes underlying such effects are poorly understood. The most widely proposed idea comes from a Bayesian perspective, and proposes that learning-to-learn involves refining the structure and hyperparameters of a generative model of the relevant task domain (Lake et al., 2015). Braun and colleagues initially proposed, and later investigated (Genewein et al., 2015) a model of this sort to account for their structure learning results.

A different computational proposal, which has been less widely considered in cognitive science, comes from neural network or deep learning research. In classic work, Hochreiter and colleagues (2001) showed how a recurrent neural network (RNN) can learn to learn, by integrating information about past outcomes into predictions concerning new observations. Recent applications of this idea (Wang et al., 2016; Duan et al., 2016) have treated the RNN in Hochreiter's scheme as a mechanism for directly selecting actions. In the present work, we leverage Hochreiter's (2001) insight in a different way, using an RNN as an adaptive model of the task domain, which is leveraged by a separate actionselection mechanism. In this sense, the aim of our work is to bridge Bayesian and deep learning perspectives on learning-to-learn. On a more immediate level, we show how the resulting approach can be used to account for the findings of Braun

Figure 1: Results redrawn from Braun et al.(2009), showing mean cumulative error on a series of five reaches under a 60degree visuomotor rotation.
and colleagues (2009) in motor adaptation.
The motor control literature suggests that actions such as reaching are based, at least in part, on an internal predictive or forward model of reaching dynamics (Wolpert et al., 1995; Miall \& Wolpert, 1996), and analyses of motor adaptation have portrayed adaptation as reflecting a progressive adjustment of this internal model to fit with current observations (Berniker \& Kording, 2008; Haith \& Krakauer, 2013). Following this idea, and a great deal of previous work in computational motor control, we construe action selection as a form of model-based reinforcement learning (RL).

Formulating the problem in this way begins by casting it as a finite-time Markov decision process (MDP) $M$, which is made of a set of states $S$, a set of possible actions $A$, a transition function $\mathcal{T}$, and reward function $R$ (in many settings a discount factor $\gamma$ is included, but since we formulate the task as a finite-time problem this is unnecessary). The goal is to select actions that maximize the cumulative reward up to some time $T$ : $\sum_{t=0}^{T} r_{t+1}$, where $t$ indexes discrete time steps up to some maximum $T$, and $r_{t}$ is the reward received on each step. Focusing on target-directed reaching, the task studied by Braun and colleagues (2009), the problem is defined as follows: $M$ is the entire reaching task; $S$ are possible arm configurations; $A$ are possible motor inputs; $\mathcal{T}$ defines the dynamics of the arm based on motor inputs; $R$ is the negative distance from the cursor to the target. In order to be consistent with the literature on structure learning in motor control, we will use the terms reward maximization and penalty (or error) minimization interchangeably.

In model-based RL, a model $\hat{M}$ of the environment $M$ is built, and then used by a planner $P$ in order to construct an action-selection policy. The general form of a model-based learning architecture is diagrammed in Figure 2, left. Here a planner $P$ is informed of a current state $s$ by the true MDP $M$. Based on the particular policy of $P$, the planner queries the model $\hat{M}$ with a series of state-action pairs $\left(s_{t}, a_{t}\right)$, and in turn receives an estimated next state $s_{t+1}$ and reward $r_{t+1}$. After the planner completes querying $\hat{M}$, either because it has

Figure 2: Model-based reinforcement learning with a fixed model (left) and an adaptive model (right).
taken as much data as it needs or due to some outside pressure such as a time limit, it returns an action $a$ which is executed in $M$, which results in a new state and reward and the process repeats.

In the architecture shown in Figure 2 (left), one way of implementing the forward model $M$ is as a feed-forward neural network. This approach has been explored in a number of previous studies (Jordan \& Rumelhart, 1992; Hamrick et al., 2016). However, a feed-forward neural network will not suffice to address the learning-to-learn phenomena we are concerned with here. Indeed, the overall architecture must be fundamentally changed in order to address the learning-tolearn problem.

As introduced earlier, learning-to-learn arises in a setting where the learner encounters a series of interrelated problems or tasks, and must adapt to each one in turn. Using our terminology, each task $M_{n}, n=1 \ldots N$ becomes a sample from a task distribution $\mathbb{M}$. As such, the properties of each $M_{n}$ must be inferred based on observed action-outcome pairs (a process referred to in the engineering literature as system identification). On a formal level, this demand changes the MDP we have been considering into a partially observable Markov decision process (POMDP). By definition, a POMDP is an MDP which additionally has an observation space $O$ and observation function $\Omega$ which takes its internal state and outputs an observation $o$ to the agent. Instead of the true state, an agent only has access to observations, which unlike state, is generally insufficient to act optimally when considered in isolation. In order for $\hat{M}$ to adjust to each $M_{n}$, it must have some form of memory $\alpha$ to keep a relevant summary of interactions with the environment, allowing for integration over previous timesteps in order to accurately estimate problem dynamics.

These requirements yield the interaction and planning structure diagrammed in Figure 2 (right). Instead of states $s$, information presented is in terms of observations $o$. The model $\hat{M}$ must now directly consume $o$ and $r$ from $M_{n}$ at every time step, which causes it to update its memory $\alpha . P$ now only passes a sequence of actions along trajectories to the model. This is because it does not have access to the
true state, and because observations alone are not sufficient for planning or modelling ${ }^{1}$. Additionally, during the planning trajectories, the $P$ must signal to $\hat{M}$ when its evaluation of a simulated trajectory is complete so that $\alpha$ can be reset (omitted from figure for clarity).

Note that, unlike in the simpler MDP, in the POMDP setting the internal model $\hat{M}$ cannot be accurately implemented as a feed-forward neural network, because such networks do not have memory or persistent internal state. The key move in the present work is to substitute for the feed-forward network a RNN, whose recurrent connectivity endows it with the memory needed to support system identification and, as we will show, learning-to-learn.

## Simulation Study

We predicted that the proposed architecture, if trained in an appropriate multi-task setting, would display learning-tolearn, leveraging experience with past tasks to adapt rapidly to a new task sharing in the same structure. In order to test this idea, we applied the architecture to the task paradigm employed in they study of motor structure learning by Braun and colleagues (2009).

## Model implementation and task design

We implement the architecture shown in Figure 2 (right), instantiating the forward model in the form of a recurrent neural network (which is naturally deep as it is unrolled over time). More specifically, this involves one LSTM layer (Hochreiter \& Schmidhuber, 1997) followed by two more fully connected layers containing rectified linear units (Nair \& Hinton, 2010), where each layer contains 100 units. The planner is an open-loop planner based on cross-entropy optimization, as described in Weinstein \& Littman (2013), with the addition of "warm starting." In warm starting, planning is done from scratch on the first step of a trajectory, but all subsequent steps in the actual domain initiate planning with the result from the previous step. At each time step only the first action in the current plan is executed in the true domain before partial replanning in this manner occurs. For simplicity, we assume (without loss of generality) that $\hat{M}$ has access to the reachtarget coordinates and can compute the reward function.

In order to model target-directed reaching, we implemented a simple arm model. While not intended to offer a detailed model of biomechanics, this was intended to capture the most important aspects in terms of possible arm geometry, velocity, and acceleration (Nagasaki, 1989). As simulated, the underlying state space of the problem has four dimensions: horizontal shoulder angle, elbow angle, and corresponding angular velocities. Observations emitted are the Euclidian position of the cursor controlled by the arm's tip as seen in the experiment (meaning that $\hat{M}$ must also learn to

[^239]estimate velocities), and the goal. The two dimensional action space sets the angular accelerations of the joints, and the reward is the negative Euclidean distance of the cursor from the center of the goal region.

In the reaching task, the cursor is always initialized at the origin and is controlled by the transformation of the underlying position of the simulated hand. Before each trial a goal location is selected which is set to be 8 cm from the origin at a uniformly distributed angle.

## Training and testing procedure

The simulation study, like the experiment by Braun et al. (2009) was divided into training and testing phases. During training, the RNN model was trained to predict each sequential outcome observation exactly along a trajectory consisting of observations and randomly selected actions, that is, following a random walk. Again as in the empirical study, two versions of the model were trained in different environments. One model, which we label (in a minor abuse of terminology) Rot, was trained on a series of visuomotor rotations, simulated by appropriately transforming the observed cursor coordinates. The second model instance, Rot + , was trained on a combination of rotations, shears, and scales (following the design described in Braun et al., 2009, Supplemental Data). Following the design imposed by Braun and colleagues, when the rotation to be presented to Rot + fell between $\pm 50^{\circ}$ and $70^{\circ}$, a rotation of $\pm 60^{\circ}$ was substituted and no linear transform was applied. As a result, both Rot and Rot+ had roughly equal exposure to the transformation used during test trials. In both conditions, the model was trained by backpropagation through time on 2,000 trajectories of random-walk data, with each trajectory containing three seconds of simulation time, and training starting from the initial observation of each trajectory.

In the testing phase the RNN weight parameters were frozen and reaches were elicited only under only pure rotations of $\pm 60^{\circ}$, as in the testing phase of the experiment by Braun and colleagues. Goal locations were placed at a randomly selected angle 8 cm from the start location of the cursor. The radius of the goal region is 1.6 cm . In order to simulate a series of reaches, the angle of the imposed visuomotor rotation was held constant while the position of the goal varied between reaches. Test reach trajectories ran for a maximum of two seconds, terminating early if the cursor was brought within the goal region for 500 ms .

## Results

Training of models for both the Rot and Rot + conditions were successful, but the model trained on Rot was able to achieve an average error of about 0.002 cm per time step for trajectories in the training set, while Rot + an error of about 0.03 cm by the same metric. In the Rot condition, the RNN model learned to act as an adaptive forward model, adjusting its predictions to fit with accumulating action-outcome observations. Figure 3 shows the average observation-prediction errors of both Rot and Rot+ models during an initial random-

Figure 3: Model errors by step in initial trial.
walk trajectory which was not part of the training set. The initial data-point is the error of the model prior to any experience in the test MDP. In interpreting the values on the $y$-axis of the plot, it should be taken into account that in our simulation two seconds of time takes 28 discrete time steps, and error compounds over these steps. In contrast to the Rot model, the Rot+ model adapts much less successfully, despite having been trained on an identical amount of data.

Figure 4 shows the mean cumulative penalty when the model is coupled with a planner, for each reach at test for both models. This is intended for comparison with the empirical data from humans in preceeding work shown in Figure 1. As predicted, Rot is better able to conduct structure learning, by adapting more rapidly and completely to the test rotation (the manipulation both models were exposed to during training) than Rot+. This qualitatively replicates the experimental findings from Braun et al. (2009).

Figure 5a shows average trajectories for five successive reaches (normalized by rotation and goal angles), for both Rot and Rot+ models. Both models adapted across reaches (starting with smaller initial angular errors after the initial reach), but the effects were stronger in the Rot model. Quite striking is the standard deviation of the final position of the first trial of Rot, and Rot+ in cyan and magenta, respectively. Although on average Rot+ tracked toward target, there is a tremendous amount of variability in its trajectories, and was not able to consistently reach the goal region, whereas Rot usually terminated within the target.

We also consider other indirect metrics of performance which are presented in the human studies such as initial angular error, velocity, and minimum distance to goal region, which are presented in Figures 5b through 5d, respectively. In general the results with these metrics are similar to the previous plots, with Rot improving quickly and performing better than Rot+. We also note the higher variance of Rot+, which manifests itself in wider confidence intervals across all Figures, especially Figure 5d. These results are qualitatively aligned with those reported in the experimental study.

In fact, of these metrics, the only one which shows improvement by Rot+ is the initial angular error. Even with

Figure 4: Average cumulative penalty by trial.
this improvement, the agent frequently falls short of reaching goal region (which would allow for an early termination of distance penalties). This is most likely due to the fact that on average testing data in Rot + has a scaling amount of roughly 1.3 (this design is part of the original human study), and indeed Rot+ almost uniformly tells the planner that actions will result in greater changes in location than actually occur.

Although Rot+ was less effective at structure learning than Rot, it is not the case that it failed entirely. The average penalty of a trajectory for agent using a uniform random policy is approximately 220 units which is significantly poorer than what Rot+ was able to achieve.

We note that our goal was not to fit the results from the human data quantitatively, but rather to demonstrate the same phenomenon which is that structure learning becomes more difficult as the the amount of variability in the problem increases. And although Rot + was not able to perform well, the overall architecture does have the capacity to do effective structure learning; expanding the data corpus size by a factor of five produces models that have statistically equal, high quality performance on test tasks for both Rot and Rot+.

## Discussion

Learning-to-learn is a fundamental aspect of human behavior, but its computational basis is not yet well understood. We have presented a new model of learning-to-learn in the setting of motor adaptation. This task, defined by Braun and colleagues (2009) involves learning to learn in the sense that the subject must gather data on a current situation in order to infer the hidden parameters of the dynamics, and indeed Braun and colleagues state that learning to learn can be recast as structure learning. On the other hand, a stronger definition of learning to learn could require learning to adapt to a situation it has not experienced in the past, perhaps in terms of new objects to interact with that follow some prelearned rules (Harlow, 1949). This has been considered in a different simulated setting in RL where the agent learns policies (Wang et al., 2016), as opposed to models of the environment as is done here.

Adopting the standard approach, we assume that motor

Figure 5a: Average trajectories by trial. Standard deviation of final position of first trial in shaded region. Goal region in black.

Figure 5c: Average velocities by trial
adaptation involves updating an internal forward model of reaching dynamics. Our novel contribution is to instantiate this internal model as a recurrent neural network. Through simulations of a key experimental study, we have shown that the resulting system not only learns to adapt to changing perturbations, but also that its adaptation becomes more effective when there is prior exposure to structurally related conditions, as seen empirically in motor structure learning. Importantly, no special measures were required in order to secure this learning-to-learn effect. Through error-correcting learning, the parameters of the RNN are, perforce, fit to the structure of the pre-training data. That same structure is thus naturally - indeed inevitably - expressed in its later inferences at test.

We consider learning to learn as refining a (potentially implicit) hypothesis set based on experience. If the problem has a large underlying dimension, then the hypothesis set learned by the model must be of corresponding size. This is in turn fundamentally linked to the amount of data required to both train the model, as well as do inference, accurately. For these reasons, it is to be expected that when comparing the data requirements of doing both in Rot versus Rot + , Rot leads to lower data requirements. Just as is the case with Braun and colleagues (2009), we do not attempt to disentangle these issues, although a more detailed investigation warrants future

Figure 5b: Average angle error from goal after 200 ms of simulated time.

Figure 5d: Average minimum distance to goal by trial
attention.
As noted earlier, our use of RNN dynamics to capture learning-to-learn effects builds directly on pioneering work by Hochreiter and colleagues (2001), in which an RNN model was applied to the problem of function induction (see also Wang et al., 2016; Santoro et al., 2016). In contrast to that work, we deployed our RNN as a forward model situated within a larger model-based RL system. In this sense, our implementation bridges between Hochreiter's original proposal and models of motor adaptation that have embedded an adaptive Bayesian model of limb dynamics (e.g. Berniker \& Kording, 2008; Genewein et al., 2015). The approach we have introduced also relates to other work in which RNNs have been used as forward models in support of motor adaptation, but where multiple fixed models are assumed (Haruno et al., 2001; Pitti et al., 2013), rather than a single adaptive model used here. These fixed models lack memory, meaning that reweighing fixed models aside, adaptation is only possible by retraining the system. Implicitly, our work implements a sort of Kalman filter which has also been considered previously in recurrent networks (Wolpert et al., 1995). Undertaking a careful comparison between these related approaches and the one we have introduced here offers an important objective for next-step research.

Our implementation of the reaching task was deliberately minimal, simplifying both the underlying biomechanics and the motor planning process, in order to foreground our central computational proposal. Naturally, a more detailed evaluation of the approach, incorporating a higher degree of empirical constraint, will be desirable in further evaluating the viability of our approach as a theory of motor adaptation. A related opportunity is to consider the potential parallel between the recurrent connectivity underlying the function of our adaptive model and the recurrent connectivity inherent in biological neural circuits underlying motor control and adaptation, including circuits running through the basal ganglia and cerebellum.

At the same time, however, we feel it may also be fruitful to apply the model-based framework we have introduced here in domains beyond motor control, in particular other domains that display the characteristics of a POMDP and where learning-to-learn effects have been observed. Such tasks are indeed ubiquitous, ranging from structured bandit tasks to video-game play (Wang et al., 2016; Lake et al., 2015). To the extent that the framework we have presented here can be adapted and (more challenging) effectively scaled to these other settings, it offers to provide a more general new perspective on the problem of learning-to-learn.

## Acknowledgements

We would like to thank Daniel Braun and Konrad Kording for valuable feedback.

#### Abstract

We investigated children's understanding of mental life by analyzing attributions of perceptual, cognitive, affective, and other capacities. 200 children ( $7-9 \mathrm{y}$ ) and 200 adults evaluated the mental capacities of beetles or robots. By assessing which capacities traveled together when participants disagreed about these controversial "edge cases," we reconstructed the latent structure underlying mental capacity judgments from the bottom up-a novel approach to elucidating conceptual structure among children. For both children and adults, factor analyses revealed a distinction between social-emotional, physiological, and perceptual-cognitive capacities, hinting at three fundamental ways of explaining and predicting others' actions: as social partners, biological creatures, and goaldirected agents (each involving related forms of both "experience" and "agency"; Gray et al., 2007). Relative to adults, children attributed greater social-emotional capacities to beetles and robots, suggesting that intuitive ontologies of mental life could be critical for making sense of children's developing understanding of the social world.

Keywords: mind perception; sentience; animate-inanimate distinction; cognitive development.

## Introduction

Questions about the nature of mental life extend back to antiquity, but it is only recently that cognitive scientists have begun to explore lay people's conceptions of the mind.

One particularly exciting approach was pioneered by Gray, Gray, and Wegner (2007) in their work on mind perception. From participants' responses to simple questions about the mental capacities of various characters (e.g., "Which is more capable of experiencing joy: a frog or an infant?"), Gray et al. extracted a conceptual space characterized by two dimensions: "experience," the extent to which a character is capable of hunger, fear, pride, and other inner experiences; and "agency," the extent to which a character is capable of self-control, morality, memory, and other capacities central to acting in the world.

This bottom-up approach has tremendous potential in elucidating the kinds of deep conceptual structures that are difficult for participants to report on directly (and for experimenters to anticipate a priori). Rather than imposing theory-driven categories onto participants' responses, Gray et al. (2007) let the data speak for themselves.

However, Gray et al.'s (2007) study focused participants' attention on the similarities and differences between characters, thus illuminating the dimensions along which social beings are thought to differ from each other-an important part of social reasoning, but not equivalent to intuitions about the structure of mental life itself.

Inspired by their approach, we recently conducted a series of studies designed to assess intuitive ontologies of mental life directly (Weisman, Dweck, \& Markman, 2016). We focused participants' attention on the connections and divisions between different aspects of mental life by asking them to evaluate a wide variety of mental capacities for a single character (e.g., a robot or a beetle). By analyzing patterns of attributions across participants, we uncovered a 3-part conceptual structure that emerged reliably across several studies: Physiological sensations and self-initiated behaviors hung together to form a suite of capacities related to the body; social-emotional experiences and moral agency formed a suite of capacities related to the "soul"; and perceptual-cognitive abilities and goal pursuit formed a suite of capacities related to the mind. Interestingly, each of these three factors encompassed aspects of both "experience" and "agency." Instead of the broad distinction that seems to characterize adults' understanding of social beings (Gray et al., 2007), adults' understanding of the structure of mental life itself seems to hinge on distinctions among varieties of experience and agency, and connections among related kinds of experience and agency.

Intuitions about mental life are at the core of many of the oldest and richest lines of research in developmental psychology, including animism (Piaget, 1929), lay biology and psychology (Carey, 1985), and theory of mind (Wellman \& Woolley, 1990). But most of this work has relied on a priori distinctions between perception, desires, emotions, intentions, beliefs, knowledge, etc. (Flavell, 1999), leaving the actual conceptual structure underlying children's reasoning and behavior unknown; to our knowledge, there have been no attempts to map out the ontology of mental life from the ground up with children. This may be due in part to the challenges of implementing bottom-up approaches, which generally require hundreds of participants to answer dozens of questions-not the typical design for studies with young children. On the other hand, studies like Gray et al. (2007) and Weisman et al. (2016) are built on the premise that these complex conceptual structures can be uncovered from participants' answers to relatively simple questions, suggesting that this approach might lend itself to adaptation for younger participants.

Thus, in the current study we developed a bottom-up approach for uncovering children's intuitions about the structure of mental life. We believe these intuitions are critical for making sense of children's social and moral reasoning about the people, animals, and other social partners in their lives.

## Study

We based our experimental paradigm on our previous work with adults, in which participants evaluated a target character on 40 mental capacities using a 7 -point scale from not at all capable to highly capable. Pilot testing suggested two necessary modifications for children: rewording some of the mental capacity items, and using a 3-point response scale (no, kinda, yes). Although a 3-point scale is not optimal for factor analyses, it allowed children to move fast enough through the study to answer all 40 questions, and maintaining this within-subjects design was our top priority for the planned factor analysis.

As in our previous work, we focused on judgments of the mental capacities of two "edge cases" in social reasoning: a beetle and a robot. Because beetles are animals and robots are artifacts, this pair provides insight into the role of biological life in attributions of mental life-an issue of particular interest from a developmental perspective, given the long history of work on the development of the animateinanimate distinction and its relation to folk psychology. Most critically for our bottom-up approach to uncovering intuitive ontological structures, the "mental lives" of these entities are controversial: People differ in their assessments of the mental capacities of beetles and robots (Weisman et al., 2016). This allowed us to address the following question: When children disagree about the mental capacities of some entity, which capacities "go together"?

Pilot testing suggested that children as young as 7 y found the paradigm easy and enjoyable, and work on the development of lay biology and psychology has suggested that these concepts may continue to develop well into middle childhood (e.g., Carey, 1985; Hatano \& Inagaki, 1997; Piaget, 1929; cf. S. Gelman \& Opfer, 2002). Thus, we targeted 7- to $9-y$-old children for our child sample.

We also recruited a group of adults to validate our childfriendly paradigm, i.e., to evaluate whether it replicated our earlier work with adults (Weisman et al., 2016).

## Methods

Participants. 400 people participated in this study.
Children ( $n=200$ ) participated at one of several Bay Area museums or at their younger sibling's preschool (median study duration: 5.18 min ). Children ranged in age from $7.0-$ 10.0 y (median: 8.3 y ). An additional 12 children participated but were excluded for being outside the target age range ( $n=7$ ), being of unknown age ( $n=4$ ), or being shown a target character other than a beetle or a robot $(n=1)$.

Adults ( $n=200$ ) participated via MTurk. Adult participants had gained approval for $\geq 95 \%$ of previous work on MTurk; had verified accounts based in the US; and indicated that they were $\geq 18 y$ old. Adults were paid $\$ 0.30$ (median duration: 2.48 min ). Repeat participation was prevented.

Materials and procedure. Participants were randomly assigned to evaluate one of two target characters: a beetle, accompanied by a photograph of a black beetle on a leaf
( $n=98$ adults, 104 children), or a robot, accompanied by a photograph of a humanoid robot (Sony Qrio; $n=102$ adults, 96 children). The picture and label (a beetle or a robot) were present throughout the survey.

Instructions focused on the idea that we wanted to know what participants thought "[beetles/robots] can do and can not do." Participants rated the target character on 40 mental capacities, presented in a random order for each participant. On each trial, participants responded no, kinda, or yes to the question "Do you think a [beetle/robot] can...?"

The 40 mental capacities were designed to be as close as possible to those in our previous studies (Weisman et al., 2016) while being comprehensible to children in early elementary school. This set of items included physiological sensations related to biological needs (e.g., get hungry); emotional experiences (e.g., feel happy); perceptual abilities (e.g., hear sounds); cognitive abilities (e.g., remember things); capacities related to autonomy or agency (e.g., decide what to do); social abilities (e.g., feel guilty); and several additional items (e.g., be aware of itself). Each of these a priori categories included at least five items of varying valence, complexity, and phrasing (see Table 1).

We also prepared a short definition for each item, so as to be consistent in our responses to participants if they asked for clarification. Children were encouraged at the beginning of the study to ask questions if they did not know what a word meant, in which case they given these definitions; adults were told that they could access these definitions by hovering over the text. Pilot testing suggested that 7 items required clarification for most children, so these items were always accompanied by their definitions from the beginning of the trial (for both children and adults), as follows: have a personality, like when someone is shy and somebody else is silly; have beliefs, like when you think something is true; feel pleasure, like when something feels really good; have desires, like when you really want something; have selfcontrol, like when you stop yourself from doing something you shouldn't do; have goals, like when you're trying hard to do something or make something happen; and feel sick, like when you feel like you might throw up.

Data preparation. We scored responses of no as 0 , kinda as 0.5 , and yes as 1 . We dropped trials with response times that were faster than a preset criterion of 250 ms ( $n=3$ child trials, 97 adult trials) and retained participants regardless of skipped trials ( $n=55$ child trials, 1 adult trial). Overall, only $1 \%$ of adult trials and $1 \%$ of child trials were missing data.

Analysis plan. Our primary goal was to determine which mental capacities go together: e.g., if a participant indicated that a character was capable of hunger, what other capacities did she endorse? To do this, we used exploratory factor analyses (EFA) to reveal the covariance structure underlying participants' responses, collapsing across characters and using Pearson correlations to find minimum residual solutions. We first examined maximal (13-factor) unrotated solutions to determine how many factors to extract, using
the following preset retention criteria: Each factor must have an eigenvalue $>1.0$; individually account for $>5 \%$ of the total variance; and be the "dominant" factor (the factor with the highest factor loading) for $\geq 1$ mental capacity item. We focus our interpretation on varimax-rotated solutions, extracting the number of factors that met these criteria. (Using polychoric correlations and/or oblimin rotation yielded similar latent structures.)

## Results and Discussion

We first assess the validity of our child-friendly paradigm relative to our previous work with adults by examining an EFA of adults' responses. We then address our primary question-children's intuitions about the structure of mental life-via EFA of children's responses. Finally, we analyze differences in factor scores between children and adults.

EFA: Adults. EFA revealed 3 factors that met our criteria.
After rotation, the first factor corresponded primarily to physiological sensations related to biological needs. It was the dominant factor for such items as get hungry, do math (negative loading), feel pain, feel scared, and feel tired. Factor 1 accounted for $25 \%$ of the variance in the rotated maximal solution.

The second factor corresponded primarily to capacities for self- and other-relevant emotions. It was the dominant factor for such items as feel joy, feel proud, feel sad, feel happy, and feel love. Factor 2 accounted for $21 \%$ of the variance in the rotated maximal solution.

Finally, the third factor corresponded primarily to perceptual-cognitive abilities to detect and use information about the environment. It was the dominant factor for such items as recognize somebody else, figure out how to do things, remember things, sense whether something is close by or far away, and communicate with somebody else. Factor 3 accounted for $10 \%$ of the variance in the rotated maximal solution. (See Table 1 for all factor loadings.)

In sum, as in our original studies (Weisman et al., 2016), a three-factor structure emerged from adults' mental capacity attributions, characterized by a distinction between physiological, social-emotional, and perceptual-cognitive abilities. This suggests that our child-friendly paradigm was valid: Using reworded items and a 3 -point response scale elicited the same intuitive ontology of mental life, among adults, as revealed by our "adult-friendly" paradigm.

EFA: Children. Again, 3 factors met our retention criteria.
After rotation, the first factor corresponded primarily to social-emotional abilities. It was the dominant factor for such items as feel proud, feel happy, feel joy, get hurt feelings, and feel sad. Factor 1 accounted for $25 \%$ of the variance in the rotated maximal solution.

The second factor corresponded primarily to physiological sensations. It was the dominant factor for such items as get hungry, feel pain, do math (negative loading), smell things, and feel scared. Factor 2 accounted for $18 \%$ of the variance in the rotated maximal solution.

The third factor corresponded primarily to perceptualcognitive abilities. It was the dominant factor for such items as be aware of itself, figure out how to do things, be aware of things, sense whether something is close by or far away, and sense temperatures. Factor 3 accounted for $7 \%$ of the variance in the rotated maximal solution.

In sum, like adults, children's mental capacity attributions were dominated by a 3-way distinction between socialemotional, physiological, and perceptual-cognitive abilities.

Note that a number of additional or alternative latent factors could have emerged from this analysis. For example, children might have distinguished primarily between internal experience and external action (Gray et al., 2007), or they might have demonstrated finer-grained groupings of mental capacities based on phrasing, rote knowledge, etc. Instead, the latent conceptual structure underlying children's responses appears to be very similar to that of adults.

Children vs. adults. To formally compare responses from children and adults, we considered the full, combined dataset and examined factor scores by age group.

EFA using the combined dataset revealed three factors that met our retention criteria. Unsurprisingly, these three factors were very similar to those revealed for adults and children analyzed independently: They corresponded to social-emotional abilities, physiological sensations, and perceptual-cognitive abilities (see Table 1).

The purpose of this combined EFA was to examine differences in adults' and children's evaluations of beetles and robots within this 3-part structure. To do so, we derived factor scores (via the ten Berge method) using the rotated 3factor solution. This yielded 3 scores for each participant, corresponding, in principle, to holistic judgments of the social-emotional, physiological, and perceptual-cognitive abilities of the target character the participant evaluated. (Note that each of these 3 scores takes into account factor loadings for all 40 mental capacities, as listed in Table 1.)

This allowed us to examine the effects of age group (adult, child), character (beetle, robot), and factor (socialemotional, physiological, perceptual-cognitive) on these scores via mixed effects linear regression. See Table 2 for the results of a maximal model and Fig. 1 for mean scores.

Collapsing across age groups and domains (physiological, social-emotional, and perceptual-cognitive), factor scores suggest that participants generally attributed fewer mental capacities to the robot than the beetle $(b=-0.25)$. However, this appears to be entirely due to the huge discrepancy between characters in the physiological domain; the difference between characters was reduced to nothing in the social-emotional domain ( $b=0.26$ ), and reversed in the perceptual-cognitive domain ( $b=0.39$ ). Collapsing across entities (beetle, robot), children tended to attribute more mental capacities adults ( $b=0.19$ ), but this was driven primarily by the social-emotional domain ( $b=0.46$ ), and was reversed in the perceptual-cognitive domain ( $b=-0.30$ ).

Scores in the physiological and perceptual-cognitive domains were very similar for children and adults: Both

Table 1: Factor loadings from exploratory factor analyses for adults alone ( $n=200$ ), children alone ( $n=200$ ), and the combined dataset. Loadings are from 3-factor varimax-rotated minimum residual solutions. Items are grouped according to their dominant factor (the factor with the strongest factor loading) in the combined analysis; loadings $>0.60$ or $<-0.60$ are in bold. Items marked with an asterisk were accompanied by a brief definition (see main text).

children and adults marked a clear difference between the robot and the beetle in the physiological domain (Fig. 1, center), in line with the animate-inanimate distinction ${ }^{1}$; and both age groups credited the robot with slightly greater perceptual-cognitive skills than the beetle (right). In contrast, in the social-emotional domain (left) both the beetle and the robot received rather low scores among adults, but very high scores among children. See Fig. 2 for raw counts of no, kinda, and yes responses for all items, grouped by character, age group, and dominant factor.

In sum, we see only minor differences between children and adults in their attributions of physiological and perceptual-cognitive abilities to beetles and robots-but a major difference in the social-emotional domain: Relative to adults, children tended to credit both beetles and robots with much greater social-emotional abilities.

## General Discussion

A bottom-up approach designed to shed light on children's intuitions about the ontology of mental life revealed an adult-like conceptual structure in place among 7 - to 9 -y-old children. Patterns of mental capacity attributions revealed a shared fundamental distinction between social-emotional, physiological, and perceptual-cognitive abilities. To our knowledge, this is the first bottom-up exploration of children's intuitions about the structure of mental life.

In a close parallel to adults (Weisman et al., 2016), the distinction that loomed the largest in children's responses

[^240]

Fig. 1: Mean factor scores for the beetle and the robot for each of the three factors (social-emotional, physiological, perceptual-cognitive), among adults ( $n=200$ ) and children ( $n=200$ ). Error bars are non-parametric bootstrap 95\% CIs.
was not between experience and agency (Gray et al., 2007), but between three varieties of experience: emotional, physiological, and perceptual. Echoing this previous work, different aspects of agency were distributed across these factors: The social-emotional factor included several items related to moral agency (e.g., understand how somebody else is feeling, know what's nice and what's mean), while items related to goal pursuit tended to pattern with perceptual-cognitive abilities (decide what to do, make plans). ${ }^{2}$ For both children and adults, connections between related varieties of experience and agency seemed to play a particularly important role in intuitive ontologies of mental life-perhaps because they allow us to explain and predict others' actions in several fundamental domains (interactions among social partners, the bodily needs of animals, and the goal-directed actions of agents).

Although the conceptual structure underlying children's mental capacity attributions was quite similar to that of adults', there was one striking difference in their evaluation of entities within that structure: Children were far more generous in their assessment of the social-emotional abilities of both beetles and robots. The specificity of this age difference-which emerged dramatically in one domain, but not others-suggests that this is unlikely to be due either to a general tendency toward "mentalizing" these characters (or a simple "yes" bias). But its extension to both beetles and robots raises many questions. With regard to robots, children growing up in the $21^{\text {st }}$ century might be converging on a new understanding of technological "beings" as inanimate objects with some degree of social-emotional life (see Kahn, Gary, \& Shen, 2013)—but this kind of historical conceptual change would not predict the high rates of social-emotional attributions to beetles that we observed. Our findings are perhaps more consistent with a general openness to untraditional social partners that extends into middle childhood (but not adulthood)-or with a difference in construals of what it means to feel proud, happy, guilty,

[^241]
## Responses by mental capacity item

Fig. 2: Raw counts of responses to each item, by character (beetle, robot), age group (children, adults), and dominant factor (social-emotional, physiological, perceptual-cognitive), listed in descending order of absolute factor loading (see Table 1). Opacity indicates responses of yes (dark), kinda (medium), or no (light).
etc. To what kinds of entities would children of this age deny social-emotional abilities, and how do they draw this line? What aspects of attributing pride, happiness, or guilt might change between 7-9y and adulthood?

Our findings point to the importance of distinguishing between different aspects of mental life in building theories of how social cognitive reasoning might evolve-both over the lifespan and across history and cultures. The current studies offer the major advantage of making these distinctions on the basis of children's own conceptual structure, rather than a priori categories generated by experimenters-an approach that could prove particularly powerful in making sense of children's beliefs about and behaviors toward the many kinds of human, animal, and technological "beings" in the modern social world.

#### Abstract

Previous work has demonstrated that the visual complexity of letter-shapes is processed differently by naïve and expert observers. Specifically, fluent readers of the Arabic alphabet were found to discriminate complex letters more readily than less complex letters, whereas naïve observers exhibited the opposite effect. This "complexity benefit", wherein complex letters confer a processing advantage to expert observers, is not yet well understood. In a new study, we investigate whether this effect generalizes across scripts, and whether it is unique to individuals with biscriptal experience (knowledge of reading two different scripts). The results of the three experiments confirm that the complexity benefit is characteristic of expert monoscriptal and biscriptal readers, and that, furthermore, there may be a biscriptal advantage in processing visual complexity.

Keywords: biscriptal; orthography; visual complexity; perceptual expertise

## Background

Letter perception and identification require detection and processing of a letter's component visual features (Grainger, Rey, \& Dufau, 2008). For example, Pelli and colleagues (Pelli, Burns, Farell, \& Moore-Page, 2006) determined that letters are identified by detecting $7 \pm 2$ visual features. While core properties of the human visual system certainly determine how and which visual features are detected for in letter identification, there is increasing evidence that the extent and type of experience with letters influences how the visual system processes them.

Wiley, Wilson, \& Rapp (2016) examined the effects of both alphabet and expertise on Arabic letter perception by comparing same/different letter judgments of expert, biscriptal Arabic-English readers, and naïve, monoscriptal English-only readers. Among the findings was that letter complexity, defined as the number of visual features in a letter ${ }^{1}$, was associated with slower/less accurate responses for naïve observers, but faster/more accurate responses for expert, biscriptal readers. This finding suggests that

[^242]extensive experience leads to more efficient visual processing of complex shapes. In other words, whereas for naïve observers, complex letter-shapes are more difficult to discriminate than are simple ones, for expert observers the reverse is true. This effect was referred to as the "complexity benefit". As a first step to furthering our understanding of the complexity benefit, the current study seeks to determine (a) whether the complexity effect is specific to Arabic, and (b) whether the magnitude of the effect is related to the amount of experience with a specific script or if extends across scripts.

## The Current Study

Whereas Wiley, Wilson, \& Rapp (2016) focused only on comparing the effects in letter perception of the amount of expertise (naïve or expert observers), it is also the case that those participants can be divided along another dimension: monoscriptal and biscriptal. Here, we make use of the biscriptal experience to better understand the nature of the complexity benefit. Specifically, we address two questions:

Question 1: Is the complexity benefit limited to Arabic letters?

Question 2: Is the complexity benefit affected by the amount of expertise with a script?

Question 3: Does biscriptalism affect the perception of Roman letters?

The answers to these questions have implications for our understanding of whether and how the visual system is affected by extensive reading experience. There are at least two relevant hypotheses that are evaluated: (1) the complexity benefit is a consequence of extensive experience with letter identification within a specific set (e.g. the Roman alphabet). In that case, expertise with one script should have no bearing on the visual processing of another. (2) The complexity benefit may be related to the manner in which visual features are processed, regardless of the letter in which they appear; in this case, expertise with one script may influence the processing of another, depending on the extent to which they make use of similar sets of visual
features. This latter possibility would support a "biscriptal advantage", such that biscriptal Arabic-English readers should show a greater complexity benefit than monoscriptal readers. In addressing these questions, we also determine whether or not our original finding of a "complexity benefit" is replicable, whether or not it is an artifact of the Arabic alphabet, and whether or not it is true of monoscriptal as well as biscriptal individuals.

The questions are addressed in three experiments. In Experiment 1, the experimental protocol from Wiley, Wilson, \& Rapp (2016) was used with a considerably larger sample size of monoscriptal Roman-only readers, with implementation in Amazon's Mechanical Turk, with both Arabic and Roman letters. This experiment directly tests whether the complexity benefit is unique to the Arabic alphabet, or whether it is also present in monoscriptal participants viewing the Roman alphabet.

Experiment 2 is a re-analysis of the data from Wiley, Wilson, \& Rapp (2016), specifically the reaction time measurements from the same-different judgment task with pairs of Arabic letters. We separate the expert, biscriptal participants into two groups, one low-proficiency and the other high-proficiency, to shed light on whether the amount of expertise with reading a script affects the magnitude of the complexity benefit.

Finally, in Experiment 3 we use the same protocol as in Experiment 2 with new samples of both monoscriptal (Roman-only) and biscriptal (Arabic \& Roman) participants, viewing both Arabic and Roman letters. This experiment allows us to address whether expertise with reading one script affects the perception of a second script, specifically evaluating whether or not being biscriptal provides an advantage in terms of the complexity benefit.

## Experiment 1: Is the complexity benefit limited to Arabic letters?

Following Wiley, Wilson, \& Rapp (2016): we used a samedifferent judgment task with pairs of letters, using lettershapes from both the Arabic and Roman alphabet. For all experiments, the questions of interest are addressed on the basis of reaction times (RT, on correct trials), analyzed using linear mixed-effects modeling (LMEM; including random intercepts and slopes by both participants and items).

## Participants

167 participants were recruited online via Amazon's Mechanical Turk (MTurk), receiving payment of \$7.50/hour for their participation. 86 participants completed the task with Arabic letters and 81 with Roman letters. All participants reported no knowledge of any language written in a non-Roman script, and thus all are considered monoscriptal (MS).

## Stimuli

A set of 23 letter-shapes from the Arabic alphabet was presented in Adobe Arabic, in font size 24 (stimuli subtended $0.17^{\circ}-0.31^{\circ}$ and $0.05^{\circ}-0.35^{\circ}$ of visual angle, respectively in the vertical and horizontal dimensions). A set of 23 letter-shapes from the Roman alphabet was also presented in Arial, font size 16, thereby equating the size range of the two alphabets.
Both sets of stimuli included 8 pairs of allographs (i.e. 8 letters were presented with two letter-shapes, such as "A" and "a"; see Table 2). The stimuli are listed in Tables 1 and 2.

## Procedure

Each trial began with a central fixation cross ( 250 ms ), which disappeared and was replaced by a pair of letters simultaneously on either side of fixation, 48 pixels apart. Each pair of letters was presented for 2000 ms or until a response of "same" or "different" (by pressing either the "a" or "l" key on the keyboard was recorded. After a response or two-second timeout there was a 500 ms intertrial blank screen. Participants completed either the task in Arabic or in Roman letters but not both; the ratio of same to different trials was $40 / 60$, for a total of 437 trials.

## Analysis

Using only correct responses, a single LMEM was fit to the "same" pairs ${ }^{2}$ data to determine the effect of complexity (number of visual features from a list of 14) on reaction time, and whether this effect differed across groups. The regression model was fit using R ( R Core Team, 2015), package lme4 (Bates, Mächler, Bolker, \& Walker, 2015), and confidence intervals for the parameters of interest were determined using parametric bootstrapping; plots are provided based on the R package effects (Fox, 2003).

Regression predictors: For the fixed effects, two predictors of interest were included: the categorical variable Alphabet (Arabic or Roman, with sum-coding) and the continuous variable Complexity (total number of visual features, ranging from 4-12). Two additional predictors were included as control variables: Trial Order and Previous RT (reaction time on the preceding trial), to control for trends in RT across the duration of the experiment. Finally, we included the interaction Alphabet X Complexity.

The following crossed random effects were included: random intercepts were included both by participants and by items, as was a random slope for the effect of Complexity by participant.

[^243]
## Results

The results are reported in Figure 1. Confidence intervals are based on 1,000 bootstrap simulations.

The estimated complexity benefit is significant for Roman letters, beta $=-0.014[-0.017,-0.010]$, whereas there is a significant increased RT as the number of features increases for the Arabic alphabet, beta $=0.005$ [0.002, 0.009]. The interaction between alphabets is significant, a beta difference $=0.019$ [0.015, 0.024].

Summary: The finding that the complexity benefit also exists for monoscriptal participants in the Roman alphabet (in which they are experts) is replicated in a large MTurk sample, as is the finding that the opposite effect (slower RT on more complex letters) for monoscriptal observers with no experience in reading Arabic.

Figure 1: Experiment 1, predicted RT (ms) as a function of complexity (\# of visual features) in the Arabic (green) and Roman (red) alphabets, measured in response to "same" pairs.

## Experiment 2: Is the complexity benefit affected by amount of expertise?

Experiment 2 is a reanalysis of data originally presented in Wiley, Wilson, \& Rapp (2016). The procedure was the same as that described for Experiment 1, with the following differences in participants and stimuli.

## Participants

There were 34 participants, all from the Johns Hopkins University community, who took part in two one-hour sessions, receiving either course credit or $\$ 20$ for their participation. The participants were organized into three groups:

Low-proficiency biscriptal (L-BS, $\mathrm{n}=11$ ): individuals whose first written language is English and who have had 23 years of studying Arabic.

High-proficiency biscriptal (H-BS, $\mathrm{n}=11$ ): individuals who learned to read and write Arabic simultaneously with English, or as a second language with at least 4 years of study.

Monoscriptal (MS, $\mathrm{n}=12$ ): consists of participants whose first language is English, and who have had no exposure to reading or writing in non-Roman scripts ${ }^{3}$.

## Stimuli

The stimuli were a superset of the Arabic letters used in Experiment 1, for a total of 45 shapes. However only the 23 stimuli used for Experiment 1 are analyzed here in order to better compare results across experiments.

## Procedure

Stimuli were presented using E-Prime 2.0 (Psychology Software Tools, Pittsburg, PA). Participants completed the experiment over two sessions, with each session consisting of 990 trials with a $50 / 50$ ratio of $50 / 50$ same to different trials. For this analysis, a total of 506 trials were used.

## Analysis

The same analysis was used as in Experiment 1.
Regression predictors: The model structure was the same as outlined in Experiment 1 except that the predictor Alphabet replaced by the predictor Group (MS, L-BS, or HBS, with sum-coding).

Table 1: Arabic letter-shapes and their complexity, the mean RTs across Experiments 2 and 3, for each group for each letter, and the correlation between complexity and mean RT (bottom row).

[^244]
## Results

The re-analysis of data from Wiley, Wilson, and Rapp (2016) is reported in Figure 2 based on the LMEM as previously described; confidence intervals are based on 1000 bootstrap simulations.

The estimated beta-weight for the effect of Complexity is for the MS group $=0.015,95 \%$ CI [0.010, 0.020] Thus, we again find that among the naïve (monoscriptal) participants more complex letters lead to significantly slower reaction times.

For the biscriptal groups, for the L-BS the effect is estimated $=-0.002[-0.008,0.002]$; and for the $\mathrm{H}-\mathrm{BS}=-$ 0.007 [-0.013, -0.001$]$. Thus, only the H-BS show a significant complexity benefit, while the L-BS show only a trend toward faster RT on more complex letters.

The estimated difference between the MS and L-BS is $=$ 0.017 [0.011, 0.024], and between the MS and H-BS $=$ 0.022 [0.014, 0.029]. Both biscriptal groups show significantly more negative (hence, more of a complexity benefit) than the monoscriptal group. The estimated difference between the two biscriptal groups $=0.005[-$ $0.003,0.011]$, with a nonsignificant trend toward a greater complexity benefit for the H-BS relative to the L-BS.

Summary: Both biscriptal groups show a numerically larger complexity benefit than the monoscriptal group; although only for the H-BS group is the complexity benefit statistically significant.

Figure 2: Experiment 2, Predicted RT (ms) as a function of complexity (\# of visual features) in the Arabic alphabet, measured for each group of participants in response to "same" pairs.

## Experiment 3: Does biscriptalism affect the perception of Roman letters?

The same procedure as outlined in Experiment 1 was used, with a few differences noted as follows.

## Participants

29 students from Johns Hopkins University (ages 18-22), all different from those in Experiment 2, took part in the onehour experiment, receiving either course credit or $\$ 10$ for their participation. The participants were divided into L-BS
$(\mathrm{n}=7), \mathrm{H}-\mathrm{BS}(\mathrm{n}=5)$, and MS $(\mathrm{n}=17)$ for a total of 29 participants.

## Stimuli

The stimuli were identical to those used in Experiment 1.

## Procedure

The same procedure as Experiment 1 was used, except participants completed the task for both alphabets separately across two sessions, with the order (Arabic-Roman or Roman-Arabic) counterbalanced across participants.

## Analysis

The same analysis as described for Experiment 1 was conducted, plus the addition of the variable Group (MS, LBS, or H-BS, sum-coded) and the 3-way interactions of Alphabet X Group X Complexity and Alphabet X Group X Previous RT. The random effects structure was the same as in Experiment 1, with the addition of (correlated) random slopes for the effect of Alphabet by participants.

Table 2: Roman letter-shapes and their complexity, the mean RT from Experiment 3, for each group for each letter, and the correlation between complexity and mean RT

| Letter | (bottom row). |  |  |  |
| :---: | :---: | :---: | :---: | :---: |

## Results

The results from participants completing the same-different task with both alphabets are reported in Figure 3 (Arabic) and Figure 4 (Roman). Confidence intervals are based on 1,000 bootstrap simulations.

For the Arabic alphabet, the MS show significantly slower RTs on more complex letters, beta estimated $=0.013$
[0.007, 0.017$]$. The L-BS show a nonsignificant trend in the same direction, beta $=0.007[-0.001,0.014]$, whereas the HBS show a nonsignificant trend toward a complexity benefit, beta $=-0.007[-0.018,0.001]$.

While the complexity benefit is not significant within either biscriptal group, the difference between the H-BS both of the other two groups is significant: the H-BS betaweight is significantly different than that for the MS, by an estimated $0.019[0.009,0.031]$ and than the L-BS by beta $=$ 0.014 [0.003, 0.025]. The difference between the MS and LBS is not significant $($ beta $=0.006[-0.003,0.014])$.

Figure 3: Experiment 3, predicted RT (ms) as a function of complexity (\# of visual features) in the Arabic alphabet, measured for each group of participants in response to "same" pairs.

For the Roman alphabet, the MS show a significant complexity benefit $=-0.005[-0.010,-0.0002]$. The L-BS show a marginally significant complexity benefit, beta $=-$ 0.008 [-0.016, 0.0001]. The H-BS show a significant complexity benefit, beta $=-0.020[-0.029,-0.013]$.

Finally, the $\mathrm{H}-\mathrm{BS}$ show a significantly greater effect than both the MS (beta $=0.015[0.005,0.026])$ and the L-BS (beta $=0.013[0.002,0.025])$. There is no difference between the MS and the L-BS (beta $=0.002[-0.006$, 0.011]).

Figure 4: Experiment 3, Predicted RT (ms) as a function of complexity (\# of visual features) in the Roman alphabet, measured for each group of participants in response to "same" pairs.

Summary: We find a similar pattern of results for the Arabic alphabet as in Experiment 2 with the H-BS group showing a significantly greater complexity benefit than either then MS or the L-BS groups. Critically, a complexity benefit is found for the Roman alphabet for all groups, including the monoscriptal (English-only) participants, indicating that it is not an artifact of the Arabic alphabet or of being biscriptal. The magnitude of the effect is significantly greater in the H-BS than in either the MS or LBS groups, suggesting a possible biscriptal advantage.

## Discussion

We investigated the role that expertise and biscriptalism play in the visual processing of letter-shapes. Specifically, we sought to determine whether: (1) the complexity benefit, wherein expert readers of a script identify complex letters significantly more quickly than simpler letters, occurs for scripts other than Arabic where it was first reported, (2) the complexity benefit is limited to biscriptal individuals or is present also in monoscriptals, and (3) there is a biscriptal advantage for visual processing of letters, such that biscriptals show a greater complexity advantage or if, instead, the magnitude of the complexity benefit is simply tied to the amount of experience with a script. There were three participant groups: monoscriptal, English-only readers (MS), and two biscriptal Arabic-English reader groups, one with four or more years of experience (H-BS) and one with two or three years (L-BS). We used LMEM to determine the direction and strength of the relationship between letter complexity (as defined by the number of visual features), and whether this relationship differs across groups of participants and across alphabets.

The results of Experiments 1 and 3 both reveal that the complexity benefit is not an artifact of the Arabic alphabet. Monoscriptal participants who participated in the laboratory or the MTurk experiments all exhibited a complexity benefit when performing the same-different task with Roman letter stimuli. Thus, it would seem that the complexity benefit is not only a general trait of reading expertise, but also is not unique to individuals with biscriptal experience.

Additionally, the results of Experiments 2 and 3 provide further details regarding the complexity benefit phenomenon. While a significant complexity benefit was not limited to biscriptal individuals, the effect was greatest in the high-proficiency biscriptal individuals. This group showed a larger complexity benefit than the other two groups in both Arabic and Roman scripts. This is particularly interesting, given that the monoscriptal and biscriptal participants presumably had comparable expertise with the Roman alphabet. In fact, if anything the monoscriptal participants are likely to have had more experience with the Roman alphabet, as the biscriptal participants would have spent some of their time reading in Arabic instead of Roman letters. It is possible that this division of reading time between the two scripts may
underlie the overall slower reaction times exhibited by this group, analogous to the rationale provided for some of the findings in the literature on spoken word production with bilinguals (Gollan et al., 2008). This possibility will require more targeted experimental work. Nonetheless, the larger complexity benefit observed for the high expertise biscriptal participants indicates that there may be a biscriptal advantage for processing visual complexity, at least for letters.

The mechanism underlying the complexity benefit itself is not yet well understood. There are multiple possible explanations for why expert observers learn to identify more complex letters more quickly or accurately. One possibility is that expertise leads to the creation of new visual features- such that features are "bundled" together, making a complex letter no longer complex. For example, the letter " $w$ " may not be processed as four slanted lines, three intersections, two terminations, with symmetry and cyclicity, but instead as fewer features or even a single feature, "w". This type of expertise effect is consistent with findings in perceptual learning research (e.g. Goldstone, 1998; Kellman \& Garrigan, 2009; Sireteanu \& Rettenbach, 2000).

Another explanation for the complexity benefit is that it is related to the distinctiveness of letter-shapes within the set of shapes being processed. Under such an account, a complex letter like "w" may be easier to identify because its greater number of features provide more possible ways to distinguish it from other letters. This is compatible with findings from visual crowding effects, indicating that a target is easier to identify within an array of distractors if it is relatively more complex than those distractors (Bernard \& Chung, 2011; Chanceaux, Mathôt, \& Grainger, 2014). Accordingly, with increasing expertise, one learns not only the visual properties of each of the letters, but the distribution of features across the set of letters.

Relatedly, it may be that experts learn a greater number of ways to identify complex letters relative to simpler letters, allowing the identification process to terminate sooner. For example, whereas an observer with minimal experience may identify " $w$ " only after considering all of its features, an expert may identify it as soon as some distinct combination of features (a subset of the total number of features) are recognized. In this case, a "simple" letter such as ' 1 " may be more difficult to distinguish from other letters, because while a complex letter like " $w$ " can be identified without full consideration of all of its features and without searching for the absence of certain features, an " 1 " does not afford these opportunities.

Of these possibilities, perhaps the one most consistent with a biscriptal advantage would be the creation of new complex features from simpler features-biscriptal individuals' expertise with a wider range of letter-shapes may result in a larger feature 'vocabulary' that allows relatively more complex shapes to be more readily processed. In future research, it will be important to examine if the biscriptal complexity advantage extends to
other types of visual stimuli, and to identify evidence to adjudicate between possible mechanisms that support the complexity benefit.

#### Abstract

During collaborative problem solving (CPS), coordination occurs at different spatial and temporal scales. This multiscale coordination should, at least on some scales, play a functional role in facilitating effective collaboration outcomes. To evaluate this, we conducted a study of computer-based CPS with 42 dyads. We used cross-wavelet coherence as a way to examine the degree to which movement coordination is evident at a variety of scales and tested whether the observed coordination was greater than both the amount expected due to chance and due to task demands. We found that coordination at scales less than 2 s was greater than expected due to chance and at most scales (except 16s, 1m, and 2m) was greater than expected due to task demands. Lastly, we evaluated whether the degree of coherence at scales less than 2 s , and the form of coordination (in terms of relative phase), were predictive of CPS performance. We found that .25 s and 1 s scales were predictive of performance. When including relative phase, our results suggest that higher in-phase movement coordination at the 1 s scale was the strongest predictor of CPS performance. We discuss these findings and detail their relevance for expanding our knowledge on how coordination facilitates CPS.

Keywords: coordination; collaboration; problem solving; team performance; dynamical systems; synchrony.

## Introduction

Collaborative problem solving (CPS) is a cognitive skill pervasive in many human interaction contexts ranging from everyday life to highly complex work environments. CPS is defined as "a process whereby two or more agents attempt to solve a problem by sharing the understanding and effort required to come to a solution and pooling their knowledge, skills and efforts to reach that solution" (OECD, 2015, p. 6). Given the increasing complexity of problems in contemporary societal practices, and the need for multiple disciplines to solve them, CPS has been recognized as an essential $21^{\text {st }}$ century skill. However, while some research has examined CPS in a variety of laboratory (e.g., Berg, Johnson, Meegan, \& Strough, 2003; Roschelle \& Teasley, 1995) and naturalistic contexts (e.g., Fiore, Wiltshire, Oglesby, O’Keefe, \& Salas, 2014; Jordan \& McDaniel Jr, 2014), the state of the science is still limited. In this paper, we explore the implications of the notion that CPS is a multiscale phenomenon, and investigate the degree to which movement coordination, at various scales, plays a functional role in effective CPS.

Human interaction in any context is a dynamic, multiscale phenomenon (e.g., Dale, Fusaroli, Duran, \& Richardson,

2013; Steffensen \& Pedersen, 2014). For example, during a conversation, neural events transpire on the order of milliseconds, speech production and gestures over seconds, and the conversation itself on the order of minutes (Hasson, Ghazanfar, Galantucci, Garrod, \& Keysers, 2012). This point, while oversimplified, illustrates the fact that human interaction involves a variety of temporal and spatial scales (e.g., neural, physiological, bodily). Recognizing human interaction as multiscale, especially during CPS, implies that coordination, both intra- and inter-personally, must span a variety of these spatial and temporal scales in order to effectively accomplish joint goals (Eiler, Kallen, Harrison, \& Richardson, 2013).

Indeed, a common question, particularly in the movement sciences, has been to understand how systems with high degrees of freedom, are able to functionally coordinate (e.g., Mitra, Amazeen, \& Turvey, 1998). Coordination in this context is simply the ways in which components and processes of a system change together over time (Butner, Berg, Baucom, \& Wiebe, 2014). In an interpersonal context, a wide variety of terms have been used to describe different forms of coordination (Butler, 2011) such as synchronization, co-regulation, entrainment, and coupling. Evidence for many forms of interpersonal coordination are quite pervasive amongst differing modalities (Fusaroli \& Tylén, 2016; Louwerse, Dale, Bard, \& Jeuniaux, 2012) and contexts (Palumbo et al., 2016). But, while many different forms of coordination have been discovered, the ways in which they facilitate effective interaction outcomes is less studied (cf., Timmons, Margolin, \& Saxbe, 2015), particularly in collaborative contexts.

Prior research has suggested that coordination is required for the accomplishment of joint goals (Mills, 2014) and that stronger coordination should contribute to better collaborative results (Barron, 2000). Findings so far have been mixed, though, with regard to how coordination, albeit in different modalities and scales, relates to optimal performance on joint tasks (Gallotti, Fairhurst, \& Frith, 2017). In one example, performance on a dyadic movement task was predicted by a measure of coordination that reflected interaction across multiple time scales (Davis, Brooks, \& Dixon, 2016). In another example, Abney, Paxton, Dale, and Kello (2015) found that stronger coordination in bodily movements were associated with poorer performance on a movement-based dyadic problem solving task. Louwerse et al. (2012) found that as task difficulty increased, so too did coordination. Further,
coordination of bodily movements in psychotherapy, a highly collaborative endeavor (Tryon \& Winograd, 2011), were shown to link to effective treatment outcomes (Ramseyer \& Tschacher, 2011). While not related to performance specifically, a number of interactional benefits have been observed following periods of interpersonal coordination such as increased affiliation (Hove \& Risen, 2009) and cooperative behavior (Valdesolo, Ouyang, \& DeSteno, 2010; Wiltermuth \& Heath, 2009).

Given the extant research, briefly reviewed here, we expect that multiscale coordination of bodily movements should have a functional relationship with performance in complex, CPS. Relatedly, a recent theoretical account of dialog proposed that high coordination in lower level behaviors (e.g., posture) may provide a necessary foundation for more variability and complementarity at higher levels of dialog (Fusaroli, Rączaszek-Leonardi, \& Tylén, 2014). So, a key aspect that distinguishes the present work from prior research is that we focus on movement coordination in a challenging computer-based CPS context.

## The Current Study

The present work is part of a larger study examining team interaction dynamics during a dyadic CPS task (Wiltshire, 2015; Wiltshire, Butner, \& Fiore, 2017). Whereas in prior work, we have examined how transitions in communication structures and their complexity relate to CPS performance (Wiltshire et al., 2017), here we focus on coordination of bodily movements at various time scales and how that coordination relates to CPS performance.

We utilize cross-wavelet coherence as a way of examining coordination of human interaction that is largely unstructured, at least when compared to rhythmic movement tasks (Fujiwara \& Daibo, 2016; Issartel, Bardainne, Gaillot, \& Marin, 2015). This method allows for evaluation of the degree of coordination of two continuous time series and whether that coordination is in-phase or anti-phase. One of its key strengths is that it retains a high level of precision in both the time and frequency domains (Issartel et al., 2015). This method has been used previously to examine movement coordination in a variety of interactive contexts such as the exchange of jokes (Schmidt, Morr, Fitzpatrick, \& Richardson, 2012), dialog (Fujiwara \& Daibo, 2016), the coordination of jazz musicians (Walton, Richardson, Langland-Hassan, \& Chemero, 2015), and dancers (Washburn et al., 2014).

We expect that the coordination of bodily movements will serve a functional role in facilitating effective CPS performance. However, we also expect that this functional role will vary based on time scales. In other words, movement coordination at some time scales should be more relevant to CPS than others. We thus adopt an exploratory approach to determine what scales are important in predicting effective CPS performance. Given the nature of the task, it is likely that smaller time scale movements will matter such as those that occur while controlling the computer-based task as well as during speech. When
examining interpersonal coordination dynamics, it is essential to demonstrate that the observed coordination is greater than can be expected due to chance alone (Ramseyer \& Tschacher, 2010), and that it is not solely due to task constraints (Strang, Funke, Russell, Dukes, \& Middendorf, 2014). Thus, we advance the following research hypotheses $(\mathrm{H})$ and research questions (RQ):

- H1: Movement coordination will be greater than chance, at least at lower scales.
- H2: Movement coordination will be greater than can be expected due to task constraints.
- RQ1: At what scales does movement coordination predict CPS performance?
- RQ2: Does the form of coordination (e.g., in-phase, anti-phase) at these scales relate to performance?

## Method

## Participants

84 undergraduate students (31 female, $M_{\text {age }}=19.2$ years, range 18-28 years; ~ 67\% White, $8 \%$ Black, 10\% Hispanic, $10 \%$ Asian, and 5\% other) from a large United States university voluntarily participated in this experiment comprising 42 dyadic teams. There were five female-only teams, 17 male-only teams, and 20 mixed-gender teams. Participants must have had general video game experience using a mouse and keyboard for third-person video games, no prior history of seizures, no experience using the Moonbase Alpha simulation, and no prior acquaintance.

## Materials

Participants sat face-to-face with each other with two desktop computers offset to one side. This setup allowed them to view the other's face and torso. The computer screens were placed back-to-back. A Logitech HD webcam model C615 was used to record the participants from a profile view. All videos were collected in 720p resolution.

## Task

NASA's Moonbase Alpha is a complex, CPS task (NASA, 2011) that places team members in a simulated scenario where a meteor strike damages critical life support systems of a moonbase. The goal of the Moonbase Alpha task is for participants to fully restore oxygen to the settlement in 25 minutes or less. Both team members must work together to solve the problem by figuring out how to fix and/or replace damaged components of the life support system such as solar panels, power cables, couplers, and a power distributor. A variety of tools and coordination strategies must be employed to complete the task; however, there are no predefined guidelines for how to completely repair the settlement in the given timeframe.

## Procedure

Participants were briefed about the nature of the experiment and asked to introduce themselves to each other by
providing a greeting and sharing their name with the other participant. Participants were then given an informed consent document to review and asked to complete a biographical questionnaire.

Participants were then provided a PowerPoint tutorial that covered the basics of the Moonbase Alpha simulation, which were derived from the simulation's instruction manual (NASA, 2011). Further, participants were told that they would be tested on the content. After completing the PowerPoint, they received a 10 -item multiple-choice knowledge assessment (see Wiltshire, 2015).

After completion of the knowledge assessment, the necessity for communication to complete the task was reiterated. Participants were then instructed to begin the simulation. A short video introduced the problem (i.e., the moonbase was damaged by a meteorite and life support functions need to be restored) before participants began the 25-minute task. The task was considered complete either when time ran out or once participants fully restored oxygen, whichever came first.

## CPS Performance

Problem solving performance was determined by a rescaled combination of three variables: (a) the total time taken to restore life support ( $0-25$ minutes), (b) the total percentage of oxygen restored $(0-100 \%)$, and (c) a ratio of completed object repairs to the total possible repairs ( $0-25$; only for teams that restored zero oxygen). The rescale function in R (R Core R Core Team, 2016) was used to place teams whose performance restored no oxygen at all into a range of $0-33$ as a function of their ratio of object repairs/total possible object repairs. Those teams that restored some, but not all, oxygen were rescaled to fit a range of 34-66. Lastly, for those teams that restored all oxygen, the time to complete the task was inversely rescaled to fit the range of 67-100 (with lower times leading to higher scores).

## Analytic Strategy

Frame-Differencing We used Paxton and Dale's (2013) video frame-differencing technique to extract a time series representing the level of bodily movement for each participant from all videos at an 8 Hz sampling rate. For the current task, this measure of bodily movement captures behaviors such as speech, postural sway, gestures, adjustment of position, hand movements controlling the mouse and keyboard, and shifting of the legs and/or feet. In general, this technique provides an objective measure of the amount of movement a given participant is exhibiting moment-by-moment over the duration of the task with higher values corresponding to more movement. The tradeoff when using this type of method is that there is a loss of specificity with regard to the types of movements that are coordinated, but movement can be extracted with relatively little effort and time compared to more specific movement coding systems (cf. Louwerse et al., 2012; Paxton \& Dale, 2013).

Cross-Wavelet Coherence We examined dyadic movement coordination with the cross-wavelet transformation method by using the wtc function from the biwavelet package (Gouhier, Grinsted, \& Simko, 2016) in R. This is a spectral decomposition method that allows for examination of time localized oscillations in a variety of frequencies and how the spectrum changes in those frequencies over time (Issartel, Marin, Gaillot, Bardainne, \& Cadopi, 2006). This method is known to be robust to nonstationary time series (Issartel et al., 2015). We extracted the average coherence and average relative phase values from the following frequency ranges: $.25 \mathrm{~s}, .5 \mathrm{~s}, 1 \mathrm{~s}, 2 \mathrm{~s}, 4 \mathrm{~s}, 8 \mathrm{~s}, 16 \mathrm{~s}, 32 \mathrm{~s}, \sim 1 \mathrm{~m}, \sim 2 \mathrm{~m}$, and $\sim 4.5 \mathrm{~m}$ within $+/-.5$ scales (frequency scales are converted to time domain by multiplying them by the 8 Hz sampling rate and dividing by 60 for minutes). Coherence is the spectral equivalent to a cross-correlation. Values of 0 convey no coordination and a value of 1 conveys absolute coordination (Schmidt, Nie, Franco, \& Richardson, 2014). Relative phase indicates whether the oscillations are in-phase $\left(0^{\circ}\right)$, antiphase $\left(180^{\circ}\right)$, or exhibiting a lag (between $0^{\circ}$ and $180^{\circ}$ ).

Surrogate and Virtual Pairs Analyses Surrogate analysis was conducted by computing a shuffled transformation of each observed movement time series and repeated the crosswavelet analyses for each dyad. This effectively destroys the temporal pattern in the data while preserving the distributional properties (Louwerse et al., 2012). Any measures of coordination applied to these are widely interpreted as the degree of coordination expected due to chance (Ramseyer \& Tschacher, 2010).

For the virtual pairs analysis, 42 randomized combinations of individuals who did not interact together were created. Because these individuals did not interact with each other, but were performing the same task, coordination measures calculated from virtual pairs have been interpreted as the coordination that can be expected due to the task demands (Strang et al., 2014). Thus, cross-wavelet analyses were conducted on these virtual pairs. Where time series were of unequal length, the longer time series was truncated to the length of the shorter series. Separate paired-sample ttests were used to compare between observed coherence and surrogate coherence as well as between observed coherence and virtual pairs coherence for each time scale.

Examining Relationship Between Coordination and Performance Our approach to answering RQs 1 and 2 was exploratory based on the results from H1. Specifically, we first conducted a linear multiple regression model with the observed coherence values at scales that were significantly greater than chance as predictors of performance. Then, we took those values that were significant predictors of performance and included them in a second multiple regression model with the relative phase values for those respective scales.

## Results

In order to examine H 1 , that the observed coordination would be greater than chance at some scales, the coherence
values for the surrogate data were compared to the coherence of the observed data. Results (see Table 1) suggested that coherence was significantly greater than chance at the $.25 \mathrm{~s}, .5 \mathrm{~s}, 1 \mathrm{~s}$, and 2 s frequency scales.

Table 1: Paired sample t-tests comparing observed to surrogate coherence and to virtual pairs coherence.

| Freq. <br> Scale | Observed <br> Coherence | Surrogate <br> Coherence | Virtual Pairs <br> Coherence |
| :--- | :--- | :--- | :--- |

| Wavelet Coherence: T9 High Performing |  |  |  |

Wavelet Coherence: T19 Low Peforming

Figure 1: Cross-wavelet coherence plots for a high performing team (top) and low performing team (bottom).
Likewise, in order to examine H2, that the observed interpersonal movement coordination would be greater than due to task demands and environment, the coherence values for the virtual pairs data were compared to the coherence of
the observed data. Results (see Table 1) suggested that coherence was significantly greater than could be expected due to task demands and environment alone for all frequency scales except $16 \mathrm{~s}, 1 \mathrm{~m}$, and 2 m .

To better understand the relationship between coherence and performance, we present two examples of cross-wavelet coherence plots in Figure 1. The top example is derived from the top performing team and the bottom example is derived from the lowest performing team. The $y$-axis corresponds to the frequency scale (which when divided by 8 can be related to time in seconds). The x-axis corresponds to the time on task with each point corresponding to $1 / 8$ of a second (or one video frame). The colors correspond to the amount of coherence with warmer colors indicating high coherence. Arrows indicate phase relationships with right arrows conveying in-phase and left arrows conveying antiphase. Arrows shifted up or down convey a lag in the oscillations between participants.

Next, we turn to RQs 1 and 2. In our first model, we included the four scales that were significantly more coordinated than expected due to chance alone as predictors of CPS performance (. $25 \mathrm{~s}, .5 \mathrm{~s}, 1 \mathrm{~s}$, and 2 s ). Overall, this model accounted for a significant $30.2 \%\left(R_{\text {adj }}^{2}=.226\right.$; $F(4,37)=4.00, p=.009)$ of the variability in CPS performance with coherence at the .25s ( $\beta=-.584, p=.017$ ) and 1s scales ( $\beta=.789, p=.003$ ) as significant predictors of performance. The .5 s and 2 s scales were not significant ( $p$ s $>.05$ ). Regarding RQ1, these results suggest that whereas stronger movement coordination at the 1 s scale is a strong predictor of better CPS performance, stronger coordination at the .25 s scale is associated with poorer performance.

Next, we sought to better understand the form of coordination at these scales. Thus, we conducted a second model that included coherence as well as relative phase at .25 s and 1 s scales. This model accounted for a significant $34.6 \% ~\left(R_{\text {adj }}^{2}=.276 ; F(4,37)=4.90, p=.003\right)$ of the variability in CPS performance with coherence ( $\beta=.614$, $p$ $=.007$ ) and relative phase $\left(M=3^{\circ}, S D=2^{\circ} ; \beta=-.294, p=\right.$ .038) at the 1 s scale as significant predictors of performance. Now, however, coherence at .25 s was not significant ( $\beta=-.412, p=.06$ ) nor was relative phase at .25 s ( $p=.24$ ). Thus, these results suggest that movement coordination at the 1 s scale is a primary predictor of performance and further, that relative phase values at the 1 s scale closer to $0^{\circ}$ (more in-phase) are associated with better CPS performance.

## Discussion

In this work, we investigated the multiscale, movement coordination dynamics that emerge in computer-based CPS. We found that movements in $.25 \mathrm{~s}-2 \mathrm{~s}$ scales were significantly more coordinated than chance and that all but the $16 \mathrm{~s}, 1 \mathrm{~m}$, and 2 m scales were more coordinated than expected due to task demands. We also observed that where coordination was greater than chance, both .25 s and 1 s were associated with CPS performance. However, when also accounting for relative phase, it appeared that higher in-
phase coordination at the 1s scale was the best predictor of CPS performance. Thus, some significant variability in CPS performance, in this context, appears to be explained by specific, low-scale patterns of coherence.

Given the low specificity of the movement data extracted from video, the question remains as to what is coordinated at these low scales and why they matter. In general, interactional phenomena that play out on (and below) a . 25 s timescale differ qualitatively from phenomena at a .5s timescale and beyond. For example, how interlocutors orient to each other's behavior as meaningful for the interaction depends on timing. Short pauses in interaction (typically $<.25$ s) are treated as idiosyncratic variation in speech; pauses around .5 s mark a transition space where the next speaker can take the word; and longer pauses (> 1s) "are often treated as flagging something unusual or troublesome about the interaction" (Mushin \& Gardner, 2009, p. 2035). Although, in addition to capturing these aspects of dialog, the observed coordination also captures mouse and keyboard movements, which likely unfold at these low scales as well. In general, many of the modalities captured by our movement measure can be argued to be task relevant as they capture dialogical events and computer input required for collaboration, but future work could consider more specific modalities such as how mouse movements are coordinated.

As far as future work is concerned, it is important to note some observable differences in coherence between the high and low performing teams in Fig. 1. There appear to be differences at higher scales, although average coherence was not generally above chance at these scales. However, we can speculate that participants’ performance may reflect their ability to create functional coherence across scales (e.g., between bodily ability and task demands), which could be assessed with fractal analyses (Davis et al., 2016). Further, it may be that successful CPS performance relies on higher-order transitions (Wiltshire et al., 2017) in coordination at one or more slow scales, as could be tenuously suggested by the pattern of high-low-high coherence near the 2 m scale across the duration of the task. Thus, future work should also consider extracting not only specific scales, but also time ranges that could be theoretically important to CPS.

More generally, research of this nature is important because it advances an efficient means of unobtrusively examining coordination processes during collaboration with a goal of working toward systems that can elicit forms of coordination that enable effective collaboration (Fiore \& Wiltshire, 2016; Kim, Chang, Holland, \& Pentland, 2008; Wiltshire \& Fiore, 2014). However, more work is necessary to understand if movement coordination is related to CPS performance in larger teams (de Montjoye, Stopczynski, Shmueli, Pentland, \& Lehmann, 2014), with different roles and disciplinary expertise (Bergmann, Dale, Sattari, Heit, \& Bhat, 2016), and when the teams are not co-located. Of course, such pursuits may require considering alternative modalities in which multiscale coordination might also
occur. We expect that such endeavors are essential to advancing our knowledge of the way that coordination during human interaction relates to collaborative cognition.

## Acknowledgments

This research was supported by Grant CF16-0455 from the Carlsberg Foundation awarded to Travis J. Wiltshire. We greatly appreciate the efforts of Stephen M. Fiore who was instrumental in the design and collection of data used for the present paper.

#### Abstract

When choosing between multiple alternatives, people usually do not have ready-made preferences in their mind but rather construct them on the go. The 2 N -ary Choice Tree Model (Wollschlaeger \& Diederich, 2012) proposes a preference construction process for N choice options from description, which is based on attribute weights, differences between attribute values, and noise. It is able to produce similarity, attraction, and compromise effects, which have become a benchmark for multi-alternative choice models, but also several other context and reference point effects. Here, we present a new and mathematically tractable version of the model - the Simple Choice Tree Model - which also explains the above mentioned effects and additionally accounts for the positive correlation between the attraction and compromise effect, and the negative correlation between these two and the similarity effect as observed by Berkowitsch, Scheibehenne, and Rieskamp (2014).

Keywords: computational model; multi-alternative choice; choice from description; preference construction; context effects

## Introduction

The decision making process involves various steps such as setting and prioritizing objectives, identifying choice alternatives, searching for information, developing preferences, and eventually taking a course of action. Here, we focus on developing preferences in multi-alternative choice situations and use in the following decision making from description as basic paradigm. Given a set of at least three choice alternatives that are described by at least two attributes, which they have in common, how do people choose one of these options? Simon (1955) argues that preferences in this kind of situation are dynamically constructed over time due to limited processing capacities. The decision maker experiences preference uncertainty (cf. Simonson, 1989) and tries to overcome it by gradually integrating the given information (see Payne, Bettman, \& Johnson, 1992, for a review on constructive processing in decision making). The resulting preferences are stochastic and highly dependent on the context, i.e., on the alternatives in the choice set and on any external reference points. Naturally, a model describing multi-alternative decision making from description should be a context-sensitive cognitive process model. The recently proposed 2 N -ary Choice Tree Model for preference construction for N choice options (2NCT; Wollschlaeger \& Diederich, 2012) assumes that the decision maker compares attribute values within attributes and between alternatives in a pairwise manner. Attributes are selected for examination based on attribute weights that reflect salience. Within attributes,
pairs of attribute values are selected for comparison based on so-called comparison values. In the 2NCT Model, the comparison values have a "global" component that remains constant over time during preference construction, a "local" component that depends on the outcomes of previous comparisons (reflecting leakage and inhibition, cf. Roe, Busemeyer, \& Townsend, 2001; Usher \& McClelland, 2004), and a random component. Advantageous and disadvantageous comparison outcomes for each alternative are counted separately and the difference of these counters is compared to two thresholds: a positive choice criterion and a negative elimination criterion. Implementation of an asymmetric value function (emphasizing disadvantageous comparison outcomes, cf. Usher \& McClelland, 2004) into the 2NCT Model is possible. Here, we present a revised and simpler version of the 2 N -ary Choice Tree Model, the Simple Choice Tree (SCT) Model. Therein, the local component is omitted from the definition of comparison values, making the model mathematically tractable while maintaining its ability to account for similarity, attraction and compromise effects. Furthermore, a new parameter, the focus weight $\lambda$, is introduced. It replaces the asymmetric value function and allows the SCT Model to account for correlations between the effects.

## Benchmark: Context Effects

Three context effects, demonstrating the influence of choice set composition on preferences, have played a prominent role in the multi-alternative preference construction modeling literature: The similarity effect, the compromise effect, and the attraction effect. All three effects occur when adding a third alternative to a set of two equally attractive yet clearly distinguishable options described by two attributes. Let $A_{1}$ and $A_{2}$ be two choice alternatives with two common attributes, $D_{1}$ and $D_{2}$, describing them. We assume that $D_{1}$ is the unique strongest attribute for $A_{1}$ and $D_{2}$ is the unique strongest attribute for $A_{2}$, that is, $A_{1}$ scores high on $D_{1}$ but low on $D_{2}$ and vice versa for $A_{2}$. One can think of the alternatives as placed in a two-dimensional space with dimensions $D_{1}$ and $D_{2}$. We further assume that the probability for choosing alternative $A_{1}$ from the binary choice set is equal to the probability for choosing alternative $A_{2}, P\left(A_{1} \mid A_{1}, A_{2}\right)=P\left(A_{2} \mid A_{1}, A_{2}\right)$.

Similarity Effect The similarity effect was named and first studied systematically by Tversky (1972). He observed the effect when comparing the binary choice set $\left\{A_{1}, A_{2}\right\}$ to the ternary choice set $\left\{A_{1}, A_{2}, A_{3}\right\}$ where $A_{3}$ is similar
to one of the original alternatives, say $A_{1}$, in scoring high on attribute $D_{1}$ and low on attribute $D_{2}$ while overall being similarly attractive (i.e. $P\left(A_{1} \mid A_{1}, A_{3}\right)=P\left(A_{3} \mid A_{1}, A_{3}\right)$ ). The probability of choosing $A_{1}$ over $A_{2}$ decreases when the decision maker chooses from the ternary choice set as compared to the binary set: $P\left(A_{1} \mid A_{1}, A_{2}\right) / P\left(A_{2} \mid A_{1}, A_{2}\right)>$ $P\left(A_{1} \mid A_{1}, A_{2}, A_{3}\right) / P\left(A_{2} \mid A_{1}, A_{2}, A_{3}\right)$.

Attraction Effect The attraction effect (or decoy effect or asymmetric dominance effect) was introduced by Huber, Payne, and Puto (1982) as consistent violation of the regularity principle. This principle, as presumed for example by the theory of Elimination by Aspects (Tversky, 1972), states that additional alternatives cannot increase the choice probabilities of the original options. However, Huber et al. (1982) claim that the relative probability for choosing alternative, say, $A_{1}$ can be increased by adding a third alternative $A_{3}$ to the choice set that is similar to but dominated by $A_{1}$ (and symmetrically for alternative $A_{2}$ ). $A_{3}$ then serves as a decoy for alternative $A_{1}$, drawing attention to it and therewith improving its evaluation and increasing its choice probability.

Compromise Effect Originally intended to explain the attraction effect, the theory of Reason-based Choice (Simonson, 1989) predicts an additional context effect, the compromise effect. It occurs when a third alternative $A_{3}$, equally attractive as the original alternatives $A_{1}$ and $A_{2}$, but more extreme with respect to the attribute values, is added to the choice set. If $A_{3}$ is more extreme than alternative $A_{1}$, that is, if it scores higher than $A_{1}$ on attribute $D_{1}$ but lower on attribute $D_{2}$, then it increases the choice share of $A_{1}$ as compared to the binary situation (and vice versa for alternative $\left.A_{2}\right)$ : $\quad P\left(A_{1} \mid A_{1}, A_{2}, A_{3}\right) / P\left(A_{2} \mid A_{1}, A_{2}, A_{3}\right)>$ $P\left(A_{1} \mid A_{1}, A_{2}\right) / P\left(A_{2} \mid A_{1}, A_{2}\right)$. However, note that the more similar the additional extreme alternative $A_{3}$ is to its adjacent alternative $A_{1}$, the more shares it takes away from $A_{1}$ via the similarity effect.

Interrelations of the Effects Recently, several studies have explored similarity, attraction and compromise effects and their interrelations in different choice scenarios. In a withinsubject consumer choice design, Berkowitsch et al. (2014) find that the similarity effect is negatively correlated with both the attraction and the compromise effect while the latter two are positively correlated. In a similar vein, Liew, Howe, and Little (2016) criticize that most of the results regarding context effects are based on averages over participants, not taking into account individual differences. Before analyzing the data from their inference and consumer choice experiments, they cluster it according to the observed choice patterns. The differences between clusters are remarkable, some even show negative (reverse) context effects while positive effects are observed in the averaged data. Before explaining how the Simple Choice Tree (SCT) Model accounts for the similarity, attraction and compromise effects and their interrelations, we introduce the basic mechanisms of the model.

## The Simple Choice Tree Model

Let $n_{a}$ be the number of alternatives under consideration, $\left\{A_{1}, A_{2}, \ldots, A_{n_{a}}\right\}$, and $n_{d}$ the number of attributes, $\left\{D_{1}, \ldots, D_{n_{d}}\right\}$, that characterize them. The decision maker is provided with one attribute value per alternative per attribute, that is, $n_{a} \cdot n_{d}$ attribute values in total. Let $m_{i j}$ be the attribute value for alternative $A_{i}$ with respect to attribute $D_{j}$. Attribute values within attributes and between alternatives are repeatedly compared and the resulting evidence is accumulated in two counters $S_{i}^{+}$and $S_{i}^{-}$for each alternative $A_{i}, i \in\left\{1, \ldots, n_{a}\right\}$. The positive counter $S_{i}^{+}$accumulates evidence for choosing alternative $A_{i}$ and the negative counter $S_{i}^{-}$accumulates evidence for rejecting it. Here, the initial counter states are set to zero, $S_{i}^{+}(0)=0=S_{i}^{-}(0)$. Definition of non-zero initial counter states accounting for prior knowledge about the choice alternatives is possible. However, these additional free parameters make the model less parsimonious and complicate parameter estimation. The counter states at time $t, S_{i}^{+}(t)$ and $S_{i}^{-}(t)$, are the initial counter states increased by the respective evidence accumulated until $t$. Their difference defines the momentary preference state for alternative $A_{i}$ at time $t: \operatorname{Pref}\left(A_{i}, t\right)=S_{i}^{+}(t)-S_{i}^{-}(t)$. We will now answer the following questions: (1) How is attention allocated between choice alternatives and attribute values? (2) How are alternatives evaluated and how is evidence accumulated? (3) When does evidence accumulation stop and which alternative is chosen?

## Attention Allocation

At the beginning of the process, when information about the alternatives and attributes is made available to the decision maker, each attribute $D_{j}, j \in\left\{1, \ldots, n_{d}\right\}$, is assigned a weight $\omega_{j}, 0 \leq \omega_{j} \leq 1$, reflecting its salience. The attribute weights determine how much attention the decision maker gives to the respective attributes during the preference construction process. Attributes with higher weights get more attention than attributes with lower weights. To allow for at least some of the attention to be allocated randomly between attributes, we define a random component (see below) for which an additional weight $\omega_{0}, 0 \leq \omega_{0} \leq 1$ is designated. Assuming that the weights sum up to one, $\sum_{j=0}^{n_{d}} \omega_{j}=1$, they can be interpreted as attention probabilities for the attributes: At each points of the preference construction process, the decision maker concentrates on attribute $D_{j}, j \in\left\{1, \ldots, n_{d}\right\}$ with probability $\omega_{j}$.

Having selected an attribute $D_{j}$, the decision maker concentrates on the specific attribute values of two alternatives and compares them. Pairs of attribute values are selected for comparison according to their importance for the decision. The more diagnostic the attribute values are, i.e., the more they discriminate between the alternatives, the more important they become for the decision. Pair selection probabilities within attribute $D_{j}$ are therefore defined to be proportional to the absolute differences $d_{i k j}=\left|m_{i j}-m_{k j}\right|, i \neq k \in\left\{1, \ldots, n_{a}\right\}$. In order to obtain probabilities, we normalize these differences to sum up to one: The probability for selecting the pair
$\left\{m_{i j}, m_{k j}\right\}$ for comparison is $p_{i k j}=d_{i k j} / \sum_{\{l, m\}} d_{l m j}, l \neq m \in$ $\left\{1, \ldots, n_{a}\right\}$. Note that the normalization of absolute differences balances out inequalities between attributes with - on average - bigger or smaller differences. Higher salience of an attribute $D_{j}, j \in\left\{1, \ldots, n_{d}\right\}$, with, for example, higher absolute differences, is thus not hard-wired into the model but is reflected in a higher attribute weight $\omega_{j}$ instead.

## Preference Sampling

The actual comparison of the two selected attribute values $m_{i j}$ and $m_{k j}$ is ordinal and directional: Let $m_{i j}>m_{k j}$, then the comparison can be either positively phrased, e.g. " $m_{i j}$ is greater than $m_{k j}$ ", or it can be negatively phrased, e.g. " $m_{k j}$ is smaller than $m_{i j}$ ". For the positive phrasing, $m_{i j}$ is called focus value and $m_{k j}$ is called reference value. The focus value determines the counter whose state is increased by +1 , here $S_{i}^{+}$, since the comparison is advantageous for the associated alternative $A_{i}$. For the negative phrasing, $m_{k j}$ is the focus value and $m_{i j}$ is the reference value, leading to an increase by +1 of counter $S_{k}^{-}$, since the comparison is disadvantageous for alternative $A_{k}$. Which phrasing the decision maker uses for the comparison and therewith which counter is updated might, for example, depend on the wording of the task or the decision maker's attitude (cf. Choplin \& Hummel, 2002). It is implemented into the model via the focus weight $\lambda, 0 \leq \lambda \leq 1$. If $\lambda=1-\lambda=0.5$, the decision maker uses the positive and negative phrasing both about equally often. If $\lambda>0.5$, the decision maker has a tendency towards the negative phrasing and towards updating negative counters. If $\lambda<0.5$, the decision maker has a tendency towards the positive phrasing and towards updating positive counters. The focus weight $\lambda$ replaces the asymmetric value function that was applied to the absolute differences between attribute values in the original 2NCT Model (Wollschlaeger \& Diederich, 2012). While the asymmetric value function hard-wired a tendency towards updating negative counters into the 2 NCT Model, weighting with $\lambda$ allows for flexible balancing of attention to positive versus negative aspects of the alternatives in the SCT Model. It is therefore especially useful in situations without a loss/gain-framing, e.g., in perceptual or preferential choice. Note that $\lambda$ is a global weight and independent from the attributes and attribute values. However, it allows us to define counter updating probabilities for the positive and negative counter of alternative $A_{i}, i \in\left\{1, \ldots, n_{a}\right\}$ with respect to attribute $D_{j}, j \in\left\{1, \ldots, n_{d}\right\}: p_{i j}^{+}=\sum_{k:\left(m_{i j}>m_{k j}\right)}(1-\lambda) \cdot p_{i k j}$ for updating $S_{i}^{+}$and $p_{i j}^{-}=\sum_{k:\left(m_{i j}<m_{k j}\right)} \lambda \cdot p_{i k j}$ for updating $S_{i}^{-}$.

Finally, the random component accounts for times where counter states are updated at random and without any connection to the actual attribute values (for instance due to inattention or misperception, cf. Busemeyer \& Townsend, 1993). Technically, it is treated as an additional (phantom) attribute $D_{0}$. The counter updating probabilities $p_{i 0}^{+}=p_{i 0}^{-}=1 /\left(2 \cdot n_{a}\right)$, $i \in\left\{1, \ldots, n_{a}\right\}$ with respect to $D_{0}$ depend on the number of available choice alternatives and therefore sum up to one: $\sum_{i=1}^{n_{a}}\left(p_{i 0}^{+}+p_{i 0}^{-}\right)=1$.

Combining attribute-wise counter updating probabilities $p_{i j}^{ \pm}$with attribute weights $\omega_{j}$, we can now define weighted counter updating probabilities for the positive and negative counter of alternative $A_{i}$ :

$$
\begin{equation*}
p_{i}^{+}=\sum_{j=0}^{n_{d}} p_{i j}^{+} \cdot w_{j} \quad \text { and } \quad p_{i}^{-}=\sum_{j=0}^{n_{d}} p_{i j}^{-} \cdot w_{j} \tag{1}
\end{equation*}
$$

## Choice Tree and Stopping Rules

Starting with the presentation of the choice alternatives and their attribute values, the preference construction process consists of a sequence of counter updates. In principle, every possible sequence of counter updates may occur and it is therefore of interest to have them conveniently summarized. For this purpose, we introduce the $\left(2 \cdot n_{a}\right)$-ary choice tree $T=(V, E, r)$ with vertices $V$, edges $E \subseteq V \times V$ and root $r \in V$, where all vertices are directed away from $r$ and each internal vertex $v \in V$ has $2 \cdot n_{a}$ children that are associated with the $2 \cdot n_{a}$ counters. Figure 1 shows an example with three choice alternatives and six counters. The preference construction process is represented by a random walk on $T$, beginning at the root and passing from there through an edge to another vertex, triggering the update (increase by +1 ) of the associated counter, moving on through another edge and so forth. The next edge to pass through is chosen according to the updating probability of the counter associated with its endpoint. Note that for each vertex the transition probabilities of all outgoing edges sum up to one. An example path of this random walk is pictured in bold in Figure 1.

The preference construction process stops when enough evidence has been accumulated to make the required choice. To this end, the preference states $\operatorname{Pref}\left(A_{i}, t\right)=S_{i}^{+}(t)-$ $S_{i}^{-}(t), i \in\left\{1, \ldots, n_{a}\right\}$ are constantly compared to two thresholds, a positive threshold $\theta^{+}$and a negative threshold $\theta^{-}=$ $-\theta^{+}$. If the preference state for alternative $A_{i}$ hits the positive threshold, the process stops and $A_{i}$ is chosen. If, on the other hand, the preference state for alternative $A_{k}$ hits the negative threshold, $A_{k}$ is eliminated from the choice set and the process continues with the remaining alternatives until one of them is chosen or until all but one of them have been eliminated. Consider a simple example with three choice alternatives $\left\{A_{1}, A_{2}, A_{3}\right\}$ and thresholds $\theta^{+}=2$ and $\theta^{-}=-2$. The sample path in Figure 1 with its associated sequence of counter updates $S_{2}^{+}, S_{1}^{-}, S_{1}^{-}, S_{2}^{+}$, leads to elimination of alternative $A_{1}$ after three steps and choice of alternative $A_{2}$ after four steps. Other possible sequences resulting in choice of alternative $A_{2}$ include $S_{3}^{+}, S_{1}^{-}, S_{2}^{+}, S_{2}^{+}$with direct choice of $A_{2}$ after four steps, and $S_{1}^{-}, S_{3}^{-}, S_{3}^{-}, S_{1}^{-}$with elimination of alternatives $A_{3}$ after three steps and $A_{1}$ after four steps and therewith choice of the only remaining alternative $A_{2}$.

## Choice Probabilities and Expected Response Times

The probability for walking along a specific path as, for example, shown in Figure 1, is the product of the transition probabilities along the respective edges. The choice probability for alternative $A_{i}, i \in\left\{1, \ldots, n_{a}\right\}$ is equal to the sum

Figure 1: A random walk on the choice tree for three alternatives. The associated sequence of counter updates is $S_{2}^{+}, S_{1}^{-}, S_{1}^{-}, S_{2}^{+}$and the probability for walking along this specific path is $p_{2}^{+} \cdot p_{1}^{-} \cdot p_{1}^{-} \cdot p_{2}^{+}$. Supposing that the rejection threshold $\theta^{-}$is equal to -2 and the choice threshold $\theta^{+}$is equal to 2 , this sequence implicates first rejection of alternative $A_{1}$ and then choice of alternative $A_{2}$. When $A_{1}$ is eliminated from the choice set, the vertices associated with its counters no longer appear in the choice tree, as can be seen in the bottom row of vertices here.
of the probabilities for walking along all the specific paths that lead to choice of alternative $A_{i}$. Since it is not feasible to calculate probabilities separately for each path and sum them up, we will analyze preference states, choice probabilities and response times instead by interpreting them as independent birth-death Markov chains with absorbing boundaries $\theta^{+}$and $\theta^{-}$. The state space of these birth-death chains $\operatorname{Pref}\left(A_{i}, t\right)=S_{i}^{+}(t)-S_{i}^{-}(t)=: S_{i}(t), i \in\left\{1, \ldots, n_{a}\right\}$ is $\mathcal{S}:=$ $\left\{\theta^{-}, \ldots,-1,0,1, \ldots, \theta^{+}\right\}$, with $|\mathcal{S}|=\theta^{+}-\theta^{-}+1$. The transition probabilities are

$$
\left.\begin{array}{ll}
p_{i}(x, x+1) & =p_{i}^{+}>0 \\
p_{i}(x, x-1) & =p_{i}^{-}>0 \\
p_{i}(x, x)=1-p_{i}^{+}-p_{i}^{-} & =p_{i}^{0}>0
\end{array}\right\} \text { for } x \in \mathcal{S}-\left\{-\theta^{-}, \theta^{+}\right\},
$$

where $p_{i}^{ \pm}$is defined in Eq. 1 above; $p_{i}(x, x+1)=p_{i}(x, x-$ $1)=0, p_{i}(x, x)=1$, for $x \in\left\{-\theta^{-}, \theta^{+}\right\}$; and zero otherwise. They form a $|\mathcal{S}| \times|\mathcal{S}|$ transition probability matrix $P_{i}^{\prime}=\left(p_{r s}^{\prime}\right)_{r, s=1, \ldots, \mid S}$, where $p_{r s}^{\prime}$ is the probability for the birthdeath chain to transition from state $x_{r}$ to state $x_{s}$ in one step. $P_{i}^{\prime}$ can be written in its canonical form $P_{i}$ by rearranging the rows and columns (changing the indices of the states such that the absorbing states $-\theta^{-}$and $\theta$ come first). $P_{i}$ can be de-
composed into a $2 \times 2$ identity matrix $I_{2}$, a $2 \times n_{t}$ matrix 0 of zeros with $n_{t}=|\mathcal{S}|-2$ (the number of transient states in $\mathcal{S}$ ), a $n_{t} \times 2$ matrix $R_{i}$, containing the probabilities for entering the absorbing states $\theta^{+}$and $\theta^{-}$, that is, for hitting the elimination or choice threshold, and a $n_{t} \times n_{t}$ matrix $Q_{i}$, containing the transition probabilities between transient states (cf. Diederich, 1997): $P_{i}=\left(\begin{array}{cc}I_{2} & 0 \\ R_{i} & Q_{i}\end{array}\right)$.

Given a row vector $Z_{i}$ of length $n_{t}$ which represents the initial preference state (e.g., ( $\left.\begin{array}{lllll}0 & 0 & 1 & 0 & 0\end{array}\right)$ ) or the initial distribution of preference over the transient states (e.g., $\left(\begin{array}{lllll}0.05 & 0.10 & 0.70 & 0.10 & 0.05\end{array}\right)$, cf. Diederich \& Busemeyer, 2003) for alternative $A_{i}$, the probability that the process is absorbed during the first step can be obtained by multiplying $Z_{i}$ and $R_{i}$, yielding a vector of length $2: Z_{i} \cdot R_{i}=$ $\left[P\left(S_{i}(1)=\theta^{+}\right), P\left(S_{i}(1)=-\theta^{-}\right)\right]$. In the case that the process was not absorbed during the first step, the distribution of preference over the transient states after the first step is given by $Z_{i} \cdot Q_{i}$, a vector of length $n_{t}$. Multiplying the result with the matrix $R_{i}$ yields the probabilities of absorption in the second step: $Z_{i} \cdot Q_{i} \cdot R_{i}=\left[P\left(S_{i}(2)=\theta^{+}\right), P\left(S_{i}(2)=-\theta^{-}\right)\right]$. The distribution of preference over the transient states is given by $\left(Z_{i} \cdot Q_{i}\right) \cdot Q_{i}=Z_{i} \cdot\left(Q_{i} \cdot Q_{i}\right)=Z_{i} \cdot\left(Q_{i}\right)^{2}$. The entries of the $n_{t} \times n_{t}$ matrix $\left(Q_{i}\right)^{2}$ are 2-step transition probabilities between the transient states, allowing for calculation of absorption in the third step: $Z_{i} \cdot\left(Q_{i}\right)^{2} \cdot R_{i}=\left[P\left(S_{i}(3)=\right.\right.$ $\left.\left.\theta^{+}\right), P\left(S_{i}(3)=-\theta^{-}\right)\right]$. Iterating these results indicates that all the relevant probabilities can be obtained from the vector $Z_{i}$, the matrix $R_{i}$ and powers of the matrix $Q_{i}$. Since $Q_{i}$ is a tridiagonal Toeplitz matrix (the entries on the main diagonal are all equal to $p_{i}^{0}$, the entries on the diagonal above the main diagonal are equal to $p_{i}^{+}$and the entries on the diagonal below the main diagonal are equal to $p_{i}^{-}$), its eigenvalues, eigenvectors and its powers are known and given in closed form (Salkuyeh, 2006), making it easy to compute all the relevant quantities.

We are interested in the conditional probabilities and expected hitting times for each alternative $A_{i}, i \in\left\{1, \ldots, n_{a}\right\}$, given that $A_{i}$ is the first alternative to be chosen/eliminated. Therefore, we have to determine the probability that alternative $A_{k}, k \in\left\{1, \ldots, n_{a}\right\}$ with $k \neq i$, has not been chosen/eliminated until time $t$. It is given by

$$
\begin{aligned}
& P\left(-\theta^{-}<S_{k}(T)<\theta\right)=1-\sum_{t=1}^{T} Z_{k} \cdot\left(Q_{k}\right)^{t-1} \cdot R_{k} \cdot\binom{1}{1} \\
& =1-Z_{k} \cdot\left(\sum_{t=1}^{T}\left(Q_{k}\right)^{t-1}\right) \cdot R_{k} \cdot\binom{1}{1} .
\end{aligned}
$$

The choice and elimination probability for alternative $A_{i}$ at time T is then equal to

$$
\begin{aligned}
& {\left[P\left(S_{i}(T)=-\theta^{-}\right), P\left(S_{i}(T)=\theta\right)\right]} \\
& =\left(Z_{i} \cdot \sum_{t=1}^{T}\left(Q_{i}\right)^{t-1} \cdot R_{i}\right) \cdot \prod_{k \neq i}\left(P\left(-\theta^{-}<S_{k}(T)<\theta\right)\right) .
\end{aligned}
$$

Overall, this yields probabilities

$$
\begin{aligned}
& {\left[P\left(\text { choose }_{i}\right), P\left(\text { eliminate }_{i}\right)\right]} \\
& =\sum_{T=1}^{\infty}\left(\left[P\left(S_{i}(T)=-\theta^{-}\right), P\left(S_{i}(T)=\theta\right)\right]\right)
\end{aligned}
$$

and expected response times

$$
\begin{aligned}
& {\left[E\left(T_{i} \mid \text { choose }_{i}\right), E\left(T_{i} \mid \text { eliminate }_{i}\right)\right]} \\
& =\sum_{T=1}^{\infty} T \cdot\left(\left[P\left(S_{i}(T)=-\theta^{-}\right), P\left(S_{i}(T)=\theta\right)\right]\right)
\end{aligned}
$$

Note that the infinite sums over T have only a finite number of nonzero addends, since $P\left(N_{i}<\infty\right)=1$ for all $i \in\left\{1, \ldots, n_{a}\right\}$, thus the choice/elimination probabilities and expected response times can be easily computed.

## Context Effects Explained

Three interacting mechanisms produce similarity, attraction, and compromise effects in the Simple Choice Tree Model: (1) selection of pairs of attribute values for comparison based on normalized differences, (2) the possibility to eliminate unwanted alternatives from the choice set, and (3) weighting of attributes based on salience. The first mechanism leads to a higher impact of dissimilar alternatives on the updating probabilities and thus faster evidence accumulation for alternatives with more distant competitors. In the similarity and attraction settings, this applies to the dissimilar alternative $A_{2}$, and in the compromise situation to the extreme alternatives $A_{2}$ and $A_{3}$. The second mechanism and the related focus weight $\lambda$ determine whether choices are more likely to be based on eliminations or to be made directly. The greater $\lambda$, the more likely are the choices based on eliminations. In the similarity situation, greater $\lambda$ leads to faster elimination of the dissimilar alternative $A_{2}$ and subsequent choice or elimination of either alternative $A_{1}$ or $A_{3}$, that is, a small or even negative similarity effect. On the other hand, smaller $\lambda$ leads to more direct choices of alternative $A_{2}$ and thus a higher similarity effect. Regarding the dissimilar alternative $A_{2}$, the same is true in the attraction situation. Greater $\lambda$ leads to faster elimination of $A_{2}$ while smaller $\lambda$ leads to more direct choices of alternative $A_{2}$. However, the attraction effect is higher for greater $\lambda$, since after elimination of alternative $A_{2}$, either the dominating option $A_{1}$ is chosen directly or the dominated option $A_{3}$ is eliminated first. In the compromise setting, greater $\lambda$ increases the probability for the extreme options to be eliminated from the choice set, leaving the decision maker with the compromise option. Smaller $\lambda$ on the other hand more likely leads to choice of an extreme option and thus a smaller or even negative compromise effect. Attribute weights further moderate the strengths of the context effects, but as long as they are more or less balanced, they play a minor role in the explanation of the similarity, attraction, and compromise effects. However, a high attribute weight is able to bias choice towards the alternative that scores highest on that attribute, covering any context effect.

Figure 2: Simulations of choice probabilities for changing focus weight $\lambda$ in the similarity, attraction, and compromise situation. There is a positive similarity effect for smaller $\lambda$ and a negative similarity effect for larger $\lambda$ (upper left) and vice versa for the attraction effect (upper right). The compromise effect (lower left and right) shows for larger $\lambda$ and is reversed for smaller $\lambda$.

We ran several simulations to illustrate these mechanisms. The available choice alternatives were $A_{1}=(70,30), A_{2}=$ $(30,70)$ and $A_{3}=(70,30)$ for the similarity effect, $A_{3}=$ $(65,25)$ for the attraction effect, $A_{3}=(90,10)$ for the asymmetric compromise effect, or $A_{3}=(50,50)$ for the symmetric compromise effect. The attribute weights were $\omega_{0}=0.1$ and $\omega_{1}=\omega_{2}=0.45$, and the focus weight $\lambda$ varied between 0 and 1 in steps of 0.1 . For each data point we ran 10000 simulations and the resulting choice probabilities are presented in figure 2. According to the simulations, the similarity effect is opposed to the attraction and the compromise effect. The similarity effect is strongest for low $\lambda$, whereas the attraction and the compromise effect are strongest for high $\lambda$. This prediction is consistent with the finding that the attraction and the compromise effect are positively correlated with each other and negatively correlated with the similarity effect (Berkowitsch et al., 2014). Note that $\lambda$ is assumed to be a global weight that does not change between trials but may vary between participants.

## Conclusion

We propose a revised and simpler version of the $2 N$-ary Choice Tree Model (Wollschlaeger \& Diederich, 2012), the Simple Choice Tree (SCT) Model. It predicts choice probabilities and response times in multi-alternative multi-attribute preferential choice from description and accounts for several
effects observed in these situations, including the similarity, attraction, and compromise effect. The SCT Model shares several aspects with existing models: Like Decision by Sampling (DbS; Stewart, Chater, \& Brown, 2006), it proposes binary ordinal comparisons and frequency accumulation as basic mechanisms. In DbS , however, pairs of attribute values are chosen at random and reference values may be sampled from long-term memory as well as from the given context. Only advantageous comparisons are counted and the model is not able to account for the above mentioned context effects, nor does it provide solutions for choice probabilities or choice response times. Multi-alternative Decision Field Theory (MDFT; Roe et al., 2001) and the Leaky Competing Accumulator (LCA) Model (Usher \& McClelland, 2001, 2004) provide such solutions only for fixed stopping times. Both models, like the SCT Model, are based on pairwise differences of attribute values. To account for the similarity, attraction, and compromise effect simultaneously, however, additional non-linear mechanisms (among others leakage and inhibition, cf. the original 2 NCT Model) are required, preventing the models from providing mathematically tractable solutions for optional stopping times. Elimination by Aspects (EBA; Tversky, 1972) proposes "a covert elimination process based on sequential selection of aspects" (p. 296). As an early example for a cognitive process model, it does not make any predictions about choice response times and accounts only for the similarity effect. The SCT model mimics EBA for high values of the focus weight $\lambda$, where mostly disadvantageous comparison outcomes are considered and decisions are based on the elimination of choice alternatives. The Multiattribute Linear Ballistic Accumulator Model (MLBA; Trueblood, Brown, \& Heathcote, 2014), basically a deterministic version of MDFT, provides analytic solutions for expected response times and choice probabilities like the SCT Model. However, it is unclear if and how the response times are related to the actual integration of information. Furthermore, the model has mostly been applied with fixed stopping times until now. Additional mechanisms allow the MLBA model to account for the compromise effect (a curved subjective value function) and the similarity effect (a higher weight on supportive information as compared to disconfirmatory evidence). The latter is comparable to low values of the focus weight $\lambda$ in the SCT Model. To summarize, the SCT Model combines aspects of competing models in a new way, yielding qualitatively new explanations for the context effects and additionally predicting correlation patterns amongst the effects. It provides mathematically tractable solutions for both choice probabilities and expected choice response times for optional stopping times, by that outperforming existing models.

#### Abstract

We introduce the spatially correlated multi-armed bandit as a task coupling function learning with the explorationexploitation trade-off. Participants interacted with bi-variate reward functions on a two-dimensional grid, with the goal of either gaining the largest average score or finding the largest payoff. By providing an opportunity to learn the underlying reward function through spatial correlations, we model to what extent people form beliefs about unexplored payoffs and how that guides search behavior. Participants adapted to assigned payoff conditions, performed better in smooth than in rough environments, and-surprisingly-sometimes performed equally well in short as in long search horizons. Our modeling results indicate a preference for local search options, which when accounted for, still suggests participants were best-described as forming local inferences about unexplored regions, combined with a search strategy that directly traded off between exploiting high expected rewards and exploring to reduce uncertainty about the spatial structure of rewards.

Keywords: Exploration-exploitation; Multi-armed bandits; Active Learning; Gaussian Processes;

## Introduction

Modern humans descend from capable foragers and hunters, who have migrated and survived in almost every environment on Earth. Our ancestors were able to adaptively learn the distribution of resources in new environments and make good decisions about where to search, balancing the dual goals of exploring to acquire new information and exploiting existing knowledge for immediate gains. What strategies do humans use to search for resources in unknown environments?

We present a new framework for studying human search behavior using a spatially correlated multi-armed bandit task, where nearby arms (i.e., search options) have correlated rewards. Spatial correlations provide an opportunity to learn about the underlying reward function, extending the traditional reinforcement learning paradigm (Sutton \& Barto, 1998) to allow for generalization of learned rewards to unobserved actions using spatial context. We compare search behavior across different payoff conditions, search horizons, and types of environments, finding that participants adapt to their environment, tend to perform very local inferences about unexplored regions and choose arms based on a trade-off between expectations and their attached uncertainties.

## Spatially Correlated Multi-Armed Bandits

We adapt the multi-armed bandit (MAB) setting by adding spatial correlation to rewards and placing the arms in a twodimensional grid (Fig. 1). Each tile represents a playable arm of the bandit, which are initially blank and display the numerical reward value (along with a color aid) after an arm has been chosen. Traditionally, the goal in an MAB task is to

Figure 1: Examples of the underlying reward functions for the two classes of environments.
maximize cumulative payoffs by sequentially choosing one of the N -arms of the bandit that stochastically generate rewards (Steyvers, Lee, \& Wagenmakers, 2009), with learning happening independently for each arm (i.e., reinforcement learning). In our case, because proximate arms generate similar rewards, there is the opportunity to form inductive beliefs about unobserved rewards (i.e., function learning). This allows us to study how people generate beliefs about unobserved rewards and how this influences their search behavior.

The spatially correlated MAB is related to the optimal foraging context (Krebs, Kacelnik, \& Taylor, 1978), whereby a forager is not only guided by the search for resources, but also by the need to acquire information about the distribution of resources in the environment (Schulz, Huys, Bach, Speekenbrink, \& Krause, 2016). This creates a natural trade-off between exploration and exploitation (March, 1991), where an effective search policy needs to adequately balance exploring areas with higher uncertainty, while also exploiting existing information to obtain rewards. One key difference in our task is that the decision-maker must determine where to search, and not only whether to stay or to leave a patch.

## Modeling Adaptive Search Behavior

We consider various computational models for describing human behavior, which all make sequential predictions about where people are likely to search. We present both simple strategies without an explicit representation of the environment, along with more complex function generalization models representing the task as a combination of (i) a function learning model and (ii) a decision strategy. We use a form of Gaussian Process regression as a flexible and universal function learning model, which forms inferential beliefs about the underlying reward function, conditioned on previous observations of rewards. Decision strategies are used to transform beliefs into predictions about where to search next. The recovered parameter estimates of our models describe the extent to which people make spatial inferences and how they trade off between exploration and exploitation.

## Simple Strategies

Local search. While simple, a tendency to stay local to the previous search decision-regardless of outcome-has been observed in many different contexts, such as semantic foraging (Hills, Jones, \& Todd, 2012), causal learning (Bramley, Dayan, Griffiths, \& Lagnado, 2017), and eye movements (Hoppe \& Rothkopf, 2016). We use inverse Manhattan distance (IMD) to quantify locality:

$$
\begin{equation*}
\operatorname{IMD}\left(\mathbf{x}, \mathbf{x}^{\prime}\right)=\frac{1}{\left|x_{1}-x_{1}^{\prime}\right|+\left|x_{2}-x_{2}^{\prime}\right|} \tag{1}
\end{equation*}
$$

which compares the location of two arms $\mathbf{x}$ and $\mathbf{x}^{\prime}$, where $x_{1}$ and $x_{2}$ are the grid coordinates. For the special case where $\mathbf{x}=\mathbf{x}^{\prime}$, we set $\operatorname{IMD}\left(\mathbf{x}, \mathbf{x}^{\prime}\right)=1$. At each time $t$, we compute the IMD for each arm based on the choice at $\mathbf{x}_{t-1}$, and then use a softmax function (Eq. 11) to transform locality into choice probabilities, such that arms closer to the previous search decision have a higher probability of being chosen.

Win-stay lose-shift. We also consider a form of the winstay lose-shift (WSLS) heuristic (Herbert, 1952), where a win is defined as finding a payoff with a higher or equal value than the previous best. When the decision-maker "wins", we assume that any tile with a Manhattan distance $\leq 1$ is chosen (i.e., a repeat or any of the four cardinal neighbors) with equal probability. Losing is defined as the failure to improve, and results in choosing any unrevealed tile with equal probability.

## Function Generalization Models

We use a combination of (i) Gaussian Process ( $\mathcal{G} \mathcal{P}$ ) regression as a model of how people form beliefs about the underlying reward function conditioned on previous observations (Lucas, Griffiths, Williams, \& Kalish, 2015), and (ii) a decision strategy that transforms beliefs into predictions about where a participant will sample next. This approach has recently been applied to human behavior in contextual multi-armed bandits (Schulz, Konstantinidis, \& Speekenbrink, 2016) and is the only known computational algorithm to have any guarantees in a bandit setting (i.e., bounded regret; Srinivas, Krause, Kakade, \& Seeger, 2010).

Gaussian process learning. A $\mathcal{G} \mathcal{P}$ defines a distribution $P(f)$ over possible functions $f(\mathbf{x})$ that map inputs $\mathbf{x}$ to output $y$, in our case, grid location to reward. A $\mathcal{G} P$ is completely defined by a mean $\mu(\mathbf{x})$ and a kernel function, $k\left(\mathbf{x}, \mathbf{x}^{\prime}\right)$ :

$$
\begin{align*}
\mu(\mathbf{x}) & =\mathbb{E}[f(\mathbf{x})]  \tag{2}\\
k\left(\mathbf{x}, \mathbf{x}^{\prime}\right) & =\mathbb{E}\left[(f(\mathbf{x})-\mu(\mathbf{x}))\left(f\left(\mathbf{x}^{\prime}\right)-\mu\left(\mathbf{x}^{\prime}\right)\right)\right] \tag{3}
\end{align*}
$$

Here, we fix the prior mean to the median value of payoffs, $\mu(\mathbf{x})=50$ and use a radial basis function kernel (Eq. 7).

Suppose we have collected observations $\mathbf{y}_{T}=$ $\left[y_{1}, y_{2}, \ldots, y_{T}\right]^{\top}$ at inputs $\mathbf{X}_{T}=\left\{\mathbf{x}_{1}, \ldots, \mathbf{x}_{T}\right\}$, and assume

$$
\begin{equation*}
y_{t}=f\left(\mathbf{x}_{t}\right)+\varepsilon_{t} \quad \varepsilon_{t} \sim \mathcal{N}(0,1) \tag{4}
\end{equation*}
$$

Given a $\mathcal{G} \mathcal{P}$ prior on functions $f(\mathbf{x}) \sim \mathcal{G} \mathcal{P}\left(\mu(\mathbf{x}), k\left(\mathbf{x}, \mathbf{x}^{\prime}\right)\right)$, the posterior distribution over $f\left(\mathbf{x}_{T}\right)$ given inputs $\mathbf{X}_{T}$ is also
a $\mathcal{G} \mathcal{P}$ with the following mean and covariance:

$$
\begin{align*}
\mu_{T}(\mathbf{x}) & =\mathbf{k}_{T}(\mathbf{x})^{\top}\left(\mathbf{K}_{T}+\sigma^{2} \mathbf{I}\right) \mathbf{y}_{T}  \tag{5}\\
k_{T}\left(\mathbf{x}, \mathbf{x}^{\prime}\right) & =k\left(\mathbf{x}, \mathbf{x}^{\prime}\right)-\mathbf{k}_{T}(\mathbf{x})^{\top}\left(\mathbf{K}_{T}+\sigma^{2} \mathbf{I}\right)^{-1} \mathbf{k}_{T}\left(\mathbf{x}^{\prime}\right) \tag{6}
\end{align*}
$$

where $\mathbf{k}_{T}(\mathbf{x})=\left[k\left(\mathbf{x}_{1}, \mathbf{x}\right), \ldots, k\left(\mathbf{x}_{T}, \mathbf{x}\right)\right]^{\top}$ and $\mathbf{K}_{T}$ is the positive definite kernel matrix $\left[k\left(\mathbf{x}_{i}, \mathbf{x}_{j}\right)\right]_{i, j=1, \ldots, T}$. This posterior distribution is used to derive normally distributed predictions about the rewards for each arm of the bandit (Fig. 2).

The kernel function $k\left(\mathbf{x}, \mathbf{x}^{\prime}\right)$ encodes prior assumptions about the underlying function. We use the radial basis function (RBF) kernel

$$
\begin{equation*}
k_{\mathrm{RBF}}\left(\mathbf{x}, \mathbf{x}^{\prime}\right)=\exp \left(-\frac{\left\|\mathbf{x}-\mathbf{x}^{\prime}\right\|^{2}}{2 \lambda^{2}}\right) \tag{7}
\end{equation*}
$$

which is a universal function learner and assumes infinitely smooth functions (i.e., correlations between two points $\mathbf{x}$ and $\mathbf{x}^{\prime}$ slowly decay as an exponential function of their distance). The RBF kernel uses $\lambda$ (length-scale) as a free parameter, which determines how far correlations extend: larger values of $\lambda$ result in longer spatial correlations, whereas $\lambda \rightarrow 0^{+}$assumes complete independence of spatial information. We use recovered parameter estimates of $\lambda$ to learn about the extent to which humans make inferences about unobserved rewards.

Decision strategies. The $\mathcal{G} P$ learning model generates normally distributed predictions about the expectation $\mu(\mathbf{x})$ and the uncertainty $\sigma(\mathbf{x})$ for each arm, which are available to the decision strategies ${ }^{1}$ for evaluating the quality, $q(\mathbf{x})$, and ultimately making a prediction about where to sample next.

The Variance Greedy (VG) strategy values an arm using only the estimated uncertainty

$$
\begin{equation*}
q_{V G}(\mathbf{x})=\sigma(\mathbf{x}) \tag{8}
\end{equation*}
$$

and is an efficient step-wise (greedy) approximation of information gain (Srinivas et al., 2010), which seeks to learn the global reward function as rapidly as possible. VG achieves at least a constant fraction of the optimal information gain value (Krause \& Guestrin, 2005); however, it fails to adequately trade-off between exploration and exploitation, because effort is wasted exploring the function where $f(\mathbf{x})$ is small.

The Mean Greedy (MG) strategy is also step-wise greedy, valuing arms using only the estimated mean reward

$$
\begin{equation*}
q_{M G}(\mathbf{x})=\mu(\mathbf{x}) \tag{9}
\end{equation*}
$$

although this strategy carries no known guarantees and is prone to getting stuck in local optima.

Upper confidence bound sampling (UCB) combines the VG and MG strategies

$$
\begin{equation*}
q_{U C B}(\mathbf{x})=\mu(\mathbf{x})+\beta \sigma(\mathbf{x}) \tag{10}
\end{equation*}
$$

[^245]where the exploration factor $\beta$ determines how the reduction of uncertainty trades off against exploiting high expected rewards. This is sometimes referred to as optimistic "sampling with confidence" as it inflates expectations with respect to the upper confidence bounds (Srinivas et al., 2010), creating a natural balance between exploration and exploitation.

Figure 2: Modeling human performance. Column left represents the initial state of the task and column right is after 10 clicks. Top row: screenshots from the experiment. 2nd row: posterior predictions of expected reward $\mu(\mathbf{x})$, from a $\mathcal{G} \mathcal{P}$ with an RBF kernel (not shown: the estimated variance). 3rd row: the values of each tile $q(\mathbf{x})$ using the UCB acquisition function. Bottom row: the softmax prediction surface transforming the UCB values into choice probabilities.

## Choice Probabilities

For all models, we use a softmax function (Fig. 2 bottom row) to convert the value of an option $q(\mathbf{x})$ into a choice probability

$$
\begin{equation*}
P(\mathbf{x})=\frac{\exp (q(\mathbf{x}) / \tau)}{\sum_{j=1}^{N} \exp \left(q\left(\mathbf{x}_{j}\right) / \tau\right)} \tag{11}
\end{equation*}
$$

where $\tau$ is the temperature parameter. As $\tau \rightarrow 0$ the highestvalue arm is chosen with a probability of 1 (i.e., argmax), and when $\tau \rightarrow \infty$, all options are equally likely, with predictions converging to random choice. We use $\tau$ as a free parameter, where lower estimates can be interpreted as more precise predictions about choice behavior.

## Experiment

We present a bi-variate MAB problem with spatially correlated rewards. The problem space was represented by a twodimensional grid, measuring $11 \times 11$, resulting in 121 unique tiles in total. Participants could click to reveal unexplored tiles or re-click previously uncovered tiles to exploit known rewards (see Fig. 2 top row for screenshots).

## Methods

Participants. We recruited 80 participants from Amazon Mechanical Turk ( 25 Female; mean age $\pm$ SD $32 \pm 9$ ). Each participant was paid a participation fee of $\$ 0.50$ and a performance contingent bonus up to $\$ 1.50$. Subjects earned on average $\$ 1.64 \pm 0.20$ and spent $8 \pm 4$ minutes on the task.

Design. We used a $2 \times 2$ between subject design, where participants were randomly assigned to one of two different pay-off structures (Average Reward vs. Maximum Reward) and one of two different classes of environments (Smooth vs. Rough). Each grid represented a bi-variate function, with each observation including normally distributed noise, $\varepsilon \sim \mathcal{N}(0,1)$. The task was presented over 8 blocks on different grid worlds drawn from the same class of environments. In each block, participants had either a Short ( 20 clicks) or Long ( 40 clicks) search horizon to interact with the grid. The search horizon alternated between blocks (within subject), with initial horizon length counterbalanced between subjects. Per block, observations were scaled to a uniformly sampled maximum value in the range of 65 to 85 , so that the value of the global optima could not be easily guessed (e.g., a value of 100).

Materials and procedure. Before starting, participants were shown four fully revealed grids in order to familiarize themselves with the task. Example environments were drawn from the same class of environments assigned to the participant (Smooth or Rough) and underwent the same random scaling of observations. Additionally, three comprehension questions were used to ensure full understanding of the task.

At the beginning of each of the 8 blocks, one random tile was revealed and participants could use their mouse to click any of the 121 tiles in the grid until the search horizon was exhausted, including re-clicking previously revealed tiles. Clicking an unrevealed tile displayed the numerical value of the reward along with a corresponding color aid, where darker colors indicated higher point values (Fig. 1). Previously revealed tiles could also be re-clicked, although there were variations in the observed value due to noise. For repeat clicks, the most recent observation was displayed numerically, while hovering over the tile would display the entire history of observations. The color of the tile corresponded to the mean of all previous observations.

Payoff conditions. We compared performance under two different payoff conditions, requiring either a balance between exploration and exploitation (Average Reward) or a pure exploration context (Maximum Reward). Previous work
has shown that people can adapt (sometimes with great difficulty) to different payoff conditions in information acquisition tasks (Meder \& Nelson, 2012).

In each payoff condition, participants received a performance contingent bonus of up to $\$ 1.50$. Average Reward participants were told to "gain as many points as possible across all 8 grids" and were given a bonus based on the average value of all clicks as a fraction of the global optima, $\frac{1}{T} \sum\left(\frac{y_{t}}{y^{*}}\right)$, where $y^{*}$ is the global optimum. Maximum Reward participants were told to "learn where the largest reward is" and were giving a bonus using the ratio of the highest observed reward to the global optimum, $\left(\frac{\max y_{t}}{y^{*}}\right)^{4}$, taken to the power of 4 to exaggerate differences in the upper range of performance and for parity in expected earnings across payoff conditions. All 8 blocks were weighted equally, using noisy but unscaled observations to assign a bonus of up to $\$ 1.50$. Subjects were informed in dollars about the bonus earned at the end of each block.

Smoothness of the environment. We used two different classes of environments, corresponding to different levels of smoothness (Fig. 1). All environments were sampled from a $\mathcal{G} \mathcal{P}$ prior parameterized with a RBF kernel, where the lengthscale parameter $(\lambda)$ determines the rate at which the correlations of rewards decay over distance. We sampled 20 Smooth environments using $\lambda=2$ and 20 Rough environments using $\lambda=1$. Subjects performed the task on 8 grids randomly drawn (without replacement) from their assigned class of environments, while the four fully revealed environments used to familiarize subjects with the task were drawn (without replacement) from the remaining 12 environments.
Search horizons. The length of the search horizon influences the value of information learned about the environment, with respect to the assigned payoff condition. Longer horizons provide more opportunities for exploiting acquired information, thereby making early exploration more valuable. We chose two horizon lengths (Short $=20$ and Long $=40$ ) that were fewer than the total number of tiles on the grid (121), and varied within subject (alternating between blocks).

## Results

Figure 3 shows task performance. In all conditions, performance improved as a function of the trial number (i.e., with each additional click), as measured by both the overall correlation between average reward and trial number ( $r=.32$, $p=.04$ ) and between the maximum observed reward and trial number ( $r=.83, p<.001$ ). There were no learning effects across blocks (i.e., over successive grids), indicated by a lack of correlation between average reward and block number ( $r=.19, p=.65$ ), or between maximum reward and block number ( $r=-.37, p=.36$ ). Performance improved as more information was revealed (i.e., over trials), but not over additional blocks of identically parameterized environments.

Payoff conditions. Payoff conditions influenced search behavior, with participants in the Maximum Reward condition
displaying more variance in the locations sampled $(t) 78)=$ $-2.48, p=.02$ ). There were some differences in the number of unique tiles revealed (Fig. 3C) and the number of repeat clicks across the payoff conditions (Fig. 3D), although the effect size is largest for smooth environments given long search horizons. However, these behavioral differences did not manifest in terms of performance, with no systematic differences across payoff conditions in terms of the average reward obtained $t(78)=1.32, p=.2$ ) or in the maximum revealed reward $(t(78)=.001, p=.99)$.
Environment and horizon. Independent of the payoff condition, participants assigned to Smooth environments achieved higher average rewards $(t(78)=6.55, p<.001)$ and higher maximum rewards $(t(78)=5.45, p<.001)$, than those assigned to the Rough environments (Fig. 3E), suggesting that stronger correlations of payoffs make the task easier. Interestingly, longer horizons did not lead to better overall performance in the Average Reward condition $(t) 80)=.34$, $p=.73$ ), although participants given longer horizons found larger maximum rewards for all payoffs and environment conditions $(t(158)=7.62, p<.001)$. There may be a less-is-more-effect, with longer horizons leading to over-exploration, given the goal of maximizing average rewards.

Figure 3: Overview of task performance. (A) Average reward earned and (B) maximum reward revealed, where colors correspond to payoff condition and line-types to horizon length. Black lines show simulated performance of a random model averaged over 10,000 randomly sampled grids. (C) The average number of unique tiles clicked in each block and (D) the average number of repeat clicks in each block. (E) The distribution of rewards earned during each block, grouped first by environment type and then by horizon length.

## Model Comparison

We describe each model's ability to predict participant behavior using leave-one-block-out cross validation. For each participant, we analyzed the four short and the four long horizon blocks separately. Cross-validation was performed by holding out a single block as a test set, and fitting the model parameters using a maximum likelihood estimate (MLE) on the remaining three blocks. Iterating through each of the four hold-out blocks, for both short and long horizons, we calculated a model's out-of-sample log loss (i.e., test set prediction accuracy) and then summed up the results over all blocks. We use McFadden's $R^{2}$ values (McFadden, 1974) to compare the out-of-sample log loss for each model to that of a random model (Fig. 4), where $R^{2}=0$ indicates chance performance and $R^{2}=1$ is a perfect model.

Reward Condition $\square$ Average Reward $\square$ Maximum Reward
Figure 4: Model Comparison. The height of the bars show the group mean and error bars indicate standard error. McFadden's $R^{2}$ is a goodness of fit measure comparing each model $\mathcal{M}_{k}$ to a random model $\mathcal{M}_{\text {rand }}$. Using the out-of-sample log loss for each model, $R_{\mathrm{McF}}^{2}=1-\log \mathcal{L}\left(\mathscr{M}_{k}\right) / \log \mathcal{L}\left(\mathcal{M}_{\text {rand }}\right)$.

A large amount of the variance in participant behavior is explained by local search $\left(R^{2}=.28\right.$; all conditions); however, locality alone fails to achieve similar task performance as humans, with performance almost identical to random in terms of average reward and worse than random in maximum reward (Fig. 5). WSLS by comparison, was a poor approximation of search behavior ( $R^{2}=.05$ ), and was excluded from the model performance comparison.

Among the GP models, UCB performed best ( $R^{2}=.23$ ), with MG showing comparable results $\left(R^{2}=.17\right)$ and VG performing poorly ( $R^{2}=.01$ ). Interestingly, the performance of the GP-UCB model was remarkably similar to human subjects in terms of both average and maximum reward (Fig. 5). Both humans and the GP-UCB model explore beyond what is adaptive in the average reward context as evidenced by the peak around $t=15$, continuing to explore after most highvalue rewards have been revealed and thus failing to consistently improve average rewards ${ }^{2}$.

To harmonize the different aspects of human behavior captured by local search and by the GP-UCB model, we added a

[^246]local variant of each GP model (Local GP), which weighs the $q(\mathbf{x})$ for each arm by the inverse Manhattan distance to the previous choice, $q_{\text {Local }}\left(\mathbf{x}_{t}\right)=q\left(\mathbf{x}_{t}\right) \cdot \operatorname{IMD}\left(\mathbf{x}_{t}, \mathbf{x}_{t-1}\right)$. Adding locality to the GP models only improved prediction accuracy (Fig. 4 right), with the Local GP-UCB model having the highest overall out-of-sample prediction accuracy ( $R^{2}=.38$ ).

Overall, the modeling results show that humans display a preference for local search, but that locality alone fails to achieve comparable performance levels. The best model (Local GP-UCB) incorporated this tendency for local search into a computational model that combines function learning with a decision strategy explicitly trading off between both high expected rewards and high uncertainty.

Figure 5: Comparison of simulated model performance over 10,000 replications, where parameters were sampled from the crossvalidated MLEs of the subject population. Human results are averaged across payoff conditions and horizon length.

## Parameter Estimation

Figure 6 shows the cross-validated parameter estimates of the best predicting Local GP-UCB model. The estimates indicate subjects systematically under-estimated the smoothness of the underlying environments, with $\lambda$ values lower than the true underlying function $\left(\lambda_{\text {Smooth }}=2, \lambda_{\text {Rough }}=1\right)$, for both Rough environments $(t(36)=-4.80, p<.001)$ and Smooth environments $(t(42)=-18.33, p<.001)$, using the median parameter estimate for each subject. Participants not only had a tendency towards selecting local search options, but also made local inferences about the correlation of rewards.

All participants valued the reduction of uncertainty ( $\beta>$ 0 ), with long horizons often yielding larger $\beta$ estimates than short horizons ( 51 out of 80 subjects; $t(79)=-2.02, p=$ $.047)^{3}$. There were no differences between payoff conditions $(t(78)=-1.65, p=.1)$ or environments $(t(78)=.5, p>.1)$.

Subjects in the average reward condition yielded smaller estimates of the softmax temperature parameter ( $\tau$ ) than those in the maximum reward condition $(t(78)=-2.66, p=.009)$, This is consistent with almost all models making better predictions for average reward than for maximum reward subjects (Fig. 4), since smaller values of $\tau$ indicate more precise predictions. The larger number of unique tiles searched in the maximum reward condition (Fig. 3C) may indicate a more difficult prediction problem.

[^247]

Figure 6: Cross-validated parameter estimates for the Local GPUCB model, showing the median estimate for each participant.

## General Discussion

The results presented here can be seen as a first step towards uncovering how people search to acquire rewards in the presence of spatial correlations. We have re-cast the multi-armed bandit problem as a framework for studying both functionlearning and the exploration-exploitation trade-off by adding spatial correlations to rewards. Within a simple experiment about searching for rewards on a two-dimensional grid, we found that participants adapt to the underlying payoff condition, perform better in smooth than in rough environments, and-surprisingly-sometimes seem to perform as well in short as in long horizon settings.

Our modeling results show a tendency to prioritize local search options, which may indicate the presence of innate search costs (e.g., mouse movements or some additional cognitive processing). Even accounting for this local search behavior, our best predicting model (Local GP-UCB) indicates that people still systematically underestimate the extent of spatial correlation of rewards, preferring instead to make very local inferences about unexplored rewards. Additionally, we also found that search behavior was best predicted by a combination of both high expected reward and high uncertainty, embodied in the UCB decision strategy, which implicitly negotiates the exploration-exploitation trade-off.

Future studies could expand on this work by assessing a more diverse and perhaps combinatorial set of kernel functions (Schulz, Tenenbaum, Duvenaud, Speekenbrink, \& Gershman, 2016) or by speeding up GP-inference using approximation methods such as sparse inference (Lawrence, Seeger, \& Herbrich, 2003) or more parsimonious neural network representations (Neal, 2012). Indeed, the result that participants formed only very local beliefs about spatial correlations could be used to find heuristic approximations to GP models in the future, which could effectively trade-off a small loss in accuracy for reduced computational complexity.

## Conclusion

We compared both simple strategies and more complex function generalization models in their ability to make out-ofsample predictions about participant sampling behavior. Our modeling results indicate that there may be innate search costs, creating a tendency to prioritize local search options. Furthermore, even accounting for this local search behavior, our best performing model (Local GP-UCB) indicates that people also have a systematic tendency to underestimate the
extent of spatial correlation of rewards, preferring instead to make very local inferences about unexplored rewards.

# What do you really think? Children's ability to infer others' desires when emotional expressions change between social and nonsocial contexts 

Yang Wu (yangwu@mit.edu), Laura E. Schulz (Ischulz@mit.edu)<br>Department of Brain and Cognitive Sciences, MIT<br>77 Massachusetts Avenue, Cambridge, MA 02139 USA

#### Abstract

We investigate children's ability to use social display rules to infer agents' otherwise under-determined desires. In Experiment 1, seven-to-ten-year-olds saw a protagonist express one emotional reaction to an event in front of her social partner (the Social Context), and a different expression behind her social partner's back (the Nonsocial Context). Children were able to use the expression in the Social Context to infer the social partner's desire and the expression in the Nonsocial Context to infer the protagonist's desire. This ability increased between ages seven and ten (Experiment 1). When task demands were reduced (Experiment 2), seven-to-eight-year-olds, but not five-to-six-year-olds, succeeded. These results suggest that although it is not easy for observers to infer emotions masked by social display rules, changing emotional expressions between social and non-social contexts allow even children to recover not only the desire of the person displaying the emotions, but also that of the audience.

Keywords: emotional expression; social display rule; mental state inference

## Introduction

Young children can use emotional expressions to draw inferences about both external events in the world (e.g., Berman, Chambers, \& Graham, 2010; Feinman, Roberts, Hsieh, Sawyer, \& Swanson, 1992; Wu, Muentener, \& Schulz, 2015), and others' internal mental states (e.g., Repacholi \& Gopnik, 1997; Rieffe, Terwogt, \& Cowan, 2005; Wellman, Phillips \& Rodriguez, 2000; Wu \& Schulz, 2017). However, because people sometimes go to great lengths to disguise their true feelings, emotional expressions can be misleading. When speaking in front of a large audience, an adult will pretend to be calm, even if she is nervous. When receiving an undesirable gift, a polite child will pretend to be happy even if she is disappointed. As we will review, a relatively large body of work has looked at children's understanding of social display rules and masked emotions. Here however, we consider a feature of social display rules that has been largely overlooked in prior work: they may disguise an individual's feelings while being informative about the feelings of her social partner's. When someone congratulates a friend in public but fumes in private, we learn not only that this person's true feelings about the event are negative, but also that her friend's true feelings are probably positive. Thus, masked emotions may reveal (about social partner's) as much as they conceal (about the individual herself). Given evidence about someone's feelings in both social and non-social contexts, an observer might therefore recover information both about
the individual's mental states, and those of the society she keeps.

This kind of inference is non-trivial: it requires tracking someone's emotional expressions across social and nonsocial contexts, reasoning recursively about the mental states of at least two parties. To our knowledge, despite abundant work on emotion understanding and theory of mind in early childhood (see Wellman, 2014 for review), no one has yet looked at whether children can use real and apparent emotions to infer not only the true feelings of the person expressing the emotions but also of their intended audience. That is our goal here.

First however, we note that there is a long line of work on children's ability to understand others' real and apparent emotions and their ability to respect display rules in their own behavior. Research suggests that young children modulate both their verbal and nonverbal responses in social contexts (Cole, 1986; Saarni, 1984; Talwar \& Lee, 2002; Talwar, Murphy, \& Lee, 2007; Xu, Bao, Fu, Talwar, \& Lee, 2010). If for instance, an experimenter has lipstick on her nose and asks a child how she looks, children as young as three lie and tell her that she looks okay (Talwar \& Lee, 2002). By three and four, children (in the laboratory anyhow) inhibit their negative emotional responses to an undesirable gift in front of a gift giver (Cole, 1986). As children get older, they are more likely to lie for pro-social purposes than for self-protective purposes (Xu, Bao, Fu, Talwar, \& Lee, 2010), and some evidence suggests that girls are better than boys at regulating their verbal and nonverbal behaviors (Cole, 1986; Davis, 1995; Saarni, 1984).

Between ages three and ten, children also show an increasing ability to understand others' masked emotions in social contexts. When predicting a recipient's response to an undesirable gift, children invoke both verbal display rules (e.g., judging that the recipient will tell a white lie) and facial display rules (e.g., judging that she will express happiness rather than disappointment; Broomfield, Robinson, \& Robinson, 2002; see also Gnepp \& Hess, 1986). Children appear to understand verbal display rules earlier than facial display rules (Broomfield, Robinson, \& Robinson, 2002), and are better at understanding display rules for pro-social purposes than for self-protective purposes (Gnepp \& Hess, 1986; but see Misailidi, 2006). The latter may be influenced by family emotional climates. For example, negative expressiveness in a family environment correlates positively with children's understanding of self-protective display rules and negatively with their understanding of pro-social display rules (Jones, Abbey, \& Cumberland, 1998). Additionally, some
researchers (Banerjee, 2002; Banerjee \& Yuill, 1999a, 1999b; Naito \& Seki, 2009) argue that the understanding of social display rules relies on an ability to represent secondorder mental state information. In support of this, children's performance on a second-order false belief task predicts their understanding of self-protective display rules (Banerjee \& Yuill, 1999b) and a more recent study suggests that it predicts both their understanding of self-protective and pro-social display rules (Naito \& Seki, 2009).

Although fruitful, much of this literature has used tasks with very rich contextual information (Banerjee, 1997; Harris, Donnelly, Guz, Pitt-Watson, 1986; Misailidi, 2006; Josephs, 1994; Wellman \& Liu, 2004; Naito \& Seki, 2009; Gross \& Harris, 1988). This is especially true for studies involving very young children. For example, in Banerjee's study (1997), preschoolers were read stories including an eliciting event (e.g., "Michelle is sleeping over at her cousin's house but she forgot her favorite teddy bear at home"), an agent's mental state (i.e., "Michelle is really sad that she forgot her teddy bear"), an intention to hide the agent's true feeling (i.e., "Michelle doesn't want her cousin to see how sad she is"), and a reason for hiding that feeling (i.e., "because her cousin will call her a baby"). Children were then asked about what the agent really feels and what she will try to look on her face. In such contexts, children may succeed without going much beyond the information available in the stories.

Consistent with this concern, studies using less informative contexts have found that an understanding of masked emotion and social display rules emerges much later in development (Broomfield, Robinson, \& Robinson, 2002; Gnepp \& Hess, 1986; Jones, Abbey, \& Cumberland, 1998). For instance, Gnepp \& Hess (1986) provided children (first, third, fifth, and tenth graders) with an eliciting event and an agent's mental state but did not explicitly mention the agent's intention to hide her feelings or any reason for her doing so. Children failed to predict the use of verbal display rules until third grade. Even adolescents (who successfully predicted the use of verbal display rules) frequently failed to predict that the agents would try to regulate their facial expressions. However, with less information in the stories, there is more uncertainty about whether the protagonist intended to be polite or not; children may have preferred to predict the emotional expression that directly mapped onto the protagonist's true mental state.

Thus, there remains some ambiguity about what children understand, and when, about masked emotions. Rich detailed scenarios may overestimate children's ability to understand social display rules, while less informative scenarios may be open to interpretations that do not involve social display rules at all.

More critically for the present purposes, previous work does not ask whether children can recover information, not only about the person displaying the emotion, but also about the person who is the intended audience of the emotion. To test this, we introduce children to a simple context where one of two teams wins a game. An observer of the game
displays one of two emotional reactions (happy or sad) in front of a social partner and the contrasting emotional expression (sad or happy) behind the social partner's back. We ask children both the desire of the person expressing the emotion, and that of his social partner. Since abundant work suggests that even infants and toddlers understand that someone whose desires are fulfilled will be happy and that someone whose desires are thwarted will be sad (see e.g., Skerry \& Spelke, 2014; Stein \& Levine, 1989; Wellman \& Woolley, 1990; Yuill, 1984), we took it for granted that by middle childhood, children could make this inference. The critical question was whether children could recover each participant's true desires given that one person (henceforth the Protagonist) displayed contradictory emotions in the social and non-social contexts, and the other person (henceforth the Social Partner) never displayed any emotion at all. (Not only do children not see the social partner's face, they have no other source of information about his emotions or desires. Thus the only way they can infer the social partner's desires is by using the protagonist's display of a false, misleading emotion in his presence. Given that without considerable scaffolding, children only appear to understand masked emotion relatively late in development (e.g., Broomfield et al., 2002; Gnepp \& Hess, 1986; Jones et al., 1998), in Experiment 1 we test seven- to ten-year-olds. In Experiment 2, we reduce the task demands and test fiveto eight-year-olds. In both cases, we look at whether children can use the emotional expression in the nonsocial context to infer the protagonist's desire and the emotional expression in the social context to infer the social partner's desire.

## Experiment 1

## Method

Participants Thirty-two children $(\mathrm{M}=8.8$ years; range: 7.2-10.8; 56\% girls) were recruited from an urban children's museum. To ensure a balanced distribution across ages, children were recruited in age bins consisting of 16 sevenand eight-year-olds ( $\mathrm{M}=7.9$ years; range: 7.2-8.8; $63 \%$ girls) and 16 nine- and ten-year-olds ( $\mathrm{M}=9.8$ years; range: $9.0-10.8 ; 50 \%$ girls). While most of the children were white and middle class, a range of ethnicities and socioeconomic backgrounds reflecting the diversity of the local population (47\% European American, 24\% African American, 9\% Asian, $17 \%$ Latino, $4 \%$ two or more races) and the museum population ( $29 \%$ of museum attendees receive free or discounted admission) were represented throughout.
Materials Each child saw two illustrated stories, one presenting the Happy-Sad condition (e.g., Tom was happy in front of Bryan but sad behind Bryan's back) and the other presenting the Sad-Happy condition. The facial expressions were from istock photos (http://www.istockphoto.com/) and have been used by previous research (Wu \& Schulz, 2017). The mapping between stories and conditions, and the order of conditions were counterbalanced across participants, resulting in a total of 4 storybooks. Different agents and
games were used in each storybook (Tom, Bryan, and basketball in one story and Sally, Diana, and volleyball in the other).
Procedure Children were tested individually; all sessions were videotaped. Children were asked check questions to encourage them to follow along. Incorrect responses were corrected throughout. Children had little difficulty with the check questions. Check questions were used only to maintain children's attention; they were not analyzed or used as inclusion criteria.

Each story was read consecutively, as follows (using the basketball-game story as an example). The experimenter placed the first picture on the table and said, "There is a basketball game today. It's the Tiger team against the Lion team." She introduced the next picture and said, "This is Tom. Tom is a basketball fan. He loves watching basketball games. He goes to watch the game. He is either a fan of the Tiger team, or the Lion team, but we don't know which one." Children were asked (Check question 1): "Do we know which team Tom is a fan of?" The experimenter introduced the third picture and said, "This is Bryan. Bryan was Tom's friend when they were little, but now they don't get to see each other very much. Bryan becomes a basketball player. He plays in the game. He either plays for the Tiger team or the Lion team, but we don't know which one." Children were asked (Check question 2): "Do we know which team Bryan plays for?" The experimenter introduced the fourth picture and said, "The result of the game was that the Tiger team won, and the Lion team lost." Then the experimenter introduced the fifth picture and said, "After the game, Bryan ran back to the locker room. Tom was passing by and saw Bryan. It was a very noisy and crowded room and they didn't have a chance to talk. However, in front of Bryan, when Tom came passing by, Tom made a face like this." Children were asked (Check question 3): "Did Tom look happy or sad?" The experimenter introduced the sixth picture and said, "However, behind Bryan's back, as soon as Bryan passed by and couldn't see Tom, Tom made another face." Children were asked (Check question 4): "Did Tom look happy or sad?" We controlled for the complexity between the social and nonsocial contexts by having two people in both contexts; the difference was only that in the social context, they were facing towards each other, and in the nonsocial context, they were facing away from each other. (See Figure 1.)

Finally, the experimenter asked two test questions. The first question was about the protagonist (Protagonist Question): "Now I am going to ask you some questions. In front of Bryan, Tom looked [happy/sad] but behind Bryan's back, Tom looked [sad/happy]. Do you think Tom is a fan of the Tiger team or Lion team?" The experimenter then asked the other test question (Social Partner Question): "Does Bryan play for the Tiger team or the Lion team?" ${ }^{1}$

[^248]

Figure 1 Example of the materials used in Experiments 1 and 2 (corresponding to the fourth to sixth pictures described in Procedure).

Coding We scored children's responses separately for the Protagonist and the Social Partner. Children received one point for answering a question correctly and none for answering it incorrectly.

## Results and discussion

Participants performed equally well in the Happy-Sad and Sad-Happy conditions (protagonist: $X^{2}=.59, p=.442$; social partner: $X^{2}=.00, p=1.00$ ). Additionally, there was no order effect between the first and second stories (protagonist: $X^{2}=.07, p=.798$; social partner: $X^{2}=.00, p=$ 1.00). Thus, we collapsed children's scores across the two conditions. This resulted in a score of $0-2$ for the Protagonist and a score of 0-2 for the Social Partner.

Using age as a continuous variable, we found that children between ages seven and ten showed an increasing ability to use the emotional expression in the nonsocial context to reason about the protagonist's desire $(\beta=.75, S E$ $=.36, z=2.11, p=0.035$; Ordinal Logistic Regression), and the emotional expression in the social context to recover the

[^249]social partner's desire ( $\beta=.69, S E=.34, z=2.02$, $p=0.044$ ). See Figure 2.

Overall, children did not recover the protagonist's desire above chance ( $z=$ 1.40, $p=.230$ ) and showed a non-significant trend towards recovering the social partner's desire ( $z=$ 2.13, $p=.052$ ) but there was no significant difference between the two ( $z=-1.13, p$ $=.453$ ). Because of the age effect, we did a median split on age. Seven- and eight-year-olds did not perform above chance on either

Figure 2 Results of Experiments 1 and 2. The top row shows individual children's performance on the questions about each agent, collapsing across the Happy-Sad and Sad-Happy conditions. The bottom row shows children's performance by age bin. Error bars indicate $95 \%$ confidence intervals. question (protagonist: $z=-$
$.58, p=.774$; social partner: $z=.00, p=1.00$ ); however, nine- and ten-year-olds performed above chance on both (protagonist: $z=2.50, p=.022$; social partner: $z=2.67, p$ $=.013$ ). See Figure 2.

These results suggest that nine- and ten-year-olds can use changing emotional expressions between social and nonsocial contexts to recover the desires of both the protagonist and the social partner in a masked emotion context. However, why did younger children fail? As noted, many previous studies suggest that by seven and eight, children can predict an agent's real and apparent emotions given relatively rich contextual information (Banerjee, 1997; Harris, Donnelly, Guz, Pitt-Watson, 1986; Misailidi, 2006; Josephs, 1994; Wellman \& Liu, 2004; Naito \& Seki, 2009; Gross \& Harris, 1988; Gnepp \& Hess, 1986; Broomfield, Robinson, \& Robinson, 2002; Jones, Abbey, \& Cumberland, 1998). They can also represent second-order mental state information (Perner \& Wimmer, 1985; Sullivan, Zaitchik, \& Tager-Flusberg, 1994), which supports the understanding of social display rules. Thus, it is possible that children's chance performance here was due to task demands. In particular, children may have tripped up by the fact that the first expression they saw was an apparent, misleading emotional expression. Only when children saw the second expression, did they have the information to tell that the first expression was a fake one.

In the next experiment, we reduce these task demands by flipping the order of the social and nonsocial contexts. Thus, children first see the agent's emotional expression in the nonsocial context and then a different one in the social context. This order does not require children to re-interpret the first emotional expression; additionally, the first expression may provide a basis for children to understand the expression displayed in the social context. To see if even younger children might succeed given these reduced task demands, we test both seven- and eight-year-olds and five- and six-year-olds.

## Experiment 2

## Method

Participants Thirty-two children ( $\mathrm{M}=7.0$ years; range: 5.3-8.8; $66 \%$ girls) were recruited from the children's museum. Half of them were seven- and eight-year-olds ( $n=$ $16 ; M=8.0$ years; range: $7.1-8.8 ; 75 \%$ girls) and the other half were five- and six-year-olds ( $n=16 ; M=6.0$ years; range: 5.3-6.8; $56 \%$ girls).
Materials, procedure and coding The materials, procedure and coding were identical to Experiment 1 except that we flipped the order of the social and nonsocial contexts. See Figure 1. For example, instead of first showing Tom's emotional expression in front of Bryan, the experimenter presented Tom's expression behind Bryan's back: "After the game, Tom made a face like this. At this moment, Bryan was nearby but Tom didn't see him." Children were asked a check question: "Did Tom look happy or sad?" The experimenter then introduced the next picture and said, "However, Tom turned around and saw Bryan. Tom made another face." Children were asked another check question: "Did Tom look happy or sad?"

## Results and discussion

As in Experiment 1, participants performed equally well in the Happy-Sad and Sad-Happy conditions (protagonist: $X^{2}=$ $2.82, p=.093$; social partner: $X^{2}=.67, p=.412$ ). There was no order effect between the first and second stories (protagonist: $X^{2}=.93, p=.335$; social partner: $X^{2}=.67, p$ $=.412$ ). Thus, children's scores were collapsed across the two conditions.

We used the same analyses as in Experiment 1. Taking age as a continuous variable, we found that children between ages five and eight showed an increasing ability to recover both the protagonist's $(\beta=.89, S E=.35, z=2.53, p$ $=.011$ ) and the social partner's desires $(\beta=.81, S E=.36, z$ $=2.25, p=0.024$ ). See Figure 2.

Overall, there was a non-significant trend for children to recover the protagonist's desire $(z=1.96, p=.078)$ and children successfully recovered the social partner's desire ( $z$ $=3.15, p=.002$ ); there was no significant difference between the two $(z=-1.13, p=.453)$. Given the age effect, we performed a planned median split on age. Five- and six-year-olds did not perform above chance in either question (protagonist: $z=.00, p=1.00$; social partner: $z=1.34, p$ $=.375$ ) but seven- and eight-year-olds succeeded in both (protagonist: $z=2.50, p=.022$; social partner: $z=2.89, p$ $=.006$ ). See Figure 2. Thus, we found that at least by ages seven and eight, children can use changing emotional expressions between social and nonsocial contexts to recover the desires of both participants in a social exchange, even when one participant is masking her emotions and the only cue to the other participant's desires is that misleading, masked emotional reaction.

## General Discussion

In two experiments, we investigated children's ability to use the information embedded in social display rules to recover others' otherwise under-determined mental states. Children saw an emotional expression when a protagonist was in front of a social partner, and a different expression when the protagonist was behind the social partner's back. Children successfully used the expression in the nonsocial context to infer the protagonist's desire, and the expression in the social context to infer the social partner's desire. Children's ability to draw these inferences improved between ages five and eight.

Our study builds on many previous studies that have looked at children's ability to predict an agent's real and apparent emotions given rich mental state information (e.g., the agent's desires, true feelings, her intentions, and a motivation to hide her true feelings; Banerjee, 1997; Harris, Donnelly, Guz, Pitt-Watson, 1986; Misailidi, 2006; Josephs, 1994; Wellman \& Liu, 2004; Naito \& Seki, 2009; Gross \& Harris, 1988; Gnepp \& Hess, 1986; Broomfield, Robinson, \& Robinson, 2002; Jones, Abbey, \& Cumberland, 1998). In contrast, here we provided children with very minimal background information, and no direct information about the agent's mental states. Children's ability to use the social context to recover the desires of an agent who provided two contradictory emotional reactions to an event, and also the desire of a social partner, whose emotional expressions were never observed at all, is consistent with other studies finding that children can recover rich unobserved information from observed emotional cues (e.g., Berman, Chambers, \& Graham, 2010; Feinman, Roberts, Hsieh, Sawyer, \& Swanson, 1992; Wu, Muentener, \& Schulz, 2015; Repacholi \& Gopnik, 1997; Rieffe, Terwogt, \& Cowan, 2005; Wellman, Philips \& Rodriguez, 2000; Wu \& Schulz, 2017). However, our study goes beyond those studies in suggesting that children can also detect and understand the conditions in which real emotions are masked.

Although emotional expressions are misleading when people mask their true feelings, our results indicate that the
masking behavior itself (if detected) can be richly informative. Note that feigning an emotional expression in front of others reflects one's beliefs and desires about others' beliefs or desires. Thus when a feigned emotional expression is detected, it contains recursive mental state information about what one agent thinks about what another agent thinks. Although there has been debate on the extent to which reasoning about pro-social display rules requires second-order mental state representation (Banerjee, 2002; Banerjee \& Yuill, 1999a, 1999b; Naito \& Seki, 2009), in our task, the social partner's beliefs, desires, and emotions were unknown throughout. To recover information about the social partner, children had to refer to the protagonist and selectively use the protagonist's emotional expressions to gain insight into the mind of his audience. We suggest that this kind of inference does require recursive mental state reasoning, and the current results suggest that the ability to make these inferences develops over middle childhood.

Critically, children succeeded here in a very tightly constrained context: there were only two possible outcomes (one of two teams won a game), two possible emotional responses (happy or sad) and two social partners. Moreover, the task design virtually eliminated any memory demands: children did not need to track the changing emotional expressions over time; they were all concurrently displayed in the storybook card format, together with the social context. Future work might look at children's ability to draw comparable inferences when they must track changing emotional dynamics over time and in more complex, multi-participant scenarios. Note however, that although more realistic scenarios may add processing demands and complexity, they may also provide children with richer cues to agents' mental states.

The current results however, suggest that by age seven, children can recover underlying mental states from changes between real and apparent emotional expressions. Intriguingly, the current results also suggest that there is a limit to how much we can hide when we hide our feelings: in disguising our true feelings, we may reveal what we think about what other people want.

#### Abstract

Human interaction involves the organization of a collection of sensorimotor systems across space and time. The study of how coordination develops in child-parent interaction has primarily focused on understanding the development of specific coordination patterns from individual modalities. However, less work has taken a systems view and investigated the development of coordination among multiple interdependent behaviors. In the present work, we used Granger causality as a mathematical model to construct dyadic causal networks of multimodal data collected from a longitudinal study of child-parent interaction. At a grouplevel, we observed increases in the number of causal links and in the strength of such links in dyadic interaction from 9months to 12 -months. At an individual-level, we observed high variability in the types of causal links that emerged across developmental ages. We discuss these results in terms of a multicausality hypothesis for the development of human coordination.

Keywords: Interpersonal Coordination; Social Interaction; Child-Parent Interaction; Granger Causality; Multimodal Social Interaction; Multivariate Autoregressive Model

## Introduction

Human interaction entails the organization of a vast array of sensorimotor systems across space and time (Kendon, 1970). We imitate, align and synchronize over a spectrum of social behaviors with our social partners during communication and studies have shown fine-grained temporal structures across modalities in interpersonal coordination (Fusaroli \& Tylén, 2016; Garrod \& Pickering, 2009; Louwerse, Dale, Bard, \& Jeuniaux, 2012). How we are able to organize behaviors across multiple modalities and achieve seamless coordination in only fractions of a second is one of the most important questions about human cognition (Marsh, Richardson, \& Schmidt, 2009).
One effective approach to answering this question is to examine how such smooth coordination evolves during development. In developmental science, past research have shown that within specific behavioral modalities, coordinated behaviors emerge early in life and develop incrementally with age (Yale, Messinger, Cobo-Lewis, \& Delgado, 2003). For example, infants start to follow and
coordinate the gaze direction of their social partner (Scaife \& Bruner, 1975) and form vocal and facial expression feedback loops with their parents early in their first year of life (Cohn \& Tronick, 1988). Such social contingencies are suggested to be indicative of later language development (Goldstein, King, \& West, 2003; Mundy \& Newell, 2007; Warlaumont, Richards, Gilkerson, \& Oller, 2014).

Development is about change. The multicausality assumption in dynamical systems theory (Smith \& Thelen, 2003) indicates that change and growth in the system emerge through the relationships between different interdependent components, without an executive preprogrammed and unified path. Certain patterns and behavioral influences emerge or diminish at different developmental ages, and through different developmental pathways. In light of this, the aim of the present study is to examine the change in the organization of coordination among multiple interdependent behaviors. More specifically, we want to investigate the connectivity and directional influences from one modality to another in the course of development.

Towards this goal, in this paper, we proposed a novel approach to modeling multimodal coordinated behaviors between children and parents as a directed graph network with Granger causality (Bressler \& Seth, 2011; Granger, 1969). A longitudinal study was conducted in which we invited children at 9 months and their parents to participate in a toy play experiment, and again at 12 months. During the toy play sessions, we recorded the dyad's momentary eye gaze and manual action data with eye-trackers and multiview video recording. With this study and our analytic approach, we can investigate the development of human coordination through directional causal relations among a network of interdependent behavioral variables.

This framework of modeling child-parent interaction as causal networks allowed us to determine changes in the amount of causal links and the strength of causal links across 9- and 12-months. We tested two specific hypotheses about the development of coordination. First, the developmental hypothesis: on a group level, we expected that the number and strength of causal links in the childparent coordination network would increase from 9- to 12-
months. Second, the multicausality hypothesis: we expected the increased coordination to be achieved by the emergence of new causal influences in the network, among multiple different behavior variables. One key assumption of this hypothesis is that no causal link has developmental priority. If dyads show individual differences in their coordination development pattern, it would be an indication that they each follow distinct pathways to achieve increased levels of sensorimotor coordination.

## Granger Causality for Point Process Data

Coordination patterns change throughout the course of an interaction and require real-time adjustment of actions and predictions in accordance with their sensorimotor input (Clark \& Brennan, 1991; Yu \& Smith, 2016). When we study interpersonal coordination and development from a dynamical approach, one challenge is quantifying directional influence and connectivity between two specific variables. This is due, in part, to the interconnectivity and complexity of information exchange among behavioral variables (Fusaroli, Konvalinka, \& Wallot, 2014; Hidaka \& Yu, 2010).

Granger causality, or G-causality, is a well-established and effective method for the investigation of directional relationships among a set of interdependent variables in many domains (Bressler \& Seth, 2011). Granger (1969) formalized the basic idea of causality between signals introduced by Wiener (1956) based on multivariate autoregressive (MVAR) models: if past values of $\boldsymbol{Y}$ contain information that help predict $\boldsymbol{X}$ above and beyond the information contained in the past values of $\boldsymbol{X}$ alone, then $\boldsymbol{Y}$ is said to Granger-cause $\boldsymbol{X}$.
Kim et al. (2011) proposed a point process framework to enable G-causality to be applied to point process data with a discrete nature. A temporal point process is a stochastic time series of binary events that occurs in continuous time. It can only take on two values at any point in time, indicating whether or not an event has occurred. With a time series dataset of an ensemble of variables, the occurring likelihood of the event variable $\boldsymbol{X}$ can be modeled by the generalized linear model (GLM): a linear combination of time series $\boldsymbol{X}$ 's dependency to the history of each individual element in the ensemble. Given a set of multivariate temporal streams, the causal relationships from variable $\boldsymbol{Y}$ to $\boldsymbol{X}$ is assessed by calculating the relative reduction in the likelihood of producing this particular history of time series of $X$ when the history of $\boldsymbol{Y}$ is excluded, compared with the likelihood if all the available covariates are used in the prediction calculation. If the prediction likelihood is reduced when the history of variable $\boldsymbol{Y}$ is excluded from calculation, then there exists a Granger causal relationship from $\boldsymbol{Y}$ to $\boldsymbol{X}$. In addition, Kim et al. (2011) proposed that the sign of averaged influence of the occurring history of variable $\boldsymbol{Y}$ on $\boldsymbol{X}$ can be used to distinguish excitatory (positive estimate) and inhibitory (negative estimate) influences: whether the event history of $\boldsymbol{Y}$ is more or less likely to lead to the event occurring for variable $\boldsymbol{X}$. Finally, the point process
framework also affords researchers to identify the statistical significance of a causal link based on the likelihood ratio test statistic. The goodness-of-fit statistics were applied by comparing the deviance between the estimated model with trigger variable $\boldsymbol{Y}$ excluded and the estimated full model in the GLM framework. Then, a multiple hypothesis testing error measure, FDR, proposed in (Benjamini \& Hochberg, 1995; Storey, 2002) was used to control the expected proportion of false discovery rate when the number of hypothesis tests is large and the number of rejected null hypotheses is consequentially large.

Calculating G-causality with GLM model fitting makes very general assumptions about the data (Barnett, Barrett, \& Seth, 2009) and with the point process framework, we are able to apply G-cause to categorical behavioral data. In the present paper, we used this framework to construct quantitative causal networks among different behavioral modalities in child-parent interaction and study child's coordination development.

## Methods

## Participants

21 parent-child dyads participated in this study. Dyads came into the lab when the children were 9 -months-old and 12-months-old.

Figure 1: (a) A dual eye-tracking child-parent interaction paradigm. (b) Eye movement and object manipulation events from both the child and parent were coded into categorical data streams. The data streams were then divided into three different ROI groups, preserving only the onset of events. Finally, per subject, the three groups were concatenated as input for subsequent calculations of Granger causality.

## Procedure

Figure 1(a) shows the experimental setup of our dual eyetracking child-parent interaction experimental paradigm (Yu \& Smith, 2013, 2016). Parents and their children were seated across from each other at a plain white table $(61 \mathrm{~cm} \times$ $91 \mathrm{~cm} \times 64 \mathrm{~cm}$ ). Head-mounted Positive Science eye trackers (Franchak, Kretch, Soska, \& Adolph, 2011) were put on both the child and parent to capture their gaze data in real time. Each eye-tracking system includes an infrared camera that records eye images (mounted on the head and pointed to the right eye, see Figure 1a), and a scene camera capturing the first-person view from the participant's perspective. The scene camera's visual field is 108 degrees providing a broad view. Each eye-tracking system recorded both the first-person view video and precise gaze allocation in that view, with a sampling rate of 30 frames per second. Another high-resolution camera was mounted above the table and provided a bird's-eye view at a recording rate of 30 frames per second.

For each trial of the experiment, there were two sets of toys. Each set consisted of three toy objects with three different colors (blue, green, red). The toys were of similar size and weight. Parents were told that the goal of the experiment was to study how parents and toddlers interacted with objects during free play and they were asked to engage their children with the toys as what they would naturally do in daily life. Each of the two sets of toys was played with twice for 90 seconds, resulting in approximately six minutes of play over four trials from each dyad. Toy set order (ABAB or BABA) was counterbalanced across dyads.

## Data Processing

Human coders went through the videos from multiple viewpoints and manually annotated frame-by-frame about which object was gazed at and held by the child and the parent with both of their hands. In this study, we coded four Region-Of-Interest (ROI)s for the eye movement data: blue, green and red object categories (1-3) and other (0). Each value represents where the child or the parent was looking at in every frame. The participants could be looking at each other's face, but our analysis didn't include face looking events in this paper. The same object and empty ROIs (0-3) were also the coding categories for hand action data streams, indicating the target object was held by either the left or the right hand of the child and the parent. For each trial, after data processing, four coded categorical data event streams (child gaze events, child holding events, parent gaze events, and parent holding events) were obtained.

The next step was to convert our behavioral temporal data streams into multivariate point processes. All behavioral data streams were divided into three groups by different ROIs and then only the onsets of object ROI events were preserved to fit the point process framework for calculating G-causality. Figure 1(b) shows the point process data streams from one experimental trial. After point process conversion, for each dyad, three groups were concatenated as input data for calculating G-causality. In each group, all
streams contained the onset of the same category of events. With this point process data transformation, we extracted Granger causality among different behavioral variables acting on the same object. For example, we estimated Gcausality from the event of child looking at the red object to the occurrence of the parent looking at the same object.

## Analysis

For each dyad, we constructed a dyadic causal network among four behavioral variables (child eye movement, child hand action, parent eye movement and parent hand action) at 9 months and 12 months. Figure 2 shows the G-cause network constructed with two dyads' interaction data. In each network, there are 4 behavioral variables (child eye, child hand, parent eye and parent hand) and 12 different types of directional links between every pair of variables. The different types of directional links are illustrated in Figure 2.

Significance tests based on the likelihood ratio test statistic with FDR controlling false positive causal interactions (Storey, 2002; Kim et al., 2011) was performed to determine the statistical significance of every causal link with regard to the entire network. In Figure 2, red colored links indicate the significantly positive links with number at the end of each link representing the G-cause value from one behavioral variable to the other. For example, at 12 months, Dyad\#1 had a significantly positive causal link from child's gaze to child's holding behavior. This means that the child was looking at a certain object and the occurrence of this event significantly increased the likelihood of the child holding the same object. In addition, to best comprehend the magnitude of G-cause values for our

Figure 2: (a) The G-cause coordination network among child eye, child hand, parent eye and parent hand time series for Dyad\#1 at 9 months (left) and 12 months (right); red links are significantly positive G-cause links and the number indicates the G-cause value of that causal relation. (b) The G-cause coordination network for Dyad\#2 at 9 months (left) and 12 months (right).
multimodal coordination data, we also calculated the baseline G-cause network for every interaction. This was done by randomizing the order of event streams (with all ROIs and their event durations) for the behavioral variables. Then, the randomized onsets of object ROI events were preserved to convert the data to fit point process model for baseline G-cause network calculation.
The source code, a more detailed explanation of the Granger causality calculation process and more supplementary materials of this study are available at: https://github.com/lingerxu/Granger_causality_coordination

## Results

To examine our developmental hypothesis - increased coordination from 9 -months to 12 -months - we first looked at two group-level measures: the number of significantly positive G-cause links and the average G-cause value per link in each interaction network. For example, in Figure 2a, Dyad\#1 had 3 significantly positive links at 9 months and 5 links at 12 months and the average G-cause value per link was 2.96 at 9 months (baseline value 0.19 ) and -2.27 at 12 months (baseline value -0.04). Average baseline G-cause values obtained with the randomized event streams were close to 0 for both age groups. In the present paper, we focused on examining the significantly positive G-cause links, which have much higher values than baseline and entail a strong causal link from one behavior variable to another.
As shown in Figure 3, we observed more significantly positive G-cause links at 12 months ( $M=3.95, S D=0.23$ ) compared to each dyad's network at 9 months ( $M=2.38$, $S D=0.20), t(20)=3.27, p=.004$. We also observed that the Gcause network for 12 month olds ( $M=5.50, S D=0.39$ ) had significantly higher average G-cause values per link than 9 months ( $M=2.52, S D=0.26$ ), $t(20)=3.85, p<.0001$. Overall, the multimodal coordination between child and parent showed increased developmental changes from 9 months to 12 months. The observation of increased positive causal links in the network and higher G-cause values on average from 9 - to 12 -months, suggests that the coordinative patterns of the child-parent dyadic system are becoming more dense and stronger.

## Multicausality and Individual Differences

The main proposal of the multicausality hypothesis is that increased coordination is achieved by the emergence of multiple new causal influences between different pairs of behavioral variables and that no causal link has developmental priority. The results observed in the last section provided clear evidence that child-parent dyadic systems become more coordinated from 9 months to 12 months. Next, we want to look at how this increased level of coordination was achieved and whether we will observe individual differences in the developmental pattern in the dyadic causal network.

Figure 3: (a) Amount of significantly positive G-cause links and (b) average G-cause values of child-parent eye hand coordination networks at 9 months and 12 months.

When we take a closer look at the individual development between the two networks of each dyad, and how each causal link in the network changed from 9 months to 12 months, there are multiple types of change. Here we will mainly focus on examining the emergence of new significantly positive link, which means that this positive causal link did not exist in the 9 -month coordination network, and only appeared in the 12 -month network.

With 12 different types of G-cause links in total, the development of the coordination network can be described by a vector of developmental changes in each type of causal relations. The developmental coordination row vector for each dyad is visualized in Figure 4a. Three causal relation links, child hand $\rightarrow$ child eye, parent hand $\rightarrow$ child hand and child hand $\rightarrow$ parent hand, are omitted in the illustration because we did not observe any emergence of new positive links in these three link types. For example, the two dyads in Figure 2 can be mapped to the first two vector representations in Figure 4a. For Dyad\#1, two new positive links emerged in their G-cause network at 12 months. This emergence is depicted in the developmental coordination vector: two red cells in parent eye $\rightarrow$ child eye and child eye $\rightarrow$ child hand categories (see Figure 4a, row 1). In another example, for Dyad\#2 (see Figure 4a, row 2), five new links emerged from 9 months to 12 months. And we can see that, between the two dyads, four out of five emergent links from Dyad\#2 were completely different from the G-cause relation types in which Dyad\#1's emergent links belonged to.

Finally, if increased coordination from 9 months to 12 months was achieved through one type of causal link with causal priority, then the hypothesized frequency distribution of emergent links will be similar to Figure 4b. We can observe that the majority of emergent links belong to the same causal relation type. Alternatively, the multicausality hypothesis entails that increased coordination is achieved via multiple different causal relations. In an ideal situation, we would observe a uniform frequency distribution of emergent causal relations. This possibility is depicted in Figure 4 c . Figure 4 d shows the empirical frequency distribution of emergent links. The empirical distribution provides evidence for a diffuse collection of emergent causal relations, supporting the multicausality hypothesis

RANK ORDERED DIStribution of New Links among 12 types of g-Cause link
Figure 4: (a) The development coordination vector for each dyad's G-cause network. Red cells indicate the emergence of significantly positive G-cause links from 9 months to 12 months between different pairs of behavior variables. Each row represents the developmental change in coordination network for one dyad. Each column represents the developmental change for a particular type of causal relation link. Three causal relation links, child hand $\rightarrow$ child eye, parent hand $\rightarrow$ child hand and child hand $\rightarrow$ parent hand, are omitted here because we did not observe the emergence of significantly positive links. (b) The hypothesized frequency distribution of emergent causal links if increased coordination was achieved by only one link with causal priority. (c) Illustration of the frequency distribution of emergent links for the ideal uniform distribution under the multicausality hypothesis. (d) The empirical frequency distribution of emergent links in our results.
that child-parent dyads are utilizing multiple coordination patterns to achieve increased coordination.

## General Discussion

The goal of the present paper was to investigate the development of multimodal organization in naturalistic child-parent interactions. We used a novel causal network modeling approach to better understand how multimodal dyadic systems change across developmental age. The observed results provide preliminary evidence for the developmental and multicausality hypotheses that we proposed at the outset of the paper.
At a group-level, we observed an increase in the amount of causal links and an increase in the strength of causal links from 9 months to 12 months. These results provided support for the developmental hypothesis, suggesting that the multimodal coordination patterns across the child-parent dyadic system became stronger with more components being coordinated within the dyadic system. This is an important observation because it provides novel evidence for an important property of the developing child-parent dyadic system: development includes adding redundancy to the social interaction by creating new pathways for coordination to occur (Yu \& Smith, 2016). Redundancy is an important property for any complex system because it affords adaptability in the face of intrinsic and extrinsic
perturbations (Kugler \& Turvey, 1987; Thelen \& Smith, 1998).

At an individual level, we observed that the causal relation links were distributed among all types of G-cause relations between two behavioral variables both within and between agents. Furthermore, the frequency distribution of emergent causal links was approximately uniform suggesting that there was no single behavioral link taking developmental causal priority in the network. These results add preliminary support for the multicausality hypothesis. These observations provide important conceptual and empirical contributions. Multicausality has been proposed to be an important property of a complex system (Smith \& Thelen, 2003), however there has been little work to extend the proposal of multicausality to a dyadic model of childparent interactions. This framework quantifies the directional causal influences between different behavioral variables to model the complex system of interpersonal coordination at sensorimotor level. Thus, it can provide heuristics towards understanding the individual differences in the establishment of joint attention and possibly the reasons underlying the correlations between joint attention and many developmental outcomes (Mundy et al., 2007; Tomasello \& Farrar, 1986; Yu \& Smith, 2016). Finally, to our knowledge, this is the first study to use MVAR-based Granger causality to model multimodal coordination as directed causal networks. Our results provide evidence for
the promise of this analysis method as a novel dynamic modeling method for many domains, such as developmental science, behavioral science, etc.

#### Abstract

The enormous scale of the available information and products on the Internet has necessitated the development of algorithms that intermediate between options and human users. These algorithms do not select information at random, but attempt to provide the user with relevant information. In doing so, the algorithms may incur potential negative consequences related to, for example, "filter bubbles." Building from existing algorithms, we introduce a parametrized model that unifies and interpolates between recommending relevant information and active learning. In a concept learning paradigm, we illustrate the trade-offs of optimizing prediction and recommendation, show that there is a broad parameter region of stable performance that optimizes for both, identify a specific regime that is most robust to human variability, and identify the cause of this optimized performance. We conclude by discussing implications for the cognitive science of concept learning and the practice of machine learning in the real world.

Keywords: Recommender systems, active learning, concept learning, filter bubble

Historically, the information each individual had access to was defined by one's local environment: what one could directly observe , who one had to talk to or do business with, and available texts or catalogs one could access. With the advent of the Internet, information and products became available at a global scale. This vast potential resource creates a problem: how to choose-from billions or trillions of options-which information or products to present to an individual at a given time. Solutions to these problems form the foundation that supports major players in the online business world-from search engines and e-commerce to social network services-such as Google, Amazon, and Facebook. These algorithmic solutions radically affect not only what information and products we are exposed to, but also which information and products we have the chance to be exposed to. Thus, these algorithms mediate between us and reality, not by providing a random sample from what is possible, but by carefully selecting a sample which optimizes some underlying goals and metrics. The consequences of these humanalgorithm interactions have been insufficiently explored despite recent interest in cases such as filter bubbles (Pariser, 2011), algorithmic bias (Baeza-Yates, 2016), and humanalgorithm interaction biases (Nasraoui \& Shafto, 2016).

A well-established doctrine in cognitive science asserts that a driving factor of our beliefs is the information we are exposed to. However, the situations investigated in the most typical concept learning experiments (Bruner, Goodnow, \& Austin, 1956; Shepard, Hovland, \& Jenkins, 1961) differ sharply from the kinds of situations we encounter with recommender systems. In concept learning experiments, examples are typically sampled either exhaustively or randomly, neither
of which is feasible in the context of Internet-scale problems. Obviously, enumeration is not feasible. Random sampling is also not feasible because if the quality of the algorithm's suggestions were too poor, human users could simply choose to go elsewhere. This yields a thorny problem: how to select information and products to maximize relevance, while also accurately estimating what users want.

Two classes of algorithms-information filters (Sparck Jones, 1970; Van Rijsbergen, 1979; Salton, Fox, \& Wu, 1983) and recommender systems (Goldberg, Nichols, Oki, \& Terry, 1992; Maes et al., 1994; Adomavicius \& Tuzhilin, 2005)—have been developed to facilitate selection of information for users. Although different in some ways, they share a core assumption that the goal is to deliver humans relevant information or products. Given that these sorts of algorithms have raised concerns about not exposing people to the breadth of potentially relevant information, basic questions one might raise are whether the data they obtain allow them to accurately estimate human users' preferences, and whether there are small adjustments that could be made to optimize for recommendation and learning about the users' preferences.

One approach for obtaining optimally informative data is active learning, well known in both cognitive science (Nelson, 2005) and computer science (MacKay, 1992). Active learning has been proposed both as a model for how humans search for information and as an algorithm for how machines learn about the world. In the current context, active learning is a method for learning what information is relevant to the human user (Elahi, Ricci, \& Rubens, 2016), whichwhile having advantages for estimating the user's beliefs-is unlikely to produce quality recommendations.

Drawing inspiration from real-world problems of information filtering and recommendation, we seat these problems in a concept learning framework that allows for experimental control of which examples are relevant. This framework allows for an exploration of algorithms that perform better or worse on the joint problems of optimizing recommendations and inferring relevance. We introduce a novel approach to investigating algorithm performance that merges aspects of computational simulation and user testing: people are trained on the true concept, then they interact with the algorithm to test performance. Unlike in computational simulations and user testing, there is both defined ground truth and naturalistic human variability in behavior.

Our approach uses the simple concept learning task previously used by Markant and Gureckis (2014). We present two experiments. The first validates the method by demon-
strating expected limitations of recommendation and active learning. The second investigates a simple one-parameter generalization-active recommendation-that unifies both approaches. We show that while the extreme cases of pure active learning and pure recommendation yield poor performance, all intermediate values converge to near optimal recommendation and prediction. We also observe that due to human variability, parameter values that are closer to pure recommendation yield the best performance. We conclude by discussing implications for cognitive science in the lab and machine learning in the real world. Overall, the main contributions of our work are: (i) the use of an experiment to gauge how real human users interact with a system that spans graded shades between recommendation and active learning and (ii) how a unified, yet simple and generic model is beneficial in the design and interpreting of real user experiments.

## Unifying recommending and active learning

Given a dataset, $D=\left\{x_{i}, y_{i}\right\}_{i}^{N}$, the goal of a probabilistic classification algorithm is to predict the probability that a new data point $x^{*}$ belongs to class $y, P\left(y \mid x^{*}, D\right)$. We will be concerned with learning two classes corresponding to irrelevant and relevant information, $y \in\{0,1\}$. These predictions form the basis of the recommendation and active learning algorithms we will consider. Intuitively, the goal of recommendation is to provide the user with examples that are relevant. This intuition can be formalized directly,

$$
\begin{equation*}
x_{\text {rec }}=\underset{x^{*}}{\arg \max } P\left(y=1 \mid x^{*}, D\right) \tag{1}
\end{equation*}
$$

At any point-given previously observed data-this defines which examples are optimal for recommendation: those that maximize the probability of being relevant. Within the closely related problem of probabilistic retrieval (ranking relevant information), this coincides with optimal probabilistic retrieval for the most relevant item (Robertson, 1977).

One intuitive formalization of active learning is to select examples that reduce our uncertainty about which examples are relevant. This can also be formalized directly,

$$
\begin{equation*}
x_{a c t}=\underset{x^{*}}{\arg \min }\left|0.5-P\left(y=1 \mid x^{*}, D\right)\right| . \tag{2}
\end{equation*}
$$

Given previously observed data, the optimal example to observe is the one about which we have the greatest predictive uncertainty.

It is worth noting that this is not the only formalization of active learning that one may consider. Other well known strategies include optimizing information gain (K-L divergence), diagnosticity, and probability gain (Nelson, 2005). While each differs in formal detail, in many practically relevant situations, their predictions are quite similar. We formalize active learning as the selection of maximally uncertain data to facilitate integration with the recommendation criterion in Eq. 1, as will be seen below.

We propose a unified model of active recommendation that exploits the parallel structure in previous models. Our single parameter generalization includes filtering and active learn-
ing as extreme cases and thus unifies the two approaches and interpolates between them. Formally,

$$
\begin{equation*}
x_{\alpha}=\underset{x^{*}}{\arg \min }\left|\alpha-P\left(y=1 \mid x^{*}, D\right)\right|, \tag{3}
\end{equation*}
$$

where $\alpha \in[0.5,1]$. When $\alpha=0.5$ we recover active learning, as is obvious from inspection of Eq. 2. When $\alpha=1$, we recover recommendation. In our context, subtracting from 1 and taking the min is equivalent to taking the max in Eq. 1.

Of interest is what happens between the extremes that correspond to recommendation and active learning. Are there parameterizations of active recommendation that optimize accuracy in terms of recommendation and prediction? Are there parameterizations that are more robust to the kinds of variability that are characteristic of human behavior?

## Experiments

In what follows, we empirically investigate these questions using a novel approach. Human subjects were first trained on the underlying conceptual structure that defines which examples are relevant and which are not. The classes of relevant examples are defined by axis-aligned logistic function with data standardization in two dimensions. Next, people are randomly assigned to an algorithm, and are presented with a series of examples, which they label as being in the relevant class or not. The algorithm updates upon receiving each example-label pair, and then selects a new example. This method combines aspects of computational simulation and user testing by providing a ground truth, yet allowing human variability in responses. It thus provides information about when we would expect algorithms to perform well-both absolutely and in the presence of human variability.

The questions of interest are: which algorithms perform well in terms of recommendation and prediction and which ones perform well in terms of robustness to human variability? An algorithm's trial-by-trial recommendation accuracy is the fraction of examples labeled as relevant, at each trial, by a population of participants. Its predictive accuracy for trial $i$ is the fraction of correct predictions-made by the classification algorithm trained with data up to trial $i-$ where predictions are tested on a grid of predetermined, held-out test examples. The correctness is judged against the optimal decision boundary that was set in the beginning of the experiment.

Two experiments follow. Experiment 1 investigates the performance of pure recommendation and active learning, and compares them with random sampling. This experiment allows us to validate that recommendation and active learning fail to predict and recommend well, respectively, and provides a random sampling baseline. Experiment 2 investigates the unified active recommendation model, which interpolates between pure recommendation and pure active learning. This experiment characterizes recommendation and prediction accuracies of the algorithm in the context of concept learning.

## Experiment 1

Participants. The experiment was run on Amazon's Mechanical Turk (MTurk) with 30 participants in each of the
three conditions: recommend, active learning, and random.
Stimuli. Following Markant and Gureckis (2014), the stimuli were circles with a central diameter. The stimuli varied along two dimensions- the size of the circle's radius in pixels and the orientation of the central diameter in degrees (for an example, see Figure 5 B in Markant and Gureckis (2014)). The ranges of the size and orientation were fixed to 110 pixels and 140 degrees, respectively. The minimum radius and minimum orientation for the classes were sampled independently and uniformly from 10 to 30 units and fixed for the whole experiment. This procedure determined a pair of minimum and maximum values $\{\min , \max \}$ for each dimension.

For each experiment, one of the dimensions (size or orientation) was randomly selected as the separable dimension. Let the $\left\{\min _{s}, \max _{s}\right\}$ be the minimum and maximum values of the separable dimension, and $\left\{\min _{t}, \max _{t}\right\}$ be the values for the other dimension. Two classes were defined by two two-dimensional normal distributions. Along the separable dimension, the variances of the two classes were both 75 , and their means were set at $\left(\min _{s}+\max _{s}\right) / 2 \pm 30$. Along the other dimension, the variances were both 2250 , and the means were both $\left(\min _{t}+\max _{t}\right) / 2$. Stimuli were sampled from the twodimensional Gaussian described above. Those that happened to be outside the determined range were resampled.

The experiment consisted of three phases: training, interaction, and testing. In each trial of the training phase, a class was randomly sampled, and a stimulus was sampled according to its class distribution. In the interaction phase, there were several sampling algorithms. Random sampling used the procedure as in the training phase. Recommendation and active-learning sampling followed Eqs. 1 and 2 respectively. The choice was made from a fixed pool of 400 randomly sampled stimuli for each experiment. In the test phase, the stimuli were no longer sampled from the classes but from a test set. The test set consisted of $16 \times 16$ samples that lied on a regular grid covering the area of feature space defined by $[10,140]$ pixels $\times[10,170]$ degrees. Five stimuli were randomly selected from each of the four quadrants in that area to form the 20 test stimuli used in the test phase.

Procedures. Before the training phase, participants were instructed that throughout the experiment, they would see a series of "loop antennas" that receive signals from music stations called "Beat" and "Sonic" (the two classes of stimuli described above). They were instructed that the station received depends upon the antenna's radius and the orientation of its diameter. The goal of the training phase, as described to the participants, was for them to learn which station was received by a given class of antennas (e.g., Beat antennas have large diameters and Sonic have small). Participants provided input by clicking on one of two buttons (labeled Beat and Sonic respectively). After responding, participants received feedback on whether or not their input was correct. The participants moved on to the interaction phase once they had 19 correct answers in the past 20 trials.

The interaction phase was comprised of two parts. Participants were first instructed to pretend that they preferred either Beat or Sonic. Given this preference, participants were told that they would teach an algorithm to recommend the station that they preferred by indicating-by clicking on a button-that the antenna it chose was one that they "like" or "dislike." Participants were instructed to pay attention to whether the algorithm was improving or not. This part of the interaction phase continued for 20 trials. Next, participants rated the algorithm's improvement-that is, how well the participants thought the algorithm learned to recommend their preferred station-using a slide bar from "very poor" to "excellent."

The final phase of the experiment, the test phase, entailed a classification test to confirm whether participants still remembered the categories correctly. This phase followed the same procedure as the initial training phase, but did not provide participants with feedback (i.e., they were not told whether or not their categorization was correct). Afterwards, participants were asked to provide feedback about the experiment and identify the rule behind the classification they were trained on. Participants who successfully completed all phases of the experiment were compensated via MTurk.
Analysis. We quantify the behavior of the sampling algorithms by their trial-by-trial recommendation and predictive accuracies, as described previously. The test examples for computing the predictive accuracy consisted of a grid of 10-by-10 examples covering the area spanned by two pairs of \{min, max\} sampled for each experiment (see the Stimuli section under Experiment 1).

We report the first trial index by which an algorithm's recommendation accuracy becomes statistically different from $50 \%$ as well as the first trial index at which its recommendation accuracy becomes statistically no different from $95 \%$. For these we use the binomial test and claim statistical significance when p-value is less than 0.05 . We also report the trial index at which an algorithm's predictive accuracy converges. We formalize this as the first trial at which the predictive accuracy is not statistically different from the prediction accuracy at the last trial, using a one-sample t-test. The accuracy at the final trial is reported as the converged value.

We omit subjects whose test accuracy is below 18 out of 20 (below 90\%). For the included subjects, we compute a consistency score, which is the fraction of their responses to the recommended examples that matched the expected response. For subjects whose consistency score is below $50 \%$, we computed the predictive accuracies after flipping all their responses in the recommendation phase. This allowed us to correct for the responses from subjects who misremembered the preference during the interaction phase. A $0 \%$ consistency would flip the classification algorithm's prediction on every test example. We assume that the fraction of properly predicted examples is proportional to consistency. Thus, to maximize the fraction of proper predictions, we flip responses when consistency is $<50 \%$. The number of included subjects are 26/30 (3 flipped) for random, 27/30 (4 flipped) for active

Figure 1: Predictive accuracy and recommendation accuracy for all six conditions over time (trial index indicated on x -axis).
learning, and 27/30 (3 flipped) for recommendation.
Results. Figure 1 shows the recommendation and predictive accuracies of the different sampling algorithms. As expected, examples chosen under the recommendation objective result in high recommendation accuracy, but low predictive accuracy. As a function of the number of examples seen (trial index), recommendation accuracy rises above chance level and reaches $95 \%$ after 4 examples, ${ }^{1}$ while predictive accuracy converges after 5 examples to $81 \%$, which is low compared to the active learning or random algorithms.

Conversely, recommendation accuracy under the activelearning algorithm results in low recommendation accuracy, but high predictive accuracy. As a function of trial index, recommendation accuracy remains at chance level, while predictive accuracy converges after 5 examples to $92 \%$.

For reference, results of random sampling are also presented. These show a pattern similar to that observed for active learning. There is a rapid increase in predictive accuracy, converging after 8 examples to $95 \%$. Recommendation accuracy remains at chance level throughout.

## Experiment 2: Exploring active recommendation

An ideal algorithm would combine both high recommendation and high predictive accuracy. As a function of the number of examples given, one hopes that the recommendation accuracy will approach 1 after a few examples, and the predictive accuracy will steadily increase to 1 . Given the sharp dichotomy between the performance on recommendation and active learning, it is not obvious how best to achieve this.

We explore a simple, one parameter generalization of recommendation and active learning that we call, active recommendation. We investigate its trace of accuracy under a range of $\alpha=(0.55,0.75,0.95)$. We look at how the predictive and recommendation accuracies interpolate between the active learning and recommendation sampling as a function of $\alpha$. The new sampling algorithm is as described in Eq. 3. The stimuli and procedure are the same as Experiment 1.

[^250]

Figure 2: Predictive and recommendation accuracies for all included subjects broken down by condition. Red traces corresponds to individual subjects, and the blue curve is the average. (a) Active training; (b) $\alpha=0.55$; (c) $\alpha=0.75$; (d) $\alpha=0.95$; (e) Recommend. Note that a few mislabeled examples in the early trials can lead to unstable behavior, such as those curves that dip below chance level.

Participants. The experiment was run on MTurk with 30 subjects for each of the 3 conditions: $\alpha=(0.55,0.75,0.95)$. Following the criteria described above, the number of subjects included in the analysis is 27/30 (4 flipped) for $\alpha=0.55$, $26 / 30$ (5 flipped) for $\alpha=0.75$, and 23/30 (3 flipped) for $\alpha=0.95$.
Results. Figure 1 shows the plot of predictive and recommendation accuracies for all conditions. The predictive accuracies in the active-recommendation conditions converge to $93 \%, 90 \%$, and $93 \%$ for $\alpha=(0.55,0.75,0.95)$, respectively. These are similar to the $92 \%$ in the active condition and bet-

Figure 3: The distributions of like/dislike examples for each condition. The dotted lines in the distributions indicate the distributions' quartiles.
ter than the $81 \%$ in the recommend condition. The predictive accuracies of the active-recommendation conditions converged after 5 , 5 , and 8 examples for $\alpha=(0.55,0.75,0.95)$, respectively. The recommendation accuracies in the activerecommendation conditions reached $95 \%$ after 12, 16, and 4 examples for $\alpha=(0.55,0.75,0.95)$, respectively. These are similar to the recommendation condition in that all reached $95 \%$, whereas recommendation accuracies in the active and random conditions remain at chance level.

Importantly, if we move slightly away from the active condition (sampling from slightly farther away from the boundary than active; i.e., from $\alpha=0.5$ to 0.55 ), we can achieve much higher recommendation accuracy (it rises above chance after 8 examples and reaches $95 \%$ after 12 examples vs. at chance level throughout), while also achieving similar predictive accuracy. Similarly, if we move slightly away from the recommendation condition (from $\alpha=1$ to 0.95 ), we can maintain the recommendation accuracy while improving the predictive accuracy. Thus, these intermediate conditions (in terms of $\alpha$ ) appear to allow the algorithms to uncover more of the space that is relevant.

Figure 2 employs the same measures as Figure 1, but displays each of the six conditions separately, with individual participant performance (red lines) and the results averaged over all participants (blue lines). Figures 2a-2e allow for a closer look at individual variability during the experiment, and in particular highlight the difference in recommendation accuracy from the active learning and $\alpha=0.55$ conditions. If we compare Figures 2 a and 2 b , we can see that variation in recommendation accuracy across individuals persists for all trials in the active condition, while reducing greatly after 8 to 12 trials in the $\alpha=0.55$ condition. Comparing Figure 2 d and 2 e , we can see the predictive accuracy across individuals varies much less in the $\alpha=0.95$ condition than in the recommendation condition, resulting in the better average predictive accuracy for $\alpha=0.95$.

The cause of the improved performance of intermediate $\alpha$ values can be traced back to the examples they select. The distributions of "likes" and "dislikes" are plotted in Figure 3 alongside random sampling, active learning, and recommen-
dation. At the top, random sampling replicates the true distribution (up to some small number of inconsistent responses). Active learning selects examples that are evenly distributed across likes and dislikes but shifted toward the boundary between the two categories. At the bottom, recommendation selects examples that are skewed away from the boundary and the balance of examples is strongly tilted toward likes, consistent with the goal of recommending relevant examples. Of particular interest are the three alpha conditions. There are minor differences focused on the distribution of disliked items. What is most notable are the similarities among them and the active learning distribution for likes. Unlike the recommend condition, all three intermediate conditions disproportionately select "liked" examples that are close to the boundary. They all also select relatively few "disliked" examples. Cross-referencing against Figure 2, these disliked items happen only in the early trials. To summarize, the advantage of the active recommendation approach is a bias to select uncertain items within the relevant category. This allows them to achieve both high recommendation and predictive accuracy.

Interestingly, if we include only the fully consistent subjects, the $\alpha$ values dictate a strict ordering in both the predictive and recommendation accuracy. Increasing $\alpha$ from 0.5 to 1 , one sees a monotonic decrease in the converged predictive accuracy and a monotonic increase in the rate at which recommendation accuracy reaches 1 . The stochasticity in the subjects' responses can break the ordering in two ways. First, algorithms that provide examples closer to the boundary will receive more noisily labeled examples. Second, randomness in responses slows down the convergence of the classification algorithm. These effects cause the converged prediction accuracies, in small $\alpha$ conditions, to be lower than what they could be with less variable responses.

## Discussion

Information filters and recommender systems mediate between humans and the vast information and product stores on the Internet. Naturally, these algorithms aim to provide relevant information, but this goal may also lead to negative consequences by overly restricting experience. Embedding recommendation into a concept learning framework, we investigate the conditions under which we may observe high recommendation and predictive accuracy, in the presence of naturalistic human variability. We introduced a unified model of recommendation and active learning which we call active recommendation. In well-controlled experiments, we show that-across a wide range of parameterizations-active recommendation converges toward optimal predictive and recommendation accuracy. We also observe that parameterizations closer to pure recommendation yield better performance in terms of faster convergence and greater robustness to human variability. We trace the success of active recommendation to the fact that all parameterizations automatically combine rapid convergence toward selecting only relevant items and actively exploring informative examples from within that
set. Parameterizations close to pure recommendation perform best because they minimize exploration of regions of the space where human actions are most variable-near the boundary and in the non-focal category.

Our approach is unusual in that the goal is to use humans to investigate the behavior of algorithms. This makes sense because the algorithms are meant for recommending options to humans. In contexts where recommendation is typically applied, however, there is no known ground truth, which makes assessing the performance of algorithms difficult. One could assume a ground truth and perform computational simulations, but these assume that your simulation is robust to human-like variability, which is rarely known or checked. In our experiments, humans were taught very simple concepts that governed relevance. They then labeled data for the algorithm, which captures the kinds of uncertainty associated with cognition-stochasticity across time, in response to recent input, and features of the concepts. The results bear the fruits of the approach. If one considers only the people who labeled correctly in their interactions, active recommendation performs comparably well across a wide range of parameterizations. However, human variability is concentrated at the boundary and toward the non-focal concept, which gives parameterizations closer to pure recommendation a distinct advantage in recommendation and predictive accuracy.

Our proposed unified model of active recommendation takes pure recommendation and active learning as a starting point. However, across a wide range of parameterizations, the unified model exhibits behavior that is qualitatively different from either. That is, it achieves good performance on both goals of recommendation and active learning simultaneously. It is useful to consider this behavior in contrast with more explicit alternative approaches, namely, managing the exploitation-exploration trade-off in reinforcement learning. Formalizing and training a policy about when to apply recommendation (exploitation) or active learning (exploration) would certainly be more involved than the simple model we presented; it would also arguably miss the point. The active recommendation approach, in denying the existence of the dichotomy, allows simultaneous optimization of recommendation and prediction.

Active recommendation can be recast as a social active learning model where an agent asks questions to learn from another agent who may not answer because of disinterest, ignorance, or some other factors. In these social scenarios, good questions should depend on the answerer's preference, knowledge state, etc.. In the cognitive development literature, empirical studies have shown that children select questions based on the answerer's expertise (Kushnir, Vredenburgh, \& Schneider, 2013). This exemplifies an interesting connection between our model and human social learning.

Although active recommendation has demonstrated excellent performance, the problems considered here are vastly simpler than those more typical of real-world recommendation or information filtering. In light of this, one may rea-
sonably ask whether the results are likely to generalize to more complex, high-dimensional problems. Of course, active learning becomes decreasingly tractable as the space grows. This is why active recommendation may be expected to perform well. Instead of exploring the space of possibilities, active recommendation focuses on exploring the space of relevant possibilities. An important direction for future work is to formalize and test this question.

Often experimental control and real-world relevance are seen in competition. However, there are ways in which they can and should be complementary. Real-world applications of machine learning are especially amenable to this due to their algorithmic nature. In addition to the user studies that are typical of the applied computer science, we propose that more controlled experimental and modeling approaches in cognitive science can shed light on the core strengths and limitations of these algorithms.

#### Abstract

Human perceptual grouping of sequential auditory cues has traditionally been modeled using a mechanistic approach. The problem however is essentially one of source inference - a problem that has recently been tackled using statistical Bayesian models in visual and auditory-visual modalities. Usually the models are restricted to performing inference over just one or two possible sources, but human perceptual systems have to deal with much more complex scenarios. To characterize human perception we have developed a Bayesian inference model that allows an unlimited number of signal sources to be considered: it is general enough to allow any discrete sequential cues, from any modality. The model uses a non-parametric prior, hence increased complexity of the signal does not necessitate more parameters. The model not only determines the most likely number of sources, but also specifies the source that each signal is associated with. The model gives an excellent fit to data from an auditory stream segregation experiment in which the pitch and presentation rate of pure tones determined the perceived number of sources.

## Introduction

Ambiguity in perceptual systems is a blight for inference. When we hear two sounds sequentially, we may infer that they came from two different sources, $A$ and $B$, or the same source repeated. A third sound is heard - are the sources $\mathrm{AAA}, \mathrm{AAB}, \mathrm{ABA}, \mathrm{ABB}$ or ABC ? By the time four, five and six sounds are heard the number of combinations reaches 15, 52, 858. The ambiguity breeds to generate $a$ combinatorial explosion, and yet the human auditory system is able to reliably allocate multiple sources of sound in complex, real world situations. Features of the signal are consistently associated with different sources, allowing us to keep track of a speaker's voice and the wail of an ambulance siren, separate from the noise of background traffic and falling rain.

For several decades, the human ability to segregate sequential sounds into streams corresponding to sources has been investigated using simple sequences of either pure tones or more complex sounds (reviewed in (B. C. J. Moore \& Gockel, 2012)). The time interval between tones, their pitch difference and the duration of a sequence are among the factors that play an important role (Anstis \& Saida,

1985; Bregman \& Campbell, 1971; van Noorden, 1975): explanations of how the factors are used based on principles such as Gestalt laws and Occam's razor have been incorporated into the sophisticated conceptual model of Bregman (Bregman, 1994). Descriptive models based on peripheral excitation (Beauvois \& Meddis, 1997), coherence of coupled oscillators (Wang, 1996) and cortical streaming modules (McCabe \& Denham, 1997) provide mechanisms to estimate the number of streams, but do not specify which sound is associated with which source. While some of the models are expandable to allow more sources to be inferred, it is not known if they would cope with the combinatorial explosion. Furthermore, Moore \& Gockel (B. Moore \& Gockel, 2002) conclude from an extensive review of the literature that any sufficiently salient factor can induce stream segregation. This indicates that a more general model of inference is needed, that can incorporate any auditory perceptual cue and multiple sounds with different sources.
If ambiguity is a blight for inference, regularities in natural signals are the cure. Not all combinations of signal sources are equally likely - when perceptual systems generate a model of the world, we assume that they infer the most likely interpretation because the perceptual systems are optimized to the statistics of natural signals (Barlow, 1961; McDermott \& Simoncelli, 2011). Bayesian inference has had considerable success in modeling many visual and multi-sensory percepts as a generative, probabilistic process (Shams, et al. 2005; Weiss et al. 2002). Despite these successes, and the increasing evidence for the importance of predictability for auditory perception (for a review see Bendixen, 2014), we still have no general, principled model of how the auditory system solves the source inference problem.

A Bayesian approach to auditory stream segregation has been used to model the dynamics of perceptual bistability (Lee \& Habibi, 2009) but assumes that only two percepts are possible. Turner (2010) has developed methods of analyzing statistics of sounds based on Bayesian inference, and constructed a model to synthesize realistic auditory textures. Promisingly, inference in the model can qualitatively replicate many known auditory grouping rules.

In our model the probability of many alternative stream configurations (given the input signal) are calculated and the percept generated corresponds to the most probable configuration. The probabilities are calculated using Bayes'
rule to combine the likelihood of generating a signal given a postulated stream configuration, with the prior probability of sounds being associated with different sources. The likelihood and prior probability distributions are iteratively updated in a principled manner as information accumulates. The forms of the distributions are presumably optimized to natural signal statistics: the likelihood distribution we use is based on considerations of the physical limitations of oscillators. However, the framework of the model allows formulations of multiple explanatory factors, such as those determined by Bregman (1994) from psychophysics experiments, to be simply incorporated in the distributions. Furthermore, while the current study uses simple pure tones (replicating work by Bregman), the framework allows more complex cues from audition and other modalities to be used as long as their perceptual difference can be quantified.

## Human inference model

Pure tones are the indivisible atoms of input to the model each being assigned to just one sound source, or stream. Inspired by work done on non-parametric priors (Froyen, Feldman, \& Singh, 2015; Orbanz \& Teh, 2010; Wood, Goldwater, \& Black, 2006) we assume the existence of an infinite number of potential sources, leading to a sequence of tones with pitch $f_{1}, f_{2} \ldots$, onset time $t_{1}^{o n}, t_{2}^{o n} \ldots$ and an offset time, $t_{1}^{\text {off }}, t_{2}$ off $\ldots$ and the sound sources/streams that generated the tones are denoted by positive integers $S_{l}, S_{2} \ldots$ We rename the sources when necessary so that the first tone heard will always be generated by source 1 (i.e. $S_{l}=1$ ), and a subsequent tone, $S_{n}$ can be associated with source $1: \max \left(S_{1} \ldots S_{n-1}\right)+1$.

## Generative model

Given a source $S_{i}$ we assume that the frequency of tone $i$ is governed by physical constraints and statistical regularities of the source. If two sounds $f_{l}$ and $f_{2}$ with frequencies $F_{I}$ and $F_{2}$ are produced by the same source, the pitch cannot change at an infinitely fast rate: to make an oscillator change its frequency discontinuously would require an infinite impulse of energy. We assume that, all things being equal, a pure tone sound source is most likely to continue oscillating at the same frequency as it has in the past, and the probability of it changing at a rate $\Delta F / \Delta t$ will decrease as $\Delta F / \Delta t$ increases. More specifically we assume a normal probability distribution:

$$
\begin{equation*}
p\left(f_{i} \mid S_{i}, f_{i-t}, S_{\mathrm{i}}=S_{i-t}\right)=\frac{1}{\sqrt{2 \pi \sigma^{2}}} e^{-\frac{\left(\frac{\Delta F}{\Delta t}\right)^{2}}{2 \sigma^{2}}} \tag{1}
\end{equation*}
$$

where $\sigma$ is a constant. We here assume that the observer has a perfect noise free access to the generated frequency.

## Inference

The task of the observer is to infer the sources generating each of the tones, i.e. to find the $S_{1} S_{2} S_{3} \ldots$ that maximize $p\left(S_{1} S_{2} S_{3} \ldots \mid f_{1} f_{2} f_{3} \ldots\right)$, as illustrated in figure 1. As an example we use a sequence of three tones $f_{1} f_{2} f_{3}$, for which the observer wishes to infer the likely sources $S_{1} S_{2} S_{3}$. Thus the probability $p\left(S_{I} S_{2} S_{3} \mid f_{1} f_{2} f_{3}\right)$ that a sequence of three

Figure 1: a) Example of the integration or segregation of tones, either as 1 stream or 2 streams. b) Example of the condition [ $\begin{array}{lllll}3 & 1 & 9 & 1 & 3\end{array} 9$ ] from Exp. 2 (top) and the model's sequential maximum a posteriori assignment of tones within a stream (bottom). As each tone arrives the model reassigns the entire set of tones to streams (1->12->123 etc.).
tones was generated by sources $S_{1} S_{2} S_{3}$, has to be calculated over the five combinations: [ $\left.S_{l}=1, S_{2}=1, S_{3=1}\right]$, $\left[S_{l}=1, S_{2}=1\right.$, $\left.S_{3=2}\right],\left[S_{I=1}, S_{2}=2, S_{3=1}\right], \quad\left[S_{I=1}, S_{2}=2, S_{3=2}\right], \quad\left[S_{l=1}, S_{2=2}\right.$, $S_{3}=3$ ] corresponding to the five unique configurations of sources generating three sounds. Note that the first source is always assigned the value 1 , the next different source is assigned 2, etc.. Bayes' rule relates each conditional probability (the posterior distribution) to the likelihood $p\left(f_{1} f_{2} f_{3} \mid S_{1} S_{2} S_{3}\right)$ of each configuration of sound sources generating the sequence of tones, by

$$
\begin{equation*}
p\left(S_{1} S_{2} S_{3} \mid f_{1} f_{2} f_{3}\right)=p\left(f_{1} f_{2} f_{3} \mid S_{1} S_{2} S_{3}\right) p\left(S_{1} S_{2} S_{3}\right) / Z \tag{2}
\end{equation*}
$$

where $Z$ is a normalization constant, and $p\left(S_{1} S_{2} S_{3}\right)$ is the prior probability of the particular configuration of sound sources, regardless of the frequency, etc. of the tones

Assuming conditional independence of the tones and tone-source causality, this can be rewritten as

$$
\begin{align*}
& p\left(S_{1} S_{2} S_{3} \mid f_{1} f_{2} f_{3}\right)  \tag{3}\\
& =p\left(f_{3} \mid S_{1} S_{2} S_{3}\right) / p\left(f_{3}\right) \times p\left(S_{3} \mid S_{1} S_{2}\right) \times p\left(S_{1} S_{2} \mid f_{1} f_{2}\right)
\end{align*}
$$

The final term is the posterior generated from the first two tones. The latter two terms can be considered together as the prior for the third source, allowing us to use an iterative approach to the inference. After each tone we grow the tree of possible source sequence (e.g. $11 \rightarrow 111$ and 112), by multiplying the previous posterior $p\left(S_{1} S_{2} \mid f_{1} f_{2}\right)$ with two terms; the likelihood $p\left(f_{3} \mid S_{1} S_{2} S_{3}\right)$ and a prior for how likely the next 'branch' is, $p\left(S_{3} \mid S_{1} S_{2}\right)$.

We now consider how to determine the likelihood and prior probabilities. The first source can only be associated with one source, so $p\left(S_{l}=1\right)=1$. The principle of Occam's razor would suggest that $p\left(S_{I}=1, S_{2}=1\right)>p\left(S_{I}=1, S_{2}=2\right)$, i.e. if we haven't heard any of the sounds, the most probable acoustic scene is the simplest one: all sounds come from the same source. The value of $p\left(S_{1}=1, S_{2}=1\right)$ for an individual can be determined from fitting their data, and the value $p\left(S_{1}=1, S_{2}=2\right)$ is simply $1-p\left(S_{1}=1, S_{2}=1\right)$. The values may depend on factors such as the environment, which are not considered in the model: natural signal statistics may
provide guidance for how the prior probabilities are assigned. For successive sources, we use the probability given by a Chinese restaurant process (CRP) (Aldous, 1985), which can be considered as an extension of Occam's rule:

$$
\begin{aligned}
& p\left(S_{N}=\right.\left.i \mid S_{l} \ldots S_{N-I}\right)=n_{i} /(N-1+\alpha) \\
& \text { when } \mathrm{n}_{\mathrm{i}} \text { of the previous sources } S_{l} \ldots S_{N-I} \text { is equal to } i \\
& p\left(S_{N}=i \mid S_{l \ldots} . \ldots S_{N-I}\right)=\alpha /(N-1+\alpha) \\
& \text { when none of the previous sources is equal to } i
\end{aligned}
$$

where $N$ is the total number of sounds heard.
Regarding the likelihood function, the observer assumes the generative probability $p\left(f_{i} \mid S_{i}, f_{i-t,}, S_{i}=S_{i-t}\right)$. Note that this applies even when the sounds generated by the same source are separated by one or more sounds associated with different sources. The only transition that matters is that between the most recent tone and the last tone in the same stream, so if three tones $f_{1} f_{2}$ and $f_{3}$ had all been associated with the same stream, we would only consider the transition from $f_{2}$ to $f_{3}$, whereas if $f_{2}$ was associated with a different stream, we would only consider the transition from $f_{1}$ to $f_{3}$.

If a sound comes from a new source, then we assume that the likelihood is independent of previous tones:

$$
\begin{equation*}
p\left(f_{n} \mid S_{l}, \ldots S_{n-l}, \quad S_{n} \notin S_{l} \ldots S_{n-l}\right)=\frac{1}{\sqrt{2 \pi \sigma^{2}}} e^{-\frac{\left(f_{n}-\widehat{f}\right)^{2}}{2 \sigma^{2}}} \tag{5}
\end{equation*}
$$

where $\hat{f}$ is the midpoint of the range of auditory frequencies presented for the trial. The final model has two parameters, $\alpha$ and $\sigma$.

## Posterior approximation

Using the iterative scheme above we can calculate analytically the possible combinations of tones, but as the tone sequence progresses the number of possible source combinations - and hence the size of the posterior distribution - increases exponentially. To prevent combinatorial explosion two methods are used to generate an approximation of the full posterior distribution. The first limits the number of tones that are retained when using the previous posterior as the next prior, i.e. the algorithm only retains e.g. the last 10 tones and their potential allocations to sources

Limiting the number of tones eases the computational load, and can also be seen as a crude model of a limited memory capacity. Although the iteratively constructed prior retains some stream information of all previous tones, when a very short memory is used this may not be sufficient to generate stable stream allocation as the CRP prior probabilities fluctuate greatly when the number of previous tones is small. Furthermore, if the structure of the sequence is an important cue for streaming, a larger memory may be necessary to determine regularities in the sequence.

Even when the memory is limited to the previous six tones, allocating a stream to the seventh tone requires a posterior distribution taking 858 values, most of which must necessarily have very small probabilities. A second method to limit the size of the posterior is simply to select only the most probable stream combinations by imposing a probability threshold, hence we only used stream
combinations with $p>0.001$. Together these approximation methods allow a reasonable memory length of 10 tones (to avoid instability), while avoiding combinatorial explosion.

## Experiment 1

To compare the model to human performance we conducted a psychophysics experiment, in which six participants with normal hearing listened to simple auditory sequences and performed a subjective judgment task (a variant of experiments by van Noorden (1975)). Subjects were undergraduate students and received course credits for their participation. Each subject was fully briefed, provided informed consent and was given brief training on the task through exposure to 5 trial stimuli.

## Experimental setup

Figure 1a shows a schematic of the stimuli used - each sequence comprised 30 tones in repeated LHL- triplets, where the dash represents a silent gap. Each tone was 50 ms in duration, including 10 ms raised cosine onset and offset ramps. A $2 \times 2$ factorial design was used: the pitch of the high tones taking values of $3,6,9,12$ and 15 semitones above the low tone, which had a fixed frequency of 1000 Hz , and the offset to onset interval taking values $17,33,50$ and 67 ms . The duration of the silent gap was equal to the tone duration plus the offset-onset interval. Conditions were ordered randomly - each condition was tested 20 times over 5 runs, each run lasting approximately 7 minutes. Stimuli were presented through Sennheiser 280 headphones at a comfortable supra-threshold level. At the end of the sequence participants pressed a key to report whether the percept at the end of the sequence was most like a single stream (a galloping rhythm) or two separate streams of notes. The fraction of 2 -stream responses per condition is shown in figure $2 b$ for all six participants.

## Model response

To determine the response of the model to a tone sequence, the posterior for each possible sequence, $C$, is calculated tone-by-tone until all 30 tones have been presented. To relate the final posterior over sequences to subject responses, $s_{r}$ ('1 or 2 streams') $P_{\text {model }}\left(s_{r} \mid t o n e s, C\right.$ ), we defined a metric between two sequences. While the simple Hamming distance was considered we found it did not capture the similarities and differences between sequences. As an example, the Hamming distance between the sequence [11111] and [12222], $H(11111,12222)=4$, does not capture the intuition that a change of labels ( $2->1$ ) implies a distance of 1 . Instead we define a transition matrix, $M_{C}$ with elements $m_{i, j}=C_{i}-C_{j}$ i.e. the difference in the stream number for entry $i$ and $j$ of sequence $C$.

A transition matrix $M_{p C}$ is calculated for each posterior stream combination $C$, and also for the 'ideal' one or two stream response percepts (i.e. $M_{l}$ corresponding to 111 $111 \ldots$ and $M_{2}$ corresponding to $121121 \ldots$ ). The sum of the absolute difference between elements of $M_{p C}$ and both $M_{I}$ and $M_{2}, d_{C l}=\left|M_{p C}-M_{1}\right|$ and $d_{C 2}=\left|M_{p C}-M_{2}\right|$ give measures of the distances $d_{C 1}$ and $d_{C 2}$ from $C$ to the ideal response

Figure 2: a) Model prediction, based on fitted parameters from subject KC, giving the fraction of trials in which participant responded ' 2 ' for the number of streams perceived. Axes give the pitch difference for the middle tone and the inter stimulus interval (ISI): the time between the offset of one tone and the onset of the next. b) The results from 6 subjects.
percepts. This method can also give the fixed distance $\mathrm{d}_{12}$ between the ideal responses, $d_{12}=\left|M_{1^{-}}-M_{2}\right|$, thus streams $C$, $111111 \ldots$ and $121121 \ldots$ are represented by a triangle with sides of length $d_{C 1}, d_{C 2}$ and $d_{12}$. The vertex corresponding to stream $C$ can be projected onto the side $d_{12}$ giving $D_{l}$, the relative difference between $C$ and the two response percepts:

$$
D_{1}=\left(d_{12}^{2}+d_{C 1}^{2}-d_{C 2}^{2}\right) / 2 d_{12}^{2}
$$

$D_{l}$ is restricted to the range $[0,1]$, and each projected point is weighted by its posterior probability to give the marginal distribution of the posterior projected onto the axis joining the two responses. The distance $D_{l}$ gives the probability of subjects response, $s_{r}, 1$ or 2 , given $C$, i.e. $P\left(s_{r}\right.$ $=2 \mid C)=D_{l}$ and $P\left(s_{r}=1 \mid C\right)=1-P\left(s_{r}=2 \mid C\right)$. Lastly we marginalize over the possible sequences, and assume that participants draw a sample from the posterior when responding, giving

$$
P_{\text {model }}\left(s_{r} \mid \text { tones }\right)=\sum_{\mathrm{C}} P\left(s_{r} \mid \text { tones }, C\right) P(C \mid \text { tones })
$$

The parameters of the model (as well as for the alternative models below) were optimised using the MATLAB fminsearch routine to maximise the log-likelihood of the data, $\Sigma \ln \left(P_{\text {model }}\left(s_{r} \mid\right.\right.$ tones $\left.)\right)$ independently for each subject. During each iteration of the search, a sequence of 30 tones was presented to the model for each condition, and the probability of response ' 1 ' was calculated per condition.

## Model performance and comparison

The model was compared against three alternatives that used different priors to constrain the number of possible streams to two:
A. When the stream combination comprised only one stream (repeated), the prior probability of the next stream being 1 or 2 was allocated according to the CRP, but if the combination already contained two streams, the prior probability of allocating stream 1 or 2 was simply the fraction of previous tones that were allocated to stream 1 or 2 respectively.
B. The prior probabilities of a new tone being allocated to stream 1 or stream 2 was given by $P_{1}$, and $1-P_{1}$ respectively, where $P_{1}$ is a free parameter.
C. The prior probabilities of a new tone being allocated to stream 1 or 2 were fixed at 0.5 .
As mentioned earlier, an alternative response measure based on the Hamming distance was also tested: in this case we used the original, unconstrained CRP prior model. In the results, this is referred to as alternative D.

Because alternative model C has only one free parameter (all others have two), we use the Bayesian information criterion ( $\mathrm{BIC}=-2 \log P($ resp $\mid$ tones $)+k^{*} \log (n)$, where $k$ is the number of parameters and $n$ is the number of data points fitted over) to compare model performance in table 1. With the exception of participant LHH, the unconstrained model gives a better fit (smaller BIC) than all the alternatives considered. The mean $\pm$ SEM of the optimised parameters for the unconstrained model are $\alpha=0.81 \pm 0.12$ (equivalently $P(11)=0.56 \pm 0.04$ ) and $\sigma=105 \pm 7$ [semitones/sec]. Data from all subjects and the unconstrained model output for participant KC is shown in figure 2.

| Partici- <br> pant | Uncon- <br> strained | Alternative <br> A | B | C | D |
| :---: | :---: | :---: | :---: | :---: | :---: |
| SAG | $\mathbf{2 4 6 . 3}$ | 328.9 | 276.6 | 395.2 | 286.1 |
| TAY | $\mathbf{2 1 9 . 5}$ | 279.8 | 225.3 | 313.3 | 302.7 |
| KC | $\mathbf{2 8 7 . 4}$ | 345.4 | 314.1 | 414.1 | 489.9 |
| LHH | 288.5 | 335.9 | $\mathbf{2 5 7 . 8}$ | 424.1 | 284.5 |
| GM | $\mathbf{2 0 0 . 7}$ | 303.7 | 207.8 | 323.9 | 227.3 |
| MLP | $\mathbf{3 0 8 . 7}$ | 338.7 | 322.1 | 431.3 | 566.3 |

Table 1. BIC per participant. A smaller number indicates better relative performance (best model for each subject indicated in bold).

Figure 3: Averaged subject responses as a function of the auditory tone condition (see example in Fig. 1b). The horizontal labels indicate the tone-sequence of the condition, ordered by increasing step sizes. Error bars are standard errors.

## Experiment 2

While the model above theoretically allows an unlimited number of tones to be segregated into an unrestricted number of streams, the classical experiment (presented above) only allows a sequence of 3 tones to be separated into 1 or 2 streams. However, the model predicts that subjects should generally segregate based on frequency and temporal distances between tones. To test this further we performed a novel follow-up experiment where subjects were presented with seven tones and had to indicate the number of streams perceived. Nine conditions were created with sequentially larger discrepancy in frequency between tones and thus a larger probability of being assigned to different streams according to the model. The temporal gap between tones (ISI) were kept constant at 33.3 ms , unlike experiment 1 . For each condition, of the seven tones (see fig 1 b for one condition) three tones were unique. Five further subjects (see above) performed this new task. Results showed that subjects perceived an increasing number of streams (fig. 3), in accordance with predictions from the model, rising from 1 to close to 3 ( $\mathrm{p}<0.0001, \mathrm{~F}=20.39$, oneway anova, $\mathrm{df}=8$ ). None of the subjects perceived more than 3 streams for any of the conditions.

## Discussion

We have presented a simple Bayesian statistical model for grouping of discrete sequential stimuli. Utilizing a nonparametric Bayesian prior the model iteratively updates the posterior distribution over the assigned group of each stimuli and provides an excellent description of the perceptual interpretation of simple auditory sequences in human observers.

With just two parameters, the model gives a good account of the basic characteristics of auditory stream segregation the variation in the probability of perceiving a single sound source as a function of the repetition rate and pitch difference of the sounds. Although the ultimate goal is to characterize complex problems such as human speech
segregation, for experimental simplicity we tested a well known paradigm from auditory psychophysics. The proposed model gave a better fit to the data than alternative models that were constrained to interpret the sounds as being produced from just one or two streams. Predictions from the model were also in accordance with results from a novel experiment with larger number of tones (exp. 2).

Importantly the model goes beyond giving just the number of sources, but says which sounds are produced by each source. While the combinatorial space of the posterior distribution in experiment 1 was collapsed to give a marginal distribution in a continuous 1-d response space (leading to an estimate of response probability), the maximum a posterior (MAP) for all participants was always located at either 111-111... or 121-121..., depending on the stimulus condition (figure 2 b ). This is reassuring as it is consistent with the anecdotal evidence that participants always perceive either a galloping rhythm (streams 111111...) or a high-pitch and a low pitch stream (121-121...), i.e. the percept is always at the MAP. Indeed, the percept cannot in general be at the mean because the space of possible percepts is discrete: there is no percept between, say, 111 and 121.

One consequence of the inference model that is not addressed by mechanistic models of stream segregation is that when a percept changes from say 111-111 to 121-121, the source allocation of previous sounds is changed. Ironically, this 'non-causal' effect is essentially a feature of causal inference - when an observer decides that the percept has changed to 121-121, this is based on previous evidence, and yet at the time that the previous tones were heard, they were all associated with one source. A similar effect is commonly encountered when mis-interpreted speech (perhaps mis-heard due to background noise) suddenly makes sense when an essential word is heard - the previous words are reinterpreted, similar to the letters in predictive text message systems.

The framework of the model is very general, and allows for the incorporation of other factors into the likelihood to describe other aspects of auditory stream segregation. Adding terms in the likelihood function may be able to explain other effects seen in the literature, such as segregation based on bandwidth (Cusack \& Roberts, 2000), or build-up and resetting of segregation (Roberts, Glasberg, \& Moore, 2008). Furthermore, in the current study we assume that there is no ambiguity in the percept of the pure tones, the uncertainty arises from lack of knowledge about the underlying generative structure of the data. In a realistic situation perceptual ambiguity would have to be taken into account using an approach such as suggested by Turner and Sahani (Turner \& Sahani, 2011). Nevertheless, we should emphasize that even though we are dealing with a Markov property (each tone within a stream only depends on the previous tone), the mixture of streams makes the problem very different from work on e.g. Hidden Markov Models (or even Infinite Hidden Markov Models) for which the goal would be to infer underlying states despite perceptual ambiguity. Note also that while there are algorithms
developed to separate audio signals (e.g. Roweis, 2001), these are not meant to mimic human perception, although a future comparison would be very interesting.

In the current implementation we used numerical approximations in order to handle the complexity of the model. As an alternative to calculating our results analytically we could use Monte Carlo techniques (e.g. Markov Chain Monte Carlo sampling, a different type of approximation), which have become a standard tool for solving complex statistical models.

The proposed model of auditory stream segregation is a specific instantiation of an iterative probabilistic approach towards inference of perceptual information. A major issue for this approach is the problem of dealing with multiple sources, as represented by the work done on causal inference (Shams \& Beierholm, 2010). Until now models of causal inference have been unable to handle more than two sources, due to the escalating number of parameters needed for parametric priors. The use of a non-parametric prior allows a complex of many stimuli to be interpreted without running into this problem, potentially allowing for an arbitrary number of causes in the world. This approach is very general - it can be applied to any set of discrete sequential cues involving multiple sources - and it gives a simple, principled way to incorporate natural signal constraints into the generative model.

# Perceived similarity mediates violations of independence in probabilistic judgments 

James M. Yearsley (james.m.yearsley@ vanderbilt.edu)<br>Daier Yuan (daier.yuan@ vanderbilt.edu)<br>Jennifer S. Trueblood (jennifer.s.trueblood@ vanderbilt.edu)<br>Department of Psychology, Vanderbilt University, Nashville TN, USA

#### Abstract

We outline a simple way of representing sets of non-normative judgements that makes them look as similar as possible to normative ones. This representation allows us to view certain types of non-normative judgments, such as conjunction fallacies, as arising from a misestimation of the correlation between events, that might arise when decision-makers have no prior information about the frequency of co-occurrence. We suggest that decision-makers use the perceived similarity between events to make inferences about correlation, and we describe the results of an experiment showing that judged correlation and violations of independence in probabilistic judgments are strongly influenced by the perceived similarity between events.

Keywords: Conjunction fallacy, similarity, normative reasoning

## Introduction

Being able to make unbiased and reasonably accurate likelihood judgments about simple events is a foundation for more complicated tasks such as inference or causal reasoning. Human reasoners are often very competent at providing such judgments, in the sense that their judgments align well with normative prescription. However there are classic results, such as those associated with the famous Tversky and Kahneman research program, which show that in some cases human reasoners may provide likelihood judgments for simple combinations of events that show systematic biases. In causal reasoning tasks for example, this can lead to violations of the predictions of models based on classical probability theory, with a resulting need to supplement classical models with extra unobserved relationships (Rehder, 2014), or even to reject classical probability theory entirely and attempt to construct models based on other theories of probability, such as quantum probability theory (Pothos \& Busemeyer, 2013).

Several decades of experience have taught researchers where to expect violations of normative rules when making likelihood judgments, but there has been less success in determining why such violations occur. Tversky and Kahneman (1983) argued that conjunction fallacies occur because of a representativeness heuristic, while explanations for violations of normative rules such as the Markov Condition in causal reasoning often involve the presence of additional enabling or disabling causes (Rehder, 2014). Meanwhile models based on non-classical probability theory posit that violations of classical probability rules occur because of a somewhat mysterious property known as 'incompatiblity' (Busemeyer \& Bruza, 2012). Perhaps one or more of these explanations is correct, perhaps none are, but regardless they all
suffer from the same problem that it is difficult to predict in advance whether a given set of events will be 'representative' or 'incompatible' etc.

An additional problem faced when attempting to understand why some judgments are normative and some are not is that different frameworks are used to model the different types of judgments. Partly this is due to the fact that non-normative judgements are defined by what they are not, viz. those that can be explained by an underlying classical (Bayesian) belief state. One way of modeling non-normative judgments is via heuristics (see e.g., Gigerenzer et al, 2015) which may bear no relationship to classical probability computations. Another is to replace classical sample spaces with quantum vector (Hilbert) spaces, as done in quantum models of cognition (Busemeyer \& Bruza, 2012), which again appear to have little relation to classical probability theory.

There would appear, therefore, to be a disconnect between the way cognitive states, and computations on them, are represented depending on whether one is dealing with normative or non-normative reasoning. This poses a challenge if we wish to understand the reasons why we might sometimes give normative judgments and sometimes not, or, for example, if we wish to understand how corrective feedback may improve performance.

What we want to do in this contribution is to introduce a way of thinking about non-normative judgments that makes them look as similar as possible to normative ones. This representation can be used in a variety of settings to study transitions between non-normative and normative behaviors. We will show that for non-normative judgments the notion that an underlying probability distribution 'does not exist' can be formalized by considering quasi-distributions, which are similar to standard probability distributions except that some elements may be negative. This gives us a way to think about smoothly transitioning from non-normative judgments, represented by quasi-distributions, to normative ones, where all elements of the distribution are positive and it may be interpreted as a classical probability distribution.

By itself this achieves little beyond expressing the problem of non-normative judgments in a different language, however we will argue that this representation provides a new way to understand the origin of non-normative judgments, and even a way of visualizing how learning can cause a transition to normative behavior. We will see that non-normative judgments can arise because of an misestimation of the correlation be-
tween events, and we will argue that this may occur when events are perceived to be highly similar. We test this in an experiment, looking at judgments about the joint occurrence of events with different degrees of similarity.

The rest of this contribution is structured as follows, first we provide a brief introduction to quasi-probability distributions, our aim being to show how they may be used to encode non-normative judgments. Next, we use this framework to develop a novel empirical prediction that a high degree of perceived similarity between features of an object can give rise to violations of independence and conjunction fallacies in probabilistic judgments. Then, we describe an experiment to test this prediction. We conclude with some possible avenues for further study.

## Probability distributions and quasi-distributions

A common theme in experiments on probabilistic judgment is that participants are asked to make a set of judgments about the likelihood of some events, e.g. $p(A), p(B), p(A \cap C)$ etc, and the normative status of these judgments is assessed by proving that there either does or does not exist a probability distribution $p\left(A_{i}, B_{j}, C_{k}\right)$ such that all the measured judgments can be thought of as marginals of this joint distribution. For example, the conjunction fallacy, wherein participants judge $p(A \cap B)>p(A)$, is non-normative because it is impossible for participants to have a single joint probability distribution for $A$ and $B$ with this property.

## Joint probability distributions

Establishing whether a set of probability or likelihood judgments is normative is therefore equivalent to the following:

Given some set of probabilities, $S=$ $\{p(A), \ldots p(A, B), \ldots, p(A, B, C), \ldots\}$ etc does there exist a joint distribution $p\left(A_{i}, B_{j}, C_{k} \ldots\right)$ of which all elements of the set $\mathcal{S}$ may be considered as marginals?

If such a probability distribution exists, then the set of judgments $\mathcal{S}$ are normative, otherwise they are non-normative.

## Some Examples

- This definition includes trivial cases, e.g. where $\sum_{i} p\left(A_{i}\right) \neq$ 1. Such cases are obviously non-normative.
- A simple example is provided by the set $S=$ $\left\{p\left(A_{i}\right), p\left(B_{j}\right), p\left(C_{k}\right), \ldots\right\}$ where participants are only asked to make judgments about a single event. In this case we can easily find a joint distribution that has the single event probabilities as marginals, e.g. $p\left(A_{i}, B_{j}, C_{k}, \ldots\right)=$ $p\left(A_{i}\right) p\left(B_{j}\right) p\left(C_{k}\right) \ldots$ will work (there are many choices).

A Less Trivial Example Suppose we have three binary events $A, B, C$ and we are given the joint probabilities, $\mathcal{S}=$ $\left\{p\left(A_{i}, B_{j}\right), p\left(B_{j}, C_{k}\right), p\left(A_{i}, C_{k}\right)\right\}$. An important result is that it is not always possible to find a joint distribution $p\left(A_{i}, B_{j}, C_{k}\right)$ with these marginals. The conditions under which this is possible are when the Bell inequalities are satisfied (Fine, 1982).

## Joint quasi-probability distributions

If a set of judgments $S$ is not normative, then a probability distribution capturing these judgments does not exist. However there may still exist some function $q\left(A_{i}, B_{j}, C_{k} \ldots\right)$ such that all the elements in the set $S$ can be obtained by summing out the other variables in $q(\ldots)$. This function $q\left(A_{i}, B_{j}, C_{k} \ldots\right)$ will generally fail to be a probability distribution because it will not be non-negative.
Example Suppose $\mathcal{S}=\{p(A), p(B), p(A \cap B)\}$ for some binary valued features $A, B$ and $p(A \cap B)>p(A)$. Clearly there is no probability distribution which can have $\mathcal{S}$ as its marginals. However a quasi-distribution with these properties may be given as:

$$
\begin{aligned}
& q(A, B)=p(A \cap B) \\
& q(A, \bar{B})=p(A)-p(A \cap B) \\
& q(\bar{A}, B)=p(B)-p(A \cap B) \\
& q(\bar{A}, \bar{B})=1-p(A)-p(B)+p(A \cap B)
\end{aligned}
$$

Note that this has the desired marginals, e.g. $q(\bar{A}, B)+$ $q(\bar{A}, \bar{B})=1-p(A)$, but that $q(A, \bar{B})<0$.

The use of quasi-distributions in psychology to understand inconsistent judgments has been advocated before, most notably by de Barros, (e.g. de Barros, 2013). In physics there is a long history of trying to apply 'extended' probabilities to understand aspects of quantum theory (see e.g. Muckenheim, 1986). Their interpretation can be challenging (Halliwell \& Yearsley, 2013) but here we shall avoid assigning any meaning to them and regard them simply as a computational tool.

So far all we have done is to express some classes of nonnormative judgments in terms an object which is superficially similar to a joint probability distribution, but which fails to be one in some (rather drastic) way. Why is this useful? Well the usefulness of quasi-probability distributions lies in part in the fact that they smoothly capture the idea of transitioning between non-normative behavior (where one or more of the elements of the distribution is negative) to normative behavior, where all elements are non-negative. Suppose for example that we are performing an experiment where participants have to bet on the outcome of some gamble involving a conjunction. If they commit a conjunction fallacy in their reasoning, they may initially perform badly, but with corrective feedback they may revise their estimate of the probabilities of the outcomes. At some point their beliefs will change from non-normative to normative discontinuously, but in terms of quasi-distributions their their belief state may change smoothly as they learn.

Quasi-distributions also allow us to define a notion of distance from normative behavior, for example one could define the degree of non-normativity as,

$$
\begin{equation*}
\Delta=\sum_{i, j, k \ldots}\left|q\left(A_{i}, B_{j}, C_{k} \ldots\right)\right|-1 \tag{1}
\end{equation*}
$$

which is zero if $q(\ldots)$ is a probability distribution and nonzero otherwise. For example, for the case above of a conjunction fallacy, $\Delta=2|p(A, B)-p(A)|$, which is an appealing measure of the non-normativity.

One reasonable proposal would be to look at cases where a set of judgements $\mathcal{S}$ only just fails to be normative by this measure. One could then try to define a genuine probability distribution $p(\ldots)$ and a new set of judgments $S^{\prime}$ which are 'close' to the real judgments $\mathcal{S}$ in the sense that $p(\ldots)$ is close to $q(\ldots)$. If there is a sense in which this is possible then one might regard the judgments $\mathcal{S}$ as almost normative, and perhaps attribute the discrepancy to some sort of response noise.

We will not pursue this further here. Instead we will make use of another advantage of quasi-distributions, which is that by expressing normative and non-normative behaviors in a similar language, they suggest ways to understand how nonnormative behaviors may come about. We shall explore one such idea in the next section.

## A Simple Proposal

In a typical conjunction fallacy type experiment, participants might be expected to have some information about the rate of occurrence of the features $A$ and $B$, and be asked to guess the likelihood of the conjunction $p(A \cap B)$. It is important to realize that even given $p(A), p(B)$ there is no 'correct' answer to this question. Rather there are a range of possible allowed values, in other words, the marginal probabilities $p(A), p(B)$ under-specify the joint distribution. One extra piece of information is needed, one of the joint probabilities would do, as would some linear combination of these. One possibility is to consider the quantity,

$$
\begin{equation*}
S_{A B}=p(A \cap B)+p(\bar{A} \cap \bar{B}) \tag{2}
\end{equation*}
$$

which is closely related to the correlation. The difference between a normative probability distribution and a nonnormative quasi-distribution can be thought of, perhaps simplistically, as the difference between choosing a value for $S_{A B}$ within or outside of the allowed range. This is important because decision makers armed only with $p(A), p(B)$ have no information about $S_{A B}$, and there is therefore a significant possibility that they may chose incorrectly. To put it another way, if decision makers make an incorrect guess for the correlation between $A$ and $B$, this can lead to a non-normative set of judgments.

Now $S_{A B}$ is a number which varies between 1 if the events always happen together, to 0 if the presence of one event implies the absence of the other and vice versa. One possibility is that decision makers simply pick a value for $S_{A B}$ based on a uniform prior. Another possibility is that decision makers equate $S_{A B}$ with a more primitive quantity such as the similarity between $A$ and $B$. (We note in passing that the idea of similarity as essentially joint probability appears in accounts of similarity judgment based on quantum cognitive models (Pothos et al, 2015).)

This leads to an important prediction, which we will test below: In the absence of any information about joint occurrence, human decision makers will use features of events such as their similarity to construct a joint distribution. Manipulating these relationships in an experimental setting should lead
to greater or lesser degrees of violations of independence for these events, and more generally to changes in the correlation between events. We describe an experiment to test these ideas in the next section.

## An Experiment

## Methods

58 undergraduate students from Vanderbilt University participated in the experiment online at a time of their choosing for course credit. Participants answered questions about three different novel categories, an animal, a natural object and a human made object, adapted from previous work on causal reasoning (Rehder, 2014). Each object had three binary features $(A, B$, and $C)$. For each feature participants were told that 'most' members of the category had a high value for that feature, while 'a few' members of the category had a low value for the feature. Participants were not told about any relationships between the features. For example, in the Kehoe Ant category, $A=$ Blood iron level (high or low amount), $B=$ Immune system activation level (hyperactive or suppressed), and $C=$ Blood thickness (thick or thin).

After this, participants answered a number of questions where they were told that a new member of the category had been discovered, and were asked to indicate how likely they thought it was that the new object had various features. There were three question types: (1) how likely it was that the object had a particular feature, e.g. blood high in iron sulphate, (2) how likely it was that the object had a combination of features, e.g. blood high in iron sulphate and an immune system that is hyperactive, and (3) a conditional, e.g. a hyperactive immune system given that a previous test had established a high level of iron sulphate in the blood. Participants were asked about all possible conjunctions of events, but only about conditionals where one feature was conditioned on the presence of a low value for another feature. The reason for this was to reduce the overall number of questions in the experiment, particularly since our expectation was that features would be positively correlated, which would be likely to lead to floor or ceiling effects for the other possible conditionals.

The responses were either requested as whole numbers between 0 and 100 , or as points on a 9 point Likert scale. The response format for all questions concerning a given category were the same, and participants were randomly assigned either the whole number or the Likert response options for each category. After completing the likelihood judgment questions for each category, participants were asked to rate the similarity between the feature types on a 7 point Likert scale. The order in which the features appeared in the similarity question (e.g. how similar is feature 1 to feature 2 ) was randomized between participants for every judgment, however there were no significant order effects in the similarity judgments.

After finishing the main part of the experiment, participants completed an extended version of the Cognitive Reflection Test (CRT, Frederick, 2005), but there was no significant effect of CRT and it will not be discussed further here.

## Results

We first wanted to examine whether we had conjunction fallacies and violations of independence in this data set. For each pair of likelihood judgments, e.g. $\{A, A \cap B\}$ or $\{A, A \mid B\}$ we can perform a paired samples t-test to assess the presence of these effects, however this procedure would generate a substantial volume of test statistics without giving much insight. Instead we will plot the relevant likelihoods, and quote some representative statistics. In this contribution, we only report Bayesian statistical tests that were performed using JASP (JASP team, 2016). In particular we report Bayes factors for the alternative versus the null hypothesis, so that values $>1$ indicate evidence for the alternative hypothesis.

We begin by assessing the conjunctions. For each pair $\{A, A \cap B\}$ we plotted the average values across participants of the single event and the conjunction. It is useful to split these pairs up into four different types, depending on whether each of the events has high or low individual probability. The results are shown in Fig 1, and we have separated out data that comes from responses using whole numbers and from the Likert scale. Points that lie above the diagonal correspond to conjunction fallacies. The first thing to note is that there are three obvious clusterings of data points. We see straight away that pairs of the form $\{A, A \cap \bar{B}\}$ behave as expected, there are no conjunction fallacies. Equally the pairs $\{A, A \cap B\}$ do not display robust conjunction fallacies (All Bayes factors for t-tests $<1$ ), although these data points are slightly odd in another way, which we will return to shortly. The pairs which do display conjunction fallacies are $\{\bar{A}, \bar{A} \cap B\}$ and $\{\bar{A}, \bar{A} \cap \bar{B}\}$.

The pairs of the form $\{\bar{A}, \bar{A} \cap B\}$ display robust conjunction fallacies. For the whole number responses 14 out of 18 of the Bayes factors for t -tests are $>3$, and 10 out of 18 are $>10$. For the Likert responses 16 out of 18 of the Bayes factors for t-tests are $>3$, and 11 out of 18 are $>10$. These are the pairs for which conjunction fallacies are typically expected, with one likely and one unlikely event. In contrast the presence of conjunction fallacies in the pairs of the form $\{\bar{A}, \bar{A} \cap \bar{B}\}$ are less expected. For the whole number responses none of the Bayes factors for t-tests are $>3$, but for the Likert responses 7 out of 18 of the Bayes factors for t -tests are $>3$, and 5 out of 18 are $>10$. We will return to why this may be so later.

Overall then, we have good evidence for conjunction fallacies in some of these judgments, for both response types. Note also that there do not appear to be large systematic differences between the data obtained from different response modes, which is reassuring.

Next we check for violations of independence. Note that these violations are not necessarily non-normative, since no information about the relationship between features was given to participants. However systematic violations of independence would still be a surprising finding. We proceed as for the conjunctions, plotting the pairs $\{A, A \mid \bar{B}\}$ and $\{\bar{A}, \bar{A} \mid \bar{B}\}$ separately and also separating out whole number and Likert responses. The results are shown in Fig 2. Independence would be indicated by data points lying on the diagonal.

Figure 1: Plots of likelihood judgments for conjunctions against single constituent events. Data points above the diagonal indicate conjunction fallacies. a) Likert scale responses. b) Whole number responses.

For the pairs of the form $\{A, A \mid \bar{B}\}$ all points appear to lie below the diagonal, and this is confirmed by Bayesian t-tests. For the whole number responses and for the Likert responses all Bayes Factors are $>10$.

For the pairs of the form $\{\bar{A}, \bar{A} \mid \bar{B}\}$ all points appear to lie above the diagonal, and this is confirmed by Bayesian t-tests. For the whole number responses 13 out of 18 Bayes Factors are $>3$, and 7 out of 18 are $>10$. For the Likert responses we also have 13 out of 18 Bayes Factors $>3$, and 7 out of 18 $>10$. Again overall there is good evidence for violations of independence in this data.

More specifically, the conjunctions and the conditionals point to similar behavior - namely participants appear to believe that there is strong correlation between the different features, such that "high" or "low" values of these features are likely to occur together.

Now we turn to the question of whether the perceived similarity between features mediates the correlations and violations of independence.

We begin with the correlation, defined for each pair of features $A, B$ as $p(A \cap B)+p(\bar{A} \cap \bar{B})-p(A \cap \bar{B})-p(\bar{A} \cap B)$. We ran a Bayesian ANOVA with the perceived similarity as the

Figure 2: Plots of likelihood judgments for conditionals against the conditioned events. Data points on the diagonal indicate independence. Data points off the diagonal indicate violations of independence. a) Likert scale responses. b) Whole number responses.
independent variable. Note that we collapse across features and scenarios here, since we have similarity data for each individual feature pair.

For the whole number responses the results of the Bayesian ANOVA show that a model including perceived similarity is preferred over the null model $\left(\mathrm{BF}_{10}>10^{7}\right)$. For the Likert responses the results of the Bayesian ANOVA also show that a model including perceived similarity is preferred over the null model $\left(\mathrm{BF}_{10}>10^{3}\right)$. Analysis of effects for both ANOVAs are given in Table 1.

We plot in Fig 3a below the correlation as a function of the similarity. Since we saw in the analysis of the conjunctions and conditionals there were no obvious differences between the response types we have converted the Likert scale responses to numbers in the range $0-100$ and plotted them on the same axis. This lets us establish that the same qualitative pattern holds for both response types, namely there is some apparent decrease in correlation for very small similarity ratings, but then a robust increase in correlation with increasing perceived similarity. The reason for the decrease in correlation for small similarity ratings is unclear, although it is worth noting that the number of participants who gave similarity ratings from 1-3 is small (7-11) compared with the number of
participants who gave higher similarity ratings (40-66). In addition, for the lowest similarity rating a higher than expected proportion of participants giving this rating ( 5 out of 8 for the Likert scale and 6 out of 9 for the whole numbers) had the highest possible CRT score. This is significant because if two events, each of which has an individual probability of 0.8 , are independent, then the expected correlation is 0.32 , which is in fact close to the observed value for a similarity rating of 1 in the whole numbers condition.

Next we analyze the violations of independence. We compute a violation 'score' which is just the sum of the absolute value of the difference between the conditional and the single event, e.g. $|p(A \mid B)-p(A)|$ for all the conditionals we measured. Again we ran a Bayesian ANOVA, with perceived similarity as the independent variable.

For the whole number responses, the results of the Bayesian ANOVA show that a model including perceived similarity is preferred over the null model ( $\mathrm{BF}_{10} \sim$ " $\infty$ "). For the Likert responses the results of the Bayesian ANOVA show that a model including perceived similarity is again preferred over the null model $\left(\mathrm{BF}_{10}>10^{10}\right)$. Analysis of effects for both ANOVAs are given in Table 2.

In Fig 3b we plot the violation of independence score as a function of perceived similarity. Again we transform the values for the Likert scale responses allowing us to plot them on the same axes. The pattern is qualitatively similar to that for the correlation; a general trend towards larger violations of independence for higher values of the perceived similarity.

Table 1: Analysis of effects for Bayesian ANOVA of Correlation

| Whole Numbers |  |  |  |
| :--- | :--- | :--- | :--- |
| Effect | $p($ incl $)$ | $p($ incl $\mid$ data $)$ | $\mathrm{BF}_{\text {Inclusion }}$ |
| Similarity | 0.500 | 1.000 | $3.01 \times 10^{7}$ |
|  |  |  |  |
| Likert Scale |  |  |  |
| Effect | $p($ incl $)$ | $p($ incl ldata $)$ | $\mathrm{BF}_{\text {Inclusion }}$ |
| Similarity | 0.500 | 0.999 | $1.58 \times 10^{3}$ |

Table 2: Analysis of effects for Bayesian ANOVA of Violations of Independence

| Whole Numbers |  |  |  |
| :---: | :---: | :---: | :---: |
| Effect | $p$ (incl) | $p$ (incl ${ }_{\text {data }}$ ) | $\mathrm{BF}_{\text {Inclusion }}$ |
| Similarity | 0.500 | 1.000 | " ${ }^{\prime \prime}$ |
| Likert Scale |  |  |  |
| Effect | $p$ (incl) | $p$ (incl data) | $\mathrm{BF}_{\text {Inclusion }}$ |
| Similarity | 0.500 | 1.000 | $3.08 \times 10^{10}$ |

Overall the data provide strong support for our proposal that perceived similarity mediates perceptions of correlation and violations of independence in probabilistic judgments. It is also worth noting that there are strong positive correlations between the correlation function and violations of independence, (Pearson's rho $=0.481, \mathrm{BF}_{10}>10^{14}$ for whole number responses, Kendall's tau $=0.345, \mathrm{BF}_{10}>10^{13}$ for the Likert responses.)

Figure 3: Plots of the correlation and degree of violation of independence against the perceived similarity. a) Correlation as a function of perceived similarity for the whole number responses (blue line) and the Likert scale responses (red line.) b) Violations of independence as a function of perceived similarity for the whole number responses (blue line) and the Likert scale responses (red line.)

## Conclusions and Future Directions

We have shown that quasi-probability distributions can be used to encode certain sets of probabilistic judgments which are non-normative, in the sense that they cannot be regarded as marginals of a joint probability distribution. Quasidistributions generalize regular probability distributions in that they can have negative elements. By themselves these do not provide any great insight into non-normative behavior, but the fact that one can define analogues of properties such as correlations for quasi-distibutions lets us examine the ways in which sets of judgments fail to be normative, and perhaps suggest some possible reasons why. We proposed that in the absence of information about joint occurrence, human decision makers might use properties such as the similarity between features to set the correlation, which we demonstrated experimentally. Similarity does seem to mediate correlation and violations of independence. We also showed that these results are largely independent of the response format.

These findings are particularly significant for attempts to assess the normative status of human causal inference using stimuli of this nature (e.g. Rehder, 2014). In these experi-
ments, participants are given extra information about the features in the form of causal relationships between them. Judgments about correlations in this case could then reasonably be interpreted as meaning participants believe the presence of one feature caused another. This work suggests that care is needed when interpreting these studies - participants may believe that features are correlated even in the absence of causal relationships, which may lead to overestimation of perceived causality. Future work should explore this possibility.

Finally, the results of this study suggest quasi-distributions may be a valuable way of thinking about non-normative reasoning, and we are hopeful that this approach may be used fruitfully in other areas. One important task is the development of a learning model which works directly with quasidistributions. This could help us understand how people learn to avoid committing probabilistic fallacies (Nilsson, 2008).

#### Abstract

From a quick glance or the touch of an object, our brains map sensory signals to scenes composed of rich and detailed shapes and surfaces. Unlike the standard approaches to perception, we argue that this mapping draws on internal causal and compositional models of the physical world and these internal models underlie the generalization capacity of human perception. Here, we present a generative model of visual and multisensory perception in which the latent variables encode intrinsic (e.g., shape) and extrinsic (e.g., occlusion) object properties. Latent variables are inputs to causal models that output sense-specific signals. We present a recognition network that performs efficient inference in the generative model, computing at a speed similar to online perception. We show that our model, but not alternatives, can account for human performance in an occluded face matching task and in a visual-to-haptic face matching task.

#### Abstract

In risky decision-making, expected utility (EU) theory is widely used to examine people's risk attitude and choice behavior. However, it is unknown how risk attitude relates to attention and information search. In this paper, we explore the relationship between risk attitude (as measured by a variant of EU) and eye movement patterns (which serve as a proxy for attention and information search). Participants made choices between gambles presented perceptually as flickering grids in which monetary values were indicated by colors and probabilities by color proportions. To explore attention and information search patterns, we investigated eye movement patterns when faced with different gambles and correlated these patterns with the parameters of EU. We observed that people who are more risk-seeking (as determined by modeling) tend to look at risky options more often. These results bridge choice behaviors conceptualized by EU and information search strategies under risky decision-making revealed by eye movements.

Keywords: risky decision-making; eye movements; cumulative prospect theory; hierarchical Bayesian parameter estimation; individual differences

## Introduction

We face decision-making under risk every day in our lives, from financial investment decisions, choosing a new job, to voting for a presidential candidate. Lotteries, or gambles, consisting of well-defined sets of options, are widely used in psychological research to explore how people make decisions under risk. Expected Utility (EU) theory (Neumann \& Morgenstern, 1947) has been widely used to predict choices with well-defined sets of gambles in different forms, but its connection to information search and attention (e.g., as measured by eye movements) has not been clearly revealed. For example, do people who are more riskseeking look more often at risky options?

Eye movements, which have been studied as a process tracing methodology (Glaholt \& Reingold, 2011), have been shown to be related to decisions under different tasks (Krajbich, Armel, \& Rangel, 2010; Krajbich \& Rangel, 2011; Shimojo et al., 2003; Stewart, Hermens, \& Matthews, 2016) and tested by different models (Brandstätter \& Körner, 2014; Fiedler \& Glökner, 2014). Nevertheless, the link between risk attitude revealed by EU and attention and information search strategy is still missing.

In the present study, participants were asked to make risky decisions between two gambles presented perceptually
while their eye movements were monitored. Gambles were represented as a grid of colored pixels where the colors were associated with monetary amounts and the proportion of pixels with the probability of winning that amount. One gamble was risky (higher possible monetary payout, but lower probability) and one was safe (lower possible monetary payout, but higher probability). We used a variant of EU to model participants' choice behavior and then examined the relationship between model parameters and eye movement characteristics. This experimental paradigm enables us to bridge the gap between decision processes (as modeled by EU) and attention and information search patterns (as measured by eye movements).

## Experiment: Speeded Risky Gambling

## Participants

39 undergraduate students (31 female) from Vanderbilt University participated in the experiment for course credit. Their age ranged from 18 to 22 years old (mean $=19.3$ ). We tested 28 participants with a right dominant eye and 11 with a left dominant eye.

## Methods

All stimuli were presented on a 23.5 -inch ViewSonic screen with a 60 Hz refresh rate at $1980 \times 1020$-pixel resolution. The viewing distance was 68 cm and each gamble had an overall size of $4.5^{\circ} \times 4.5^{\circ}$ of visual angle. In this experiment, each trial began with a fixation cross displayed for 0.5 second. Following the fixation cross, two square grids were always presented diagonally at two of the corners on the screen for maximal 2 seconds. These two grids consisted of $20 \times 2010$-pixel squares, which were filled in with grey indicating a zero payout and one of three colors (blue, rose, and yellow) indicating different positive monetary payouts that participants learned from instructions and practice. The proportion of color to grey (i.e., positive payout to zero payout) was randomly selected from 15 pairs of gambles (Table 1). Thus, participants were faced with a choice between two nonnegative gambles that offered different probabilities of winning different amounts of money. The configuration of colored elements in the grids was randomly rearranged every four frames to avoid potential perceptual pattern biases (thus the grids

Figure 1. Speeded risky gambling experiment procedure. There were three practice blocks before the main task. In this case, rose, yellow, and blue represent $\$ 2, \$ 4.5$, and $\$ 7$. In the second and the third practice blocks as well as the main task, participants pressed ' $z$ ' or ' $m$ ' to indicate choosing the left or the right grid, respectively. In practice block 2, participants were instructed to select the gamble with a higher expected value. The feedback indicated whether their choice was correct or not. In practice block 3, participants were allowed to select whichever gamble they preferred. They received feedback about their choices after every trial. In the main experiment, the participants received feedback at the end of blocks. There was no trial-by-trial feedback during the main task.
appeared to flicker). Participants were instructed to select the gamble that they wanted to play. The results of the chosen gambles were provided to participants during block breaks as their cumulative payouts.

Table 1: Gambles used in the Speeded Risky Gambling Task

| $v(\mathrm{R})$ | $p(\mathrm{R})$ | $v(\mathrm{~S})$ | $p(\mathrm{R})$ | $\Delta \mathrm{EV}(\mathrm{R}-\mathrm{S})$ |

| $\$ 7$ | 0.3 | $\$ 4.5$ | 0.70 | -1.05 |

$R$ denotes the risky gamble, $S$ denotes the safe gamble
The experiment had three practice blocks before the main experiment, which consisted of 16 blocks (Figure 1). The first practice had 20 trials. In the first practice block, we asked participants to select the monetary value associated with a particular color and provided feedback based on their responses. In the second practice block, two grids were presented that had two different colors (i.e., different monetary amounts), but in the same proportions. Participants needed to choose the grid with the greater expected value (i.e., the grid with the color associated with the higher value). The third practice block was similar to the main experiment, except that feedback on the gambling results was provided for each trial. Both the second and the
third practice had 15 trials. In the main experiment, each block had 66 trials of which $10 \%$ are catch trials. During block breaks, the payout for the current block and cumulative payout were provided. Each gamble pair had one risky gamble and one safe gamble. Risky gambles were defined as gambles where positive payouts were greater than that of safe gambles, but where probabilities of winning were less than that of safe gambles. The difference in expected values ( $\Delta \mathrm{EV}$, defined as EV (risky gamble) EV(safe gamble)) of 15 gamble pairs ranged from about -1 to 1 (Table 1). We had three gamble pairs for each $\Delta \mathrm{EV}$ condition: $\$ 4.5$ and $\$ 2, \$ 7$ and $\$ 2$, and $\$ 7$ and $\$ 4.5$. Catch trials were gamble pairs where the risky gamble had a higher probability and greater monetary payout than the safe gamble.

Figure 2. Panel A: Areas of interest diagram. Panel B: Representative eye trajectory (red lines) within one trial. Two gambles were presented diagonally in randomized locations. Solid black square is the center of fixation. Solid rose and yellow squares are the center of two gambles. Black squares are AOIs (solid: the chosen gamble; dotted: fixation area and the unchosen gamble).

Eye movements were monitored by an EyeLink 1000 desk-mounted eye tracker (SR Research, Ontario, Canada). We tracked participants' dominant eye movement with both pupil and corneal reflection settings at a sampling rate of 1000 Hz . Area of interest (AOI) was defined around the centers of the grids and fixation cross with the size of $400 \times$ 400 pixels. We used these AOIs to determine when participants were looking at each gamble and to explore the gaze dynamics during their deliberation (Figure 2).

After the speeded risky gambling task, every participant completed a set of surveys, which included the Cognitive Reflection Test (CRT, Frederick, 2005), DOSPERT scale (Blais \& Weber, 2006), and Holt and Laury gambles (Holt \& Laury, 2002). In this paper, we did not include the results from the CRT, DOSPERT scale, and Holt and Laury gambles. Those results will be reported elsewhere.

## Results

Two participants, one of whom had less than $30 \%$ correct on the catch trials, one who did not move his or her eyes at all throughout the experiment, and another five participants’ data were not successfully recorded due to technical issues, were excluded. We first analyzed the effect of $\Delta E V$ and different gamble pairs on risky choices and response time. We observed that the probability of risky choice increased as the $\Delta \mathrm{EV}$ increased (Figure 3A). The probabilities of risky choice under the three gamble pairs were different, with the probability of risky choice under the $\$ 7-\$ 4.5$ pair being the highest and the $\$ 7-\$ 2$ pair being the lowest. When $\Delta \mathrm{EV}$ is greater than zero, which indicates that the risky gamble had a greater EV compared to the safe gamble, the risky gamble was more likely to be chosen. We used Bayesian methods to analyze the data and report the resulting Bayes Factors (BF), Based on a Bayesian two-way ANOVA, we found that the model with $\triangle \mathrm{EV}$ and gamble pair without their interaction was preferred to all other models $\left(\mathrm{BF}_{\text {Model }}=636.06\right)$ as well as to the null model $\left(\mathrm{BF}_{10}=2.03 \times 10^{37}\right)$. The Bayes Factors for including the variables $\Delta \mathrm{EV}$, gamble pairings, and their interaction were $\mathrm{BF}_{\text {Inclusion }} \sim \infty$, and $\mathrm{BF}_{\text {Inclusion }}=731.74$, respectively. Regarding response time, risky decisions in general took longer as the $\Delta \mathrm{EV}$ increased. Response time increased as $\Delta E V$ increased under the $\$ 7-\$ 2$ and $\$ 4.5-\$ 2$ pairs, but did not change much under the $\$ 7-\$ 4.5$ pair. Based on a Bayesian two-way ANOVA, we found that a model with both $\Delta \mathrm{EV}$ and gamble pairings and no interaction was preferred to all other models $\left(\mathrm{BF}_{\text {Model }}=\right.$ $580.70)$ as well as the null model $\left(\mathrm{BF}_{10}=2.36 \times 10^{13}\right)$. The Bayes Factors for including $\triangle \mathrm{EV}$ and gamble pair were $\mathrm{BF}_{\text {Inclusion }}=2.17 \times 10^{2}$ and $\mathrm{BF}_{\text {Inclusion }}=2.98 \times 10^{2}$, respectively.

Next, we used number of fixations to investigate information search patterns under the five $\triangle \mathrm{EV}$ conditions with the three gamble pairs (Figure4A). The number of fixations is the average fixation count in non-catch trials prior to the decision. We observed that the number of fixations increased with increasing $\Delta \mathrm{EV}$, which was consistent with response time patterns. Based on a Bayesian two-way ANOVA, we found that the model with both $\triangle \mathrm{EV}$
and gamble pair and no interaction was preferred to all other models $\left(\mathrm{BF}_{\text {Model }}=133.90\right)$ as well as the null model $\left(\mathrm{BF}_{10}=\right.$ $5.32 \times 10^{5}$ ). The Bayes Factors for including $\Delta \mathrm{EV}$ and gamble pair were $\mathrm{BF}_{\text {Inclusion }}=1.48 \times 10^{3}$ and $\mathrm{BF}_{\text {Inclusion }}=$ 286.17, respectively.

Figure 3. Psychometrics in speeded risky gambling experiment. Panel A: probability of risky choices under different $\triangle E V$ conditions. Panel B: the effect of different $\Delta \mathrm{EVs}$ and gamble pairs on response time. Error bars are the standard error of the mean. Dark, medium, and light green lines represent the three gamble pairings.

Figure 4. Eye movement results. Panel A: Fixation numbers under different $\triangle E V$ conditions. Panel B: Probability of choosing the last seen gamble and the other gamble. The error bars are the standard error of the mean.

We also observed the same gaze biases reported in previous studies showing that eye movements made during a choice have a strong relationship with the final choice (Krajbich, Armel, \& Rangel, 2010; Krajbich \& Rangel, 2011; Stewart, Hermens, \& Matthews, 2016). We compared choice proportions when the last gaze was on the chosen gamble with that of the unchosen gamble, and found that the last seen gamble was more likely to be chosen as compared to the other gamble for the three gamble pairs separately $\left(\$ 7-\$ 4.5: \mathrm{BF}_{10}=37.93 ; \$ 7-\$ 2: \mathrm{BF}_{10}=4.58 \times 10^{4} ; \$ 4.5-\$ 2\right.$ : $\mathrm{BF}_{10}=79.17$ ) (Figure 4B). To investigate the influence of different gamble pairs on the relationship of last gaze and risky choices, we further examined the difference in proportion of risky choice given the first or the last gaze was in the AOI of the risky gambles. The first gaze had less influence on final choice of the risky gambles compared to the last gaze. For the three gamble pairs, the proportion of choices for the risky gambles was greater when the last gaze
was on the risky gamble than when the last gaze was on the safe gamble (Table 2 and Figure 5).

Figure 5. Proportion of risky choices given the first or last gaze was on the risky versus safe option. Solid lines: proportion of risky choices when the first or last gaze was on the risky gamble. Dotted lines: proportion of risky choices with the first or last gaze was on the safe gamble. The error bars are the standard error of the mean.

Table 2. Bayesian ANOVA for first and last gaze effects.

|  | Gamble pairs | Best model | $\mathrm{BF}_{\text {model }}$ | $\mathrm{BF}_{10}$ |
| :---: | :---: | :---: | :---: | :---: |
| First Gaze (FG) effect | \$7-\$4.5 | $\Delta \mathrm{EV}$ | 6.3 | $1.4 \times 10^{24}$ |
|  | \$7-\$2 | $\Delta \mathrm{EV}$ | 26.9 | $1.4 \times 10^{17}$ |
|  | \$4.5-\$2 | $\Delta \mathrm{EV}$ | 21.2 | $1.9 \times 10^{55}$ |
| Last Gaze (LG) effect | \$7-\$4.5 | LG $+\Delta \mathrm{EV}$ | 146.9 | $2.8 \times 10^{24}$ |
|  | \$7-\$2 | $\mathrm{LG}+\Delta \mathrm{EV}$ | 34.9 | $1.3 \times 10^{17}$ |
|  | \$4.5-\$2 | $\begin{gathered} \mathrm{LG}+\Delta \mathrm{EV}+ \\ \mathrm{LG}^{*} \Delta \mathrm{EV} \end{gathered}$ | 4.4 | $6.0 \times 10^{53}$ |

The first (last) gaze effect is the difference in the probability of selecting the risky option when the first (last) gaze is on the risky option as compared to the safe option.

## Hierarchical Bayesian Parameter Estimation of "Perceptual" Expected Utility Theory

To account for choice behavior, we developed a "perceptual" variant of EU theory. The parameters of this model were estimated using a hierarchical Bayesian parameter estimation approach. There are two components of our variant of EU: (1) the subjective utility function and
(2) the perception of probabilities. The subjective utility function is governed by alpha, which indicates an individual's risk attitude. If alpha is less than 1 , it indicates that the person is risk-aversive. If alpha is greater than 1 , it indicates that the person is risk-seeking. If alpha is equal to 1 , that person is risk-neutral.

In EU theory, the subjective value of a two-outcome gamble $G$ is determined by

$$
\begin{equation*}
E U(G)=p_{1} u\left(x_{1}\right)+p_{2} u\left(x_{2}\right) \tag{1}
\end{equation*}
$$

where $u(\cdot)$ is the utility of the outcomes defined as

$$
\begin{equation*}
u\left(x_{i}\right)=x_{i}^{\alpha} \tag{2}
\end{equation*}
$$

where $\alpha$ is a free parameter that is greater than 0 and quantifies the curvature of the utility function.

In EU theory, the objective probabilities are used to compute the expected utilities of the gambles. In our experiment, however, the probabilities of both safe and risky gambles are presented as proportions of colors in the flickering grids. It is possible that people's perception or estimation of the actual proportion does not match the exact probabilities shown in the grids. That is, there may be perceptual distortion of the probability estimation. In order to capture this feature, we assume that perceived probability is given by the following function:
where $\varphi$ is the adaptation level for the proportion of color in the grid and $\beta$ is a shape parameter. The probability of choosing option A over option B is modeled as:

$$
\begin{equation*}
p(A, B)=\frac{E U(A)}{E U(A)+E U(B)} \tag{4}
\end{equation*}
$$

Hierarchical modeling serves as a compromise between a no-individual-differences model and a full-individualdifferences model. In a hierarchical model, individual parameters are drawn from group-level distributions, usually normal distributions with estimated mean and standard deviation. The estimated means quantify different cognitive processes. The standard deviations quantify the similarity among individual participants' behavior.

We used the prior distributions for these three parameters as following. Individual $\alpha_{i}$ is drawn from the normal distribution with two group-level parameters $\mu^{\alpha} \sim U(0,5)$ and $\sigma^{\alpha} \sim U(0,10)$. Individual $\varphi_{i}$ is drawn from the normal distribution with two group-level parameters $\mu^{\varphi} \sim U(0,100)$ and $\sigma^{\varphi} \sim U(0,10)$. Individual $\beta_{i}$ is from the normal distribution with its group-level parameter $\mu^{\beta} \sim U(0,100)$ and $\sigma^{\beta} \sim U(0,10)$. We implemented the hierarchical EU model in JAGS. Posterior distributions were approximated by 3 MCMC chains with 5000 samples from each chain, after a burn-in of 1000 samples. Convergence of chains was evaluated by computing the $\hat{R}$ statistic. Figure 6 shows the posterior distributions of three group-level means. The means of $\mu^{\alpha}, \mu^{\varphi}$, and $\mu^{\beta}$ are $0.92,0.41$, and 13.13, respectively.

By comparing observed choices with the predicted choices, we are able to assess how accurately the model captures people's choice behavior. We plot the observed risky choice proportions from the data with the posterior predictive of the model using the individual-level parameters (Figure 7). The model predictions are reasonably close to the actual proportion of risky choices indicating that the model accounts for the group-level data.

Figure 6. Posterior distributions of EU group-level parameters.

Figure 7. Comparison of the risky choice proportions from the data and predicted by EU theory. Light grey bins represent risky choice proportion from data, and dark grey bins represent risky choice proportion predicted by EU theory.

Figure 8. Comparison of risky choice proportion from the data and that predicted by EU. The line is $\mathrm{y}=\mathrm{x}$.

To examine the performance of EU theory at the individual level, we plot the individual data and predictions from EU theory using the individual-level parameters (Figure 8). Most of the data points fall on the diagonal,
meaning that the performance of EU is reasonable at the individual level as well.

## Individual differences in gaze dynamics

To bridge the gap between the conceptualized EU model and actual information search dynamics, we examined the correlation of EU parameters and eye movement statistics. We examined the correlations with four eye movement measures: \% of trials with first fixation on risky, \% of trials with last fixation on risky, proportion of gaze duration on risk, proportion of gaze duration on chosen gambles, as well as response time. See Table 3 for definitions of these five measures.

In EU, the parameter $\alpha$ captures participants' risk preferences. Note that EU assumes that the subjective utility function is concave if $0<\alpha<1$, implying that people are risk-averse, while the subjective utility function is convex if $\alpha>1$, implying that people are risk-seeking. A larger value of $\alpha$ implies less risk-aversion (or relatively greater riskseeking behavior). We found that $\alpha$ was positively correlated with \% of trials with last fixation on risky and proportion of gaze duration on risky gamble (see Table 3). For the two measures, the $\mathrm{BF}_{10}$ was greater than 100 , indicting extremely strong support for the correlations. These correlations suggest that people who are more riskseeking tend to look more at risky options.

Table 3. Correlations and Bayes Factors (BF) between eye movement statistics, response time, and EU parameters

| Eye movement measures | EU parameters |  |  |
| :---: | :---: | :---: | :---: |
|  | $\alpha$ | $\varphi$ | $\beta$ |
| \% of trials with first | 0.31 | -0.47 | -0.1 |
| fixation on risky | (0.942) | (7.21) | (0.29) |
| \% of trials with last | 0.65*** | -0.60*** | -0.14 |
| fixation on risky | (479.29) | (133.72) | (0.30) |
| proportion of gaze | 0.70*** | $-0.73 * * *$ | -0.23 |
| duration on risky | (2787.37) | (11149.51) | (0.46) |
| proportion of gaze | $\begin{gathered} -0.14 \\ (0.29) \end{gathered}$ | $\begin{aligned} & -0.17 \\ & (0.33) \end{aligned}$ | $\begin{gathered} 0.05 \\ (0.23) \end{gathered}$ |
|  | (0.29) | (0.33) |  |
| response time | $\begin{gathered} 0.38 \\ (1.87) \\ \hline \end{gathered}$ | $\begin{array}{r} -0.29 \\ (0.76) \\ \hline \end{array}$ | $\begin{aligned} & 0.004 \\ & (0.22) \\ & \hline \end{aligned}$ |
| $\mathrm{BF}_{10}$ enclosed in parentheses. * $\mathrm{BF}_{10}>10, * * \mathrm{BF}_{10}>30$, *** $\mathrm{BF}_{10}>100$ |  |  |  |
| - \% of trials with first fixation on risky: proportion of trials i which the first fixation after gambling presentation was on the |  |  |  |
| which the last fixation before decisions were made was on the risky. |  |  |  |
| - proportion of gaze duration on risk: ratio of gaze duration on th risky to the response time of each trial. |  |  |  |
| - proportion of gaze duration on chosen: ratio of gaze duration on the chosen gamble to the response time of each trial. |  |  |  |
| - response time: from stimuli onset to responses by pressing keys. |  |  |  |

The parameter $\varphi$ determines the adaptation level of the perceived probability transform function. When $\varphi<0.5$,
individuals are more adapted to small probabilities, which also correspond to riskier options in our task (i.e., risky gambles in our experiment have high values and small probabilities). Thus, smaller values of $\varphi$ indicate increased adaptation for risky options. We found that the parameter $\varphi$ was negatively correlated with $\%$ of trials with the last fixation on risky and the proportion of gaze duration on risky.

The $\beta$ parameter is the shape parameter for the probability transform function. This parameter was not correlated with any of the eye movement measures we calculated.

## Discussion

In this study, we investigated the relationship between gaze dynamics and "perceptual" EU parameters in risky decisionmaking. First, we corroborated previous findings that the last fixation was closely related to actual choices (Krajbich, Armel, \& Rangel, 2010; Krajbich \& Rangel, 2011; Shimojo et al., 2003; Stewart, Hermens, \& Matthews, 2016). Going beyond this, we observed that people with different risk attitudes have different patterns of eye movements, which serve as a proxy for information search and attention. In particular, we found that (i) the utility shape parameter of EU was positively correlated with measures related to gaze duration on the risky option and to the proportion of last gaze on the risky option, and (ii) the adaptation level in perceived probability was negatively correlated with the proportion of the last gaze on the risky option and with the gaze duration on the risky option. These results establish the connection between risky choice behavior conceptualized by EU and information search strategies under risky decision-making revealed by gaze dynamics.

Given the fact that eye movements are only considered as a proxy of internal processes of attention, we cannot rule out the possibility that participants held the two gambles in a mental comparison while moving their eyes. Thus, we cannot conclude that the decision processes conceptualized by the EU model caused specific information search strategies or vice versa. Future studies are needed to explore the causal relationship between gaze dynamics and choice. For example, future studies could examine if changing information search strategies by manipulating the salience of risky gambles might influence people's risky choices. Also, manipulating exposure time of options might influence choices.

We conclude by addressing some of the limitations of the present study. First, all thirty-nine students were granted course credit regardless of their performance. It is possible that their behavior might change if there was actual monetary reward rather than a hypothetical situation. The three estimated parameters of EU might be different when participants are more engaged to maximize their final payouts (Holt \& Laury, 2002). Second, in this study we did not include gambles with pure losses or mixtures of both gains and losses. People may adopt different strategies in
this speeded risky gambling task when losses are introduced. Addressing these issues would be suitable for future studies. Nevertheless, we did observe individual differences in risk preferences as measured by EU and these differences where related to differences in gaze dynamics. This suggests that information search and attention is related to underlying decision processes.

# Novel Evidence for the Bilingual Advantage: Effects of Language Control on Executive Function in Balanced and Unbalanced Dual-Language Users 

W. Quin Yow (quin@sutd.edu.sg), Adam C. Oei (adam_oei@sutd.edu.sg), \& Xiaoqian Li<br>(xiaoqian_li@mymail.sutd.edu.sg)<br>Singapore University of Technology and Design, 8 Somapah Road, Singapore 487372, Singapore

#### Abstract

Bilinguals' need to monitor and inhibit non-relevant languages over a relevant one confers advantage in cognitive control. No studies have demonstrated that the dual-language control process directly contributes to the bilingual cognitive advantage. We utilized a novel language control manipulation paradigm where 83 English-Chinese bilingual adults completed a reading and comprehension task in either singlelanguage (low-language-control) or dual-language (high-language-control) prior to performing nonverbal executive control tasks (Stroop, task-switching, and n-back). Results showed that language control had significant effects on subsequent cognitive performance, depending on whether the participants were regular dual language users or not. In the dual-language condition, but not the single-language condition, participants who used both languages regularly demonstrated a smaller mixing cost in task-switching and a greater sensitivity in $n$-back detection compared to participants who did not. This suggests that dual language control utilizes similar resources as executive function and frequent dual language use enhances this resource.

Keywords: bilingualism; cognitive resources; task mixing; working memory; adults

## Introduction

Research evidence suggests that the ability to speak more than one language confers an advantage in cognition, specifically in executive control. Executive control refers to a set of top-down mental processes such as the ability to inhibit impulses, monitor and update working memory representations and task switching (Miyake et al., 2000). The evidence for the bilingual advantage in executive control (henceforth bilingual advantage) is robust and is seen across the lifespan from young children to the elderly across several executive control tasks (e.g., Bialystok, Craik, \& Luk, 2008; Macnamara \& Conway, 2013).

Why would being bilingual have positive consequences to executive control? The transfer from bilingualism to enhanced executive control is likely a two-step process.

First, for a bilingual, different languages are activated in parallel during language processing (e.g., Crinion et al., 2006). Increased executive control resources are therefore needed to monitor this parallel activation and prevent crosslinguistic interference. Various executive control processes are hypothesized to be necessary for language control in different interactional contexts (Green \& Abutalebi, 2013). For example, a bilingual speaker must maintain a task goal and inhibit the non-relevant language when speaking in one language rather than another. These processes are akin to updating and inhibition components in the Miyake et al.
(2000) model of executive control. The cognitive demands on such processes are likely to increase in a dual-language context whereby both languages known to a bilingual are used and switched within a conversation. Such codeswitching acts (i.e., switching between languages) add another dimension of control necessary for disengagement from a prior language and engagement of the language in use. Neuroimaging studies have shown overlapping neural substrates between language control and nonverbal executive control (e.g., De Baene, Duyck, Brass, \& Carreiras, 2015; Rodríguez-Pujadas et al., 2014).

Second, the control processes associated with language control in bilingual speakers are hypothesized to adapt to the demands imposed on them, in turn enhancing domaingeneral cognitive control (e.g., Bialystok \& Craik, 2010; Green \& Abutalebi, 2013). Behavioral evidence indicates that executive control processes implicated in language control such as updating, interference suppression and shifting are enhanced in bilinguals (e.g., Morales, Calvo, \& Bialystok, 2013; Wiseheart, Viswanathan, \& Bialystok, 2014). Neuroimaging work suggests that bilingual language control exerts neuroplastic effects both structurally and functionally in brain areas of importance for executive control (e.g., Klein, Mok, Chen, \& Watkins, 2014). Bilinguals show reduced activation relative to monolinguals when performing conflict and inhibitory control tasks in the anterior cingulate (Rodríguez-Pujadas et al., 2014), indicating greater neural efficiency. These findings suggest that bilingual speakers may hold larger cognitive resources because of the adaptive language control processes.

A more specific account has been put forward recently, that these general "spill-over" positive effects of bilingualism in executive control skills may be due to the dual language switching behavior that bilinguals regularly engage in, which represents a skillful control of language use (e.g., Prior \& Gollan, 2011; Yim \& Bialystok, 2012). For example, Soveri, Rodriguez-Fornells, and Laine (2011) found that higher self-reported daily language switching frequency is associated with reduced task-mixing cost in adults from 30 to 75 years old. In addition, Yow and Li (2015) demonstrated that bilinguals who used both languages regularly have lower Stroop interference effects and task mixing costs than those who used one language significantly more than the other language. This bilingual advantage based on how often a bilingual uses both languages is also apparent across the lifespan from childhood to the elderly. Specifically, Thomas-Sunesson, Hakuta, and Bialystok (2016) showed that the more
balanced Spanish-English bilingual young children were in their language proficiency between two languages, the better they performed in working memory and conflict resolution.

Bilinguals often differ from each other in language proficiency and usage frequency of each of their languages, as well as language switching behavior. These differences in language usage behavior might lead to different neural and cognitive consequences due to the executive control processes implicated in language control. However, it is currently unknown whether active engagement in language control activities would have a positive or negative impact on bilingual speakers' performance in nonverbal tasks tapping executive control processes. No studies have experimentally manipulated language control to determine its effects on executive control. This present study aims to explore this question and to further understand the mechanisms underlying the effects of language control on executive control.

In the current study, we manipulated active engagement in language control by introducing a novel reading and comprehension task. In the single-language condition, participants read articles and answered questions in only English. In the dual-language condition, participants read and answered questions intermixed in English and Chinese, which would induce higher cognitive demands on language control compared to those in the single-language condition. Following the reading comprehension task, participants completed three executive control tasks (i.e., Stroop, number-letter task-switching, and n-back) to assess different executive control components (i.e., inhibition, shifting, and updating, respectively) (e.g., Miyake et al., 2000). If the engagement in language switching behavior indeed caused a higher cognitive demand (in the dual-language condition), then it could be expected that less cognitive resources would be available for integrating the text information, resulting in lower performance in the comprehension test. We also hypothesized that participants' performance in the subsequent executive control tasks would be negatively affected if they were in the dual-language condition, as cognitive resources would be depleted for these participants who had to engage in greater language control.

Since previous studies indicate that bilinguals who regularly use both languages may have a protective advantage in cognitive control, current participants who are balanced bilinguals (defined as either a balanced use or a balanced level of proficiency in two language systems) would be less likely to be affected by the language control manipulation than those who are unbalanced bilinguals.

## Method

## Participants

Eighty-three undergraduates ( 56 females, $M_{\text {age }}=22.60, S D$ $=1.83$, range $=19-25$ ) were recruited from the authors' university. All participants are Chinese Singaporeans and have been living in Singapore since they were born.

Singapore is a multilingual country with English as the main official language. The bilingual policy in Singapore encourages citizens to be proficient in both English and a mother tongue, which is Chinese for the participants of this study. All participants provided written informed consent prior to their participation and received credit points or reimbursement for their time of participation.

## Materials and Measures

Language Background Questionnaire (LBQ) This questionnaire asked participants to name all the languages that they know and to provide details about each of the listed languages (e.g., age of language acquisition, language proficiency, usage frequency, and language switching habits). For language proficiency, participants rated their proficiency in listening, reading, speaking and writing for each language on a 10 -point scale $(1=$ not proficient to $10=$ very proficient). We defined most and second most proficient language based on the two languages that have the highest average rating across these four domains. Usage frequency for each of the languages was assessed by asking participants to approximate the percentage they use each language when communicating with different groups of people (e.g., family members, colleagues, friends) in different contexts in a typical week. The usage of all different languages would add up to $100 \%$. In addition, participants rated on a 5 -point scale $(1=$ never to $5=$ always) for nine questions relating to how frequent they switch languages during discourse. A higher score therefore indicates more frequent language switching.

We followed the procedures in Yow and Li (2015) to estimate the individual differences in the degree of bilingualism:
(I) Balanced Proficiency: Most proficient language rating minus second most proficient language rating; a metric of balanced bilingualism of relative competency between participants' most and second most proficient languages.
(II) Balanced Usage: Frequency of most used language minus frequency of second most used language; a metric of balanced bilingualism of relative usage frequency between participants' most used and second most used languages.

For both measures, a score closer to 0 indicates more balance between two languages. Conversely, a higher score indicates more dominant proficiency or use in one language over the other. See Table 1 for all key language variables, including details between the balanced and unbalanced users related to the current study. Differences between the balanced and unbalanced users are reported as this is of interest in the current study.

Reading Comprehension Task This task was administered as a manipulation of language control. Participants were randomly assigned to a single-language condition (i.e., $\boldsymbol{S L}$; $n=38$ ) or a dual-language condition (i.e., $\boldsymbol{D L} ; n=45$ ). For both conditions, participants read four passages pertaining to current events happening at the authors' university (two before executive control tasks and two after).

Table 1: Language background measures.

| Language variable | Overall | Balanced users |  |
| :--- | :--- | :--- | :--- |
| Mean (SD) | Unbalanced users <br> Mean (SD) <br> $n=40$ | Mean (SD) <br> $n=39^{*}$ |  |
| Age of first acquired language | $n=83$ | $2.23(1.51)$ | $2.35(1.29)$ |
| Age second acquired language | $2.79(1.75)$ | $2.40(1.26)$ | $3.00(1.69)$ |
| Most proficient language proficiency rating | $8.49(1.29)$ | $8.47(1.10)$ | $8.47(1.48)$ |
| Second most proficient language proficiency rating | $6.54(1.76)$ | $7.36(1.34)$ | $5.63(1.80)$ |
| Frequency of most used language | $0.76(0.19)$ | $0.66(0.93)$ | $0.91(0.58)$ |
| Frequency of second most used language | $0.21(0.17)$ | $0.32(0.09)$ | $0.09(0.06)$ |
| Balanced proficiency (Most proficient minus $2^{\text {nd }}$ most proficient) | $1.95(1.84)$ | $1.11(1.00)$ | $2.84(2.16)$ |
| Balanced usage (Most used minus $2^{\text {nd }}$ most used) | $0.55(0.34)$ | $0.35(0.17)$ | $0.82(0.11)$ |
| Language switching | $25.96(4.26)$ | $26.60(4.60)$ | $25.11(3.91)$ |

*Note: Four participants did not provide their usage frequency for their languages. Hence, we were not able to categorize them as balanced or unbalanced users.

Participants assigned to the SL condition read passages presented in English only. The English reading passages are suitable for students in grade 12 (between grade 11 to 13), based on Flesch-Kincaid readability tests performed online (https://readability-score.com). The English passages contained on average 332.75 words (range $=305$ to 366 words). In the DL condition, participants were presented with passages intermixed in English and Chinese. The passages contained 438.5 words on average (range $=406$ to 458 words). Only inter-sentential switches (i.e., switching from English to Chinese sentence and vice versa) were used ( $M=13.5$ switches, range $=11$ to 15 ).

After reading each passage, participants were required to answer eight questions in oral and then written form. For each passage, four questions required an oral response and four required a written response. However, four were filler questions (two oral and two written) that were not scored. Participants were given one point for each correctly answered question (not including the filler questions). A maximum score a participant can receive is therefore four. Participants could answer in either English or Chinese for any of the questions, regardless of whether they are in the SL or DL condition. The questions were all presented on the computer screen. The passages remained on screen for the participants to refer to if needed.

In the SL condition, all questions were posed in English only. In the DL condition, participants were presented the questions in English and then Chinese in alternating fashion. For each of the four questions posed (oral and written), the answers could only be found in the passage printed in the opposite language. In other words, for a question posed in English, its corresponding answer is printed in Chinese in the passage and vice versa. This therefore necessitated participants in the DL condition to engage in codeswitching to answer the questions.

The sum of all correct responses was calculated for each form of questions (oral or written) and for each two passages before or after the executive control tasks as DVs
(dependent variables) from this task.
Executive Control Tasks We selected three tasks, colorword Stroop, number-letter switching, and n-back, to measure executive control components of inhibition, mental-set shifting, and information updating and monitoring, respectively (Miyake et al., 2000; see Yow \& Li, 2015 for details about stimuli design and procedure for each of the tasks).

In the Stroop task, participants were required to indicate the color that the stimuli were printed in and ignore the color names. The dependent measure in this task is the Stroop effect, taken as the difference in response time (RT) between the incongruent and neutral trials. Greater Stroop effects reflect the poorer inhibition.

In the letter-number switching task, participants saw number-letter pairs and either determined if the number was even or odd or if the letter was a vowel or consonant. The DVs for this task are switch cost and mixing cost. Switch cost reflects more transient control processes to updating goals or task demands, while mixing cost reflects cognitive control in actively maintaining representations of multiple task demands.

In the n-back task, participants completed two blocks of 2-back and two blocks of 3-back test trials. The dependent measures in this task are $d^{\prime}$ calculated separately for 2 and 3-back, reflecting detection sensitivity according to the signal detection theory.

## General Procedure

All tasks were administered individually in a quiet room at the authors' university. Participants first completed the LBQ. Participants then performed the two reading comprehension tasks and subsequently completed three executive control tasks: Stroop task, task-switching and nback task, programmed in MATLAB (Version 7.10). The order of the Stroop and task-switching task was counterbalanced between participants but the n-back task
was always performed last. When all the executive control tasks were completed, participants completed two other reading comprehension tasks. Visual stimuli were presented to participants from about 70 cm via a 23 -inch monitor with a refresh rate of about 60 Hz . For the executive control tasks, participants were instructed to respond as quickly and as accurately as possible. Each experimental session took about 1.5 to 2 hours.

## Results

Prior to data analyses, we screened the data from all executive control tasks to remove incorrect trials as well as trials with those RTs shorter than 200 ms or longer than 3000 ms . These discarded trials amounted to less than $6 \%$ ( $3 \%-5 \%$ ) of the total number of trials for each task. We also discarded DVs (Stroop interference RT, switch cost RT, mixing cost RT, 2-back $d^{\prime}$ and 3-back $d^{\prime}$ ') of interest that were greater or less than 2.5 SDs from the group mean. These outliers were rare and amounted to about $2 \%$ of the total number of data points. These data trimming procedures are typical in studies using similar experimental tasks.

We performed a median split on balanced proficiency and balanced usage to categorize participants into balanced and unbalanced proficient groups as well as balanced and unbalanced dual-language users. This is to directly compare these groups and subsequently perform analyses to determine the effect of proficiency and usage interactions on executive control. As participants' language switching could potentially confound the relationship between language usage and proficiency on our executive control measures, we controlled for its effects by entering language switching as a covariate in separate analyses of covariance.

## Reading Comprehension Performance

We first performed 2 (time: reading comprehension before and after executive control tasks) x 2 (response type: oral and written) x 2 (condition: SL and DL) x 2 (balanced usage: balanced and unbalanced) x 2 (balanced proficiency: balanced and unbalanced) mixed ANCOVA with language switching as a covariate to determine whether performance in the reading comprehension task differed as a function of time, bilingualism, response type and condition. Importantly, this also allowed us to perform a manipulation check to determine if the DL condition was indeed more cognitively demanding than the SL condition.

There was a Condition effect, $F(1,63)=21.71, p<.001$, $\eta_{p}^{2}=0.26$. This was qualified by a Condition x Balanced Usage interaction, $F(1,63)=4.14, p=.05, \eta_{\mathrm{p}}{ }^{2}=0.06$. Specifically, unbalanced language users' reading comprehension performance was poorer when required to codeswitch in the DL condition $(M=11.80)$ compared to the SL condition where codeswitching was not required ( $M$ $=13.56), t(36)=2.34, p=.03$. Similarly, balanced users performed poorer in reading comprehension in the DL ( $M=$ 10.22) than in the SL condition $(M=14.12)$.

There was also a Time effect, $F(1,63)=8.10, p=.01, \eta_{\mathrm{p}}{ }^{2}$ $=0.11$, indicating that participants performed better in the
reading comprehension task following $(M=3.18)$ the executive control tasks than before $(M=3.06)$. This was however qualified by a Time x Language Switching interaction. We followed up this significant interaction with a median split of language switching and compared the reading comprehension scores for frequent and infrequent language switchers. While the infrequent language switchers performed better $(M=6.57)$ after the executive control tasks than before $(M=5.87), t(36)=-3.03, p=.01$, the frequent language switchers performed equally well before $(M=$ 6.13) and after $(M=6.16)$ the executive control tasks, $t(37)$ $=-0.1, p=.93$. This suggests infrequent switchers but not the frequent switchers gained from a prior practice in the reading comprehension task. No other main effects or interactions approached or were statistically significant.

Overall, the significant main effect of condition showed that the dual-language condition was more demanding and indicated that our manipulation was successful in increasing executive control load.

## Executive Control Performance

Inhibition A 2 (balanced proficiency) x 2 (balanced usage) x 2 (condition) ANCOVA with language switching as a covariate to account for unintentional switching in language use as a potential confound was conducted. Language switching was not significantly related to Stroop effect ( $p=$ .53). There was a significant Balanced Proficiency x Condition interaction, $F(1,65)=4.22, p=.04$. Follow up comparisons however showed no significant difference in Stroop interference effects between the two conditions amongst balanced proficient bilinguals ( $p=.095$ ). This was similar for the unbalanced proficient bilinguals $(p=.22)$. No other significant effects were found (all $p \mathrm{~s}>.43$ ).

Shifting The switch cost and mixing cost in task-switching were evaluated in a similar way. There were no significant main effects or interactions on the switch cost (all $p \mathrm{~s}>.23$ ). In contrast, for the mixing cost, the Balanced Usage x Condition interaction was significant, $F(1,67)=4.87, p=$ $.03, \eta_{\mathrm{p}}{ }^{2}=0.07$ (see Figure 1). In the SL condition, no significant differences were found between balanced and unbalanced dual language users in mixing cost ( $p=.26$ ). However, in the DL condition, the balanced users had a significantly smaller mixing cost than the unbalanced users ( $p=.04$ ). These results suggest that codeswitching in the DL condition negatively affected unbalanced participants in task mixing but not on balanced usage participants.

Updating On the 2-back trials, there was a significant Balanced Usage x Condition interaction on the sensitivity to targets, $F(1,67)=4.48, p=.04, \eta_{\mathrm{p}}^{2}=0.06$ (see Figure 2). Follow up comparisons revealed that although there was no difference in 2-back $d^{\prime}$ between balanced and unbalanced users in the SL condition ( $p=.31$ ), 2-back $d^{\prime}$ differed between the two groups in the DL condition $(p=.047)$. This demonstrated that codeswitching adversely affected
information updating (in 2-back) for the unbalanced users, but had no effect on the balanced users.

On the 3-back trials, a significant main effect of balanced usage was evident, $F(1,68)=6.17, p=.02, \eta_{\mathrm{p}}{ }^{2}=0.08$. This main effect was qualified by a Balanced Usage x Condition interaction, $F(1,68)=4.80, p=.03, \eta_{\mathrm{p}}^{2}=0.07$. Similar as the 2-back task, no significant differences in performance were found between balanced and unbalanced duallanguage users in the SL condition ( $p=.84$ ). However, balanced users had significantly higher 3-back $d^{\prime}$ scores compared to unbalanced dual language users in the DL condition ( $p=.001$ ). This indicates that balanced dual language users were less affected by codeswitching than did their unbalanced counterparts (see Figure 3). Additionally, a significant balanced proficiency main effect was found for the 3-back $d$ ' scores, $F(1,68)=5.72, p=.02, \eta_{\mathrm{p}}{ }^{2}=0.08$. The Balanced Usage x Balanced Proficiency interaction was also significant, $F(1,68)=6.91, p=.01, \eta_{\mathrm{p}}^{2}=0.09$.

## Discussion

This study investigated the effects of language control on domain-general executive control in bilingual adults who differed in the degree of bilingualism. By implementing a novel language control manipulation and adopting an individual differences approach to study the bilingual advantage, we found that (1) engaging bilingual speakers in a dual-language context (involving codeswitching) increased cognitive load and interfered with information organization and integration, resulting in poorer comprehension performance, (2) increased cognitive demands on language control depleted general executive control resources and negatively impacted executive control components such as maintenance of mental representations and sensitivity to targets, and (3) effects of language control on executive control were modulated by factors that influenced the exposure and opportunity for bilingual speakers to practice language control in daily life.

When required to codeswitch prior to performing executive control tasks, participants who were balanced dual language users demonstrated smaller mixing cost and better target discrimination compared to those unbalanced users. These results suggest that a more balanced use of two languages may function as a cognitive reserve that would mitigate the effects of language control on executive control, i.e., balanced bilinguals may have larger cognitive resources for executive control than less balanced bilinguals. This advantage is likely due to balanced dual language users having more opportunity to be involved in interactional contexts where both languages are used with different speakers, and the constant need to monitor and control attention to the target language system over the competing other language, which in turn lead to the development of larger cognitive resources for adaptive language control processes.

The interaction effects of balanced usage and language control condition were significant for only mixing cost and working memory updating, but not for Stroop interference

Figure 1. Mixing cost for balanced and unbalanced usage participants in single- and DL conditions. Error bars denote $95 \%$ confidence intervals.

Figure 2. Performance in 2-back ( $d^{\prime}$ ) by balanced usage and condition. Error bars denote $95 \%$ confidence intervals.

effect or switch cost, indicating that only some cognitive control processes were used in the current dual-language context. This is consistent with the adaptive control hypothesis proposing that the demand on different control processes varies as a function of the interactional context. For instance, it is hypothesized that, for bilingual speakers, both single-language and dual-language contexts increase the demands on interference control that was assessed by the Stroop task in this study. Thus, resources for inhibition may not be depleted in the dual-language context, even amongst unbalanced users. Our failure to find bilingual advantages in switch cost has been documented previously (e.g., Yow \& Li, 2015). Being more balanced in dual language use may not have conferred an advantage to the transient switching cost because task switching is also akin to frequent topic changes during discourse, in which both balanced and unbalanced users are equally likely to engage in (Wiseheart et al., 2014). In contrast, mixing cost reflects global
sustained control necessary for maintaining competing mental representations, which is akin to using different languages in dual-language contexts. Balanced dual language users may have developed a larger executive control resource to hold multiple language rules "on-line", preventing resource depletion following our codeswitching manipulation. Lastly, updating and monitoring is postulated to be necessary for maintenance of task goals during dual language discourse. Unbalanced dual language users who hold smaller working memory resources are therefore more affected in updating after having to codeswitch. Taken together, these results indicate that bilingual advantage is limited to certain but not all components within the Miyake et al. (2000) model.

One limitation inherent in our study is the use of selfreport for language proficiency. Although this approach is consistent with many other studies (e.g., Wiseheart et al., 2014), we acknowledge that using self- report measures may result in less accurate proficiency ratings than objective measures. However, given that many participants may know more than two languages, objective measures of their language proficiency may not be feasible without substantially prolonging the experimental session.
In conclusion, we provide novel evidence showing that language control and executive control depend on shared resources by experimentally manipulating language control via codeswitching. Crucially, we provide evidence of the bilingual advantage in showing that bilinguals who are more balanced in dual language use have larger working memory and task mixing resources that buffered against performance decline following language control. Theoretically, our results add to the current understanding of the mechanism of the bilingual advantage in executive control: language and executive control share similar resources, and this shared resource can be enhanced by using more than one language equally frequently.

## Acknowledgments

The authors wish to thank the participants who participated in the study, and Stephanie Dietz and Tony Lim for their help in experiment design and data collection. This work was partially supported by the AcRF (SUTDT12015007) and DIRP grant (IGDSP1502032) to the first author.

# Inconvenient samples: Modeling the effects of non-consent by coupling observational and experimental results 

Yue Yu ${ }^{12}$ (yue.yu@ rutgers.edu), Elizabeth Bonawitz ${ }^{2}$ (elizabeth.bonawitz@rutgers.edu), Patrick Shafto ${ }^{1}$ (patrick.shafto@gmail.com)<br>Department of ${ }^{1}$ Math and Computer Science \& ${ }^{2}$ Psychology, Rutgers University - Newark Newark, NJ 07102 USA

#### Abstract

Biased sampling of participants presents a major limiting factor for the generalizability of findings from behavioral studies. This effect may be especially pronounced in developmental studies, where parents serve as both the primary environmental input and decide whether their child participates in a study. To estimate the effects of parental non-consent, we coupled naturalistic observations of parent-child interactions with a behavioral test. Results showed that one particular parenting practice, the tendency to use questions to teach, associated with both children's behavior in the test and parents' tendencies to participate. Exploiting these associations with a model-based multiple imputation, we estimated that the means of the consented and not-consented groups could differ as much as 0.2 standard deviations for five of the seven test measurements we used, and standard deviations are likely underestimated. These results suggest that ignoring the role of consent may lead to systematic biases when generalizing beyond lab samples.

Keywords: sampling; generalization; parent-child interaction; learning; exploration; multiple imputation.

## Introduction

Sampling and generalizability are the methodological bedrocks of science. Researchers often rely on measurements taken from a small group of volunteers to draw conclusions for a much broader population, so knowing whether the sample is representative of the population becomes critical to the validity and generalizability of research findings. Among the many factors that may bias the sampling process, one prevalent but under-studied factor is the refusal to participate in research. Because ethical treatment of research participants requires informed consent prior to their participation, we know very little about what characteristics are associated with non-consent, and what those who did not consent would have done if they had participated.

The problem is potentially more acute for fields in which behavior tends to be heterogeneous along factors that may associate with non-consent. One such field is experimental research with young children: On the one hand, before the start of schooling, children's experiences are heavily influenced by the values and practices of their parents, which are known to be heterogeneous both within and between social groups (Bornstein, 1991; Hoff, Laursen, Tardif, \& Bornstein, 2002). At the same time, parents are also the ones who decide whether their children could participate in research, and the same values and practices may play a role in their decision. Given that parents' decisions are crucial for the composition of research
samples for most of the prevalent recruitment methods used in developmental experiments with young children (e.g., direct phone calls, recruitment from day care centers, preschools, and public spaces like museums), non-consent can present a major hurdle when evaluating the generalizability of findings from the field.

However, to date little is known about the factors associated with parents' non-consent to have their young children participate in experiments; consequently, it is difficult to speculate on the behavior of children who did not participate or on the implications for generalizability. This is in sharp contrast with the field of survey-based research with school-aged children and adolescence, where an extensive literature has associated parental consent and nonconsent with both parents' characteristics and children's behavioral outcomes. For example, studies from 1970s-80s have shown that U.S. parents who are female, white and well-educated are more likely to return written consents for their children to participate in research (Kearney, Hopkins, Mauss, \& Weisheit, 1983; Lueptow, Mueller, Hammes, \& Master, 1977), and children who have better school performance and fewer behavioral problems are more likely to receive parental consents (Kearney et al., 1983; Severson \& Ary, 1983). Moreover, the method of consent also matters. Compared to passive consent which requires a reply to opt out of a study, active consent which requires a reply to optin can bias the sample towards parents who are white and well-educated, and towards children who live in two-parent households, who have better school performance and satisfaction, who involve in more extracurricular activities and less risk-seeking behavior, and who are higher on selfesteem and assertiveness (Anderman et al., 1995; Dent et al., 1993). Critical to estimating these effects is the availability of relevant correlates, such as school records that contain demographic information and students' performance.

This study takes a first step to investigate whether parents' non-consent is also associated with preschoolers' behavior in standard experimental settings. Given that methods used to discover factors associated with non-consent in schoolaged children (such as passive consent procedures and school records) are not usually applicable in the research with preschoolers, we developed a new method that is wellsuited to many settings in which developmental psychologists collect data: coupling naturalistic observations of parent-child interactions with behavioral experiments.

By conducting the observation in public spaces without the awareness of the dyad, we aim to start with a relatively representative population that is unaffected by the consent
process. We then invite participation in a behavioral test to those who were observed. By analyzing the correlations between the observational and test data, and between the observational data and participation, we look for predictors that may associate test data from the participated group with participation itself, which would indicate the potential effects of non-consent on estimates of test measurements. If such association can be established, we would then use a model-based multiple imputation to simulate the behavior of children who did not participate, and compare the participated sample with the initial population on the test measurements.

The domain we chose to examine is one where there is known heterogeneity in parenting practices: the use of questions to teach. This line of research is grounded in a rich literature about informal pedagogy (Bonawitz et al., 2011; Csibra \& Gergely, 2009), which suggests that the format in which parents and educators chose to present evidence to children influence how children infer and learn. Specifically, recent experiments (Yu, Bonawitz, \& Shafto, under review) have shown that pedagogical questions asked by knowledgeable teachers are particularly effective in facilitating children's learning and exploration of a novel artifact. Given that the tendency to ask pedagogical questions has been shown to vary across parents (Yu, Bonawitz, \& Shafto, 2016), we explore the effects of children's experiences with pedagogical questions on their responses in the experiment. We did so by replicating one condition of the previous experiment with an added observation phase, in which parents' pedagogical questions towards children were measured along with other parentchild interaction measurements. This allows us to look for associations between parents' pedagogical questions and children's responses to these questions. And because the observational data is available for children who did not participate, these associations could then be used to estimate the test data for the whole population.

## Method

## Testing sites

We set up the study in two sites: an indoor reptile exhibit in a zoo, and an indoor playground. The zoo is in Essex County, NJ, which is one of the nation's most racially diverse counties, and has one of the nation's most unequal economies measured by the Gini Index (U.S. Census Bureau, 2016). The playground is in Middlesex County, NJ, which is overall more affluent, but also has a highly racially diverse population, of which $30 \%$ were born outside the U.S. (U.S. Census Bureau, 2016). We chose these two sites to ensure diversity in the population we initially observed. Consents from these two sites and from the internal review board was obtained before conducting the study.

These two sites differ in the expected level of supervision and involvement from parents. The zoo is an open environment that requires parents to constantly supervise their young children. Exhibits in the zoo also feature many
textual materials which require parents' explanations for young children to understand. In comparison, the playground features spaces and activities which young children can navigate on their own, and the closed environment allows minimal supervision from their parents. This contrast allows us to test whether the characteristics associated with parental non-consent differ by the type of facilities from which they were recruited.

## Participants

Between the two sites, we observed a total of 109 parentchild dyads. Of these 109 dyads, 31 were not invited for the test because of one of the following: the dyad left before the observation was finished (18), parent interrupted researchers during observation (1), researchers did not get a chance to invite parent (4), adult accompanying child was not the child's parent (4), child was out of the target age range (2), or child did not speak English (2). The remaining 78 parentchild dyads comprised our "population", which is unaffected by the consent process. Among them 41 were recruited from the zoo, and 37 were recruited from the playground.

## Procedure

During each trip to the testing sites, three researchers collected data from parent-child dyads in three phases: Two coders first observed and coded the interactions between the parent and the child (observation phase). Then a third researcher invited the dyad to a test (recruitment phase). She and one of the coders conducted the test if the dyad agreed to participate (testing phase).

Observation phase. Two coders pretended to be visitors of the zoo or the playground, so that they could code parentchild interactions without the dyad's awareness. The coders first looked for a child who was estimated to be between 3 and 6 years of age, and determined who were the adults accompanying the child. If at least one adult looked like the child's parent, the coders would record the members in the group (e.g., father, mother, and two daughters), and agree on a target dyad for observation (e.g., mother and younger daughter). To reduce potential selection biases from the coders, they always observed the first dyad they saw that fitted the requirements, and the observation always started immediately once the target dyad was determined. Each dyad was observed for 5 minutes, during which the coders independently coded both the quantity and the quality of parent-child interactions. Quantity of interaction was measured by the length of time period of dyadic activities (parent and child engaging in the same activity), supervised activities (parent watching, following, or taking pictures of child while child is engaging in his or her own activities), and unsupervised activities (parent and child engaging in different activities). We coded these as mutually exclusive categories, and they added up to the total time length (5 minutes). Quality of interaction was coded as a set of frequency measurements, adapted from the Dyadic ParentChild Interaction Coding System (Eyberg, Nelson, Ginn,

Bhuiyan, \& Boggs, 2013): The coders recorded the numbers of parents' questions, statements, and commands towards children.

Critical to our interest, parents' questions were further differentiated based on their functions (Yu et al., 2016): Those used to help children learn were coded as "pedagogical questions", whereas those used to request information from children were coded as "informationseeking questions". All coders were trained for approximately 5 hours and practiced the coding scheme with at least 5 parent-child dyads before formal data collection. Inter-rater reliabilities were high for both the quantity and quality of parent-child interactions: Inter-rater correlation $r$ $=.78 \sim .84$ for quantity codes, and $r=.79 \sim .86$ for quality codes. The average of the two coders' codes were used for data analysis.

Recruitment phase. After the 5-minute observation, a third researcher who was blind to the observation phase approached the parent and invited the parent-child dyad to participate in a test. The recruitment procedure followed a script which resembled that of a typical developmental experiment: The research started with a brief selfintroduction, then described the research as a study of how children learn and explore a novel toy, then briefly explained the consent form, and finally asked if the parent would be interested to have his or her child participate in the test. For parents who had multiple children with them, we specifically asked for the child who had been observed. Among the population of 78 parent-child dyads that were observed, 59 agreed to participate (the "consented" group) and 19 refused (the "not-consented" group). Of the 59 parents who agreed, 11 children did not participate in the test ( 2 were busy playing and did not get a chance to come, 8 refused to come, and 1 did not understand English), and the video was missing for one additional child, so data from the testing phase were available for 47 children. According to parental report, children who participated in the testing phase were diverse regarding race ( $51 \%$ white, $4 \%$ black, $15 \%$ Hispanic-Latino, $13 \%$ Asian, $17 \%$ multi-racial), but most came from middle- or upper-class families $(91 \%$ of the main caregivers have college diploma or above, $84 \%$ of the families have annual house hold income of $\$ 50 \mathrm{~K}$ or above).

Testing phase. Parents and children who agreed to participate were led to a corner of the zoo exhibit or a separate room in the indoor playground, where the test was conducted by the recruiter (acting as an experimenter) and one of the coders (acting as a confederate). The materials and procedure of the test was adapted from Bonawitz, et al. (2011), and was identical to the pedagogical question condition in our recent experiment ( Yu et al., under review).

A novel toy of approximately $14 " \times 7.5^{\prime \prime} \times 14.5^{\prime \prime}$ was used in the test. In addition to several inert properties, the toy had five functional parts: a tower that lit up when a button was pushed, a knob that produced a squeaking sound when squeezed, a lady bug pin light that flashed in three
different patterns when pushed, a flower magnet that moved between three different places on the toy, and a turtle hidden in a pipe that was visible through a magnifying window.

During the test, the child sat at a table opposite the experimenter and the confederate. The toy was initially hidden out of sight. The experimenter first said that she knows about the toy and the confederate does not, and asked the confederate to bring out the toy. After the confederate brought out the toy and handed it over to the her, the experimenter then asked a pedagogical question to the child, "I'm asking you to think about: What does this button do?", while pointing to the button on the tower without activating it. Then she told the child it is his or her turn to play with the toy, and to let the researchers know when he or she is done. The test ended when the child stopped playing and signaled the researchers, and a sticker was presented as a reward. The whole phase was video recorded.

## Video coding

After data collection, the videos from the testing phase were coded by another research assistant who was blind to the observation phase and to the hypotheses of the study. She first determined the total time children spent playing with the toy, and then coded three measurements regarding both the whole playing period, and the first minute after children started playing: whether children activated the target function (the tower with the button), the number of unique actions they performed with the toy, and the number of nontarget functions (out of 4) they activated. A second coder coded $14(30 \%)$ of the videos, and the inter-coder reliability was high for all measurements: total time playing: $r=.98$; activating target function: Cohen's $\kappa=1$ for both total time and first minute; number of non-target functions activated: Cohen's $\kappa=81$ (total time) and $\kappa=75$ (first minute); number of unique actions performed: $r=.79$ (total time) and $r=.92$ (first minute).

## Results

Our population consisted 32 mother-son dyads, 16 motherdaughter dyads, 17 father-son dyads, and 13 father-daughter dyads. Parent-child interactions varied both across sites and within sites: Compared to dyads in the playground, dyads in the zoo spent more time on dyadic activities, and less time on supervised (but not dyadic) activities or unsupervised activities, $t \mathrm{~s}>2.6, p \mathrm{~s}<.01$. Parents also asked more pedagogical and information seeking questions, and said more statements in the zoo than in the playground, $t \mathrm{~s}>3.4$, $p \mathrm{~s}<.001$. The difference in parents' commands toward children was marginally significant, $t(67.7)=1.75, p=.09$. These results suggest that the testing site needs to be taken into account when interpreting parent-child interactions. Therefore, testing site had been entered as a control variable for all further analyses. We also observed large within-site variations: For all measurements, standard deviations were higher than $1 / 3$ of the mean for both the zoo and the playground. These variations suggest that the population we observed was diverse with regard to parent-child

Figure 1. The estimated effects of non-consent on one of the test measurements: the number of unique actions children performed during the first minute of play. We tested whether the mean and the standard deviation measured from the consented group (1c, blue bars) are unbiased estimates of the population. To do so, we separated the consented group according to the number of PQs parents asked children during the observation prior to the test (1a). Parents who asked more PQs tended to have children who performed more unique actions during the test. On the other hand, as shown in (1b), parents who asked more PQs also tended to consent their children to participate (blue) rather than not consent (red). These two associations resulted in the simulated not-consented group to have a lower mean than the consented group (1c), by an estimated effect size (Cohen's $d$ ) of 0.2. Compared to the population (purple bars), focusing on the consented group may result in an overestimation of the mean and an underestimation of the standard deviation. $P Q=$ pedagogical questions. Error bars denote standard errors across children (1a) or across simulations (1c).
interactions, which serves as a basis for further correlational analyses. Though parent-child interactions differed by site, the proportion of parents who agreed to participate did not differ significantly, playground: 25 agreed, 12 refused ( $68 \%$ vs. $32 \%$ ); zoo: 34 agreed, 7 refused ( $83 \%$ vs. $17 \%$ ); Fisher's exact $p=.19$.

## Are parent-children interactions associated with children's behavior in the test?

Test data was available for 47 children ranging from 3.0 y to $6.3 y$, of which 27 were recruited from the zoo and 20 from the playground. Children from the two sites did not differ with regard to the activation of target and other functions, or the number of unique actions they performed on the toy, $t$ < $1.4, p \mathrm{~s}>.1$. However, there was a trend of children playing longer with the toy in the playground than in the zoo, $M_{\mathrm{zoo}}=$ $189 \mathrm{~s}, M_{\text {playground }}=132 \mathrm{~s}, t(29.4)=1.83, p=.08, d=0.58$. When comparing these results with previous experiments we conducted in preschools ( $n=30$, age range $=4.0 \mathrm{y}$ to 6.0 y ) using the exact same protocol (Yu et al., under review), none of children's response measurements differed significantly across the three sites, $F \mathrm{~s}<2.2, p \mathrm{~s}>.1$.

Next we looked at the relation between children's responses during the test and parent-child interaction measurements during the observation. After controlling for testing site and age, measurements regarding the composition of the group being observed (parent' and child's gender, and whether they were accompanied by other adults or children) did not correlate with any of children's responses, $p \mathrm{~s}>.1$. However, measurements of parent-child interaction did correlate with children's responses: Children of parents who spent more time
watching and following them were less likely to discover the target function during the first minute of play, $r(42)$ $=.33, p=.02$. At the same time, children whose parents asked more pedagogical questions discovered more other functions of the toy, $r(42)=.32, p=.03$, and also performed more unique actions during first minute of play (Figure 1a), $r(42)=.29, p=.05$. These results suggest that patterns observed in parent-child interactions were indeed associated with children's learning and exploration during the test.

## Are parent-child interactions associated with participation?

We then examined whether patterns observed in parentchild interactions also predicted parents' responses to the invitation for research. We fitted a logistic regression model with participation as the dependent variable and the observational measurements as the predictors. Overall the model predicted actual participation with $80 \%$ accuracy. With regard to individual predictors, parents were more likely to have their boys participate than girls, $B=1.47, p$ $=.03$; and those parents who asked more pedagogical questions during the observation were more likely to participate, $B=1.49, p=.05$ (Figure 1b).

## What can be predicted for children who did not participate?

Results so far have shown that the number of pedagogical questions parents asked children predicted both children's participation in a test and their behavior during the test. This indicates that children's participation and behavior may be related as well-that is, if we have tested children whose
parents did not consent them to participate, they may have responded differently than children who did participate.

To test this hypothesis, we applied model-based multiple imputation to our data (Rubin, 2004). ${ }^{1}$ The model we used for multiple imputation was a stochastic regression model, implemented with IBM SPSS 22. The seven observational measurements were used to model the seven test measurements, based on data from the consented group. The resulting models were then used to predict behavior of the not-consented group stochastically (with random noise) for 100 independent runs of simulations. ${ }^{2}$

Results showed that across the 100 runs of simulations, the means of the not-consented group were consistently different from that of the consented group for five out of seven test measurements including activating target function (total time and first minute), number of non-target functions activated (first minute), and number of unique actions performed (total time and first minute). The departure was towards the same direction-the participated children learned and explored more with the toy (Figure 1c shows one example). The differences between the means of the consented and not-consented group were estimated to be between 0.09 and 0.20 standard deviations for these five measurements. In addition, compared to the population, focusing on the consented group alone would lead to consistent underestimation of the standard deviations across children, and this is true for all test measurements we examined.

## Discussion

This study takes a first step towards evaluating whether

[^251]results from children who participated in an experiment could generalize to children whose parents did not consent for them to participate. We attempted to estimate these potential biases with a novel approach by pairing a behavioral test with naturalistic observations of parent-child interactions prior to parental consent. Results have shown that a specific parenting practice-asking questions to help children learn-correlated with both parents' tendencies to have their children participate in the test, and children's learning and exploration during the test. And since the observational data was available for both those who participated and did not participate, we were able to exploit these associations to impute behavior for children who did not participate. Results from the imputation showed differences in group means between the consented and notconsented group for five out of the seven test measurements, with estimated effect sizes (Cohen's $d$ s) between 0.09 and 0.20 . Furthermore, the consented group showed a lower standard deviation than the population for all test measurements.

Before discussing the implications of the results, it is worth noting that several assumptions underlie these simulated estimates. First, we assumed no direct causal relation between parents' decisions to have their children participate and children's potential behavior in the test. This assumption is plausible in our case: Because parents were not given much detail about the testing procedures, their decision to participate is unlikely to be based on what they expect their children to do. However, in other situations this assumption could be violated, which could render the imputation analysis invalid. For example, in a study that measures children's executive functions, if children drop out from the study exactly because of low executive functions, then it would be invalid to impute executive functions for the dropout group even when all relevant correlates have been observed and entered into the model. Second, our approach is valid because we saw variations in parent-child interactions for both the consented and not-consented groups, as well as significant overlap between the two groups. This allows imputation to be done as interpolations within the ranges of empirical support. In cases where the consented and not-consented groups do not overlap, our approach could be invalid, as the relations found in the consented group may not extend to the not-consented group. In sum, our methods to generalize experimental results are themselves subject to usual conditions for generalization.

How much this new approach could be and should be implemented in developmental experiments would also depend on various factors. The first factor is the recruitment method. Our approach could be beneficial for research settings that provide opportunities to observe and recruit from a relatively diverse population, such as in public spaces. On the other hand, for studies recruiting from places with a preselected population, such as preschools, the demographics of the preselected population may present a stronger sampling bias than parents' consent. The second factor is the research topic. Our approach could be more
valuable for domains in which parent-child interactions have been, or are expected to be, associated with children's behavior. The last factor is the research ethics. Pre-consent observations are ethically viable only for public actions, and needs to be performed with caution.

In cases where our approach can be applied, it could benefit the interpretation and generalization of experimental findings in several ways: First, it could reveal correlations between parent-child interactions and children's behavior, which may help explain the cognitive mechanisms and environmental inputs associated with the observed behavior. Second, it could inform the generalizability of experimental findings to children whose parents did not consent them to participate. Third, it can serve as an empirical base for future research to recruit a more representative sample. By knowing the associations between parental consent and patterns in parent-child interaction, it may be possible to intentionally focus recruitment on parent-child dyads who are likely underrepresented in typical recruitment procedures.

Our results may also have implications for developmental theories. Many developmental theories are built upon findings from experiments, as experimental design has advantages in addressing a range of developmental questions: These include depicting developmental trajectories ("Children do X at age Y "), disentangling causal mechanisms underlying children's behavior ("Children do X because of Z'), and testing causal effects of interventions ("T helps children do X "). In typical cases, random assignment of participants across groups removes unwanted systematic differences between groups, so that the effects of age, condition, or treatment can be detected by comparing between-group differences with within-group differences. Our results have shown that parental non-consent may have biased this comparison in two ways that random assignment cannot solve: First, it could lead to an underestimation of within-group variations, and thus Type I errors may be underestimated and effect sizes may be overestimated. Second, compared to the general population, children who received consent may be more susceptible or insusceptible to certain manipulations or treatments, therefore biasing the estimation of the between-group differences. Because findings from developmental experiments often guide realworld practices which apply to the general population, understanding factors and biases associated with nonconsent is essential when interpreting and applying these findings.

To conclude, this study provided a first empirical demonstration that children with and without parental consent to participate in research may have differed in behavior measured in an experiment. Therefore, parental non-consent should be considered an important factor when evaluating the generalizability of experimental findings, and the theories built upon them. In addition, we provided a method that, in certain contexts, could be used to estimate the effect of parental non-consent and generalizability of experimental results.

# Seeing Is Not Enough for Sustained Visual Attention 

Lei Yuan, Tian Linger Xu, Chen Yu and Linda Smith<br>Department of Psychological and Brain Sciences, and Cognitive Science Program, Indiana University Bloomington, IN, 47405 USA

#### Abstract

Sustained visual attention is crucial to many developmental outcomes. We demonstrate that, consistent with the developmental systems view, sustained visual attention emerges from and is tightly tied to sensory motor coordination. We examined whether changes in manual behavior alter toddlers' eye gaze by giving one group of children heavy toys that were hard to pick up, while giving another group of children perceptually identical toys that were lighter, easy to pick up and hold. We found a tight temporal coupling between the dynamics of visual attention and the dynamics of manual activities on objects, a relation that cannot be explained by interest alone. In the Heavy condition, toddlers looked at objects just as much as did toddlers in the Light condition but did so through many brief glances, whereas in Light condition looks to the objects were longer and sustained. We discuss the implication of hand-eye coordination in the development of visual attention.

Keywords: Sustained visual attention; hand-eye coordination; multimodal; perception action; manual behavior; developmental systems

## Introduction

The ability to focus attention on an individual object or event for a period of time, often in the face of distractions, is predictive of learning and general cognitive capacities (Lansink, Mintz, Richards, 2000; Ruff \& Lawson, 1990). The ability to sustain visual attention undergoes substantial developmental change from infancy to early childhood with a steady increase in both total duration and the ability to resist distractions (Ruff \& Lawson, 1990; Kannass, Oakes \& Shaddy, 2006). Prior research on the development of visual attention has focused on both the effect of low-level stimulusdriven properties (exogenous) and the emergence of topdown internal control of attention (endogenous) (Colombo, 2001). However, like the development of many other cognitive capacities, visual attention interacts with and is influenced by other sensory modalities within the developmental system (Thelen \& Smith, 1994). The ability to sustain attention may not emerge directly from the development of internal controls but rather externally-from the coupling of vision with physical action.

Within this view, visual attentional skills are not built solely on the development of vision; but rather are influenced, altered, and coordinated with other sensory modalities (Yu, Smith L, Shen, Pereira, \& Smith T, 2009). One apt example is the demonstration that deaf children performed worse on a non-auditory visual attention task than their age-matched controls; but, deaf children who had cochlear implant for at least one year performed similarly to hearing children (Quittner, Smith, Osberger, Mitchell, \& Katz, 1994). Because the visual attention task did not rely on
auditory process at all, the deficit shown by deaf children without the implant was solely attributable to an impoverished capacity of visual attention. A history of having auditory experience with the aid of cochlear implant helped to build visual attention, which was then successively recruited to perform a task that did not rely on auditory information. Thus, visual information alone is not enough for building visual attention; the interaction of multiple sensory modalities may be critically involved in the pathways to internal control of attention.

We focus here on the role that manual behavior plays in the control of visual attention. It has long been recognized that the development of perception is driven by the development of motor behaviors (Gibson, 1979). For example, as infants achieve motor milestones (e.g., sitting, crawling and walking), they are able to receive different perceptual experiences (e.g., stably held objects, optical flow), leading to the development of various perceptual abilities such as object recognition and depth perception. Research has also shown that changes on the affordance of objects (or how they can be held) alters the visual input infants receive, which in turn alters the outcome of object recognition (Pereira, James, Jones, \& Smith, 2010). Thus, changes in manual behavior may alter infants' visual attention on objects through the coordination between hands and eyes.

Recent research suggests that infants' hands and eyes are dynamically coupled during toy play (Pereira, Smith, \& Yu, 2014; Yu \& Smith, 2014, 2016) and this coupling may play a causative role in sustained attention. The natural learning environment is complex, often presenting multiple visually interesting objects in a cluttered setting. In these visually complex contexts, infants may rely on manual behaviors to externally select and maintain attention on a target of interest. For example, Pereira, Smith, \& Yu (2014) have shown that infants own manual actions on objects help them to select target, reduce visual clutter, and create larger input images in the visual field, leading to sustained visual attention on objects, better object recognition and early word learning. In this sense, manual action helps to regulate and sustain visual attention. Conversely, it has been found that irregular attentional patterns in atypical development co-occur with perturbations between the visual and manual modalities (Koterba, Leezenbaum, \& Iverson, 2014).

Both between- and within-person hand and eye coordination may contribute to a more mature control of visual attention in social contexts. Yu and Smith (2016) demonstrated that parent's visual attention often follows infant's hands to the object to which the infant was directed; this between person hand and eye coordination substantially prolonged infant's sustained attention on the same object during toy play. Thus, visual attention is not a sole product of
vision or perhaps even the individual but also influenced by cross-person sensory-motor coordination. Consistent with this idea, recent findings suggest that joint attention is also dependent on the child's hand-eye coordination. One- to two-year-olds who showed more tightly coordinated hands and eyes were also better able to coordinate their attention with their parents and better able to sustain joint attention with a parent (Yu \& Smith, 2013, 2014).

All previous findings linking hand-eye coordination in toddlers to sustained visual attention were correlational. Here we attempt to show a causal link. We manipulated manual behavior by giving one group of children heavy toys that were hard to pick up but that could be poked and touched in various interesting ways. We gave another group of children perceptually identical toys that were lighter and easy to pick up and hold. The expectation is that the duration of each individual hand contact will be less for the heavy toys than the light toys that can be picked up and held. However, if the toys are equally engaging-which we designed them to bethe total amount of hand contact may not differ between the two conditions. The key expectation then is on the dynamics of individual contacting events: more briefer touches (pokes and touches) in the heavy case and fewer but longer touches (poking and touching while holding) in the light case.

We illustrate the expectations under the two hypotheses in Figure 1. First, if infants' hands and eyes are dynamically coupled-when hands are on an object, eyes are more likely to be on the same object-then the different dynamic properties of the manual behaviors caused by the weights of object should lead to different dynamic patterns of visual attention, with less sustained attention in the heavy condition (Fig. 1, H1). Second, and in opposition, if visual attention is independent of hand actions (if visual properties of objects solely determine gaze) then, when presented with novel and interesting toys, infants would visually look at them and for similar durations at each looking event, irrespective to whether the object can be held or not (Fig. 1, H2). We expect that the results will support Hypothesis 1: children from both conditions will manually handle and visually attend to the objects for the same total amount of time over the whole play session, but the dynamic properties of gaze will differ considerably and aligned with the different dynamics of the hands.

Figure 1. Two hypotheses for the looking patterns in the heavy condition

## Methods

## Participants

The final sample consisted of thirty-one parent - toddler (mean age $=21$ months old, range $=18-25$ ) dyads. Roughly half (16) of the dyads were assigned to play with light weight toys, while the other half (15) played with heavy weight toys. Children were recruited from a population of working and middle class families in a Midwestern town.

## Stimuli

Two sets of six novel toys (12 in total) were developed from extensive pilot work to be engaging for manual play with moveable elements, openings, and possible actions. They were made of hardened clay, painted in red, blue or green, and were roughly the same size $(9.5 \times 6.5 \times 5 \mathrm{~cm})$. The two sets were identical in terms of shape, size and color, with the only difference being their weights. The heavy set of toys was on average 1.4 lbs , seven times heavier than the average weight of the light set, which was 0.21 lbs .

## Apparatus

Parent and child sat across a small table ( $61 \mathrm{~cm} \times 91 \mathrm{~cm} x$ 64 cm ) (see Fig. 2). The child was strapped loosely into a small chair and the parent sat cross-legged on a pillow. Both participants wore head-mounted eye trackers with a sampling rate of 30 hz (positive science, LLC; also see Franchak et al., 2011). The eye tracker consists of a scene camera that captures the egocentric view of the participant, and an infrared camera that is mounted on the head, points to the right eye of the participant, and records the eye-in-head position ( x and y ) in the captured scene. Another highresolution camera (recording rate 30 frames per sec) was mounted above the table and provided a bird's eye view that was independent of participants' movements.

Figure 2. The experimental setup.

## Procedures

To place the eye tracker on the child head, one experimenter attracted the child's attention with an interesting toy, while another experimenter put the eyetracking gear low on the child's forehead. To calibrate the eye tracker, the experimenter directed the child's eyes toward an interesting toy, which were repeated 15 times while the toy was placed at various locations on the table. Parents were instructed to place the eye tracker on their heads. Parents' eye

Figure 3. Frequency of manual activity events that last for different durations
tracker was calibrated in a similar way. After this initial set up, parents were told that the goal of the experiment is to study how parents and their toddlers interact during toy play, and were instructed to play with their toddlers as naturally as possible.

The free play session lasted for a total of 6 minutes that was composed of four trials with each lasted 1.5 minutes. The six novel toys were grouped into two sets (A and B) with each set having three different colored objects (red, blue and green). The sets were interleaved with the order of the sets counterbalanced across dyads (ABAB or BABA). At the end of each trial, the experimenter signaled parent with a clicking sound, and quickly replaced the old set of toys with a new set.

## Coding

Three regions-of-interest (ROI) were defined for both the eye tracking data and the manual action data: the green, blue and red object. These ROIs were coded manually by coders who annotated frame-by-frame when the cross-hairs overlapped with any of the three ROIs. Another coder independently coded $10 \%$ of the frames with $95 \%$ agreement between coders. The final dataset consisted of a total of 203,316 frames.

## Results

Because our manipulation was on the weight of objects, we first analyzed toddlers' manual activity. We then turned to visual attention as measured by gaze patterns. Finally, we examined the hand-eye coordination as a possible mechanism that drives the observed effects.

## Manual activity

We defined manual activity event as any event during which the toddles' hands were in contact with any of the three objects (data from two hands were coded individually and then combined with a manual contact defined as either or both hands). Results showed that children in the heavy condition handled the objects for a comparable amount of total time as those in the light condition (Fig. 4), suggesting that overall the Heavy and Light versions of the toys were both manually engaging. There was no significant difference in the proportion of total time children in the light ( $M=84 \%$, $S D=7 \%$ ) and heavy condition ( $M=87 \%, S D=6 \%$ ) were in manual contact with the objects, $t(29)=.24, p=.8$. This is important to rule out the possibility that due to object weight,
children in one of the conditions were more interested in the objects and played with them more than the other condition.

Children in the heavy condition $(M=21.31, S D=7.26)$ produced manual activities at a higher frequency (count of events per minute) than those in the light condition ( $M=$ $15.48, S D=4.42$ ), $t(29)=2.67, p=.01$ (Fig. $3 \& 4$ ). But, children in the heavy condition ( $M=2.63 \mathrm{~s}, S D=.99 \mathrm{~s}$ ) spend less time in each manual activity event than those the light condition $(M=3.46 \mathrm{~s}, S D=1.38 \mathrm{~s}), t(29)=1.91, p=.06$. Thus, it appears that children in the light condition would pick up and hold objects, resulting in many long manual activity events. In contrast, children in the heavy condition generated more short manual activity events because they can't hold the objects for a long time if at all, and would probably more often touch the object that sat on the table. This prediction was confirmed by the data: during manual activity events, compared to the heavy condition, children in the light condition had on average a larger visual image size (the size of the object in proportion to the entire visual field captured by the ego-centric view recording in the eye tracker), Light: $M=5.84 \%, S D=.99 \%$, Heavy: $M=4.21 \%$, $S D=1.17 \%, t(29)=4.24, p<.001$.

Figure 4. The proportion of time, mean duration and frequency of manual activity events for both conditions.

Despite the similarity in the total duration of manual activity, the way children handled the objects were different between the two conditions. Because previous studies have used 3 seconds as the threshold of sustained attention (Ruff \& Lawson, 1990; Yu \& Smith, 2016), here we defined sustained manual activity as any manual action that lasted for more than 3 s . Consistent with our prediction, children in the heavy condition had significantly more short (less than 3 seconds) manual activity events per six minutes (session length) than did children in the light condition (Heavy $=1553$, Light $=994$ ); in contrast, the number of sustained manual action events per six minutes were comparable between conditions (Heavy $=493$, Light $=399$ ). Chi-square test of independence indicated that there was a significant

Figure 5. Frequency of looking events that last for different durations
relationship between the number of sustained manual activity events and the weight of objects, $\chi^{2}(1, \mathrm{~N}=3439)=8.92, p=$ .002.
These results set the stage for answering the key question: given that hand dynamics differ, do eye dynamics-and sustained attention episodes-differ as well?

## Visual attention

To analyze children's visual attention, we first examined all looking events during which the child had fixated on any of the objects (the ROIs). There was no significant difference in the proportion of total time children in the Light ( $M=67 \%$, $S D=2 \%$ ) and Heavy conditions ( $M=65 \%, S D=2 \%$ ) looked at the objects, $t(29)=.51, p=.61$. Thus, children from both conditions were visually interested in the objects by this measure.

The mean duration of looking events was significantly lower in the heavy condition ( $M=2 \mathrm{~s}, S D=0.44 \mathrm{~s}$ ) than the light condition $(M=2.43 \mathrm{~s}, S D=0.63 \mathrm{~s}), t(29)=2.21, p=.03$. However, the looking events in the heavy condition ( $M=$ 20.55, $S D=5$ ) had a slightly higher frequency (count per minute) than those in the light condition ( $M=17.64, S D=$ 4.6), although this difference was not statistically significant, $t(29)=1.67, p=.1$. Similar to the manual activity analysis and to previous research (Ruff \& Lawson, 1990; Yu \& Smith, 2015), we defined sustained looking as any looking event that lasted for more than 3 seconds. As shown in Fig. 5, children in the heavy condition had significantly more short (less than 3 seconds) looking events per six minutes (session length) than did children in the light condition (Heavy $=1789$, Light $=1625$ ); in contrast, the number of sustained looking events per six minutes were comparable between conditions (Heavy $=350$, Light $=425$ ). Chi-square test of independence indicated a significant relationship between the number of sustained looking events and the weight of objects, $\chi^{2}(1, \mathrm{~N}=$ $4189)=13.25, \mathrm{p}=.0003$.

Overall, the results of the looking patterns mirror the results from the manual activity: children in the heavy condition produced more rapid but frequent manual activity events, as well as more rapid but frequent looking events. By our hypothesis, the dynamic hand-eye coordination is responsible for the corresponding differences in the hand and eye patterns in the two conditions.

## Hand-eye coordination

We propose that the result-that heavy condition had more short and rapid manual activity events, as well as more short and rapid looking events than the light condition-is driven by the hand-eye coordination of the child. In other words, because child's hands and eyes are closely coupled such that when hands are on the object, the eyes are also more likely to be on the same object-sustained hand actions create and support sustained visual attention. To demonstrate this link, we measured the durations of joint hand-eye to the same object. If this is the case, then we would expect to see more short but rapid hand-eye coordination events-the hands and eyes of the child were on the same object-in the heavy than the light condition.

As predicted, the mean duration of hand-eye coordination events was significantly lower in the heavy condition ( $M=$ $1.04 \mathrm{~s}, S D=0.25 \mathrm{~s})$ than the light condition $(M=1.33 \mathrm{~s}, S D=$ $0.44 \mathrm{~s}), t(29)=2.26, p=.03$. However, the hand-eye coordination events in the heavy condition $(M=17.83, S D=$ 3.93) had a significantly higher frequency (count per minute) than those in the light condition $(M=14.19, S D=3.26)$, $t$ $(29)=2.55, p=.01$. Again, we used 3 seconds as the threshold to define sustained hand-eye coordination event and found that children in the heavy condition had significantly more short hand-eye coordination events per six minutes (session length) than did children in the light condition $($ Heavy $=1577$, Light $=1116)$; in contrast, the number of sustained hand-eye coordination events per six minutes were comparable between conditions (Heavy $=134$, Light $=151$ ). Chi-square test of independence showed a significant relationship between the number of sustained hand-eye coordination events and the weight of objects, $\chi^{2}(1$, $\mathrm{N}=2978)=14.05, p=.0002$.

## General Discussion

When actively engaged with objects-the context for much real-world learning and problem solving-infants' visual attention is dynamically tied to their hand actions. The implications of this for the development of visual attention and for the underlying brain mechanisms are profound: this sensory motor coordination could be a core driving force for visual development, setting up the behavioral and neural networks for the mature control of visual attention (Byrge, Smith, \& Sporns, 2014).

The direct connection between bodily movement, gaze direction and internal cognitive processing has been supported in many studies of adults' cognition. For example, it has been shown that bodily movement or direction of eye gaze serves as the basis for establishing deictic (pointing) reference to objects as well as the spatial relations between objects, suggesting that visual attention and action may share overlapping spatial referent frames (Ballard et al, 1997; Yuan, Uttal, \& Franconeri, 2016). Manual actions can also directly guide or bias visual attention. The position of hands elicits unique neural responses in several brain areas and serves to prioritize visual attention (Makin, Holmes, \& Zohary, 2007). Using a visual covert-orienting paradigm, for example, Reed, Grubb and Steele (2006) have shown that placing a hand on the side of the screen where a target would appear facilitated target detection, but the presence of visual anchors did not produce the same effect. This result suggests that adults have a hand-centered representation within peripersonal space (i.e., space that is close to a person's body), raising the possibility that children may have a similar or even stronger hand-centered representation in near space as they had shorter arms than adults and often hold objects very close to their body.

Manual action is a crucial way through which infants select and learn about the visual properties of objects in the world. Despite the complex and often cluttered real-world learning environment, the ego-centric view of infants suggests that they often attend to one dominant object at one time (Yu et al., 2009), which is crucial for developing visual attention to the detailed properties of objects. Importantly, although social partner occasionally brings an object in front of an infant's face, the predominant pathway through which infants create this optimal learning moments is through his or her own hand actions - it is hand actions that bring objects closer to the body and eyes, allowing for close examination of the various properties of the object, multiple sampling of the dynamic views of objects, leading to sustained visual attention and helping to build representations of the threedimensional structure of objects (Bambach, Crandall, Smith, \& Yu, 2016; Soska, Adolph, and Johnson, 2010).

The current study offers another pathway through which manual action exerts influence on visual attention-by changing the frequency and duration of looking events. Because hands and eyes are closely synchronized during play, the temporal characteristics of manual actions can influence those of vision. An analogous example is the demonstration that auditory input, particularly the rhythm of sounds, can facilitate visual learning for both adults (Iordanescu, Guzman-Martinez, Grabowecky, \& Suzuki, 2008) and children (Bahrick \& Lickliter, 2000). This multimodal learning not only provides redundant information to recruit sustained attention, but also capitalizes on the interconnection among sensory modalities-activities in one domain can influence and promote that of another domain. In this sense, the sensory motor coordination is the core driving force for the development of cognitive capacities.

Hand-eye coordination can help to build and integrate multiple neural networks that underpin cognitive development. Time-locked signals from perception and action not only afford the direct mapping between the physical properties of the object to the neuronal activity of the visual network, between the physical properties of the object to the neuronal activity of the haptic system, but also allow for cross-modality integration and enrichment: activity of the visual system and the activity of the haptic system are directly mapped to each other (Edelman, 1987; Smith \& Gasser, 2005). For example, as one holds and manipulates an object, the neuronal activity of the visual system is timelocked to the activity of the haptic system-each different hold is linked to each unique visual representation of the object. As a result, a particular sight of an object may elicit its corresponding neuronally mapped action. For instance, in one visual recognition task, adults were shown a picture of a pitcher and answered the question "Is this a pitcher" by pressing either a left or a right button. Adults responded faster when the "yes" button was on the same side of the pitcher's handle, suggesting that the sight of the object may have elicited corresponding motor activity, facilitating the motor execution of button press on the same side (Ellis \& Tucker, 2000).

This multimodal learning mechanism has important implications for development and learning. For example, manual actions can be leveraged to train a mature control of visual attention. One classic demonstration of this idea is the A-not-B error (Piaget, 1954). After repeating the sequence of seeing one object being hidden at location A and retrieving the object at location A several times, infants were shown the object being hidden at location $B$. Despite seeing the object being hidden in the new location B , infants continued searching at location A. However, changes in the motor actions or giving infants more motor experiences led to improved performance (Bertenthal, Campos, \& Barrett, 1984). For instance, changing the manual behavior that children need to perform to approach the object through changes in posture (sitting vs. standing) led children to search at the correct location much often (Smith, Thelen, Titzer, \& McLin, 1999).

In conclusion, the current study supports the developmental systems view of visual attention: visual attention emerges from the interaction among multiple sensory modalities, which are dynamically coordinated during moment-by-moment perception and action events to support cognitive development. In particular, the current study showed that changes in manual behavior alter the patterns of toddlers' visual attention during toy play. Further, we provided evidence that the hand-eye coordination is the underlying mechanism: toddlers' hands and eyes were dynamically coupled, such that when hands were on an object, the eyes were also likely to be on the same object. These results have implications for the research and development of visual attention, as well as the possibility to leverage on manual action as a way for training the control of visual attention.

# Mindshaping the world can make mindreading tractable: Bridging the gap between philosophy and computational complexity analysis 

Andrea Zeppi (azeppi@unime.it)<br>Department of Cognitive Science, University of Messina Messina, Italy<br>Mark Blokpoel (m.blokpoel@psych.ru.nl)<br>Department of Artificial Intelligence, Radboud University<br>Nijmegen, The Netherlands

#### Abstract

It is often assumed that the socio-cultural context positively influences mindreading performances. Among the available theories, mindshaping is proposed to consist of cultural mechanisms that make the social domain homogeneous and, hence, easier to interpret. Proponents of the mindshaping hypothesis claim that homogeneity is responsible for the computational tractability of mindreading, which is otherwise intractable. In this paper, we examine this core claim of mindshaping and investigate how homogeneity influences mindreading tractability. By taking action understanding as a case-study for mindreading, we formally operationalize mindshaping homogeneity in different ways with the goal of bridging the gap between informal claims and formal (in)tractability results. The analysis shows that only specific combinations of homogeneity may lead to tractable mindreading, whilst others do not. Additionally, the analysis reveals the possibility of a yet undiscovered mindshaping mechanism.

Keywords: mindshaping; mindreading; computational intractability; culture; goal inference; conceptual/philosophical analysis; computational modeling

## Introduction

The ability to understand what motivates other people's behavior is often considered a defining capacity of human cognition. Theories of this mindreading capacity, however, are challenged with explaining how humans can interpret behaviors in a timely manner, because the available theories are often computationally intractable (Alechina \& Logan, 2010; Apperly, 2010; Zawidzki, 2013). As Gigerenzer and colleagues proposed:

> "The computations postulated by a model of cognition need to be tractable in the real world in which people live, not only in the small world of an experiment with only a few cues. This eliminates NP-hard models that lead to computational explosion, ..." Gigerenzer (2008)

Given that mindreading is performed in a complex, realworld socio-cultural environment (Adams et al., 2010; PerezZapata, Slaughter, \& Henry, 2016; Tomasello, Carpenter, Call, Behne, \& Moll, 2005), it stands to reason that intractable (NP-hard) theories of mindreading cannot explain how humans can perform the computations postulated by the theory quickly.

In an attempt to address this theoretical paradox, Zawidzki has proposed that the socio-cultural environment plays a key role. Zawidzki proposes that this environment is shaped by agents themselves so that mindreading can be tractable (Mameli, 2001; Zawidzki, 2008, 2013). Introduced as the mindshaping hypothesis, this claim entails a collection of (social) cognitive and evolutionary mechanisms that bring structure to the environment.

In this paper, we assess the potential that the mindshaping hypothesis has to solve the intractability paradox of mindreading. Given that computational (in)tractability is a well-defined mathematical property of computational-level theories (Marr, 1982; van Rooij, 2008), a bridge will have to be built between Zawidzki's informal theoretical contributions and formal complexity-theoretic results. We propose that such a bridge can be built by taking action understanding as a special-case proxy for evaluating how mindshaping mechanisms may pave the way for tractable mindreading.

In order to do this, we take two steps. First, we analyze the mindshaping hypothesis and extract specific claims about the effects that mindshaping mechanisms may have on the structure of the socio-cultural environment and consequently the (in)tractability of mindreading. Second, we assess the plausibility of the claims identified in the first step by operationalizing the mindshaping structuring effects in a computational-level model of action understanding (viz., Bayesian inverse planning; Baker, Saxe, \& Tenenbaum, 2009; Baker, Tenenbaum, \& Saxe, 2008). This allows us to relate mindshaping effects to formal (in)tractability results (Blokpoel, Kwisthout, van der Weide, Wareham, \& van Rooij, 2013). The analysis will show that only certain combinations of mindshaping effects lead to tractable mindreading, whilst other effects do not. Furthermore, the analysis also suggests the possibility of a novel effect that is necessary for tractability, which may lead to the discovery of new mindshaping mechanisms.

## Mindreading as abductive inference

Several theoretical accounts of mindreading have been proposed. Fast and frugal heuristics theories (Chater, Oaksford, Nakisa, \& Redington, 2003) conjecture that humans can understand what motivates other people's behavior through simple cue-based rules. Simulation theory
(Goldman, 2006) conjectures that we understand external behaviors by the means of mental simulations. In this paper, we focus on a third hypothesis proposed by Zawidzki. By rejecting modularity, acknowledging domain-generality and the relevance problem (Fodor, 1983; Heal, 1996) for social reasoning, Zawidzki implicitly accepts isotropy and with it a mindreading account that is inferential in nature (Zawidzki, 2013). ${ }^{1}$ Under this view, mindreading can be construed as a mapping from an observed socio-cultural environment (consisting of observed behaviors, actions and context) and social knowledge to the intentional attributions that best explain the observed social environment. Unfortunately, with the notion that mindreading is inferential also comes intractability.

Zawidzki attributes intractability of mindreading to the problem of holism/isotropy. Because in principle any information that a person has might be relevant for any inference that is made, every possibility must be considered (Fodor, 2001). The intractability of inferential mindreading is corroborated by the fact that many of our best theories of inferential cognitive capacities are computationally intractable (NP-hard or worse) (Cherniak, 1986; Frixione, 2001; Levesque, 1988; Thagard \& Verbeurgt, 1998; Tsotos, 1990; van Rooij, 2008; van Rooij \& Wareham, 2012).

An intractable theory makes unrealistic (exponential or worse) demands on computational resources (van Rooij, 2008). Hence, such a theory cannot satisfactorily explain why people can 'mindread' as quick as they do (see Table 1). This leads to the paradox mentioned in the introduction. However, rather than rejecting the inferential mindreading account altogether, the paradox may be resolved if the effects of mindshaping mechanisms are adequately fleshed out. In the next section, we discuss the different possible structuring effects that mindshaping mechanisms may have on the environment.

## Deconstructing mindshaping

First proposed by Mameli (2001) and later developed by Zawidzki (2009; 2008; 2013), the mindshaping hypothesis proposes that the success of human social cognition is explained by the (evolutionary) development of behavioral mechanisms that "shape our socio-cultural environment in ways that make coordination exponentially more tractable" (Zawidzki, 2013). Examples of mindshaping mechanisms are: imitation, over-imitation, the chameleon effect (Chartrand \& Bargh, 1999), pedagogy, norm following and self-constituting narratives (Zawidzki 2013). Although these mechanisms are individually quite different, they all implement a form of social expectancy and conformity mechanism that 'mindshape' both the socio-cultural environment and social knowledge through biased transmission and selection of behaviors. Under the

[^252]assumption that mindreading is a capacity that operates on the social environment and social knowledge, mindshaping may potentially have a positive effect on the tractability of mindreading. To assess this claim, however, it is necessary to characterize in more detail the different kinds of effects that mindshaping may have on the input of mindreading.

Table 1: An illustration of polynomial and exponential time requirements. The input size corresponds to the size of the representation of the input (e.g., the observed social environment and social knowledge encoded in a Bayesian network). The other columns illustrate the difference between tractable (i.e., polynomial time) intractable (i.e., exponential time or worse). The time required to compute intractable theories quickly outgrows the age of our universe.

| Input <br> size $\boldsymbol{n}$ | Polynomial time <br> required $\boldsymbol{n}^{\mathbf{2}}$ | Exponential time <br> required $\boldsymbol{2}^{\boldsymbol{n}}$ |
| ---: | ---: | ---: |
| $\mathbf{5}$ | $0,25 \mathrm{msec}$. | $0,32 \mathrm{msec}$. |
| $\mathbf{1 0}$ | 1 msec. | 10 msec. |
| $\mathbf{2 0}$ | 4 msec. | $10,5 \mathrm{sec}$. |
| $\mathbf{5 0}$ | 25 msec. | 130312 days |
| $\mathbf{1 0 0}$ | $0,10 \mathrm{sec}$. | $4 \times 10^{17}$ years |
| $\mathbf{2 5 0}$ | $0,63 \mathrm{sec}$. | $5,7 \times 10^{62}$ years |
| $\mathbf{5 0 0}$ | $2,50 \mathrm{sec}$. | $1,0 \times 10^{138}$ years |

Unfortunately, the literature only vaguely provides such a characterization of the effects of mindshaping, which is thought to 'homogenize' the social environment and knowledge to make mindreading easier. Such a characterization is insufficient as it states only the ultimate effect of mindshaping (i.e., tractability of mindreading), which is exactly that which needs to be explained. In order to unravel if and how mindshaping can render mindreading tractable, we need to understand two things. First, we need to understand that by putting constraints on the input of a mindreading, those constraints may render mindreading tractable. Second, we need to understand how mindshaping can implement such constraints through homogeneity.

## How homogeneity should affect mindreading

The main claim put forth by mindshaping is that mindshaping mechanisms positively affect the reliability of mindreading (Zawidzki, 2013). The term reliability, however, conflates two different meanings: accuracy and tractability. In order for mindreading to be reliable, inferred propositional attitudes need to be good and the computations need to be performed in a short amount of time (tractability). Perhaps counterintuitively, accuracy does not always cause intractability. An intractable function can be extremely inaccurate and it is also possible for a tractable function to,
bathwater. If, as originally proposed, we can show how Mindshaping mechanisms can render inferential mindreading tractable, it would strengthen the plausibility of the mindshaping account whether it is separate of mindreading or not.
instead, be accurate. Even approximate accuracy (compared to e.g., optimality) does not necessarily grant tractability (van Rooij \& Wareham, 2012). It seems, therefore, that the reason mindreading is tractable for humans lies not in mindreading trading off accuracy, but in the homogeneity effect that mindshaping has.

Research has focused on characterizing the phylogenetic, ontogenetic and cultural evolution of human social cognition (Mameli, 2001; Zawidzki, 2008, 2013). Although the computational details are underspecified, the mindshaping hypothesis clearly states that the tractability of mindreading is not obtained by altering the mindreading capacity, but by changing the socio-cultural environment and social knowledge on which mindreading operates. Mindshaping mechanisms are hence not modules (Zawidzki, 2009, 2013). Therefore, for the purpose of assessing the claim about mindreading tractability, they can be considered complementary to mindreading. This allows us to abstract away from the evolutionary mechanisms that underlie mindshaping and focus on their homogeneity effect.

The solution for tractable mindreading lies "not within human mind readers, but, rather, outside of them" (Zawidzki, 2009). The idea is promising, since it is known that some intractable functions $f: I \rightarrow O$ can be tractable when their input domain is constrained $f^{\prime}: I^{\prime} \rightarrow O$, where $I^{\prime} \subset I$ (Downey \& Fellows, 1999; van Rooij, 2008). These constraints can be the result of naturally occurring or 'mindshaped' structure in the world. They are formally defined as restrictions on properties of the input of computational-level models, called parameters (e.g., see Figure 1). When the tractability of a function is obtained through such restrictions it is said to be fixedparameter tractable for that subset of the input. Fixedparameter tractability, however, is a formal, mathematical property of computational-level models. In order to assess if homogeneity can render mindreading tractable, we need a formal computational-level model of mindreading. Although such an account does not yet exist for mindreading in general, we can investigate the tractability claim using a special-case capacity for mindreading. In the next section, we take (inferential) action understanding as a special case of (inferential) mindreading and present possible ways of operationalizing homogeneity in Bayesian inverse planning (Baker, Saxe, Tenenbaum 2009). We then show that only certain combinations of homogeneity effects render Bayesian inverse planning tractable, whilst other do not.

## Bridging homogeneity to tractability of Bayesian inverse planning

The ability to understand what goals underlie the actions of others is a prime example of the human capacity to mindread. In the Bayesian inverse planning model (Baker et al. 2009), action understanding is characterized as inferring the most probable goal given observed social behavior. In other words, a mapping from an observed socio-cultural environment (consisting of observed behaviors, actions and context) and social knowledge (about planning) to the intentional attributions (goals) that best explain the
observations. Table 2 compares the input and output domains of mindreading and Bayesian inverse planning and Figure 1 illustrates the Bayesian network that underlies Bayesian inverse planning.

Figure 1. In Bayesian inverse planning knowledge about planning is represented by state, action and goal variables (circles) and the probabilistic dependencies between them (arrows). Each variable has a domain (boxes). The input of the model consists of such a network and observed states and actions (gray variables). The output is the most likely value assignment to the goal variables. Several parameters
are: The number of goals $|G|$, the number of observed actions $|A|$, the maximum number of values a goal variable can have $g$ and the maximum number of values an action variable can have $a$.

Table 2. Comparing the input and output of the mindreading capacity with those of the special case Bayesian inverse planning model.

|  | Mindreading | Bayesian inverse <br> planning |
| :--- | :--- | :--- |
| Input | observed socio- <br> cultural environment <br> and | observed states, <br> actions <br> and |
| social knowledge | knowledge about <br> planning encoded in a <br> Bayesian network |  |
| Output | intentional <br> attributions | most probable goals, <br> given the input |

Like Bayesian inference (Chater, Tenenbaum, \& Yuille, 2006; Martignon \& Hoffrage, 2002), Bayesian inverse planning is computationally intractable in general (Blokpoel et al., 2013). This is consistent with the idea that (inferential) mindreading is computationally intractable too. Blokpoel et al. (2013), however, used formal analysis to prove that when certain constraining assumptions are made on the input of Bayesian inverse planning, it becomes tractable. To investigate whether or not a more homogeneous sociocultural environment and more homogeneous social knowledge may lead to tractable mindreading, we have to build a bridge all the way to Bayesian inverse planning. We
first start by illustrating possible interpretations of homogeneity. We then operationalize these interpretations in Bayesian inverse planning, and finally relate the operationalized homogeneity effects with known computational tractability results.

## Interpreting homogeneity effects

There are two types of homogeneity that are consistent with the mindshaping literature: Cognitive homogeneity and mindshaping homogeneity. This analysis is a first attempt and by no means exhaustive, i.e., more homogeneity effects may be postulated/discovered in the future. For example, our analysis will point to possible novel homogeneity effect that is not yet covered by a mindshaping mechanism.

## Cognitive homogeneity

Since all humans have similar biological and cognitive systems, one could argue that humans also share the majority of their propositional attitudes. For example, if all humans behave rationally, they all have the same (rational) bias when deciding how to act to achieve a goal.

Cognitive homogeneity mechanisms may result in a population where sets of intentions overlap a lot (i.e., most of people's possible intentions are shared; CH-S). This, however, does not necessarily restrict the number of possible intentions, as the shared set can still be very large.

Furthermore, Zawidzki argues that tractability of mindreading cannot be achieved only by cognitive homogeneity. This seems to make sense from a computational perspective as well. Even if, for example, all humans mindread 'rationally' this does not explain why mindreading is tractable. And even if all humans share most of their intentions, that set can still be extremely big. Other restrictions are needed to provide any computational benefits.

## Mindshaping homogeneity

Mindshaping homogeneity is effected by a set of mechanisms either cognitive, cultural or evolutionary that decrease the heterogeneity of the socio-cultural environment and social knowledge. For example, by having a culture that keeps reinforcing the same knowledge and behaviors through pedagogy, norms enforcement and imitation (Zawidzki 2013), the knowledge in that population can become more and more homogeneous over generations.

Mindshaping homogeneity can be conjectured to result in the following restrictions as a consequence of biased transmission of knowledge over generations:

- Biased transmission can restrict on the number of available behaviors in a population (MH-B);
- Biased transmission can make social knowledge (i.e., the relations between behaviors and intentions) less ambiguous (MH-A).
- Mindshaping mechanisms resulting in ritualization phenomena may limit, regardless of the total number of possible actions available, the number of executed and observed actions (MH-R).
- Habitualization and culture codification may further limit the complexity of what people can achieve to facilitate social understanding (MH-C).
In the mindshaping literature, the focus has been on identifying the nature of the mindshaping mechanisms that lead to homogeneity. Here instead, we focus on the actual contribution of mindshaping mechanisms and the relative homogeneity. Hence, we assume the validity of mindshaping as a starting point, together with homogeneity, and investigate if their effect can render an intractable model of a mindreading capacity tractable.

## Operationalizing homogeneity effects in Bayesian inverse planning

Taking Bayesian inverse planning as our case-study we can now investigate the possible input-restrictions that can result from the mindshaping hypothesis for action understanding, and show which of the homogeneity-based restrictions may lead to tractability of action understanding. To this end, we build the final part of our bridge by linking the homogeneitybased restrictions to input restrictions of the Bayesian inverse planning model. The effect of these restrictions on the (in)tractability has been investigated by Blokpoel et al. (2013). Table 3 and Figure 1 provide an overview of the five parameters they analyzed.

The above-mentioned parameterizations of Bayesian inverse planning and the previously given interpretations of homogeneity make it possible to operationalize homogeneity. Our contribution is to provide these operationalizations as restrictions on input parameters for Bayesian inverse planning. We go beyond what is currently in the literature by fleshing out more detailed effects that mindshaping might have.

Table 3. Possible parameters for the Bayesian inverse planning model (taken from Blokpoel et al. 2013) and their associated homogeneity hypothesis.

|  | Homogeneity | Description |
| :--- | :--- | :--- |
| $\|\mathbf{A}\|$ | MH-R (partly) | The number of actions that are <br> observed by an interpreter. |
| $\boldsymbol{a} \mid$ | MH-C | The number of goal variables <br> that are inferred by an <br> interpreter. |
| $\boldsymbol{g}$ | unknown | The number of available actions <br> values per action variable. <br> The number of available values <br> per goal variable. |
| $\mathbf{1 - p}$ | MH-A | The probability of the most <br> likely goal inference, dependent <br> on the probabilistic knowledge <br> encoded in the Bayesian <br> network. |

## Restricting the number of observed actions $|A|$

Parameter $|A|$ defines the number of actions that an interpreter observes in order to infer the underlying goal.

Mindshaping mechanisms at work in phenomena like ritualization may limit the number of executed and observed actions. However, ritualized behavior may only explain why $|A|$ may be small in those codified situations. Action understanding transcends those cases. If MH-R proponents are committed to small $|A|$ in general, the account needs to be strengthened. Regardless, restricting $|A|$ does not lead to any known tractability result.

## Restricting the number of inferred goals $|G|$

If action understanding is to be tractable, then one option is for $|G|$, the number of possible goals that an interpreter actually pursues, to be small (together with $g$ ). If, within a social community, an actor would like his/her actions to be timely interpretable to others, then this actor might pursue few goals at a given time so as to make $|G|$ small. This behavior might be the result of mindshaping mechanisms such as habitualization, culture and phenomena like ritualization (MH-C).

## Restricting the domain of actions $a$

Parameter $a$ can be seen as the maximum number of possible actions that are available at any point in time. This number is upper-bounded by the total number of possible actions that are available to a person (MH-B).

## Restricting the domain of goals $g$

Parameter $g$ can be seen as the maximum number of possible goal attributions available for the given inference. This number is upper-bounded by the total number of intentions available to an agent. One might argue that sharing the same intentions (CH-S) may lead to a restriction on $g$, but it does not as humans may in principle share even an infinitely large set. If anything restricts $g$, it seems there must be some not yet discovered mindshaping process that does so, or another cognitive process that selects the relevant intentions from the set of all possible intentions. The latter, however, would imply solving the relevance problem (Fodor, 1983, 2001; Pylyshyn, 1989) which is notoriously hard but perhaps the solution lies in a combination of mindshaping and cognitive relevance selection. Due to the ubiquity of $g$ in tractability results discovering these processes would be paramount for having a complete picture of the relation between homogeneity and tractability of mindreading.

## Restricting the ambiguity of behavior to make 1-p low

The relational probabilities between variables can be seen as encoding the social knowledge that is brought to bear when inferring the most probable goal. The prior probabilities of variables can be seen as the disposition a person has towards particular unobserved variables (such as goals) at the time of the inference. Together, these probabilistic relations between variables and the prior probability of variables may be shaped

[^253]by pedagogy, norm following and imitation such that, 1-p is low (MH-A).

## Computational complexity of Bayesian inverse planning in 'mindshaped' worlds

Blokpoel et al. (2013) proved several computational complexity results for Bayesian inverse planning. ${ }^{2}$ These results show that tractability is not easily achieved. Even restricting multiple parameters simultaneously does not necessarily render the model computationally tractable. The following two intractability results prove that either by themselves or in combination, these restrictions do not make Bayesian inverse planning tractable:

1. Restricting $|A|, a$, and $|G|$ simultaneously, or
2. Restricting $|A|, a$ and $g$ simultaneously

Importantly, none of the parameters by themselves render Bayesian inverse planning tractable. ${ }^{3}$ Only when the right combination of parameters is restricted, i.e., only when the world is mindshaped in the right way, Bayesian inverse planning does become tractable. The following two results show that if either (3) or (4) or both conditions hold, then action understanding is tractable.
3. Restricting $|G|$ and $g$, and/or
4. Restricting $1-p$ and $g$

These two tractability results show that in principle, under the correctly (mind)shaped conditions, Bayesian inverse planning can be tractable. However, the results also reveal (at least for the restricted case of action understanding) a gap in the mindshaping theory. While one of the main claims of mindshaping is the importance of homogeneity for the tractability of mindreading, homogeneity alone cannot (yet) fully explain tractability. All known tractability results show that a restriction on $g$ is always necessary for tractability, but no known mindshaping process leads to that restriction.

## Discussion

Explaining why people can understand what motivates other people's behavior quickly is, at least from a computational perspective, not trivial. Often, culture or evolution are used to trivialize the paradox of mindreading intractability and explain the speed at which people understand the social world around them. These ideas are embodied by Zawidzki's mindshaping hypothesis. In our analysis, we have shown that, a bridge can be built between mindshaping and a special-case capacity for mindreading, a lot of ground still needs to be covered if these ideas are to fully deal with the intractability paradox.

By detailing possible interpretations of mindshaping effects and relating those to known (in)tractability results for a computational model of action understanding, we have

[^254]shown that only very specific combinations of mindshaping effects have the potential to explain the performance of human mindreading.

The analysis has also revealed that a restriction on the number of available intentions (specifically, the maximum number of possible goal attributions) is a necessary condition for tractability. At the same time, no clear homogeneity effect leads to this restriction. Theoreticians interested in computationally explaining the speed of human mindreading through mindshaping may look for mindshaping mechanisms that specifically lead to this constraint.

Even for a restricted case of mindreading such as action understanding, some of these restrictions have an effect on the tractability of this capacity, while others do not. It stands to reason that caution is in order when claims about tractability are concerned. While not exhaustive, our analysis can be seen as a structured attempt at capturing philosophical and psychological claims about the influence of culture on mindreading into a systematic computational framework.

#### Abstract

Computerised paradigms have enabled decision making researchers to gather rich data on human behaviour, including information on motor execution of a decision, e.g., by tracking mouse cursor trajectories. As the number and complexity of mouse-tracking studies rapidly increase, more sophisticated methodology is needed to analyse the decision trajectories. Here we present a new computational approach to generating decision landscape visualisations based on mouse-tracking data. Decision landscape is an analogue of energy potential field mathematically derived from velocity of mouse movement during a decision. Visualised as a 3D surface, it provides a comprehensive overview of motor evolution of decisions. Employing the dynamical systems theory framework, we develop a new method for generating decision landscapes based on arbitrary number of trajectories. The decision landscape visualisation have potential to become a novel tool for analysing mouse trajectories during decision execution, which can provide new insights into the dynamics of decision making.

Keywords: decision making; mouse tracking; dynamical systems; visualisation

## Introduction

Traditionally, decision making studies have been focused on what people choose and explaining the mechanisms leading to the observed choice outcome distributions. Sequential sampling models (Busemeyer \& Townsend, 1993; Ratcliff \& Rouder, 1998) make predictions on the time required for the decision maker to arrive to a decision, thereby stimulating empirical research to measure response times in addition to choice outcomes. However, in the past decade, decision making researchers have been employing more advanced experimental paradigms, measuring behavioural activity during decision-making to investigate whether how we choose is meaningfully related to what we choose.

A variety of experimental methods have been used to study the cognitive processes underlying decision making. One class of paradigms, including eye tracking (Orquin \& Loose, 2013) and different variations of information search paradigm (Payne, 1976), taps attentional processes, trying to answer the question of what information is attended to in the course of decision. Another strand of research, focused on
hand or mouse tracking, examines how decisions are executed through motor system. These studies interpret motor output of a decision as a continuous trace of decisional processes. In a typical experiment on mouse tracking, the participant chooses between the two options presented in the corners of a computer screen (Fig. 1). The dynamics of the response, as expressed in recorded mouse cursor trajectories, can then reveal the degree of competition between the two options during choice.

Mouse (or hand) tracking have been employed to investigate decision making dynamics in a variety of different domains, e.g., speech processing (Spivey, Grosjean, \& Knoblich, 2005), social categorisation (Freeman, Ambady, Rule, \& Johnson, 2008; Freeman \& Ambady, 2011), and intertemporal choice (Dshemuchadse, Scherbaum, \& Goschke, 2013; O'Hora, Carey, Kervick, Crowley, \& Dabrowski, 2016). The recent development of "off-the-shelf" solutions for capturing mouse cursor data (Freeman \& Ambady, 2010; Kieslich, Wulff, Henninger, \& Haslbeck, 2017) has further increased the amount and complexity of the data generated by mouse-tracking studies. However, the vast majority of available studies utilise only few basic measures derived from rich mouse-tracking data. At the same time, much potentially important information conveyed by mouse trajectories is still very often ignored. More advanced analysis methods can potentially enable us to get deeper insights from the rich data provided by the mouse-tracking paradigm.

Here we present a new computational approach for illustrating mouse-tracking data via three-dimensional visualisations of decision landscape. Recently, a method was suggested to infer such visualisations directly from the data (O’Hora, Dale, Piiroinen, \& Connolly, 2013). Here, we build up on this work, employing an alternative, modelbased approach. We assume that the decision process, as reflected by a mouse trajectory, is governed by a 'potential energy' landscape. The parameters defining the form of the landscape for each decision can then be fitted to capture specific mouse motion trajectory during that decision. Visualised as a 3D surface, this decision landscape provides a com-

Figure 1: Typical setup of a mouse-tracking experiment. Plotted in green is an actual mouse trajectory representing binary choice in a learning task (O’Hora et al., 2013)

prehensive overview of motor evolution of decisions. The suggested method can generate illustrations of decision landscapes based on arbitrary number of trajectories. Using previously collected data on a learning task (O'Hora et al., 2013), we demonstrate how decision landscape visualisations can be used to compare sets of mouse trajectories between experimental conditions or individual decision makers in a comprehensive, visually appealing way.

## Visualising decision landscape

The proposed method is aimed at reconstructing a 3D decision landscape based on a mouse trajectory of a decision (or a set of trajectories). We assume that each trajectory can be described by a dynamical system of a specific form, which incorporates a parametrised function describing the shape of the two-well landscape. By fitting this dynamical system to a set of trajectories, we obtain specific values of the parameters characterising these particular trajectories. We can then use these parameters to generate the 3D visualisation of the decision landscape characterising all of the given decisions. The source code implementing all the procedures of the method in Python is available via Open Science Framework (Zgonnikov, Aleni, Piiroinen, O’Hora, \& di Bernardo, 2017).

## Data requirements and preprocessing

To visualise decision landscapes, we use two-dimensional trajectories obtained in a typical mouse-tracking experiment (Fig. 1). We assume that each decision trajectory starts in the bottom centre part of the screen and ends in either top left or top right corner. The method can be generalised to the case of more than two choice options; with minor adjustments (e.g., using two-dimensional projections of 3D trajectories) it can as well be used with any other experimental paradigm generating simple enough continuous trajectories, for instance, arm reaching (Song \& Nakayama, 2008; Gallivan \& Chapman, 2014).

Importantly, the current version of the method assumes continuity and smoothness of the trajectories, which is not always the case. In a fraction of experimental trials, participants change their mind in the course of a trial, which is indicated by major shifts in the $x$-direction of a decision trajectory (Resulaj, Kiani, Wolpert, \& Shadlen, 2009; Freeman, 2014). The deterministic dynamical model of a decision trajectory utilised in the present method does not account for such changes-of-mind, so we recommend using the method only with the trajectories without abrupt shifts.

As screen size and proportions can differ between experiments, we illustrate the method for spatially normalised trajectories. In particular, the screen coordinates are assumed to be rescaled such that each trajectory originates near $(x, y)=$ $(0,0)$ and ends in the vicinity of $(x, y)=(-1,1)$ (left target) or $(x, y)=(1,1)$ (right target).

Each trajectory is supposed to be described by the time series of $x$ - and $y$-coordinates of the mouse cursor on the screen. In addition to this data, the method also requires $x$ - and $y$ velocities of the mouse cursor at each time step, which are computed numerically.

## Model of trajectory dynamics

Without aiming at developing a model explaining the dynamics of a decision, we use a simple dynamical system to describe the decision trajectory, capturing the high-level features of motion of the mouse cursor. We describe the time dependent $x$ - and $y$-components of a decision trajectory by a system of ordinary differential equations

$$
\begin{align*}
\tau \dot{x} & =-\frac{\partial V}{\partial x} \\
\tau \dot{y} & =-\frac{\partial V}{\partial y} \tag{1}
\end{align*}
$$

where $\dot{x}=\frac{\mathrm{d} x}{\mathrm{~d} t}$ and $\dot{y}=\frac{d y}{d t}$ are the time derivatives of $x$ and $y, \tau>0$ is the time scale parameter expressed in seconds, $V(x, y)$ is a function describing the decision landscape, which defines the dynamics of the system, and $\frac{\partial V}{\partial x}$ and $\frac{\partial V}{\partial y}$ are its partial derivatives with respect to $x$ and $y$.

Our method is not constrained by some particular function $V(x, y)$; here we use one of the simplest possible variants. We assume that $V(x, y)$ comprises a fixed baseline component
$V_{x}(x)+V_{y}(y)$ and a parametrised component $V_{x y}(x, y)$ so that

$$
\begin{equation*}
V(x, y)=V_{x}(x)+V_{y}(y)+V_{x y}(x, y) \tag{2}
\end{equation*}
$$

where $V_{x}(x)$ and $V_{y}(y)$ are polynomials chosen in a way that the two target locations, $(-1,1)$ and $(1,1)$, are attracting steady states ("attractors"), and the starting location $(0,0)$ is a repelling state of the system (1) given that $V_{x y}(x, y) \equiv 0$. Thus,

$$
\begin{gather*}
V_{x}(x)=\int \frac{\partial V_{x}}{\partial x} \mathrm{~d} x=\int x(x+1)(x-1) \mathrm{d} x=\frac{x^{4}}{4}-\frac{x^{2}}{2}  \tag{3}\\
V_{y}(y)=\int \frac{\partial V_{y}}{\partial y} \mathrm{~d} y=\int y(y-1) \mathrm{d} y=\frac{y^{3}}{3}-\frac{y^{2}}{2} \tag{4}
\end{gather*}
$$

Having a two-attractor decision landscape as a baseline, we introduce the parametrised polynomial component $V_{x y}(x, y)$ to be able to account for asymmetry in the landscape and other, more intricate properties of experimental trajectories. Here, also for the reason of simplicity, for $V_{x y}(x, y)$ we use a polynomial function of $x$ and $y$

$$
\begin{equation*}
V_{x y}(x, y)=\sum_{k=2}^{\alpha} \sum_{\substack{i, j>0 \\ i+j=k}} c_{i j} x^{i} y^{j} /(k-1), \tag{5}
\end{equation*}
$$

where the parameter $\alpha \geq 2$ determines the number of terms in the polynomial, which in turn regulates flexibility of the model, and the coefficients $c_{i j}$ are fitted to the data. Note that with increasing $\alpha$ the number of free parameters increases, thus the fitted values of these parameters may be difficult to interpret for large $\alpha$. We recommend using the method with $\alpha=2,3$, or 4 , depending on the complexity of the trajectories, and to take into account the trade-off between approximation accuracy and interpretability of the parameters.

The effect of the model parameters $\tau$ and $c_{i j}$ on the shape of the decision landscape can be analysed independently of the experimental data (Fig. 3). For any $\alpha$, two parameters always enter the model, $\tau$ and $c_{11}$. The parameter $\tau$ affects the characteristic time scale of the system motion: the larger the value of $\tau$, the slower the motion of the mouse generated by the model (in both directions). In what follows we use the baseline value $\tau=0.05 \mathrm{~s}$.

The parameter $c_{11}$, corresponding to the only second-order polynomial term of the model, is the primary determinant of the asymmetry of the decision landscape. Such asymmetry may be caused, for instance, by strong prevalence of one decision outcome over the other. Another possible example of asymmetry would be a situation when the trajectories towards one option are consistently faster compared to the trajectories pointing to the other option, with the two options being chosen equally likely.

When $\alpha \geq 3$, additional polynomial terms enter $V_{x, y}(x, y)$. The effects of the parameters $c_{i j}$ in front of these higher-order terms are somewhat similar to those of $\tau$ and $c_{11}$, but allow for much finer tuning of the decision landscape to the experimental trajectories.

## Fitting the model to the single trajectory

For a single experimental trajectory, we aim to find the parameters allowing the model (1)-(5) to reproduce this trajectory as closely as possible. We can define the fitting error in two ways: as a function of the positional difference between the data and the modelled trajectory, or based on the difference in mouse velocities between the data and the model. The first approach would result in a more accurate approximation of trajectories, but requires substantially more computational time, as on each step of the fitting algorithm the system of differential equations (1) has to be integrated numerically. The second approach, employing the velocity-based fitting error, is much more efficient in terms of computational resources, sometimes at the expense of approximation accuracy. Here we focus on the latter; the supplied source code implements both approaches.

Given an experimental mouse trajectory sampled at $m$ time steps and the numerically derived mouse velocities $\left\{v_{x}^{\text {data }}\right.$, $\left.v_{y}^{\text {data }}\right\}$, we define the fitting error

$$
\begin{align*}
& H\left(\tau, c_{i j},\left\{v_{x}^{\mathrm{data}}, v_{y}^{\mathrm{data}}\right\}\right)= \\
& \frac{1}{m} \sum_{i=0}^{m}\left(v_{x}^{\mathrm{model}}\left(x_{i}, y_{i}\right)-v_{x}^{\mathrm{data}}\left(t_{i}\right)\right)^{2}+\left(v_{y}^{\operatorname{model}}\left(x_{i}, y_{i}\right)-v_{y}^{\mathrm{data}}\left(t_{i}\right)\right) \tag{6}
\end{align*}
$$

where $v_{x, y}^{\text {model }}\left(x_{i}, y_{i}\right)$ are the values of the right-hand side of the system (1) computed at each point $\left(x_{i}, y_{i}\right)$ along the experimental trajectory. These values depend on the current parametrisation of the model, so the defined error function depends both on the model parameter values and the experimental trajectory.

Using numerical optimisation routines (available, e.g., in the Python package scipy.optimize), one can find the values of the model parameters $\tau, c_{i j}$ minimising function (6) for a given mouse trajectory. These parameters are substituted in Eq. (5), which, along with Eqs. (2)-(4), fully specifies $V(x, y)$. The 3D plot of the function $V(x, y) / \tau$ then visualises the decision landscape representing the original trajectory.

## Fitting to multiple trajectories

Visualising a decision landscape that would integrate the properties of multiple trials (within a single experimental condition, individual participant, or a group of participants) is where the method can prove most useful. To be able to do this, we use the same approach as in the case of a single trial, and minimise the average error across individual trials in a set of trials. Given the set of $N$ trajectories and their velocities $\left\{v_{x}^{\text {data }}, v_{y}^{\text {data }}\right\}_{n=1}^{N}$, the fitting error for multiple trajectories is defined by

$$
\begin{equation*}
\hat{H}\left(\tau, c_{i j},\left\{v_{x}^{\mathrm{data}}, v_{y}^{\mathrm{data}}\right\}_{n=1}^{N}\right)=\frac{1}{N} \sum_{n=1}^{N} H\left(\tau, c_{i j},\left\{v_{x}^{\mathrm{data}}, v_{y}^{\mathrm{data}}\right\}_{n}\right), \tag{7}
\end{equation*}
$$

where $H$ is defined in (6).

Figure 3: Changes in the baseline decision landscape depending on the parameters of the model for $\alpha=2$. In each panel, all parameters except for the one in the panel title are fixed at the baseline levels $\tau=0.05, c_{i, j}=0$; the baseline landscape is shown in grey colour. In this and the following figures, the black marble marks the starting location of a trial.

## Example scenarios

We illustrate several potential scenarios of using our method to visualise mouse tracking data by applying it to the previously obtained experimental data on a simple learning task (O'Hora et al., 2013). The task consisted of a series of binary choices between abstract symbols, with each symbol yielding either low or high reward (e.g., 5 or 20 points). The goal of the participants was to get as many points as possible throughout a set of 36 trials, which included low vs. low, high vs. low, and high vs. high choices. By the end of the experiment, most of the participants successfully learned to choose only the symbols associated with high reward.

Here we only consider part of the dataset corresponding to high vs. low choices, so that there is always a "correct" choice. The data are preprocessed so that the correct ("high") option is mapped to right-hand corner of the screen, and incorrect option is located in the left-hand corner. To fit the experimental data, we used the version of the model with $\alpha=4$, which has seven free parameters. The baseline values of the parameters were set to $\tau=0.05, c_{i j}=0$.

Fig. 4 shows the example decision landscapes obtained for three trajectories generated by Participant 444 . The shape of the fitted landscape changes depending on the dynamics of the decision. Two key properties of a mouse trajectory reflected by the fitted decision surface are: motion time, i.e., the how long it takes for the cursor to reach the response area once it leaves the starting location, and maximum deviation of the trajectory from the ideal, straight-line trajectory (termed "max-d").

Importantly, the decision landscape is supposed to capture dynamics rather than geometry of the mouse trajectory. However, with increasing deviation of the trajectory towards unchosen option, the strength of the attractor corresponding to that option increases. Moreover, in extreme cases, when deviation towards competitor option is very large, the attractor representing the unchosen option can be even stronger than the attractor corresponding to the eventually chosen option (yellow surface in Fig. 4). This situation, paradoxically indicating that the attraction towards the unchosen option during

Figure 4: Decision landscapes of three representative trials of Participant 444. In all three trials, the subject had chosen the option on the right ("correct choice"). Trial 2 (yellow surface) was slow (motion time 0.72 s ) and mildly conflicted (max-d 0.23 ). In trial 15 (purple surface), the mouse trajectory was fast (motion time 0.15 s ) and was close to straight line (maxd 0.02). In trial 28 (green surface), the trajectory was still relatively fast (motion time 0.37 s ), but substantially curved towards the unchosen option (max-d 0.77).

Figure 5: Decision landscapes of the two representative participants. Participant 2 (blue surface) had chosen right- and left-hand-side options 7 times each (mean motion times 0.56 and 0.45 s). Red surface illustrates Participant 3 with the right-hand-side option chosen 3 times (mean motion time 0.5 s) and the left-hand-side option chosen 10 times (mean motion time 0.4 s ).
the trial was stronger than towards the chosen one, is very rare and happens only for landscapes of individual trajectories with high max-d.

One of the potential applications of the present method is highlighting individual differences between two participants performing the same task. To do this, one needs to obtain decision landscapes individually for each participant by fitting the model to all trials of that individual simultaneously. In the case of multiple-trajectory fitting, the fitting error is defined as the average error across all trajectories of a given participant, so the resulting decision landscape will integrate the information on how often and how fast each option was chosen, providing a comprehensive overview of the participant's decisions throughout the experiment.

We illustrate this by comparing the decision landscapes of the two participants (Fig. 5). Participant 2 was equally likely to chose either option, with faster trajectories reaching towards the incorrect (left-hand-side) option. Participant 3 had chosen the incorrect (left) response more often, and it was chosen on average faster than the correct option.

If the experimental task involves adaptation, the current method can be used to highlight learning patterns within subjects. Fig. 6 represents three decision landscapes separately fitted to the trajectories of three consecutive blocks of trials of Participant 4 (with each block containing six to eight trials). The decision surface gradually changes from the twoattractor landscape slightly favouring the right attractor to the single-attractor configuration, thereby tracking the learninginduced evolution of preference across blocks.

## Discussion

The decision landscape visualisations provide comprehensive overview of a mouse-tracking data. Each visualisation integrates the information on 1) the likelihood of each option to

Figure 6: Evolution of decisions of Participant 4 throughout three consecutive blocks of trials. Each surface corresponds to all trials of a block.
be chosen, 2) the duration of the response, and 3) the degree of competition between the options.

The first attempt to develop an algorithm to visualise decision landscapes based on mouse tracking data has been recently made by O'Hora et al. (2013). Their approach, however, is purely data-driven, and thus requires hundreds of trajectories to generate a reliable visualisation of the decision surface. By incorporating prior assumptions about decision landscape $V(x, y)$ into a parametrised model, we dramatically reduce the data requirements of our method. As demonstrated above, the method proposed here can be used with as few trajectories as one, but can also incorporate arbitrary number of trajectories.

One of the main limitations of the proposed method is its focus on trajectories without changes-of-mind. An important (although relatively rare) class of decisions are those involving preference reversals during choice execution. These happen even in simple perceptual discrimination tasks (Resulaj et al., 2009); in more cognitively demanding tasks the frequency of changes-of-mind can increase up to $20 \%$ (Freeman, 2014). Developing a way of visualising decision landscapes of the change-of-mind trajectories is one of our foremost future research directions.

Attractor models have proved useful in understanding outcomes of cognitive processes such as categorisation (Tuller, Case, Ding, \& Kelso, 1994), risky decision making (van Rooij, Favela, Malone, \& Richardson, 2013), and binary decision making in intermittent motor control (Zgonnikov \& Lubashevsky, 2015). This work is among the first attempts to apply the concepts of dynamical systems theory to process data characterising decisions. We hope that the proposed decision landscape visualisation approach will eventually grow in a new tool for analysing decision trajectories, which will be able to provide new insights into dynamics of decision making.

#### Abstract

Insomniacs were found to have compromised perception of facial expressions. Through eye movement examinations, here we test the hypothesis that this effect is due to impaired visual attention functions for retrieving diagnostic features in facial expression judgments. 23 individuals with insomnia symptoms and 23 non-insomniac controls completed a task to categorize happy, sad, fearful, and angry faces. The insomniacs were less accurate to recognize angry faces and made more "fearful" mistakes than controls. A hidden Markov modeling approach for eye movement data analysis revealed that when recognizing angry faces, more insomniacs adopted an eye movement pattern focusing on the mouth while more controls adopted a pattern attending to both the eyes and the mouth. This result is consistent with previous findings that the primary diagnostic feature for recognizing angry faces is the eyes suggesting that impaired information selection through visual attention control may account for the compromised emotion perception in insomniac individuals.

Keywords: insomnia; eye-tracking; hidden Markov model; facial expression

## Introduction

Insomnia is closely related to emotional disorders such as anxiety and depression (see Baglioni et al., 2010 for a review). In particular, compromised perception of emotional facial expressions, which has an important role in one's socioemotional functioning, has been frequently found among sleep-deprived individuals or those with insomnia symptoms. For example, individuals with physiological insomnia were found to perceive fearful and sad faces as less emotional compared with good sleepers (Kyle et al., 2014). Another study found that 31.5 -hour sleep deprivation led to less accurate recognition of sad faces (Cote et al., 2014). In addition, an fMRI study found that sleep deprivation made participants more likely to classify facial expressions as angry, and this effect was coupled with their diminished neural discrimination between threatening and non-threatening stimuli (in the anterior cingulate and anterior insula; Goldstein-Piekarski et al., 2015). Nevertheless, the underlying mechanism for the disturbed perception of emotional facial expressions among insomniacs remains unclear (Kyle et al., 2014).

In addition to emotional functioning, insomniacs and sleep-deprived individuals are commonly found to have impaired performance in visuospatial attention tasks
(Marchetti et al., 2006), and this behavioral impairment is associated with attenuated activation in the attention neural network comprising the prefrontal, parietal, and cingulate cortex (Tomasi et al., 2009; Mander et al., 2008). The impairment in the attention network may have a profound impact on cognitive performance in general, as it can significantly influence how task relevant information is selected. Indeed, attenuated activations in the attention network were reported to be associated with less explorative eye movement patterns and worse performance in face recognition (Chan et al., 2016). It is thus possible that insomniac individuals adopt different eye movement patterns from good sleepers in emotional facial expression judgments as a result of their impaired visual attention control, leading to compromised recognition performance.

Here we aim to investigate the role of visual attention functions in accounting for insomniacs' compromised identification of emotional facial expressions through eye tracking. Individuals with insomnia symptoms and noninsomniac controls completed an emotional facial expression judgement task in which they were required to recognize emotional facial expressions and rate the emotional intensity with eye tracking. Recent studies have suggested four basic facial expressions that are recognized across cultures: 'happy', 'sad', 'fear' and 'anger' (Jack et al., 2016). Accordingly, here we examine participants' perception of these four facial expressions. Previous research did not consistently find disturbed perception of a particular facial expression in sleep-deprived or insomniac individuals. However, most of the expressions reported to be affected were negative expressions (e.g., sadness in Cote et al., 2014; anger in Goldstein-Piekarski et al., 2015; sadness and fear in Kyle et al., 2014). Thus, here we hypothesize that insomniac individuals may be less accurate in recognizing the negative facial expressions than noninsomniac controls, and that this behavioral difference may be associated with differences in eye movement patterns adopted by the two groups.

While eye movements are important measures for visual attention functions, recent studies have reported substantial individual differences in eye movements in visual tasks (e.g. Kanan et al., 2015), which were not adequately reflected in most of the current analysis methods. In view of this, Chuk, Chan, and Hsiao (2014) have recently proposed a Hidden

Markov Model (HMM, a type of time-series probabilistic model in machine learning) based approach for analyzing eye movement data. This approach assumes that the current eye fixation during a task is conditioned on previous fixations. Thus, eye movements in the task can be considered a Markov process, which can be better understood using HMM. In this approach, each individual's eye movements are modeled with an HMM, including both person-specific regions of interests (ROIs) and transitions among the ROIs. Thus, it reflects individual differences in both spatial and temporal dimensions of eye movements. Individual HMMs can be clustered to discover common patterns among individuals (Coviello, Chan, \& Lanckriet, 2014), and similarities between individual eye movement patterns can be quantitatively assessed by calculating the likelihoods of the patterns being generated by a given HMM. Thus, this approach is especially suitable for examining the relationship between eye movement patterns and other outcome measures such as task performance (e.g., Chuk, Chan, \& Hsiao, in press). Here we aim to apply this method to examine the relationship among insomnia, eye movements, and performance in facial expression categorization. We hypothesize that there may be more insomniac individuals adopting an eye movement pattern that overlooks diagnostic features for the negative facial expressions than non-insomniac controls, and participants' likelihoods of adopting this pattern may be associated with their performance in recognizing the negative expressions.

## Methods

## Participants

23 individuals with insomnia symptoms and 23 noninsomniac controls classified by the Sleep Condition Indicator (SCI, Espie et al., 2014) were recruited (Table 1). The SCI consists of 8 items concerning an individual's sleep condition during the recent month in a 0-4 Likert-style scale. The Chinese SCI has been validated and recommended as a screening tool for clinical insomnia with an original cut-off at 21/22 (Wong et al., 2017). To increase the contrast between the two groups, individuals with SCI scores $\leq 19$ were classified as individuals with insomnia symptoms, and those with SCI scores $\geq 24$ were classified as non-insomnia controls. Participants in the two groups were individually matched in gender and age. They were ethnically Chinese from Hong Kong and right-handed (Edinburgh Handedness Inventory, EHI; Oldfield, 1971). They had normal or corrected-to-normal vision and no history of head trauma or psychiatric conditions.

## Design \& Procedures

Participants completed an emotional facial expression judgment task adapted from Kyle et al. (2014), which required participants to categorize and rate emotional intensity of 4 facial expressions (i.e. happiness, sadness, fear, and anger; Figure 1A). The task consisted of 2 blocks with 40 trials in each block ( 10 trials for each expression). In each trial, a solid dot first appeared at the screen center for drift correction, and it was replaced by a fixation cross for 500 ms . Once a fixation was detected at the cross at the end of the 500 ms , a color picture of an Asian individual's face with an emotional facial expression (Figure 1B; 450 x 600 pixels) was presented either above or below the center of the screen until the participants categorized it as a happy, sad, fearful, or angry face by pressing corresponding buttons. Participants were asked to respond as quickly as possible. After a $250-\mathrm{ms}$ pause, they were asked to rate the emotional intensity of the facial expression on a 6-point scale, ranging from " 1 -not very intense" to " 6 -extremely intense". Half of the face images were male faces; the faces spanned around $8^{\circ}$ of visual angle at the viewing distance of 60 cm (Hsiao \& Cottrell, 2008). The participants had a practice of 24 trials at the beginning of the task.

Participants' eye movements were recorded by an EyeLink 1000 eye tracker. The standard 9-point calibration procedure was used at the beginning of each block and was repeated whenever the drift-correction error was larger than $1^{\circ}$ of visual angle. The tracking mode was pupil and corneal reflection and the sampling rate was 2000 Hz . A chinrest was used during the task to reduce head movements.

Figure 1. (A) A demonstration of a trial with an angry face. (B) The average pictures of the 20 stimuli used in each emotional expression. From left to right: happiness, sadness, fear, anger.

The eye movement data were analyzed using the EMHMM (Eye Movement analysis with Hidden Markov Models, http://visal.cs.cityu.edu.hk/research/emhmm/; Chuk et al., 2014) approach. Each participant's eye movements while viewing one type of facial expressions was summarized with an HMM. The optimal number of ROIs for each model was determined automatically through a variational Bayesian approach, by selecting the model with the highest marginal likelihood. For each facial expression, we clustered all individual HMMs into 2 groups to reveal common patterns. We then examined the distributions of the insomniacs and the controls in the 2 common patterns, and
the correlations between their likelihoods of adopting each pattern and behavioural performances.

## Results

## Behavioral results

A 2 (group: insomnia vs. control) by 4 (emotion: happy, sad, fearful and angry) repeated measures ANOVA revealed a significant interaction between group and emotion on the accuracy of the facial expression judgment task, $F(3,132)=$ 2.68, $p=.049, \eta^{2}=.057$. Independent t -tests between the insomnia and the control group in each emotion condition indicated that there was $8.4 \%$ higher accuracy on average to recognize angry faces in the control group than the insomnia group, $t(44)=2.12, p=.039, d=.63$ (Figure 2A). This group difference was not found in other emotion conditions, $p s>.05$. When we examined the responses participants made towards angry faces (Figure 2B), the 2 by 4 repeated measures ANOVA indicated a significant interaction between group and emotion, $F(3,132)=3.57, p=.016, \eta^{2}=$ .075. Post-hoc between-group t-tests showed a significantly higher percentage of "fearful" responses in the insomnia group than the control group, $t(44)=2.07, p=.045, d=.62$.

Figure 2. (A) The accuracy to categorize happy, sad, fearful, and angry facial emotions in the control and the insomnia group. (B) Reponses made while angry faces were presented. (C) Response time to accurately categorize emotional facial expressions. (D) Emotional intensity rating of the 4 facial emotions in the two groups. (* $p<.05 ; \dagger .05<p<.10$; error bars: 1 s.e.m.)

In the correct response time (RT) data (Figure 2C), a 2 (group) by 4 (emotion) repeated measures ANOVA indicated a main effect of emotion (adjusted post-hoc comparisons: happy < sad, fear, and anger), $F(3,132)=$ 40.72, $p<.001, \eta^{2}=.48$. This effect did not interact with group. When we examined the difference between the two groups in categorizing different expressions separately, the insomnia group responded marginally slower in identifying angry faces than the control group, $t(44)=1.768, p=.084, d$ $=.53$. The group by emotion repeated measures ANOVA on
emotional intensity rating showed a main effect of emotion (adjusted post-hoc comparisons: fearful > happy, angry > sad; Figure 2D), $F(3,132)=23.24, p<.001, \eta^{2}=.35$. However, this effect did not interact with group.

## Eye movement data

We modeled each participant's eye movements for viewing each type of facial expressions with an HMM. For each expression type, we clustered all participants' HMMs into 2 representative patterns and examined the distributions of the insomniacs and controls adopting the 2 patterns. We observed that the insomnia and control groups differed significantly in their frequencies of adopting the 2 representative patterns when viewing angry faces. Consistent with our behavioral data, this difference was not observed in viewing other expressions ${ }^{1}$. Figure 3A and 3B show the 2 representative patterns. The 3 ROIs were in red, green, and blue respectively and the table showed the priors (the probability of the first fixation being located at an ROI) of the ROIs and the transition probabilities among them. In the eye-mouth pattern (Pattern 1; $n=21$ ), the first fixation was most likely to be in eye region (red ROI, $47 \%$ ) or the mouth region (blue ROI, 42\%). The next fixation from the eye ROI had a high probability to stay in the same (eye) ROI, whereas the next fixation from the mouth ROI had a $26 \%$ probability to move to the eye region. Thus, participants adopting this pattern focused the most on the eye region, followed by the mouth region, while viewing angry faces. In the nose-mouth pattern (Pattern 2; $n=25$ ), the first fixation was most likely to be at the nose/face center (red ROI, $46 \%$ ) or the mouth and chin region (green ROI, $42 \%$ ). The next fixation following the first was most likely to stay in the same ROI as the first fixation (> 99\%), suggesting few transitions among the ROIs. Thus, participants adopting this pattern tended to focus on the lower part of the face (nose, mouth and chin) but neglect the eye region. Figure 3C shows the difference heat map between the two patterns: the eye-mouth pattern had more fixations on the right eye region (warm colors) while the nose-mouth pattern had more fixations on the mouth and chin regions (cold colors). This clear separation of the eye movement patterns demonstrated well the power of machine learning methods.

Importantly, significantly more insomniacs adopted the nose-mouth eye movement pattern, and more controls adopted the eye-mouth pattern (Figure 3D), $\chi^{2}(1)=4.29, p=$ .038. In addition, insomniacs' eye movement patterns had higher similarities to the nose-mouth pattern than those from controls, $t(44)=-2.37, p=.022, d=.713$, as measured in the log-likelihoods of their eye movement patterns being generated by the HMM of the nose-moth pattern. In contrast, there was no significant difference in the similarity of eye movement patterns to the eye-mouth pattern between insomniacs and controls, $p>.05$.

Figure 3. (A and B) The eye-mouth and nose-mouth representative eye movement patterns for viewing angry faces as the result of clustering. Images from left to right: 3 ROIs, actual assignments of the fixations to the ROIs, and heat map of eye fixations. The tables contain the priors and transition probabilities of the ROIs. (C) Difference map of actual fixations between the two patterns. (D) Distribution of the eye-mouth (Pattern 1) and nose-mouth (Pattern 2) patterns in the insomnia group and the control group.

To demonstrate the advantage of using the EMHMM approach to reveal these differences, we plotted the heat maps of the fixations of the insomnia and control groups and the difference map between them (Caldara \& Miellet, 2011). As can be seen in Figure 4 difference map, the significantly different areas (circled in white) were scattered and not easily interpretable. This phenomenon was due to significant individual differences in eye movement patterns within each group. The EMHMM approach allows us to identify the eye-mouth and nose-mouth patterns in a data driven fashion and clearly reveal the difference between the two participant groups while accounting for individual differences in eye movement patterns.

When we examined the relationship between eye movement patterns and performances in the facial expression judgment task, we found that the log-likelihood of participants' patterns being classified as the nose-mouth pattern was positively correlated the percentage of "fearful"
responses (Figure 5A), $r=.423, p=.003^{2}$ : the more similar the pattern to the nose-mouth pattern when viewing angry faces, the more "fearful" mistakes made. In addition, in the control group, the log-likelihood of being classified as the eye-mouth pattern was negatively correlated with the correct RT of identifying angry faces (Figure 5B), $r=-.451, p$ $=.031$ : the more similar the pattern to the eye-mouth pattern, the faster the correct RT. This correlation was not significant in the insomnia group, $p>.05$.

Figure 4. Fixation heat maps of the control and insomnia group and the difference map between the two groups. The areas surrounded by white contours showed significant differences. Warm colors: control > insomnia; cold colors: insomnia > control.

## Discussion

In the current study, we aim to test the hypothesis that the compromised perception of emotional facial expressions in insomniacs is related to impaired visual attention functions for selecting diagnostic features as revealed in their eye movements. Our results showed that individuals with insomnia symptoms were less accurate and marginally slower to identify angry faces than non-insomniac controls. Furthermore, insomniacs tended to misidentify angry faces as fearful faces more often than controls. Through the EMHMM approach (Chuk et al., 2014), we discovered two common eye movement patterns among the participants when viewing angry faces: an eye-mouth pattern that looked at the eyes and mouth primarily, and a nose-mouth pattern that fixated at either the nose or the mouth/chin region. Significantly more controls adopted the eye-mouth pattern and more insomniacs adopted the nose-mouth pattern. Indeed, the eye-mouth pattern was associated with faster identification of angry faces in the control group, whereas the nose-mouth pattern was associated with more misidentification of angry faces as fearful faces. These results suggest that insomniacs misidentified angry faces as fearful faces because of missing the eyes. The EMHMM approach is a data-driven method that reflects individual differences in both spatial and temporal dimensions of eye movements and provides quantitative assessments of

[^256]similarities among individual eye movement patterns, making it possible to reveal these effects. These findings were not possible with traditional approaches to eye movement data analysis such as using predefined regions of interest (ROIs; Henderson et al., 2005) or fixation heat maps (iMap, Caldara \& Miellet, 2011) between the insomniacs and the controls (Figure 3 vs. Figure 4).

Figure 5. (A) A positive correlation between the log-likelihood of being the nose-mouth pattern and the "fearful" response rate among all participants. (B) A negative correlation between the loglikelihood of being the eye-mouth pattern and the RT to identify angry faces in the control group.

Our finding is consistent with previous studies suggesting that insomnia and sleep loss are associated with compromised recognition of emotional facial expressions (e.g. Kyle et al., 2014; Cote et al., 2014). In particular, in an fMRI study, Goldstein-Piekarski and colleagues (2015) found that experimental sleep deprivation impaired behavioral and neural discrimination of angry faces from neutral faces. Angry facial emotions signal social threats, and thus misidentification or slower identification of angry faces may elevate interpersonal conflicts of insomniac individuals. Interestingly, insomniacs were more likely to misidentify angry faces as fearful faces than controls, suggesting that they may misidentify social threats senders as social threats receivers.

The misidentification of facial anger as facial fear in insomniacs corresponds to their eye movement patterns. Most of the insomniacs adopted a pattern that focused on either the nose or the mouth while missing the eye region. In contrast, most controls adopted a pattern that looked at mainly the eye region or both the eye and the mouth region.

The finding that insomniacs missed the eye region may be related to their impaired perception of angry faces. Indeed, through the 'Bubbles' reverse-correlation technique, Smith, Cottrell, Gosselin, and Schyns (2005) showed that eyes are the most diagnostic feature for recognizing angry expressions, whereas the most diagnostic features for recognizing the other three expressions (i.e. 'happy', 'sad', and 'fearful') were either mainly on the mouth region or comprised both the mouth and the eyes (see also Schyns, Petro, \& Smith, 2009). Consistent with this finding, Eisenbarth and Alpers (2011) showed that participants looked at the eyes longer than the mouth in recognizing anger and sad expressions, the mouth longer than the eyes for happy expressions, and the mouth and the eyes equally for fear and neural expressions. The exclusive importance of the eye region for recognizing angry faces may explain why we only observed behavioral differences between insomniacs and controls in identifying angry faces, since identifying other expressions do not require specific attention to the eye region as much as identifying angry expressions.

In the literature, biased interpretation of emotional information after sleep loss has typically been attributed to impaired functioning of limbic structures such as amygdala and anterior cingulate cortex and the functional connectivity between the prefrontal cortex and these limbic structures towards emotional stimuli (e.g., Yoo et al., 2007; GoldsteinPiekarski et al., 2015). In addition to this emotional brain network, the current study suggests that impaired attentional functioning may also play an important role in accounting for the misinterpretation of emotional information after sleep loss. Indeed, sleep loss is shown to affect visual attention control and activation in the attention brain network (Tomasi et al., 2009; Mander et al., 2008). Decreased activations in the attention brain network (e.g., the frontal eye field and intraparietal sulcus) are associated with maladaptive eye movement patterns and impaired recognition performance during face viewing (Chan et al., 2016). Impaired visual attention functions may cause failure of selecting diagnostic information for emotional face perception, leading to biased interpretation of emotional information. Our finding is consistent with Cote et al.'s (2014) study, which showed that impaired facial expression identification in sleep-deprived individuals was reflected in early visual ERP components including P1 and N170.

While the current study showed impaired recognition of angry expressions but not other expressions in insomniacs, some previous studies have reported disturbed perception of sad and fearful faces in addition to angry faces (e.g., Kyle et al., 2014). Cote et al. (2014) showed that altered early visual ERP responses due to sleep deprivation were observed for all expressions, whereas difference in identification accuracy between sleep deprived individuals and controls was only observed in sad faces. This effect suggests that while the modulation of sleep loss in attentional functioning may apply to all expressions in general, whether it results in decreased identification accuracy may depend on how it affects selection of diagnostic features, since different facial expressions differ in their diagnostic features (Schyns et al.,
2009). There may be individual differences in how features are selected and used for identification; individual differences in emotional functioning may also play a role. Future work will examine these possibilities.

In conclusion, here we showed that insomniacs misrecognized angry expressions because of missing diagnostic features in the eye region. This effect suggests that the impaired perception of facial expressions after sleep loss may be due to diminished visual attention control in addition to impaired emotional functioning. To our knowledge, this is the first to report the role of eye movement in the biased perception of emotional information due to sleep loss. Future studies will examine eye movements in clinical insomnia samples and sleep-deprived individuals to further examine the role of visual attention control in emotional perception after sleep loss.

#### Abstract

The study of multi-cue judgment investigates how decision makers integrate cues to predict the value of a criterion variable. We consider a multi-cue judgment task in which decision makers have prior knowledge of inter-cue relationships but are ignorant of how the cues correlate with the criterion. In this setting, a naive judgment strategy prescribes an equal weight for each cue. However, we find that many participants appear to use a weighting scheme based on a low-dimensional representation of the cue space. The use of such a representation is consistent with core insights in semantic memory research and has important optimality properties concerning judgment accuracy.

Keywords: judgment and decision making; cue integration; improper linear models; dimensionality reduction; semantic memory

## Introduction

Effective judgment and decision making involves the aggregation of multiple cues, or pieces of information, to evaluate a criterion variable. For example, individuals may receive advice from two or more friends regarding a financial investment, and aggregate this advice to calculate the expected return on the investment. Alternatively, they may have to choose between job candidates with multiple attributes, and have to aggregate these attributes to determine the quality of the candidates.

Traditionally, many normative and descriptive models of judgment and decision making adopt a linear approach and propose that decision makers compute the value of the criterion using a weighted average of the cues, with the weights being proportional to the observed relationship between the cues and the criterion (Brunswik, 1952; Keeney \& Raiffa, 1993). Linear models are often criticized as they require large amounts of information and abundant cognitive resources in order to be accurate. Thus, many researchers have proposed that individuals use improper linear models, such as heuristics. These models involve a fixed weighting scheme that assigns a priori weights to the cues. For example, an equal weights model gives each cue
the same weight, and the lexicographic model assigns all the weight to a single cue (Dawes, 1979; Gigerenzer \& Todd 1996). These models have been shown to perform as well as, if not better than, proper linear models in many situations, ranging from graduate student admission to clinical predictions (Dawes, 1979).
In addition to being cognitively simpler, improper linear models can also be used in situations where proper linear models are inapplicable. Consider settings where the relationship between the cues and the criterion is completely unknown. For example, individuals using the advice of their friends to judge an investment may not have previously observed how well their friends predict the performance of such investments. Likewise, individuals evaluating job candidates for novel or unconventional jobs may have never observed the value of different candidate attributes in the context of these jobs. In these situations, decision makers may have detailed knowledge about the relationship between the cues (e.g. how often their friends agree with each other or how frequently job candidate attributes co-occur) but have no way to assign weights to the cues in accordance with the standard linear model (where weights depend on the cues' relationship with the criterion). However, an a priori weighting scheme, as proposed by improper linear models, can still be used to make an evaluation.
For multi-cue judgment with known inter-cue relationships, but unknown cue-criterion relationships, the key questions of interest are the following: Which improper weighting scheme should decision makers use and which schemes do decision makers use. The former question has been tackled by Davis-Stober, Dana \& Budescu (2010a, 2010b). Davis-Sober et al. propose that any possible weighting scheme, $\boldsymbol{\beta}$, can be assessed with regards to how far it deviates from the true weight vector, $\boldsymbol{\beta}^{*}$, by taking the sum of squared difference between the weights in $\boldsymbol{\beta}$ and $\boldsymbol{\beta}^{*}$, i.e. $\sum_{i}\left(\beta_{i}-\beta_{i}{ }^{*}\right)^{2}$. When the cuecriterion relationships are unknown, $\boldsymbol{\beta}^{*}$ is also unknown. In these settings optimizing $\boldsymbol{\beta}$ can be seen as involving minimizing the risk, defined as the expectation of sum of squared error of $\boldsymbol{\beta}, \Sigma_{i}\left(\beta_{i}-\beta_{i}{ }^{*}\right)^{2}$. By this standard, the best improper linear weighting scheme is the eigenvector
corresponding to the first (i.e. largest) eigenvalue of the inter-cue correlation matrix (see Davis-Stober et al. 2010 for details). We will refer to this weighting scheme as $\boldsymbol{\beta}_{\boldsymbol{E V 1} 1}$. Here $E V 1$ in the subscript refers to the use of the eigenvector corresponding to the first eigenvalue.
$\boldsymbol{\beta}_{\boldsymbol{E V} \boldsymbol{1}}$ depends on the relationship between the cues in the judgment task, and can be shown, in appropriate settings, to approximate other existing improper linear models. For example, if the cues are equally, and positively, correlated with each other, $\boldsymbol{\beta}_{\boldsymbol{E V} \mathbf{1}}$ assigns an equal weight to each cue, similar to the equal weights model. In contrast, if cue 1 is highly correlated with all the other cues, and all the other cues are moderately correlated or uncorrelated internally, $\boldsymbol{\beta}_{\boldsymbol{E V} \mathbf{1}}$ overweighs cue 1 relative to other cues. This can mimic a lexicographic judgment strategy.

Normative solutions aside, descriptively, which weighting scheme do decision makers actually use when integrating multiple cues with unknown cue-criterion relationships? A first guess involves an equal weights model: Without knowing which cues are more related to the criterion than others, it seems conceivable that decision makers assign the same weights to all the available cues. This corresponds to a type of ignorance prior. However, a more principled guess could rely on insights regarding semantic representation. Decision makers with prior experience with the cues may have learnt mental representations of the cues. These representations, in many settings, correspond to projections of the decision makers' experiences with the cues onto a low-dimensional space. Such projections can be approximated by a principle components analysis on the cue-correlation matrix, or equivalently, a singular value decomposition on the matrix of cue-context co-occurrence. Indeed, such a decomposition is a key component of numerous existing approaches to modelling semantic representation, including latent semantic analysis (Landauer \& Dumais, 1997), multi-dimensional scaling (Kruskal \& Wish, 1978), and neural network models of semantic memory (Saxe, McClelland \& Ganguli, 2013). Interestingly, such a decomposition also yields the normative $\boldsymbol{\beta}_{\boldsymbol{E V} \mathbf{1}}$ model when only the first latent dimension of the projection is used to evaluate the criterion.

The goal of this paper is to investigate the plausibility of the $\boldsymbol{\beta}_{\boldsymbol{E V 1}}$ weighting scheme, and to compare its ability to predict participant judgments with alternate improper linear models such as the equal weights rule and the lexicographic rule. To appropriately test these models, we examine settings where participants have prior knowledge of inter-cue correlations but do not know how the different cues correlate with the criterion in consideration. Additionally, we systematically vary the cue-correlation matrix, and subsequently $\boldsymbol{\beta}_{E V \mathbf{1}}$, in order to adequately differentiate the predictions of this weighting scheme from those of alternate weighting schemes in our studies. We demonstrate the applicability of $\boldsymbol{\beta}_{\boldsymbol{E V} \mathbf{1}}$ for describing participant behavior in two ways: 1) by examining the model fits for $\boldsymbol{\beta}_{\boldsymbol{E V} \mathbf{1}}$ relative to other improper linear models, and 2 ) by testing whether the weights assigned by
$\boldsymbol{\beta}_{\boldsymbol{E V 1}}$ predict decision makers' use of these other improper models.

## General Method

In our three studies, the multi-cue judgment task was presented as an advice integration task, with the cues in consideration corresponding to the judgments of four advisors (similar to Bröder, 2003). They were described as predicted stock prices in Studies 1 and 2 and restaurant ratings in Study 3. Correspondingly, the criterion was the true stock price in Studies 1 and 2 and the true restaurant quality in Study 3. The cue-criterion correlations were never revealed to the participants.
The studies consisted of three tasks. The first two tasks exposed the participants to the cues, so as to allow them to form mental representations of the cue space. The third task asked participants to predict the criterion value based on the cues. In addition to being stated numerically, cue values in the three tasks were also shaded based on their magnitude. Participants were told that the cue values ranged from $0-100$ and were all centered at 50 . They were also told that some cues (advisors) might be more similar to each other, and that it was useful to pay attention to how closely different cues agreed with each other.

Figure 1. Stimuli display for Task 1-3.

In task 1, participants saw the four cues in 25 trials (Figure 1: upper left) displayed in four boxes. Each trial presented a set of cue values, and participants were asked to merely observe the cue values, without providing a response. In task 2, participants continued to learn the cue values, this time with feedback. Particularly, only three of the four cues were shown to participants (Figure 1: lower left). Participants had to guess the value of the fourth cue based on their knowledge of the inter-cue relationships. After the participant's guess, the real cue value was revealed. To increase motivation, participants were provided with a summary of their performance accuracy after every 50 trials. The cue to be guessed was determined at random in each trial.
In task 3, participants were shown all four cue values, and were asked to make a guess regarding the value of the
criterion (real stock price for Studies 1 and 2 and actual restaurant quality for Study 3; Figure 1: right). The true value of the criterion was not revealed after participants’ guesses, so that participants stayed uninformed regarding the cue-criterion relationship. Task 3 was the most relevant to our research question, as it provided a direct test of how cue values were integrated to make a judgment of the criterion.

## Study 1

Study 1 examines the predictions of the $\boldsymbol{\beta}_{\boldsymbol{E V} \mathbf{1}}$ weighting rule by considering a setting in which inter-cue relationships lead to a larger weight on one cue and smaller weights on the remaining cues.

## Methods

44 participants ( 37 females; Mean Age $=19.7$, SD Age $=$ 1.2), recruited from a university experimental participation pool, completed this study in a behavioral laboratory.

The study involved a hypothetical stock prediction task. The cue values were stock prices predicted by four advisors. For each cue, the values were normally distributed, with a mean of 50 and a standard deviation of 25. The inter-cue correlation matrix of the advisors is shown in Figure 2a.

Figure 2 (a) Inter-cue correlation matrix for Study 1 and the treatment condition of Study 2. (b) Inter-cue correlation matrix for the control condition of Study 2. (c) Inter-cue correlation matrix for Study 3.

As can be seen in this matrix, cue 1 is highly correlated with all the three other cues, with a correlation coefficient of 0.6 . The internal correlation among the remaining cues is very weak, with a correlation coefficient of 0.05 . The eigenvector corresponding to the first (largest) eigenvalue of the cue correlation matrix is $\boldsymbol{\beta}_{\boldsymbol{E V} \mathbf{1}}=[0.35,0.22,0.22$, 0.22 ]. Using this weighting vector, leads to an overweighting of cue 1 , and a relative underweighting of the remaining cues.
We used the above distributions to generate a single set of stimuli for all participants, for tasks 1,2 and 3. For each participant, the display position for each of the four cues was randomly chosen at the beginning of the study and stayed unchanged for the entire session. In other words, the specific advisor (advisor A, B, C or D) associated with cue 1 , was counterbalanced.

## Results

We first examined participants' performance in task 2, where they used three cue values for guessing the remaining cue value. Our analysis of behavior in this task suggested that participants were able to successfully learn the underlying cue structure. Particularly they placed a higher weight on cue 1 relative to the other cues when predicting the remaining cues ( $p<0.001$ ). Due to space constraints we will not outline these results in more detail (they will be reported elsewhere).
We also investigated the weighting scheme used by participants when integrating cues to predict criterion values in task 3. For this purpose, we considered a number of candidate weighting schemes, including $\boldsymbol{\beta}_{\boldsymbol{E V} \mathbf{1}}$ (corresponding to the first eigenvector of the cuecorrelation matrix) and $\boldsymbol{\beta}_{\boldsymbol{E W}}$ (corresponding to the equal weighting rule). We also considered lexicographic rules. Here, we tested four models that put all the weights on a single cue. These were referred to as $\boldsymbol{\beta}_{\text {LEX1 }}, \boldsymbol{\beta}_{\boldsymbol{L E X 2}}$, $\boldsymbol{\beta}_{\boldsymbol{L E X 3}}$ and $\boldsymbol{\beta}_{\boldsymbol{L E X 4}}$, corresponding to the cue that was given the unit weight. In addition to $\boldsymbol{\beta}_{\boldsymbol{E V} \mathbf{1}}$, we also considered the linear weighting schemes corresponding to the remaining three eigenvectors of the cue correlation matrix. These are referred to as $\boldsymbol{\beta}_{\boldsymbol{E V 2}}, \boldsymbol{\beta}_{\boldsymbol{E V} \mathbf{3}}$ and $\boldsymbol{\beta}_{\boldsymbol{E V 4} \mathbf{4}}$. Therefore, we have in total nine improper linear weighting schemes to compare. Each linear weighting scheme defined a weighting vector for the four cues. E.g. $\boldsymbol{\beta}_{\boldsymbol{E V} \mathbf{1}}=$ $[0.35,0.22,0.22,0.22], \boldsymbol{\beta}_{E W}=[0.25,025,0.25,0.25]$, $\boldsymbol{\beta}_{L E X 1}=[1,0,0,0]$, etc. For comparability, the weights in each scheme were constrained to add up to one.

In order to scale the criterion estimate generated by these improper linear models to match the participants' guesses, we introduced two additional participant-level parameters, $\alpha_{0}$ and $\alpha_{1}$, so that the predicted guess for each weighting scheme was $\alpha_{0}+\alpha_{1} \boldsymbol{\beta} \cdot \boldsymbol{C}$. Here $\boldsymbol{\beta}$ corresponds to the weighting vector of the model in consideration, and $\boldsymbol{C}$ is the vector of cue values presented in the trial. We also assumed a normally distribute error, with standard deviation $\sigma$, and subsequently fit each of these nine models by maximizing log-likelihood. $\alpha_{0}, \alpha_{1}$ and $\sigma$ were allowed to vary across the nine models. The model fitting was done on the participant level. Because the linear weighting schemes were pre-determined, each model used same number of parameters ( 3 parameters: $\alpha_{0}, \alpha_{1}$ and $\sigma$ ) to predict each participant's 100 guesses in task 3 .
We compared participant level log likelihood values for the nine candidate models (Table 1). Since all models have the same number of parameters, our model comparison is equivalent to model selection by AIC. Among 44 participants, 10 participants' predictions were best described by $\boldsymbol{\beta}_{\boldsymbol{E V} \mathbf{1}}, 23$ by $\boldsymbol{\beta}_{\boldsymbol{E W}}, 8$ by $\boldsymbol{\beta}_{\boldsymbol{L E X} \mathbf{1}}, 1$ by $\boldsymbol{\beta}_{\boldsymbol{E V \mathbf { 2 }}}$, 1 by $\boldsymbol{\beta}_{\boldsymbol{E V} \mathbf{3}}$, and 1 by $\boldsymbol{\beta}_{\boldsymbol{L E X 4}}$. When comparing only $\boldsymbol{\beta}_{\boldsymbol{E V} \mathbf{1}}$ and $\boldsymbol{\beta}_{\boldsymbol{E W}}, 19$ participants were better described by $\boldsymbol{\beta}_{\boldsymbol{E V} \mathbf{1}}$, whereas 25 were better described by $\boldsymbol{\beta}_{\boldsymbol{E W}}$. According to a paired Wilcoxon test on participant level model fits, there was no significant difference between log likelihood values of the $\boldsymbol{\beta}_{\boldsymbol{E V} \mathbf{1}}$ model (Median $=-351.38$ ) and the $\boldsymbol{\beta}_{E W}$ model (Median $=-351.59$ ), $Z=1.24, p=0.216$. Paired Wilcoxon tests also indicated that fits for all of the
remaining models were significantly worse than those for the $\boldsymbol{\beta}_{\boldsymbol{E V} \boldsymbol{1}}$ model and $\boldsymbol{\beta}_{\boldsymbol{E W}}$ model $(p<0.001)$.

Table 1: Comparison of model fits for Study 1

|  | Parameter (Median) |  |  | Log Likelihood |  |  |
| :--- | :---: | :---: | :---: | :---: | :---: | :---: |
| Model | $\alpha_{0}$ | $\alpha_{1}$ | $\sigma$ | Median | Mean | \# best |
| EV1 | 7.32 | 0.84 | 8.57 | -351.38 | -357.16 | 10 |
| EV2 | 49.92 | 0.02 | 18.66 | -424.01 | -420.56 | 1 |
| EV3 | 49.96 | 0 | 18.63 | -423.86 | -420.64 | 1 |
| EV4 | 45.37 | 0.32 | 18.63 | -424.05 | -420.6 | 0 |
| EW | 4.94 | 0.89 | 8.56 | -351.59 | -357.10 | 23 |
| LEX1 | 17.94 | 0.63 | 8.76 | -351.39 | -358.54 | 8 |
| LEX2 | 29.81 | 0.37 | 15.83 | -408.81 | -406.45 | 0 |
| LEX3 | 32.17 | 0.38 | 15.95 | -410.32 | -407.24 | 0 |
| LEX4 | 29.7 | 0.39 | 15.58 | -408.7 | -405.83 | 1 |

Although participants had no information regarding the validities of any cues, a substantial subgroup of participants did not simply assign equal weights to cues. Instead, they overweighed cue 1 as predicted by $\boldsymbol{\beta}_{\boldsymbol{E V} \mathbf{1}}$. The fact that some participants were actually best fit by $\boldsymbol{\beta}_{\boldsymbol{L E X 1}}$ suggested that some participants overweighed cue 1 even more than $\boldsymbol{\beta}_{\boldsymbol{E V} \mathbf{1}}$ recommended. Only one participant was best described by the other three lexicographic rules, indicating that $\boldsymbol{\beta}_{\boldsymbol{E V} \mathbf{1}}$ can predict which single cue participants tend to overweigh.

## Study 2

In Study 1, we found that the EV1 and EW models described participant level data about equally well, in terms of average log likelihood and proportion best fit. However, it is possible that predictions made by EV1 and EW were similar enough to be practically indistinguishable (given the noise in the data). This could confound our interpretation of model fit. Study 2 addresses this alternative explanation by manipulating the inter-cue relationships between subjects.

## Methods

64 participants ( 35 females; Mean Age $=19.9$, SD Age $=$ 1.1), recruited from a university experimental participation pool, completed this study in a behavioral laboratory.

All aspects of the study design were kept identical to Study 1, except that the cue correlation matrix varied between a treatment condition and a control condition. Participants were randomly assigned to one of these two conditions at the start of the study.

For the treatment condition, the inter-cue correlation matrix was identical to that in Study 1 (Figure 2a), generating an optimal weighting scheme with $\boldsymbol{\beta}_{E V 1}^{T r e a t}=$ [ $0.35,0.22,0.22,0.22$ ] (here we use the superscript to distinguish the treatment vs. control condition). For the control condition, the cue correlation matrix kept the correlation between all the cues constant at 0.4 (Figure 2b). Therefore, the weighting vectors predicted by the optimal weighting scheme and the equal weights rule were both $\boldsymbol{\beta}_{E V 1}^{C o n t}=\boldsymbol{\beta}_{E W}=[0.25,0.25,0.25,0.25]$. Due to different
inter-cue relationships across conditions, $\boldsymbol{\beta}_{E V 1}^{T r e a t}$ should provide a better account of behavior in the treatment condition compared to the control condition. Likewise $\boldsymbol{\beta}_{E V \mathbf{1}}^{C o n t}=\boldsymbol{\beta}_{E W}$ should provide a better account of behavior in the control condition compared to the treatment condition (even if a large subgroup of participants in the treatment condition do place an equal weight on all cues).

## Results

31 participants were assigned to the treatment condition and 33 participants were assigned to the control condition. As in Study 1, we first looked at participant learning in task 2. In the treatment condition, participants did learn the special status of cue 1. Particularly, as in Study 1, they placed a higher weight on cue 1 relative to the other cues when predicting the remaining cues ( $p<0.001$ ). In the control condition, participants placed similar weights on cues 1-4 when predicting cue values, indicating that they learnt different inter-cue relationships for the two conditions. Manipulating the cue-correlation matrix thus had an effect on participant learning. This laid the basis for task 3, where participants integrated cues to predict criterion values (again, due to space constraints, we will not expand on these results here).

Next, we examined which weighting schemes were used by participants in task 3. For both conditions, we applied the model fitting procedures of Study 1, and nine linear weighting schemes were compared on the participant level (Tables 2 and 3 ). Out of 31 participants in the treatment condition, 6 were best described by $\boldsymbol{\beta}_{V V 1}^{\text {Treat }}$, 18 by $\boldsymbol{\beta}_{\boldsymbol{E W}}, 6$ by $\boldsymbol{\beta}_{\boldsymbol{L E X 1}}$ and 1 by $\boldsymbol{\beta}_{\boldsymbol{E V} \mathbf{2}} \cdot \boldsymbol{\beta}_{\boldsymbol{E V 1}}^{T r e a t}$ outperformed $\boldsymbol{\beta}_{\boldsymbol{E W}}$ for a substantial subgroup of participants (13 out of 31). As in Study 1, some participants were best described by $\boldsymbol{\beta}_{\boldsymbol{L E X 1}}$, indicating that they overweighed cue 1 more than recommended by $\boldsymbol{\beta}_{E V 1}^{T r e a t}$. No participant was best described by the other three lexicographic rules, indicating that $\boldsymbol{\beta}_{E V \mathbf{1}}^{T r e a t}$ can predict decision makers' use of other improper linear models in the treatment condition.

We also compared the log likelihood values of the fits. Although the log likelihood values of the $\boldsymbol{\beta}_{E V 1}^{T r e a t}$ model were significantly smaller than those of the $\boldsymbol{\beta}_{\boldsymbol{E} \boldsymbol{W}}$ model ( $Z=-2.06, p=0.040$ ), the effect size was small ( Median $_{E V 1}=-350.56$, Median ${ }_{E W}=-350.17$ ). Additionally both the $\boldsymbol{\beta}_{\boldsymbol{E V 1}}^{\text {Treat }}$ model and $\boldsymbol{\beta}_{\boldsymbol{E W}}$ model predicted participant level data significantly better than all other models ( $p<0.001$ ). These results replicate findings of Study 1.
In the control condition, the inter-cue correlation matrix was balanced and the weighting schemes for $\boldsymbol{\beta}_{E V 1}^{C o n t}$ and $\boldsymbol{\beta}_{E W}$ were identical. Unsurprisingly, all 33 participants were better described by $\boldsymbol{\beta}_{E V 1}^{C o n t}=\boldsymbol{\beta}_{E W}$ than any other models (Table 3). The fact that no participants were best fit by lexicographic rules in the control condition but some were best fit by $\boldsymbol{\beta}_{\boldsymbol{L E X 1}}$ in the treatment condition again indicated that participants' cue weighting behavior can be predicted by the inter-cue correlation matrix.
Lastly, we examined the predictions of $\boldsymbol{\beta}_{E V 1}^{T r e a t}$ on the data from the control condition. For this purpose we fit a
tenth model in the control condition, with weights given by $\boldsymbol{\beta}_{E V 1}^{\text {Treat }}$ (and $\alpha_{0}, \alpha_{1}$ and $\sigma$ flexible). Unlike the treatment condition, this model outperformed the $\boldsymbol{\beta}_{E W}=$ $\boldsymbol{\beta}_{E V 1}^{C o n t}$ model for only 4 out of 33 participants in the control condition. A paired Wilcoxon test indicated that the log likelihoods of the $\boldsymbol{\beta}_{E V 1}^{T r e a t}$ model on the control-condition data (Median $=-336.73$ ) were significantly lower than those of the $\boldsymbol{\beta}_{E W}=\boldsymbol{\beta}_{E V 1}^{\text {Cont }}$ model (Median $=-335.76$ ), $Z=-4.24, p<0.001$.

Overall, the differences in the mean and median $\log$ likelihoods of the $\boldsymbol{\beta}_{E V 1}^{T r e a t}$ and the $\boldsymbol{\beta}_{E V \mathbf{1}}^{\text {Control }}=\boldsymbol{\beta}_{\boldsymbol{E W}}$ models in the control condition were 4.12 and 0.97 respectively. These were larger than the equivalent differences in the treatment condition, which were 0.20 and 0.39 (these differences were 0.06 and -0.21 in Study 1). These results indicate that the relatively good fits for the $\boldsymbol{\beta}_{\boldsymbol{E V} \mathbf{1}}$ model in the treatment condition of Study 2 and in Study 1 were not due to this model mimicking the equal weights rule.

## Study 3

Study 3 provides a more stringent test of the $\boldsymbol{\beta}_{\boldsymbol{E V} \mathbf{1}}$ model by considering a setting with more complex inter-cue relationships. It also examines judgments of restaurant quality rather than stock performance.

## Methods

46 participants ( 34 females; Age Mean = 19.3, SD Age $=$ 1.0 ) recruited from a university experimental participation pool, completed this study in a behavioral laboratory.

The study was framed as involving judgments of restaurant quality. Here the cue values were restaurant scores rated by four reviewers, and the criterion corresponded to the real restaurant quality. Other aspects of the study design were kept identical to Study 1 , except the inter-cue correlation matrix, which was changed to the matrix displayed in Figure 2c. Here cue 1 is highly correlated with cue 2 , cue 3 is moderately correlated with cue 4 , and cues 1 and 2 are weakly correlated with cues 3 and 4 . With this inter-cue correlation structure, $\boldsymbol{\beta}_{\boldsymbol{E V 1}}$ predicts a weighting vector of $[0.35,0.35,0.15,0.15]$, i.e. an overweighting of cues 1 and 2 , relative to 3 and 4 .

## Results

As in Studies 1 and 2, our analysis of behavior in task 2 suggested that participants were able to successfully learn the underlying cue structure. Particularly they relied more on cues 1 and 2 than on cue 3 and 4 when guessing for cues 1 and 2 ; they also relied more on cues 3 and 4 than on cues 1 and 2 when guessing for cues 3 and 4. Again, due to space constraints we will not outline these results in more detail.
Next, we investigated the linear weighting schemes used by participants in task 3. The nine candidate weighting schemes and the model fitting procedures were the same as in Study 1 (though, of course, $\boldsymbol{\beta}_{\boldsymbol{E V} \mathbf{1}}, \boldsymbol{\beta}_{\boldsymbol{E V 2}}$, $\boldsymbol{\beta}_{\boldsymbol{E V}}, \boldsymbol{\beta}_{\boldsymbol{E V} 4}$ assigned different weights to the cues in Study 3, compared to the corresponding models in Study 1).

Out of the 46 participants, 7 were best fit by $\boldsymbol{\beta}_{\boldsymbol{E V} 1}$ and 38 were best fit by $\boldsymbol{\beta}_{\boldsymbol{E W}}$. The remaining participant was best fit by $\boldsymbol{\beta}_{\boldsymbol{L E X 2}}$. When comparing only $\boldsymbol{\beta}_{\boldsymbol{E V} \mathbf{1}}$ and $\boldsymbol{\beta}_{\boldsymbol{E W}}$, we found that 8 participants were better described by $\boldsymbol{\beta}_{\boldsymbol{E V} \mathbf{1}}$ than $\boldsymbol{\beta}_{\boldsymbol{E W}}$. Additionally, $\boldsymbol{\beta}_{\boldsymbol{E W}}$ (Median $=-350.82$ ) was significantly better than $\boldsymbol{\beta}_{\boldsymbol{E V} \mathbf{1}}$ (Median $=-353.15$ ) according to a paired Wilcoxon test performed on participant level log likelihood values, $Z=3.98, p<$ 0.001 . Except for $\boldsymbol{\beta}_{\boldsymbol{E W}}, \boldsymbol{\beta}_{\boldsymbol{E V} \boldsymbol{1}}$ outperformed all the other candidate models (with $p<0.001$ ). As would be predicted by the $\boldsymbol{\beta}_{E V \mathbf{1}}$ model, the lexicographic models did not provide a good account of participant behavior in this study. Table 4 provides additional details regarding these fits.

Table 4 Comparison of model fits for Study 3

|  | Parameter (Median) |  |  | Log Likelihood |  |  |
| :--- | :---: | :---: | :---: | :---: | :---: | :---: |

As in previous studies, we found that a significant subgroup of participants overweighed some cues (as
suggested by $\boldsymbol{\beta}_{\boldsymbol{E V 1} 1}$ ), rather than simply averaging all the available cues (as suggested by $\boldsymbol{\beta}_{\boldsymbol{E W}}$ ). That said, the performance of $\boldsymbol{\beta}_{\boldsymbol{E V} \boldsymbol{1}}$ was relatively worse in this study compared to our previous studies. This could be due to the differences in the cue-correlation matrices, suggesting that decision makers are less likely to use the $\boldsymbol{\beta}_{\boldsymbol{E V 1} 1}$ scheme when the underlying cue structure is complex. These differences could also, however, be attributed to the change in the task frame. Restaurant quality is more subjective than stock performance, and decision makers may be less likely to rely on the cue-correlation structure in these subjective settings.

## Discussion

In three studies, we investigated how decision makers weigh cues when cue criterion relationships are unknown. The optimal improper linear model uses the eigenvector, $\boldsymbol{\beta}_{\boldsymbol{E V I}}$, corresponding to the largest eigenvalue of the cue correlation matrix (Davis-Stober et al., 2010a, 2010b). Low dimensional representations of the cue space, learnt by some common models of semantic memory (Kruskal \& Wish, 1978; Landauer \& Dumais, 1997; Saxe et al., 2013), can also produce this type of weighting scheme.

Our results suggest that $\boldsymbol{\beta}_{\boldsymbol{E V} \boldsymbol{1}}$ provides a good description of participants' behavior. This model outperformed all other improper linear models tested in this paper, except for the equal weights model (with weights $\boldsymbol{\beta}_{\boldsymbol{E W}}$ ). On the aggregate level, the log likelihoods for the $\boldsymbol{\beta}_{\boldsymbol{E V} \boldsymbol{1}}$ and $\boldsymbol{\beta}_{\boldsymbol{E W}}$ weighting scheme were relatively close, showing no meaningful differences in Study 1, very minor differences in the treatment condition of Study 2, and somewhat larger differences in Study 3. As for individual level fits, there existed a substantial group of participants for whom $\boldsymbol{\beta}_{\boldsymbol{E V} \mathbf{1}}$ outperformed $\boldsymbol{\beta}_{\boldsymbol{E W}}$. The size of this group ranged from $43 \%$ of the participant pool in Study $1,42 \%$ in the treatment condition of Study 2, and $17 \%$ in Study 3. Moreover, a comparison of the control and the treatment conditions of Study 2 showed that experimental manipulations that varied the inter-cue correlation matrix influenced relative model fits.
$\boldsymbol{\beta}_{\boldsymbol{E V} \mathbf{1}}$ was also able to predict when and how participants used lexicographic weights. When $\boldsymbol{\beta}_{E V \mathbf{1}}$ prescribed equal weights (control condition of Study 2) or the overweighing two cues (Study 3), there were almost no participants who were best described by such lexicographic weighting schemes. In contrast, in Study 1 and the treatment condition of Study 2, $\boldsymbol{\beta}_{\boldsymbol{E V} \mathbf{1}}$ overweighed a single cue. In these conditions, a substantial group of participants ( $18 \%$ in Study 1 and $19 \%$ in the treatment condition of Study 2) behaved according to a lexicographic rule that placed all of the weight on this cue (in contrast lexicographic rules that prioritize other cues all performed very poorly).

That said, $\boldsymbol{\beta}_{E V 1}$ did not provide a good account of behavior in Study 3, which adopted a more complex intercue correlation matrix. The results of this study suggest that such a weighting scheme may not be used in all settings. Additionally, the equal weights rule was the majority model in all studies, indicating that most participants tend to use the simpler equal weights strategy (corresponding to an ignorance prior) in the absence of
cue-criterion knowledge. Further work should examine the effect of inter-cue correlation structure and individual differences on the use of the $\boldsymbol{\beta}_{\boldsymbol{E V} \boldsymbol{1}}$ weighting rule. This work may extend the insights of other cognitive models of multi-cue judgment, such as those relying on neural network representations (Glöckner, Hilbig \& Jekel, 2014) or exemplar memory-based predictions (Juslin, Karlsson \& Olsson, 2008). Such models have not been applied to settings in which cue-criterion relationships are unknown. However, they nonetheless provide formal predictions regarding the learning and representation of cue knowledge and its relationship with the statistical structure of the judgment environment. For this reason they may provide a more adequate framework for understanding the cognitive underpinnings of the $\boldsymbol{\beta}_{\boldsymbol{E V} \mathbf{1}}$ weighting model.

# Using single unit recordings in PDP and localist models to better understand how knowledge is coded in the cortex 

Jeffrey S. Bowers (j.bowers@bristol.ac.uk)<br>Department of Experimental Psychology, 12a Priory Road Bristol, BS8-1TU UK

Keywords: localist representation; distributed representation; grandmother cell; neural network

## Introduction

There is long history of studies documenting that some neurons respond to images of objects, faces, and scenes in a highly selective manner. This includes neurons in the human hippocampus (e.g., the famous example of a neuron responding to images of the actress Jennifer Aniston) and neurons in high-level visual cortex in monkey (for reviews see Bowers, 2009; Ison, Quian Quiroga, \& Fried, 2015). These findings have led to a growing interest in the claim that some neurons code for information in a localist ('grandmother cell') manner, as reflected in the many contributions to a recent special issue on this topic in the journal Language, Cognition, \& Neuroscience (Bowers, 2017).

By contrast, it is only recently that interest in characterizing the selectivity of single units in connectionist networks has gathered speed. Critically, these studies also show that networks learn highly selective representations under a number of conditions, as detailed below. In this talk I will summarize recent research in my lab that explores the conditions in which artificial networks learn selective codes, and research comparing the responses of selective neurons and localist representations used in cognitive models. These findings suggest when and why some neurons in cortex respond in a highly selective manner, and highlight the biological plausibility of localist models in psychology.

## Selective codes as a solution to the superposition catastrophe

In Bowers, Vankov, Damian, and Davis $(2014,2016)$ we carried out single-unit recordings on networks trained to coactivate multiple words at the same time in short-term memory (STM). We adapted models by Botvinick and Plaut (2006) who demonstrated that recurrent PDP networks can support human-like performance on STM tasks, and claimed that the models succeeded on the basis of co-activating learned distributed representations. This claim is important because it challenges the hypothesis that overlapping distributed representations result in blend patterns that are ambiguous, the so-called superposition catastrophe (Von Der Malsburg, 1986). The superposition catastrophe has been one of the key arguments in support of localist representations (Bowers, 2002; Page, 2000)

However, we showed that the Botvinick and Plaut (2006) and related models solved the superposition catastrophe by learning localist representations. Adapting an analytical tool developed by Berkeley, Dawson, Medler, Schopflocher,
and Hornsby (1995), we carried out single unit recordings of the hidden units of trained networks. We showed that the models learned more selective codes when the superposition constraint became more challenging. For example, Figure 1 depicts a hidden unit (unit 89 of 200 hidden units) that responded selectively to the trained word 'cot' (taken from Bowers et al., 2014).

Figure 1

Furthermore, we found that recurrent networks of STM were only able to recall lists of novel words when they learned localist representations (Bowers et al., 2016), contrary to the widespread assumption that distributed codes are better able to support generalization. These findings extend our understanding of when and why some neurons respond selectively: Just as neurons in the hippocampus are thought to code information in a selective manner in order to support fast learning without forgetting (Marr, 1971), our findings suggest some neurons in cortex learn selective codes for the sake of STM.

## Selective codes as a solution to some forms of arbitrary input-output mappings.

Recently there has been an explosion of interest in characterizing the selectivity of single hidden units in socalled 'deep' networks that achieve state-of-the-art performance on a range of tasks, including object and spoken word identification (for review, see Bowers, 2017). The striking finding is that these networks often learn highly selective representations even when trained on items one-at-a-time. This raises the question as to why we found that networks learned non-selective representations when trained on items one-at-a-time (Bowers et al., 2016).

Vankov and Bowers (2017) began to explore the conditions in which PDP networks learn selective and nonselective codes when trained on words one-at-a-time. Models learned non-selective distributed codes under a range of conditions, including when trained on many arbitrary input-output mappings. For example, a 3-layered model trained to map random patterns of binary inputs (with input units taking on an activation of 1 or 0 ) to another
random pattern of binary output units learned distributed codes.

However, we found one condition in which a 3-layered network learned localist codes: when trained on images of faces when input units took on continuous values and the model was trained on many-to-one mappings (with multiple different images of a given person mapping onto the same output representation). For example, Figure 2 depicts 16 localist units (units that are highlighted) out of 500 hidden units that selectively fire to a given face. To illustrate, the face images that activate units 312 and 404 are displayed.

Figure 2

We are currently carrying out more simulations to better understand the conditions in which networks learn distributed and localist codes when trained on items one-at-a-time. For example, is it many-to-one mappings that is critical, or the nature of the images themselves?

## Comparing the selectivity of single neurons to the selectivity of single units in localist models in psychology.

Even when neurons are identified that selectively respond to images of one person or object within an experiment, it is often claimed that the neuron would responds to other (untested) categories of images. For example, Waydo et al. (2006) estimated that the most selective neurons observed in Quian Quiroga et al. (2005) study would respond to between 50-150 different people or objects if researchers had more time to find the relevant images. This is taken as inconsistent with grandmother cells.

However, Gubian, Davis, Alderman, and Bowers (2017) showed that the analysis of Waydo et al. (2006) is consistent with localist models in psychology. We carried out singleunit recordings in the Spatial Coding Model of visual word identification that represents $\sim 30,000$ words in a localist manner (Davis, 2010). Under parameter conditions that allow the model to correctly identify words we found that that the localist representations responded to approximately to 50 different words (e.g., the word DOG responds most strongly to the input DOG, but also responds above baseline to LOG, FOG, JOG, etc.). Page (2017) also provides evidence that localist models can account for single-cell recording data taken to support distributed coding.

Together, these results highlight the computational reasons why some neurons in cortex respond in a highly selective manner, and show that localist (grandmother cell) representations are in fact consistent with single-cell recording data.

# Interoception: The Forgotten Modality in Perceptual Grounding of Concepts 

Louise Connell (l.connell@lancaster.ac.uk)<br>Dermot Lynott (d.lynott@lancaster.ac.uk)<br>James Carney (j.carney@lancaster.ac.uk)<br>Department of Psychology, Fylde College, Lancaster University, Bailrigg, Lancaster LA1 4F, UK

Keywords: concepts; perceptual strength; grounded cognition; embodied cognition; word recognition

Concepts are the basis of the human cognitive system, and the question of what constitutes the content of these mental representations has long occupied the cognitive sciences. Work in psychology, linguistics and cognitive neuroscience has converged on the idea that we develop our conceptual representations through our perception of and interaction with our environment. To date, such research has typically restricted consideration to the perceptual modalities of vision, touch, sound, taste, and smell. However, there is another major modality of perceptual information that is distinct from these traditional five senses; that is, interoception, or sensations within the body. In this paper, we explore the role of interoception in the perceptual grounding of concepts.

Recently, modality-specific measures of the strength of perceptual experience (Lynott \& Connell 2009, 2013) have proven themselves important predictors of human behaviour in a range of conceptual tasks including word recognition and reading (Connell \& Lynott, 2010, 2012, 2014a, 2014b, $2015,2016)$. In a megastudy of over 32,000 words from across the abstract-concrete spectrum, we asked people to provide modality-specific ratings of perceptual strength for six modalities: the usual five (auditory, haptic, gustatory, olfactory, visual) plus the new category of interoceptive strength. We found that interoceptive information dominates the perceptual profile of a sizeable number of concepts ( $9 \%$; e.g., hangover, eternal, remorse), less than the proportion of concepts dominated by vision ( $74 \%$; e.g., book) or sound ( $12 \%$; e.g., melody), but more than are dominated by touch ( $3 \%$; e.g., silky), gustation ( $2 \%$; e.g., candy), or olfaction ( $<1 \%$; e.g., bleach). Using principal components analysis to examine how interoception relates to the other perceptual modalities, we found that it tends to be strongly loaded against visual and haptic strength (i.e., that which is sensed within the body can be neither seen nor touched) but is relatively distinct from sound, taste, and smell.

Finally, we tested whether interoceptive strength offers valuable information to conceptual content by examining its role in semantic facilitation of word recognition. Maximum perceptual strength (i.e., strength in the dominant modality) has previously been shown to predict word recognition performance better than concreteness or imageability (Connell \& Lynott, 2012). We therefore compared the predictive ability of two different versions of maximum
perceptual strength: the original measure based on five traditional modalities, and a new version based on six modalities including interoceptive strength. In a regression analysis of lexical decision and word naming performance, interoceptive information considerably improved the efficacy of maximum perceptual strength in predicting both response time and accuracy (Bayes Factors ranged from $\mathrm{BF}_{10}=3.303 \times 10^{7}$ to $\left.\mathrm{BF}_{10}=3.059 \times 10^{16}\right)$. That is, perceptually strong words were recognized more quickly and accurately than perceptually weak words, and interoceptive strength was a valuable component in this perceptual facilitation. Overall, these findings suggest that interoception has comparable status to other modalities in contributing to the perceptual grounding of concepts.

# Tracking Meaning Change Over Time: A Dynamic Field Theory Model 

Kenny R. Coventryı (k.coventry@uea.ac.uk)<br>School of Psychology, University of East Anglia, Norwich, UK

Harmen B. Gudde (h.gudde@uea.ac.uk)<br>School of Psychology, University of East Anglia, Norwich, UK<br>Holger Schultheis (schulth@informatik.uni-bremen.de)<br>Cognitive Systems Group, University of Bremen, Bremen, Germany

Keywords: meaning; spatial language; dynamic field theory

## Meaning Change

Words are often regarded as "slippery customers" (Labov, 1973). First, it is difficult to come up with a fixed content that seems to apply across all uses of a single word (Wittgensten, 1953). Second, the meaning of a word is subject to wider contextual constraints beyond the company it keeps with other words within a sentence. Third, the assumption that a word means a fixed thing is at odds with the fact that word meaning shifts over time, as do the objects a word refers to. Taken together, theories of word meaning need to be able to account for the intuition that words have content associated with them, while allowing for variation in how a word is used in context, and how word meaning can change over time.

We provide an approach to word meaning within the spirit of dynamic systems theory (DST) models of cognition that accounts for the slipperiness of words. First, we draw an analogy between models of (non-linguistic) spatial behavior and how the meaning of language changes over time while exhibiting regularity. In particular, we identify two key features of DST models - multicausality and the building of temporally-bound attractor states - that afford application to theories of meaning. Second, we take these features of DST models and test them in experiments examining the comprehension of spatial expressions over time using object placement behavior as a measure (e.g. "Place the oil paint tube over the toothbrush"). Building on earlier work examining the constraints in which spatial language is used (Carlson-Radvansky et al., 1999; Coventry, 2013, 2015; Coventry \& Garrod, 2004; Coventry et al., 2001, 2010, 2013, 2016; Gudde et al. 2016), we present a programme of studies mirroring early models of spatial memory, with experimental data showing striking similarity with results from other (non-linguistic) spatial tasks (namely the A not B error tasks and associated model produced by Smith \& Thelen; e.g. Smith \& Thelen, 2003; Thelen et al., 2001). Third, we take these data, and show that a previous DST model originally developed to account for infant
perseverative reaching behavior (Thelen et al., 2001) provides an elegant model of the changing meaning of spatial expressions over time.

Figure 1: Examples of scenes used (A) and movement manipulation

The programme of experiments involved using placement behavior as a proxy for situation-specific meaning (adapting a method from Carlson-Radvansky et al., 1999). Participants were given spatial expressions of the form PLACE OBJECT A 'PREPOSITION' OBJECT B, followed by a picture displayed on a computer screen. The task was to move OBJECT A so that the relation between objects matched the location denoted by the sentence (prepositions used were over/underlabovelbelow). OBJECT B was always an object with a functional part at one end (e.g. a toothbrush), and these objects were always displayed in sideways view (Figure 1). Critically the similarity between the probe and the prime trials was manipulated - analogous to the different object locations in the A not B error task (Thelen et al., 2001). The objects to be placed were either functionally related (e.g. a toothpaste tube and a toothbrush, hereafter $F$ ) or non-functionally related (e.g. a tube of paint and a toothbrush, hereafter NF). Previously it has been shown that placement behavior for F object pairs is different from placement behavior for NF object pairs when participants are given spatial sentences with the preposition above in them. Placements for an F object were nearer the

[^257]functional part of the other object than for NF objects; placements for NF objects were nearer the mid-point (centre of mass) of the other object than for F objects (CarlsonRadvansky et al., 1999).

The programme of studies varied the similarity between prime and probe trials (in terms of same/different spatial relations, functional relations between objects, and the way in which objects are moved) as well as the number of prime trials (i.e. the extent to which an attractor state is built prior to probe placements). Among the results in the series of studies we find evidence that object placements on a probe trial are affected by the number of prime trials presented first, and the nature of the similarity between prime and probe trials. For example, when a probe involves functionally related objects, placements are more functional (i.e. more over the bristles of the toothbrush) following previous functional prime trials with different objects than when the primes trials were non-functionally related objects, etc.

We also manipulated how participants placed objects (Figure 1B). Consistent with DST and the A not B error model, we postulated that the temporal binding of spatial language to objects might also involve interaction with those objects. Placing a toothpaste tube over a toothbrush may call up an attractor state involving an action component as the toothpaste tube and toothbrush are held in specific ways associated with a brushing routine when those objects are in that relation. Participants either moved the objects on the touch screen with their hand upright (palm pointing downwards, Figure 1B, left panel), in a manner affording normal interaction with that object, or they moved the object with hand rotated in a manner that did not afford interaction (Figure 1B, right panel). We predicted that placements would be nearer the functional part of the other object when the movement was one that afforded action. Critically, we wanted to test whether this effect, if present, occurs for both functionally related and non-functionally related objects. If the effect only occurs for functionally related objects, one can argue that it is the action at encoding that it is important rather than any affordance to do with how the objects are moved per se. This was indeed what we found.

Overall results mirror the results from the A not B error task. Following the building of an attractor state over four prime trials, placement behavior reflecting comprehension of spatial language on the critical probe trials is dragged in the direction of previous object placements for incongruent prime-probe combinations - analogous to an infant searching in the wrong location on the A not B task. Second, the (incidental) way in which an object was moved on the screen also affected placement behavior, but only reliably so for F objects. This is consistent with the view that what objects are, how they interact, and how we interact with them becomes temporally coupled during learning, and forms a multimodal attractor state for spatial language.

Taking this data, we present a working DST computational model that also makes predictions tested in further later experiments. Overall, the novel approach to
word meaning allows the appearance of stable underlying "senses' of words while accounting for changes in meaning on a moment-to-moment basis.

# Converging Evidence for Abstract Phonological Knowledge in Speech Processing 

Anne Cutler (a.cutler@westernsydney.edu.au)<br>The MARCS Institute, and ARC Centre of Excellence for the Dynamics of Language, Western Sydney University, Locked Bag 1797, Penrith NSW 2751, Australia;<br>Max Planck Institute for Psycholinguistics, P.O. Box 310, Nijmegen 6500 AH, The Netherlands.

Keywords: speech perception; phonological knowledge; first and second language; talker perception; infancy; abstraction

## Introduction

The perceptual processing of speech is a constant interplay of multiple competing albeit convergent processes: acoustic input vs. higher-level representations, universal mechanisms vs. language-specific, veridical traces of speech experience vs. construction and activation of abstract representations.

The present summary concerns the third of these issues. The ability to generalise across experience and to deal with resulting abstractions is the hallmark of human cognition, visible even in early infancy. In speech processing, abstract representations play a necessary role in both production and perception. New sorts of evidence are now informing our understanding of the breadth of this role. Two earlier and more detailed reviews of the role of abstraction in speech processing (Cutler, 2008; 2010) also embrace, respectively, evidence on the lexical representation of form versus meaning, and evidence on prosodic processing.

## Evidence from the second-language lexicon

Learners of a second language (L2) endure persistent perceptual trouble (not fixable just by accruing experience) with L2 phonemic distinctions that their first language (L1) lacks. The classic explanation of this is that L1 phonology (here, abstract knowledge about which phonemic contrasts may be encountered in speech signals) captures the input.

This is not the full account of this difficulty, however. Abstract knowledge of a contrast's existence (from reading, or from teaching, e.g., that light and write are supposed to be different) influences the construction of phonological representations in the lexicon. In the L2 lexicon, these representations thus become distinct. Speech perception, however, still fails to deliver the discrimination this requires (Weber \& Cutler, 2004; Cutler, Weber \& Otake, 2006; Broersma \& Cutler, 2008); both L2 sounds are perceived as (more or less good) realisations of a single phoneme. (That will usually be the L2 phoneme acoustically closest to the single L1 sound; for Japanese listeners hearing English [r/l], this is [1]). In righteous or rightful, the initial syllable will then actually activate light, not right. The second syllable will be needed in order to produce the desired lexical entry as the closest match to the input as a whole. The result is that word recognition in L2 is slower than it should be, because more competitor words are activated, and the competition from the spuriously activated ones is also more persistent (Broersma \& Cutler, 2011; Cutler, 2015).

## Evidence from talker adaptation

We adapt so rapidly to talkers we have never before heard by using existing knowledge to resolve phonetic ambiguity, and in consequence adjusting phoneme category boundaries for that specific talker (Norris, McQueen \& Cutler, 2003; Eisner \& McQueen, 2005). The adjustment generalises to words and phonetic contexts in which the phonemes in question have not previously been heard from the new talker (McQueen, Cutler \& Norris, 2006). Thus the adaptation has concerned phonemic categories, not veridical traces of experience (Cutler, 2010). Episodic models of lexical storage and retrieval, in which stored traces of lexical experience are activated in proportion to their match to the current input, cannot cope with this generalisation result (Cutler, Eisner, McQueen \& Norris, 2010), because the models are unable to assign the novel pronunciation instances uniquely to the phonemic category they should represent.

## Evidence from cross-modal generalisation

Cross-modal priming is popular in psycholinguistics, not necessarily because it calls on representations abstracted across different modalities; it is just a robust and useful task. Interestingly, recourse to the supra-modal representation even informs priming across modalities when the target is the same articulatory event - hearing words facilitates later phonological processing from lipreading the same spoken words, compared with new words (van der Zande, Jesse \& Cutler, 2014a). Notably, the lipreading here was facilitated whether or not the talker was the same one who had been heard in the priming phase; there was always an advantage for old words over new, but no effect of talker familiarity. Talker adaptation (as outlined in the section above) was likewise unaffected by visual information indicating another talker (van der Zande, Jesse \& Cutler, 2014b). These results confirm that phonological representations in the lexicon are shared across auditory and visual processing, and also show that talker information is not transferred across modalities at the lexical level. The abstract representations are stronger than, or unaffected by, modality-specific experience.

## Evidence from talker recognition

One of the best-known effects in talker recognition is that listeners find it easier to recognise talkers (pick them out from a set, as in a forensic lineup) when they are talking the listeners' native language. This turns out not to be due to a need to understand what is being said, because this nativelanguage effect appears even with seven-month-old infants:

Dutch-learning infants at this age perk up when a new talker is added to a set of three female talkers uttering unrelated (adult-style) Dutch sentences, but do not notice when a new talker is added to a set speaking Italian, or a set speaking Japanese (Johnson, Westrek, Nazzi \& Cutler, 2011).

At seven months, infants are acquiring the phonological structure of the language around them, but do not yet have a functional vocabulary that would allow them to understand such input. Thus the effect is here based on familiarity with the phonology in the one set of input but not in the others.

Analogously, adult listeners show equivalent efficiency with two phonologically comparable dialects of a language as opposed to a language with a differing phonology, and this works each way - native speakers of one of the dialects recognise talkers equally well in either dialect (but worse in the phonologically different language), while non-native listeners perform the talker recognition task equally badly in either dialect (but better in their phonologically different own tongue; Johnson, Bruggeman \& Cutler, in press). Again, the phonological familiarity predicts the results.

## Evidence from a lost language

Children adopted into another country lose all conscious knowledge of their first language and become essentially native speakers of a new language. But traces remain of the first, as many studies, with many languages, have shown. A recurring finding is that adoptees (in comparison to controls) show an accelerated trajectory of learning phonological structures found in the birth language but not in the current native tongue. In the largest such adoptee study so far, we replicated this for speech perception (Choi, Broersma \& Cutler, 2017), and also found that the perceptual mastery transferred to speech production (Choi, Cutler \& Broersma, 2017). This transfer, and a further generalisation of training on one phoneme contrast to other places of articulation, indicate that the observed benefit is based on abstract phonological representations. Most strikingly, the adoptee benefit was independent of age at adoption; infants adopted under the age of six months (before vocabulary building, or phoneme repertoire mastery, or talking) showed as much evidence of phonological retention as those adopted over the age of one. Thus abstract phonological knowledge is compiled and laid down even before six months of age, in preparation for the later stages of language acquisition.

## Conclusion

Abstract phonological knowledge plays a role in all aspects of speech processing. This is true even of those processing realms which may seem to form natural sources of evidence for memory-based effects. Thus we can see that abstractions are involved in many kinds of processing where differences between talkers are at issue. Likewise, though phonological structures are language-specific and hence not inborn, whereby language acquisition needs speech input to set it going, it also appears that construction of abstract phonological generalisations across this input must form part of linguistic processing even in the earliest months of life.

# Analogy and Episodic Memory to Support Domain Learning in a Cognitive Architecture: An Exploration 

Kenneth D. Forbus (forbus@ northwestern.edu)<br>Computer Science, Northwestern University, 2133 Sheridan Road<br>Evanston, IL, 60208, USA

Keywords: Analogy, Cognitive Architecture, Cognitive Simulation

## Introduction

Organisms learn from experience in many ways. One component of learning from experience is recording what has happened in the world when actions are taken, a form of episodic memory, and distilling such experience over time to learn models of phenomena for generating expectations. As further actions are taken, the accuracy of such models can be monitored, to detect surprises and to help identify and prioritize learning goals. This publication-based talk will describe some recent results in exploring the use of analogical generalization over episodic memories in the Companion cognitive architecture to formulate models of the effects of actions in a complex dynamic world. Measures of novelty, surprise and for prioritization of learning goals will be discussed.

## Episodic Memory and Analogy

How human episodic memory is organized is still an open question. Given the centrality of analogy in human cognition (e.g. Gentner, 2003), it seems reasonable that a common way of structuring episodic memories could be as cases, so that they can be accessed via analogical retrieval (e.g. MAC/FAC, Forbus et al. 1995) with more transferable knowledge constructed incrementally via generalization (e.g. SAGE, McLure et al. 2015). The Companion cognitive architecture (Forbus et al. 2009; Forbus 2016; Forbus \& Hinrichs, in press) incorporates these analogical processing models, along with SME (Forbus et al 2016), which MAC/FAC and SAGE are built upon. The Companion architecture also includes facilities for language understanding, sketch understanding (Forbus et al. 2011), and integration with simulators. For example, Companions can interact with Freeciv ${ }^{1}$, an opensource version of Civilization 2, which is a popular strategy game. The attraction of such games to players is their complexity, e.g. building civilizations and transportation networks, exploration, technology research, military operations, over hundreds of turns. Such complexity makes Freeciv useful for exploring learning about complex dynamics (McFate et al. 2014; Hinrichs \& Forbus, 2016). For example, by storing cases of both positive outcomes and negative outcomes generated by experimentation, a

Companion has learned to perform city management (Hinrichs \& Forbus, 2007).

This talk goes beyond that work by focusing on how a Companion can distill models of actions via analogical generalization while observing human players. For each action the person takes, the Companion records information about the state of the world before and after the action, and uses some general-purpose heuristics to attempt to explain immediate events in terms of the action. For each occurrence of each action, a case consisting of this information is stored. Storage occurs via a SAGE generalization pool for each command (e.g., doMove, doIrrigate). The generalization pool for a command can be thought of as an analogy-derived model for what happens when that command is used. By letting the system watch replays from six different games, it builds up over 4,200 cases across 34 different commands.

Inspecting these generalization pools leads to some interesting insights. First, the number of generalizations and outliers in a pool provides an indication of how well the action is understood. If there are many cases all forming a single generalization, then that command has straightforward local consequences (e.g. doIrrigate). When there are multiple generalizations, comparing their structures can be illuminating: For example, in doResearch, the generalizations differ only in the number of requirements and opportunities, making them artifacts of the encoding strategy, which could be eliminated via re-representation. Thus properties of the generalization pools provide a signal about how encoding strategies might be improved.

Analogical generalization also provides a means of detecting and quantifying novelty and surprise. Novelty can be detected in two ways: Failure to retrieve a similar experience, and by analysis of candidate inferences indicating differences. When little is known, all is novel surprise, I argue, occurs when a novel situation is experienced for a type of situation that was considered to already be well understood. The degree of surprise can be estimated based on the number of cases in the pool and frequency information for relationships within them that are computed for the generalizations: When there are many cases and highly certain outcomes, a new outcome can be more surprising. doMove provides an excellent example: It occurs frequently, so a dominant analogical model is quickly built up. But when a unit moves into a hut, there are five different things that might happen, leading initially to surprises.

[^258]In addition to summarizing the results of these experiments, I will describe work in progress on making adaptable encoding strategies guided by the system's own analysis of its experience.

# Non-syntactic Processing Explains Cortical Entrainment During Speech Perception 

Stefan L. Frank (s.frank@let.ru.nl)<br>Centre for Language Studies, Radboud University<br>P.O. Box 9103,6500 HD Nijmegen, The Netherlands<br>Jin-Biao Yang (ray306@gmail.com)<br>Institute of Brain and Cognitive Science, NYU Shanghai<br>3663 North Zhongshan Road, Shanghai, China 200062

Keywords: Language processing; cortical entrainment; distributional semantics

## Introduction

There is considerable debate on the precise role of hierarchical syntactic structure during the comprehension of sentences, with some arguing that a full hierarchical analysis is required for comprehension (e.g., Ding, Melloni, Tian, \& Poeppel, 2017) and others claiming that non-hierarchical processing is more common (e.g., Frank, Bod, \& Christiansen, 2012). Ding, Melloni, Zhang, Tian, and Poeppel (2016) recently presented evidence that cortical entrainment during speech perception reflects the neural tracking of hierarchical syntactic structure of simple sentences, which would support the view that hierarchical processing is unavoidable. However, we show that the same entrainment effects appear in a computational model that does not incorporate syntax or any other linguistic knowledge or process beyond the word level. Hence, the cortical entrainment results do not need to be indicative of syntactic processing.

Ding et al. (2016) had participants listen to Chinese or English four-syllable sentences, with syllables presented at a fixed rate while cortical activity was recorded with MEG. A frequency analysis of the MEG signal revealed peaks in the power spectrum at exactly the occurrence frequencies of syllables, phrases, and sentences. For example, when sentences with [NP VP] structure (such as "dry fur rubs skin") were presented at a rate of 250 ms per monosyllablic word, peaks would appear at $4 \mathrm{~Hz}, 2 \mathrm{~Hz}$, and 1 Hz , corresponding to the syllable/word, phrase, and sentence rate, respectively (see Figure 1). Likewise, a sequence consisting of only NPs or only VPs resulted in peaks at 4 Hz and 2 Hz but not 1 Hz , while presenting a sequence of Chinese syllables without word or phrase structure resulted in only the 4 Hz peak.

Although these results can indeed be interpreted in term of the sentences' syntactic structures, we propose a simpler explanation: The power spectrum merely reflects responses to regularities in word-level properties, such as (approximate) syntactic or semantic category. For example, in the [NP VP] sentences, verbs occur at 1 Hz and nouns at 2 Hz . We implemented this alternative explanation in a simple computational model and show that it indeed predicts the MEG power spectra in different experimental conditions.

## The model

The only linguistic knowledge available to the model is encoded in word vector representations. These were generated by a distributional semantics model (Mikolov, Chen, Corrado, \& Dean, 2013) trained on large corpora of Chinese or English texts (the same model and English corpus were used to obtain word representations that Frank \& Willems, in press, and Frank, 2017, applied to account for N400 and reading time effects). Words that occur in similar contexts get similar vectors so that representations of words from the same syntactic/semantic category tend to be clustered together.

The stimuli from the (Ding et al., 2016) experiments were presented to the model at a simulated rate of 4 Hz per English word or Chinese syllable. Twelve different subjects were simulated by retraining the distributional semantic model and randomly varying stimuli presentation order. The sequence of vector representations, at a simulated time resolution of 5 ms , were analysed by applying a Discrete Fourier Transform to obtain a power spectrum, just like Ding et al. (2016) do in their analysis of the MEG signal.

## Results

Figure 2 shows that the model predicts the same peaks in the power spectrum as in the original MEG study. The minor peak at 3 Hz , which did not reach significance in the MEG data, is most likely merely the second subharmonic of the 1 Hz peak (Zhou, Melloni, Poeppel, \& Ding, 2016). The model further correctly accounts for the outcomes of experiments with two-syllable NP or VP sequences that lack full sentence structure, and predicts results very similar to those in the MEG data when syllable sequences are scrambled to remove any higher linguistic structure (see Frank \& Yang, 2017)

## Conclusion

The only linguistic knowledge in the model is encoded in the input vectors, so it remains at the lexical level. Furthermore, the model does not include any intergrative processing. The resulting power spectra can therefore not reflect any (hierarchical) syntactic processing. Consequently, the original MEG results may also be explained without syntax.

Figure 1: Left: MEG results for Chinese [NP VP] sentences. Right: MEG results for English [NP VP] sentences, reproduced from Ding et al. (2016, Figure 2e) with permission (the frequency scale was adapted to match simulated presentation rate). Shaded areas represents the standard error over subjects; lines are the average over subjects. Stars indicate significant peaks after multiple comparison correction.

Figure 2: Model results for Chinese (left) and English (right) [NP VP] sentences. Grey lines represent individual simulated subjects; coloured lines are the averages over simulated subjects. Stars indicate significant peaks after multiple comparison correction.

Keywords: category learning; category density; supervision; comparative; pigeon; rat

## Introduction

Categorization is critical for our ability to organize information. A comparative analysis may provide important insights into the cognitive and neural mechanisms underlying category learning. We have examined category learning in rats and pigeons because of differences in brain organization between mammals and birds. Species differences in category learning and representation can indicate how the differences in brain organization lead to differences in cognition.

Category structure and supervision are factors importantly influencing category learning and representation in humans (Kloos \& Sloutsky, 2008; Love, 2002). Humans can learn categories with dense defining features with no supervision, but we need supervision to learn categories with sparse features. These finding have been interpreted as evidence for multiple category learning systems in the brain. The current study examined the roles of feature density and supervision in visual category learning in rats and pigeons.

## Experiment 1

Rats were trained on a discrimination task earlier used for category learning with photographic stimuli (Brooks et al., 2013). Rats were trained with two visual categories in which feature density could be precisely manipulated (see Figure 1). One category was associated with a left response, whereas the other category was associated with a right response.

Figure 1: Exemplars of one high-density (dense) category (top) and one low-density (sparse) category (bottom).

Each stimulus category had five features. In the dense condition, three of the features were category-relevant, whereas the sparse condition had only one relevant feature. High supervision was defined as delivery of a food reward only after a correct choice. In contrast, low supervision was defined as delivery of a food reward regardless of whether or not the choice was "correct." Rats were trained in a $2 \times 2$ design with density and supervision as factors: dense-high supervision, sparse-high supervision, dense-low supervision, and sparse-low supervision. The rats were trained until reaching a criterion of $75 \%$ correct responding for both categories for 2 consecutive days or for a maximum of 60 days. After meeting the training criterion, the rats were given testing sessions in which training stimuli were mixed with probe trials. Probe trials included novel exemplars (novel irrelevant features), rotated stimuli (in which the relevant features appeared in different locations), and singleton stimuli (only one relevant feature was presented, in the absence of any other features).

Figure 2: Mean accuracy of rats trained in the dense-high supervision (dense-high), sparse-high supervision (sparsehigh), dense-low supervision (dense-low), and sparse-low supervision (sparse-low) conditions.

All rats in the dense-high supervision condition (6/6) showed rapid learning of the two categories (see Figure 2). They also showed very high accuracy with novel stimuli. Accuracy
dropped significantly when rotated or singleton stimuli were presented, suggesting that the rats' representations of the categories included feature-location binding. Some of the rats in the sparse-high supervision condition (2/6) learned and showed substantial generalization to novel exemplars. Like rats in the dense-high supervision condition, the rats in the sparse-high supervision condition that learned showed a significant drop in accuracy during presentations of the rotated and singleton test stimuli. Rats trained in the low supervision conditions did not learn. Only one rat in the dense-low supervision condition reached criterion performance. Rats that did not learn showed a position bias and were slower to learn when switched to high supervision.

## Experiment 2

Pigeons were trained and tested under identical conditions as the rats. This experiment is in progress and, currently, training and testing has been conducted with a limited number of animals: dense-high supervision (2), sparse-high supervision (3), dense-low supervision (2), and sparse-low supervision (3). All of these pigeons learned relatively quickly, compared to the rats.

Figure 3: Mean accuracy of pigeons trained in the dense-high supervision (dense-high), sparse-high supervision (sparsehigh), dense-low supervision (dense-low), and sparse-low supervision (sparse-low) conditions.

As can be seen in Figure 3, pigeons in the high density conditions learned rapidly, in five or fewer sessions, regardless of the level of supervision. They also showed very high accuracy to novel stimuli (above 90\%), and to rotated and singleton stimuli as well (above 90\%). Pigeons in the sparse conditions took longer to learn but, just as in the dense conditions, the level of supervision minimally affected their rate of learning. In both sparse conditions, accuracy to novel stimuli was high, albeit lower than in the dense conditions (85\%). Accuracy to the singleton stimuli was high as well (85\%), but it dropped a bit more for the rotated stimuli (75\%). Pigeons' representations of the categories seemed to include feature-location binding as well, just as we observed in the rats; however, this factor played a much smaller role in the pigeons' performance.

## Conclusions

The results indicate clear differences in category learning between rats and pigeons. Pigeons learned rapidly in all four
conditions and their learning rate was not affected by the level of supervision. For pigeons, the most important factor was the density of category-relevant features-dense categories were learned faster than sparse categories. In contrast, rats showed robust learning only in the dense-high supervision condition. Statistical density is therefore a crucial factor for visual category learning in birds, rodents, and humans. The interaction of density and supervision is more complex, however, and may be related to whether the organism is remembering visual features, binding features and spatial locations, or learning category rules.

The differences in category learning between pigeons and rats may reflect differences in brain organization. Birds do not have a laminar cortex or a prefrontal cortex. Thus, the pigeons' insensitivity to the level of supervision might be related to the absence of prefrontal processing of differential reinforcement. The clear superiority in learning rate in the pigeons relative to the rats suggests, however, an advantage in memory for visual stimuli, which might be related to specializations within the visual areas of the avian brain.

# Cognitive mechanisms for imitation and the detection of imitation in human dyadic interactions 

Antonia F. de C Hamilton (a.hamilton@ucl.ac.uk)<br>Institute of Cognitive Neuroscience, University College London<br>Alexandra House, 17 Queen Square, London, WC1N 3AR

Keywords: imitation; mimicry; social interaction; eye contact; gaze; signaling;

## Introduction

Imitation is a ubiquitous human behavior which has been linked to both social learning and social bonding (Uzgiris, 1981). Here, we examine how imitation is used in the context of social affiliation, with a particular focus on the unconscious mimicry of body postures or gestures which are sometimes referred to as the 'chameleon effect' (Chartrand \& Bargh, 1999). The 'social glue' hypothesis of mimicry claims that mimicry behavior has a key causal role in social affiliation (Lakin, Jefferis, Cheng, \& Chartrand, 2003; van Baaren, Janssen, Chartrand, \& Dijksterhuis, 2009). For example, if Anna mimics an action by Bert (without awareness in either), the theory claims that Anna sends a prosocial signal to Bert and Bert receives that information (Wang \& Hamilton, 2012).

A correlational relationship between increased bodily mimicry in dyadic interactions and positive ratings of the interaction has been repeatedly observed (Pentland, 2008). However, direct experimental evidence that mimicry has a social signaling role remains weak. Two major types of evidence can show if an action functions as a social signal first, does the sender's behavior change depending on who can see the signal? and second, does the receiver act on the signal? This talk will examine recent evidence for each of these, and will thus test the social glue hypothesis of mimicry.

## Is mimicry changed by who can see?

Several studies suggest that mimicry is enhanced when another person makes eye contact and can receive a signal from the mimicker (Bavelas, Black, Lemery, \& Mullett, 1986; Wang, Newport, \& Hamilton, 2011). Here I will focus on three recent studies which show how mimicry in children and adults is modulated by the gaze behaviour of an observer. First, we report that children performing an overimitation task (similar to Marsh, Ropar, \& Hamilton, 2014) show more imitation behaviour when observed by an adult than when the adult turns her back (Marsh \& Hamilton, n.d.). Second, we show that rapid hand action mimicry is enhanced when the participant is observed at the time of response, but not if the observer's gaze is occluded just before the response (Wang \& Hamilton, 2013). In a third study, we asked dyads to complete a leader-follower
task where the leader demonstrated a movement sequence and we measured how closely the follower copied the kinematics of the sequence despite not being instructed to do so. We find that followers imitate with higher fidelity when the leaders eyes are open than when they are closed (Krishnan-Barman \& Hamilton, n.d.), matching the predictions of the signaling hypothesis.

Together, this series of studies provides clear evidence that the production of mimicry behavior varies according to whether the mimicry can be seen by another person or not. This is true across children, adult reaction time studies and adult dyadic interactions. These results are compatible with the idea that senders are producing mimicry as a social signal, in order to convey information to another person.

## Is mimicry detected by receivers?

For mimicry to function effectively as a signal, the message must be send and also received. That is, Bert must (on some level) detect that Anna is mimicking his action and respond to that signal. It is hard to find strong evidence for this, partly because it is not an easy experiment to implement. Most approaches require that a confederate should mimic or not-mimic the actions of a participant in a well-controlled manner. While some studies report positive effects (Chartrand \& Bargh, 1999; Müller, Maaskant, van Baaren, \& Dijksterhuis, 2012), others report mixed results or null effects (van Swol, 2003; Verberne, Ham, Ponnada, \& Midden, 2013). A full review of these results is provided in (Hale \& Hamilton, 2016a).

We propose that the most rigorous way to test the hypothesis that being mimicked leads to a positive social effect is to use virtual reality. In virtual reality mimicry, the experimenter has full control of the interaction and can ensure that mimicry (and only mimicry) is the factor which differs between experimental conditions, and that all participants receive a consistent experience. An early virtual reality study reported positive effects of being mimicked in VR (Bailenson \& Yee, 2005). We recently extended this result and examined how participants respond to being mimicked or not by a virtual character from their own culture or a different culture. In a pre-registered study with a large sample size, we find that mimicry of head motion which is not detected by participants has no impact on rapport or trust (Hale \& Hamilton, 2016b).

Several factors could account for this null result. First, we examined only mimicry of head motion, and mimicry of other motion features (e.g. gesture or posture) might lead to larger effects. Second, imperfections in the VR itself might negate any positive social effects, through similar VR systems can replicate many other psychological phenomena. Finally, it is possible that being mimicked is not implicitly detected as a social signal, arguing against the social signaling interpretation of mimicry.

## Conclusions

The present data suggests that the production of mimicry depends on who can see, but it is not yet clear if receivers respond positively to mimicry. This means that the role of mimicry as a social signal is not yet firmly established. We suggest that acquiring high-resolution motion capture data to better establish how dyads use mimicry will also enable the creation of better VR mimicry. This can provide a more definitive test of the claim that mimicry is used as a signal of social affiliation.

## Introduction

Convolutional neural networks (CNNs) trained as classifiers learn by associating visual inputs (e.g., photographs of objects) with appropriate output labels (e.g., "crow", "dog", "car"). These complex models, which contain millions of weights, are the state-of-the art in machine vision, rivaling humans in object recognition tasks (LeCun, Bengio, \& Hinton. 2015, Krizhevsky, Sutskever, \& Hinton, 2012). What these networks learn displays some commonalities with human learning (Kubilius, Bracci, \& de Beeck, 2016, Lake, Zaremba, Fergus, \& Gureckis, 2015). Furthermore, the layers in these networks have been related to neural activity along the ventral stream (Khaligh-Razavi \& Kriegeskorte, 2014, Yamins \& DiCarlo, 2016)

The similarity spaces created by these models at various network layers allow us to draw parallels with the brain's neural coding schemes (Guest \& Love, 2017). At earlier layers, networks display similarity spaces that reflect the high-level categories found in the input space, e.g., lions and tigers are more similar to one another than to mopeds. At the more advanced layers, similarity structure tends to break down such that representations of different object categories become orthogonal.

Can these networks also shed light on how non-human animals categorize? CNNs can be used to determine at what level of representation (i.e., what network layer) animals are coding similarities between images. For example, are animals learning regularities at a very low level, close to the pixels in the image, or are they seizing upon more abstract shape features? In this contribution, we address this question by examining data from pigeons trained to categorize images of cardiograms as normal or abnormal.

Pigeons are excellent at classifying visual stimuli (Bhatt, Wasserman, Reynolds, \& Knauss, 1988). For example, pigeons trained to discriminate between medical images of nor-
a)

b)

Figure 1: Two examples of the stimuli that the pigeons and network are asked to classify: a) a normal cardiogram without any perfusion damage; and b) an abnormal cardiogram with total perfusion damage 20 (of a maximum of 51 ).
mal and cancerous breast tissue generalized to novel stimuli and attained human-level accuracy (Levenson, Krupinski, Navarro, \& Wasserman, 2015). Importantly, knowledge transfer was only true in certain circumstances. Pigeons only generalized within image magnification levels - they were not scale-invariant. Also, generalization was significantly compromised, although still above chance, when tested on grayscale images (perhaps to be expected given the loss of hue and brightness cues). However, the pigeons' performance improved with additional training on greyscale images.

Can CNNs explain such patterns of performance? At the most advanced layers of these networks, representations should be somewhat invariant to changes in size, luminance, translation, etc. However, at lower layers the network will be more sensitive to such changes and will not generalize as broadly. Which network layer best captures how pigeons categorize?

Here we consider data from an a yet unpublished study by Wasserman and colleagues in which pigeons are trained to classify cardiograms as normal or abnormal, see Figure 1. Pigeons can correctly determine whether a cardiogram is ab-
normal or normal in much the same way as a skilled human, and can correctly classify unseen cardiogram images.

To parallel the pigeons, we also show the same stimuli to a CNN, namely Inception-v3 GoogLeNet (Krizhevsky et al., 2012). In line with the pigeons, the network can also determine whether a stimulus is normal or abnormal. Also like the pigeons, Inception-v3 GoogLeNet is very sensitive to changes in color, having serious problems generalizing when trained on color images and tested on grayscale without additional training. Importantly, even though the model can differentiate between the two classes at the output layer it can also do so at much lower layers. The output layer is trained to represent very high-level conceptual categories ( 1000 mutually exclusive classes, e.g., sunglasses, moped, jellyfish, etc.). Although these output classes do not contain options for normal and abnormal cardiograms, the network provides a distributed answer across these categories thus solving the classification task. In other words, the output shows a similarity structure matching the normal/abnormal distinction in the inputs.

As mentioned, at lower layers including the input layer, the network can also differentiate the two types of stimuli into normal and abnormal. This means that basic stimulus properties, which are what the network and the pigeons are extracting and learning, are sufficient to separate the two classes of cardiograms shown in Figure 1. This is important because it implies that more complex and abstract features, or even representations of basic shapes, are not required for the type of learning problem the pigeons are solving. In addition, this predicts that generalization will be poor in both the animal and computational models we have considered. We consider the broader implications of these results for how humans and non-human animals categorize.

Keywords: uncertainty; entropy; information; information gain, probability gain

#### Abstract

Notions of entropy and uncertainty are fundamental to many domains, ranging from the philosophy of science to physics. One important application is to quantify the expected usefulness of possible experiments (or questions or tests). Many different entropy models could be used; different models do not in general lead to the same conclusions about which tests (or experiments) are most valuable. It is often unclear whether this is due to different theoretical and practical goals or are merely due to historical accident. We introduce a unified two-parameter family of entropy models that incorporates a great deal of entropies as special cases. This family of models offers insight into heretofore perplexing psychological results, and generates predictions for future research.

## Uncertainty and Information

Notions of entropy and uncertainty are fundamental to many domains, ranging from the philosophy of science to physics. One important application of uncertainty is to quantify the expected usefulness of possible experiments (or questions or tests). Lindley (1956) suggested that an experiment's usefulness could be quantified in terms of how much it reduces expected Shannon (1948) uncertainty about the possible states of the world. This idea has proven useful in psychological models (Oaksford \& Chater, 1994) as well. In a psychological context, the possible states could be the different categories that an object might belong to, and "experiments" could be a child's queries to learn more about the category. Other entropy models, such as Quadratic entropy (Crupi \& Tentori, 2014) or Bayes's error (Baron, Beattie \& Hershey, 1998; Crupi, Tentori \& Lombardi, 2009) could also be used. Different models do not in general lead to the same conclusions about which tests (or experiments) are most valuable (Nelson, 2005, 2008, 2009).

What kind of entropy model best characterizes people's goals in searching for information? Some data suggest that reduction in Bayes's error (probability gain) is a more plausible intuitive model than reduction in Shannon entropy
(Nelson, McKenzie, Cottrell \& Sejnowski, 2010; Meder \& Nelson, 2012). Probability gain appears to have its own limitations, however, as it does not show a preference for questions with close to a $50: 50$ split in 20-questions games (Nelson, Divjak, Gudmundsdottir, Martignon \& Meder, 2014).

Many different ideas of important axioms for entropy measures have been proposed (Csiszár, 2008). Interestingly, particular entropy measures have been predominant in particular research areas, and it is often unclear whether this is due to different theoretical and practical goals or are merely due to historical accident.
Is there any possibility for a formal model of uncertainty that would be able to describe people's behavior across a wide variety of tasks? Could such a model also have theoretically desirable properties?

Entropy is often thought of as expected surprise. But (1) what constitutes surprise, and (2) what constitutes an expectation? Depending on how surprise and expectation are defined, different entropy measures result. Combining these two ideas, we show that many entropy measures, including Hartley (1928), Shannon (1948) and Quadratic entropy, and the families of Tsallis (1988), Rényi (1961), and Arimoto (1971) entropies, can all be derived as special cases in the Sharma-Mittal (1975) framework for entropy measures.
Figure 1 depicts the Sharma-Mittal space of entropy measures graphically, where the horizontal axis (the order $r$ ) specifies the type of averaging function, and the vertical axis (the degree $t$ ) specifies the surprise function. A number of heuristic ideas of uncertainty, for instance the number of possibilities, and whether or not you know for sure (analogous to a Popperian formulation, Popper, 1959), also arise as special cases in this framework.

Can psychological insight be derived from this formalism? We show that many heretofore disparateseeming empirical results and normative desiderata can be accommodated by specific entropy measures within this formalism. Importantly, this framework affords more than a post hoc story; novel predictions can be derived for future experiments, to better characterize the psychological bases of uncertainty and information.

Figure 1: The Sharma-Mittal framework

# What The Shape and Material Biases Can Tell Us About Object Recognition 

Lynn K. Perry (lkperry@miami.edu)<br>Department of Psychology, 5665 Ponce de Leon Blvd<br>Coral Gables, FL, 33146 USA

Keywords: vocabulary, novel noun generalization, word learning, object recognition, drawing

## Motivation and Background

Imagine a child who is just beginning to produce words. To figure out what a word like CUP means, she has to not only identify the individual cup, but also understand what properties are relevant for belonging to the category of cups in order to remember the word later and apply it to new cups she encounters (e.g., its abstract shape rather than its purple plastic material).

At the same time this child is learning all about cups, she is also learning other words, many of which also name categories of objects similar in shape (e.g., BALL and CAR), from which she will learn a bias to attend to shape when generalizing novel names to novel objects (i.e., shape bias). A child's prior knowledge and experiences help her to not only learn individual words and categories, but also, more importantly, to learn how to learn words, making subsequent word learning easier.

In this talk I will discuss my research on children's word learning biases and the consequences these biases have on their future learning and generalization. Additionally, I will discuss how our understanding of the development of these biases can inform our understanding of children and adults' visual recognition abilities.

## Attention to Shape

At first glance, the "shape bias" may seem like an artificial laboratory phenomenon. Children are presented with three novel objects: an exemplar, one object that matches the exemplar in shape but differs in material and color, and one object that matches the exemplar in material but differs in shape and color. When the experimenter names the exemplar and asks the child to generalize it to one of the other two saying, by the time children are about 2-years-old they systematically select the object mapping in shape (Landau, Smith, \& Jones, 1988). Although this phenomenon may seem simple, it has been shown to have consequences for children's future word learning (e.g., Perry et al., 2010) and is window into children's developing object recognition (Yee, Jones, \& Smith, 2012) and memory (Vlach, 2016).

Additionally, evidence from atypical populations further suggests that the shape bias can tell us about developmental process. For example, children with autism (Tek, Jaffery, Fein, \& Naigles, 2008), children who are late talkers (Jones \& Smith, 2005), and children who are deaf or hard of hearing and wear cochlear implants (Quittner, Cejas, Wang, Niparko, \& Barker, 2016) all show delayed or atypical biases when generalizing novel nouns.

My own work reveals interesting individual differences even within typically developing populations. Children whose vocabularies differ from the norm show generalization biases that differ from the norm (Perry \& Samuelson, 2011). The more words a child knew naming solid objects in categories organized by similarity in shape (e.g., CUP), the more likely she was to generalize novel names by similarity in shape. However, the more words she knew naming solid objects in categories organized by similarity in material (e.g., CHALK), the more likely she was to generalize novel names by similarity in material.

I have extended this line of research to examine how vocabulary differences lead to differences in memory for objects' features (Perry, Axelsson, \& Horst, 2015) and recognition of familiar objects (Perry \& Saffran, 2016). For example, regardless of vocabulary size, children who knew relatively few names for categories organized by shape had more trouble recognizing objects in the wrong colors (e.g., pink cow) than children who know more categories organized by shape. The particular words children already know, bias their future word learning and recognition.

Importantly, longitudinal training studies suggest vocabulary regularities play a causal role in shape bias development. Teaching young children categories organized by similarity in shape leads them to develop a precocious shape bias and learn new words at an increased rate (e.g., Perry et al., 2010). Together, this work on the shape bias offers insights about developmental process: 1) the process of learning words has cascading consequences for future word learning; and 2) the structure of a child's vocabulary influences what information they attend to and remember.

## Attention to Material

In addition to learning about solid objects like CUP, children also learn about nonsolid substances like applesauce and JUICE, for which material is important. When generalizing the names of novel nonsolids, older children and adults attend to similarity in material ("material bias"). Compared to the shape bias, the material bias is later acquired (Samuelson \& Smith, 1999) and is sensitive to stimuli and task changes (Samuelson \& Horst, 2007).

One reason for this difference in development is that children learn about nonsolids in a relatively constrained context-all early-learned nonsolids are foods seen at mealtimes, while solids are seen across a variety of contexts. I found that putting children in a highchair allows them to explore stimuli as they would at mealtimes and led them to show a material bias several years earlier than they do in a standard lab context (Perry, Samuelson, \& Burdinie, 2014).

An additional difference is that materials might be difficult to recognize from static visual information and may
require tactile information. Indeed, it was the children who touched stimuli the most who showed the strongest material bias in my study (Perry et al., 2014). And those in the highchair were messiest because that setting increased context-dependent action patterns that proved necessary for recognizing similarity between materials (cf Perry, 2015). Children's developing attention to material similarity builds on what we already know about attention to shape, and also provides new insight into the importance of context and exploration in recognition and generalization.

How do children eventually learn to pay attention to substances' materials outside of this specific context? Adults don't need to sit in a highchair to distinguish whiskey from juice. How do children learn to visually recognize materials? What do adults even know about substances? These questions have important applications beyond understanding word learning: although we can teach artificial intelligence systems to recognize solid objects, it is nearly impossible to teach them to recognize nonsolid substances (Adelson, 2001). To begin answering these questions, I conducted a study in which adults and children drew familiar objects and substances from memory.

## New Insights From Drawing

In my recent work, I assessed children and adults' drawings of familiar objects and substances from memory. Examining these drawings allows us to assess what visual information is relevant to representations of different kinds of things and how this information changes over development. As such, this study is an important first step in understanding how we recognize objects and substances.

Amazon Mechanical Turk participants identified drawings. Critically, they were more accurate in identifying drawings of solid objects than nonsolid substances. Both children and adults tended to include container information for nonsolids rather than draw the substance itself. Drawings of nonsolids that depicted distinct, prototypical containers (e.g., milk carton, coffee mug) aided recognition.

Additionally, adult were quite consistent in color usee.g., all adults drew brown (i.e., chocolate) pudding and purple grapes, while children used a variety of colors. These results suggest 1) color might be more important to object representations than previously believed and 2) that as children develop, they become more systematic and prototypical in the colors they associate with objects.

Overall, these new findings build on my previous work examining children's attention to shape and material by demonstrating what information we use to remember and recognize solids and nonsolids. These results demonstrate that visual recognition of both solids and nonsolids-is aided by shape, suggesting we may conceptualize nonsolids as more object-like than was thought.

#### Abstract

Word meaning priming has become a key method to study how listeners (and readers) retune their lexical semantic representations in response to their linguistic environment in order to facilitate access to word meanings. We present a summary of recent findings using this method that help to constrain our theories of how this important form of lexicalsemantic learning occurs.

Keywords: lexical ambiguity; semantic ambiguity; learning; speech; language

## Background: Lexical Ambiguity

Access to word meanings during natural language comprehension is made difficult by the ubiquity of lexical ambiguity: $80 \%$ of common English words have multiple dictionary definitions (Rodd, Gaskell \& Marlsen-Wilson, 2002). Take for example the first sentence of a reading comprehension text that was recently given to 11-year-old children in England: "Dawn was casting spun-gold threads across a rosy sky over Sawubona game reserve". The words in this sentence have on average 8.8 dictionary definitions. The reader must work out that "Dawn" does not refer to a girl's name and that "game" does not refer to a form of competitive sport. And they must realise that the words "casting" and "threads" are not referring to a physical action and object, but are instead being used in a somewhat metaphorical sense.
When a listener/reader encounters an ambiguous word, they usually rapidly retrieve the most appropriate meaning and ignore any other irrelevant meaning(s). A very large body of psycholinguistics experiments conducted over the last 40 years have provided important constraints on our understanding of how this disambiguation process operates. The literature has converged on the view, exemplified in the reordered access model (Duffy, Morris, and Rayner, 1988, see Vitello and Rodd, 2014 for review) that whenever a reader/listener encounters an ambiguous word, its multiple different meanings are activated in parallel, but this activation is modulated by the sentence context and the relative frequencies of the different meanings: meanings that are highly frequent or compatible with the preceding context are more readily available.

## Word Meaning Priming: Published Findings

Recent studies using a novel word-meaning priming paradigm (Rodd et al., 2013; 2016) have supplemented this view of lexical disambiguation with evidence that learning
mechanisms make a key contribution to disambiguation fluency, by allowing listeners to make use of the past experience to boost the availability of meanings that are more likely to occur in the future. For example, comprehension of a sentence such as "the sheep were put into the pen", is usually relatively difficult because the intended 'animal-enclosure' meaning of "pen" is far less frequent than the dominant 'writing-instrument' meaning. But learning mechanisms can make such sentences easier in conditions where the listener has increased prior experience with the lower frequency meaning.

Specifically, these word-meaning priming experiments have revealed the key role of recent experience in modulating the availability of word meanings. For example, if the lower-frequency meaning of "pen" is encountered as part of a sentence comprehension prime task, then this meaning will be more readily available after a 20-40 minute delay (compared with an unprimed control; Rodd et al., 2013; 2016). This form of word meaning priming does NOT reflect a general forms of semantic priming; a control condition in which participants were primed with different but synonymous words showed no priming at this relatively long delay (Rodd et al., 2013). Word-meaning priming only occurs when the specific ambiguous word (e.g., "pen") is encountered in both the prime and test phases. In natural listening situations this dynamic 'retuning' of lexicalsemantic representations will act to improve comprehension fluency for cases where an ambiguous word is encountered multiple times within the same conversation.

In addition to these lab-based experiments that have shown word-meaning priming at 20-40 minute delays (with little decay during this time window), experiments conducted with larger sets of participants outside the lab have shown that even larger priming effects occur as a consequence of naturalistic encounters with word meanings. For example when recreational rowers encounter the specific rowing-related meanings of common words like "catch" and "feather" during their training, a significant and numerically large priming effect was observed after a median delay of eight hours (Rodd et al., 2016). In addition, these relatively large effects of same-day experience with word meanings leave residual traces that accumulate incrementally over many years to alter a listener's overall preferences for the different meanings: the number of years rowing experience that an individual rower had was a strong predictor of meaning access (Rodd et al., 2016).

Taken together, these results indicate that adult lexicalsemantic representations are relatively fluid and are
constantly being retuned on the basis of experience to improve the fluency and accuracy of comprehension.

## Word Meaning Priming: Recent Developments

A set of seven (unpublished) word-meaning priming experiments have been conducted to help constrain our theories of how exactly the availability of word meanings is boosted as a consequence of our experience.

Effects of prime/target modality. Two experiments (using different tasks at test) show that word-meaning priming occurs when the ambiguous words are presented in different modalities (i.e. spoken and written) at prime and test, and that such cross-modal priming is not reduced compared with uni-modal priming. This indicates that learning may occur at a relatively abstract lexical-semantic level, and that knowledge about words learned in one modality influences comprehension in the other modality.

Effects of word position. Two experiments (using different tasks at test) show that word-meaning priming is NOT modulated by the position of the ambiguous word within the sentence: there is no significant difference in priming when the disambiguating context occurs before or after the ambiguity (e.g., "the sheep were enclosed in a PEN" vs "a PEN was used to enclose the sheep"). These results are incompatible with an account where learning is triggered by the detection of an error signal that indicates that the ambiguous word has been misinterpreted, as this would predict increased priming for late-disambiguation sentences. The results are also incompatible with an account in which the co-activation of the word form and the contextuallyappropriate drives learning: this would predict more priming for the early-disambiguation sentences. Instead the results indicate that lexical semantic representations are modulated on the basis of a word's final, comprehended meaning and do not seem to be influenced by partial, transient activation of irrelevant meaning during comprehension.

Effects of multiple encounters. Three experiments show that listeners keep track of the likelihood of different meanings across multiple encounters with the ambiguous word. If the word is used repeatedly with the same meaning, the priming effects accumulate to increase the availability of this meaning relative to a single presentation control condition. In contrast, if different meanings are encountered then the effects of these experiences cancel each other out. Importantly, the cumulative effects of repeated exposure are dependent on the spacing of the words - no benefit of repetition is observed if the word is encountered multiple times in adjacent sentences.

## Summary

Word meaning priming has become a key method to study how listeners (and readers) retune their lexical semantic representations in response to their linguist environment.

We present recent findings using this method that help to constrain our theories of how this learning occurs and will guide the development of our connectionist model of how words are represented and processed (Rodd et al., 2004).

#### Abstract

Implementing interventions that are supposed to enhance students' general learning skill and overall cognitive ability is still a common practice in education. The basic idea on which this approach relies is that improving domain-general skills provides benefits for a broad range of domain-specific areas, such as academic disciplines. Thus, it is assumed that there is far transfer i.e., the generalization of a set of skills between domains loosely related to each other. In recent years, chess instruction, music instruction, and working memory training have been claimed to be able to train domain-general abilities (e.g., fluid reasoning/intelligence) which, in turn, generalize to other cognitive and academic skills (e.g., mathematics). We tested these claims in the population of healthy children via meta-analysis. The results showed small to moderate overall far-transfer effects in all the outcome measures of the three meta-analyses. However, the effect sizes were inversely related to the design quality (e.g., presence of active control groups), which casts doubts on the effectiveness of the three activities. We discuss the theoretical and practical implications of these findings for education and expertise and extend the debate to another type of training, video games training.

Keywords: chess; education; learning; mathematics; music; transfer; working memory.

## Introduction

The question of transfer is central to cognitive science. Near transfer can be defined as the generalization of a set of trained skills across domains closely related to each other. Far transfer can be defined as the generalization of a set of trained skills across domains loosely related to each other. Ever since Thorndike and Woodworth's (1901) common elements theory, psychology has documented the difficulty of far transfer. As noted by these authors, transfer from one domain to another can only happen when the two domains share common elements. Thus, while near transfer is expected to occur fairly often (e.g., transfer is expected between geometry and calculus), far transfer is much less likely, as the source and target domains share few elements (e.g., no transfer is expected between Latin and calculus).

The field of education has been much more sanguine about the possibility of far transfer. For example, in a very influential book, Papert (1980) argued that the skills acquired in learning the programming language LOGO would transfer to mathematics and indeed would improve learning generally. (Considerable research has shown that this was unlikely to be the case; e.g., Gurtner et al., 1990.) More recently, very strong claims have been made in
educational quarters, on the web and in the popular press about the possible benefits of music, chess, and working memory training for improving academic achievements and a large variety of cognitive abilities (e.g., fluid intelligence, cognitive control, phonological processing, and spatial ability).

## Recent Evidence

In recent meta-analyses (Sala \& Gobet, 2016, 2017a, 2017b), we evaluated the evidence of transfer in three domains (chess, music, and working memory training). In all cases, we focused on healthy children and young adolescents.

The results showed null to medium overall effect sizes in all three meta-analyses. Moreover, the size of the effects was inversely related to the quality of the experimental design. Specifically, when the participants were randomly allocated to the groups and the experimental groups were compared to active control groups, the overall effect sizes were minimal or null.

Design quality thus accounts for the variability between the studies. The three treatments provide either minimal overall effects on academic achievement and overall cognitive ability (music and working memory training), or medium effects possibly due to placebo effects (chess) and/or statistical artefacts due to lack of randomization. Overall, these results support Thorndike and Woodworth's (1901) theory.

## Link with Expertise Research

The lack of far transfer in these domains might appear surprising, because there is considerable evidence in these domains for correlations with intelligence and other intelligence-related measures. In a survey, Schellenberg (2006) reported medium correlations between time spent for music lessons and several measures of cognitive ability and academic attainment in a sample of children and undergraduate students. Similarly, Burgoyne et al. (2016) found that with chess players, the correlation between skill and fluid intelligence was $\bar{r}=, 24$. Sala et al. (2017) found that chess players are more intelligent than individuals who do not play chess ( $\bar{d}=0.49$ ). Finally, the correlation between working memory and intelligence is about $r=.70$ (Kane, Hambrick, \& Conway, 2005).

Of course, this evidence is correlational, and drawing conclusions about causality is notoriously difficult. Nevertheless, the pattern of results (near absence of far transfer in training studies and correlations with intelligence) suggests that, in the domains we have reviewed, intelligence comes first and explains why some individuals perform better than others.
We also note that the difficulty of far transfer is consistent with several theories of expertise. In particular, both chunking theory (Simon \& Chase, 1973) and template theory (Gobet \& Simon, 1996) propose that the development of expertise is closely linked to the acquisition of a large number of perceptual patterns. These patterns allow experts to memorise domain-specific material better than non-experts, even when the global structure of the material is destroyed by randomization (Sala \& Gobet, 2017c). Accessing knowledge depends on productions matching these perceptual patterns. Thus, even if two domains share common elements at an abstract level, these two theories predict that far transfer is unlikely, as the perceptual patterns met in the two domains are different (Gobet, 2015, 2016; Gobet \& Campitelli, 2006).

We are currently carrying out a meta-analysis of the effects of video game playing to further test these hypotheses. We strongly predict that near transfer will be common, but that far transfer will be rare. The results of this meta-analysis will be ready for the conference.

## Implications for Education

The studies discussed above suggest that the widespread notion that practicing any cognitively demanding activity enhances one or more cognitive skills beyond the trained activity has little empirical support. In other words, the benefits of cognitive training seem to be, to a large extent, domain- and task-specific. Practically, the unlikely occurrence of far transfer suggests that the most effective way of improving a skill is to train that particular skill. This sobering conclusion should discourage educators and trainers from proposing curricula aimed at fostering domaingeneral skills. Rather, curricula and training programs with a considerable amount of domain-specific content should be preferred. Thus, if the aim is to teach mathematics, lessons focusing on mathematics are better than lessons containing material on music, chess or working memory training.

# Scientific Sensemaking: A Critical Resource for Science Learning in School 

Christian D. Schunn (schunn@pitt.edu)<br>814 LRDC, University of Pittsburgh, 3939 O'Hara St<br>Pittsburgh, PA 15260 USA

Keywords: Science Learning; cognitive resources

## Conceptualizing Integration \& Transfer

Science consists of both a body of knowledge and a process by which the knowledge is produced. Historically, these two aspects were often assessed separately (i.e., test items on knowledge and test items on skills) and taught relatively separately (e.g., with an introduction section on skills or via isolated projects or labs). The last decade has been marked by a substantial shift to an integrated view of both how science should be taught and how science learning should be assessed. Now, consensus reports (e.g., NRC, 2007, 2011) assert that scientific processes (renamed practices) should be used to learn science content (e.g., by designing, conducted, and interpreting experiments, or by arguing from existing sources). Further, new science standards (e.g., NGSS) strongly claim that science practices must be demonstrated in use with scientific content and that scientific content must be demonstrated through use with scientific practices.

While the central point about the importance of practice and content integration is well supported by existing data (for a summary, see NRC 2011), embedded within these new conceptions of teaching and learning science are some open cognitive foundations questions that bear further investigation. These questions have important implications for both assessment and instruction. The first open question is the about the generativity and transferability of practices across content. If students learn sciences practices in one science content area (e.g., in biology), are they able to apply those science practices in another domain (e.g., chemistry)? Expert scientists have some transferability of their skills (Schunn \& Anderson, 1998), but will students also show such transferability? If so, they will be better positioned to learn new content having mastered practices in a prior science content area. However, if practices are very tightly bound to science content given how they are taught and learned, students may struggle with using these practices in new content areas.

The second but related open question has to do with the coherence of practices. If science consists of independent practices, is it meaningful to report an overall mastery level of science practices? However, if science practices work together in overall cycles of inquiry, then students who master some practices will be better positioned to master other practices, and there will be meaningful overall mastery level of science practices which can be taught and assessed.

Taking on both of these open questions, here I present recent tests of the general hypothesis that there is a general overall mastery level of core scientific practices that drives
learning in new science content areas. If supported, instruction should be organized around developing these core practices early in instruction (to accelerate later learning). Also, support for this approach suggests that computational agents could be developed to systematically acquire science content through experimentation and reading using scientific sensemaking skills as a foundation.

Conceptualizing this general mastery level as scientific sensemaking, and efficiently measuring it using scenarios that invoke shared, intuitive understandings of the natural world, I will describe recently obtained evidence that 1 ) students tend to vary along coherently along this overall sensemaking dimension; 2) overall sensemaking levels are a strong predictor of science learning; and 5) this overall sensemaking dimension can improve with effective science instruction.

## Conceptualizing Scientific Sensemaking

Approaching learning of science-related content as a sensemaking activity means recognizing that science is not a series of facts, but rather an ongoing and iterative employment of a set of practices that used in the pursuit of an increasingly rich understanding of natural and physical phenomena. These practices include asking good questions, seeking mechanistic explanations for natural and physical phenomena, engaging in argumentation about scientific ideas, interpreting data tables, designing investigations, and understanding the changing nature of science (Apedoe \& Ford, 2009; Lehrer, Schauble, \& Petrosino, 2001). Each of these practices play an important and complementary role in science learning. In selecting practices for inclusion within the scientific sensemaking construct, several criteria needed to be met: 1) an existing research-base for its role in predicting science achievement; 2) uniqueness in its contribution to learning; and 3) the flexibility to be improved through targeted instruction.

## Measuring Scientific Sensemaking

To cleanly measure scientific sensemaking, it is important consider several critical issues. First, the measure had to be about some scientific content: one cannot engage in scientific sensemaking void of content-science has some logic to its processes, but most of the logic is context specific about which assumptions or inferences are merited. Consider the class Control-of-Variables strategy (Zimmerman, 2007). This strategy can only be applied when it is clear what variables are possible to vary (and plausibly causal), which involves thinking about content.

A second consideration is that the assessment be effortworthy. Engaging in scientific sensemaking requires effort, and there is often little incentive for students to put forth effort to perform on an assessment. If students are not putting effort into the assessment, then the scores obtained from the assessment are an underestimate of the abilities students have. In order to motivate students to put forth effort, the content we selected for the assessment scenarios were so-called "charismatic mega-fauna" (i.e., Dolphins, Monkeys, \& Eagles), in which a general interest in the topic motivates some basic level of effort (Bathgate, et al. 2013).

A third consideration is assessment length. Items that are cognitively demanding of students and require them to make sense of scientific information, take relatively longer amounts of time than items simply requiring content recall.

## Empirical Tests of Scientific Sensemaking

After consideration of design considerations listed above, a new measure was created, and its psychometric properties were verified. Then, the validity of scientific sensemaking as a predictor of future content learning was tested in a large-scale study of students learning diverse science content across middle school and early high school grades in diverse curricula (included more hands-on and more text-book-based). Finally, changes in scientific sensemaking were examined in relation to levels of student engagement in classroom learning, to show that is malleable, rather than a fix construct like IQ.

# Unsupervised Learning in an Animal Model 

Edward A. Wasserman (ed-wasserman@uiowa.edu)<br>Leyre Castro (leyre-castroruiz@uiowa.edu)<br>Department of Psychological and Brain Sciences, The University of Iowa<br>301 East Jefferson Street, Iowa City, IA 52242, USA<br>Vladimir M. Keywords: unsupervised learning; supervised learning; associative learning; animal model; pigeons

## Introduction

The learning of rich associative networks is foundational to language and other advanced cognitive competencies. Such learning is commonly encouraged by direct supervision entailing explicit feedback for correct and incorrect responses. The power of explicit feedback has recently been demonstrated in an animal model (Wasserman, Brooks, \& McMurray, 2015), in which pigeons successfully learned to categorize 128 stimuli into 16 human language categories via both associative strengthening and weakening processes (Roembke, Wasserman, \& McMurray, 2016).

The use of supervised training strongly implies "cajoling" an organism to respond correctly. Most supervised learning tasks for animals differentially reinforce behavior, so that reward is given when the animal's response is correct, but not when the animal's response is incorrect. Arranging unsupervised associative learning tasks in an animal model is decidedly more difficult, as doing so requires that experimenters nondifferentially reinforce behavior.

Nonetheless, unsupervised learning may materially participate in the acquisition of rich associative networks. Given that supervision can dramatically change how stimuli are learned and represented (Love, 2002), a key and as yet unmet challenge is to devise behavioral tasks that demonstrate associative learning in animals and that do not involve explicit supervision. Extending work in infant behavior (Sloutsky \& Robinson, 2013), we devised and deployed a promising new paradigm to assess unsupervised learning in a pigeon model.

## Experiment

Two groups of four pigeons each were shown eight object images and eight color patterns on a touch-sensitive computer screen. In the Consistent Pairings group, each object was paired with a particular pattern (e.g., Object A was always paired with Pattern 1, etc.), so that these birds could learn eight specific object-pattern pairs. In the Random Pairings group, each of the eight objects was presented an equal number of times with each of the eight color patterns, so that these birds could not learn any consistent object-pattern pairs. All birds were first trained
without supervision and later trained with supervision, yielding two different ways to assess associative learning.

## Unsupervised Phase

Daily sessions comprised 128 trials, in which each object image was shown 16 times: always followed by the same color pattern in the Consistent Pairings group or randomly followed by each of the color patterns in the Random Pairings group. Birds simply had to peck each of the images a fixed number of times (gradually increased to 10). After completing that requirement-first to the object and next to the color pattern-food was always given. There were no correct or incorrect responses; so, no differential feedback was ever provided. Under these unsupervised training conditions, were the Consistent Pairings birds learning the statistical relations between each object and color pattern?

To find out, after 5 sessions of training, we gave 1 testing session in which-in addition to the 128 training trials-we included 28 testing trials. On testing trials, after pecking the object, two color patterns (rather than one) appeared to the left and right of the object. In the Consistent Pairings group, one color pattern was the same one that had consistently followed the object in training sessions, whereas the other was one of the remaining color patterns, randomly chosen. In the Random Pairings group, the two color patterns were randomly chosen. We repeated this sequence of 5 sessions of training followed by 1 session of testing 8 times. Food always followed any choice response the bird made.

Figure 1: Mean percent correct for Consistent and Random Pairings groups on test trials during the unsupervised phase.

Results on testing trials are shown in Figure 1. The percent of correct responses reflects the tendency of birds in the Consistent Pairings group to choose the color pattern
that had been paired with the object. There was no correct choice possible for the birds in the Random Pairings group, so their choice was bound to lie near the $50 \%$ chance level ( $M=52 \%$ ). Surprisingly, birds in the Consistent Pairings group actually preferred to peck the other color pattern, not the one that had been paired with the object; their choice performance was significantly below chance ( $M=35 \%$ ).

Thus, pigeons in the Consistent Pairings group did learn which specific color pattern was associated with each specific object; however, in choice tests, they displayed a preference for the other color pattern. This type of choice appears to parallel the preference for novelty in the classical children's preferential looking paradigm. Critically, all of the stimuli in our experiment were equally novel in both the Consistent Pairings group and in the Random Pairings group. Thus, the difference in performance here clearly implicates associative learning.

## Supervised Phase

After eight cycles of unsupervised training and choice testing, we began the supervised training phase, which was the same for both groups of pigeons. Now, all trials presented one object followed by two color patterns. Choice of the correct color pattern was followed by food, whereas choice of the incorrect color pattern was not. Figure 2 shows the number of training sessions necessary to reach $65 \%$, $75 \%$, and $85 \%$ accuracy levels.

Figure 2: Mean number of days for Consistent and Random Pairings groups to reach $65 \%, 75 \%$, and $85 \%$ accuracy levels in the supervised phase.

Mean accuracy on the first session of supervised training was $38 \%$ for the Consistent Pairings group and $51 \%$ for the Random pairings group, agreeing with their earlier behavior. Yet, despite this initial disadvantage, the Consistent Pairings group was actually faster to reach the $65 \%, 75 \%$, and $85 \%$ correct levels than the Random Pairings group. Again, the Consistent Pairings group showed clear evidence of having learned the object-pattern pairs during the unsupervised training phase, here by learning faster than the Random Pairings group during the supervised learning phase.

## Conclusions

These results clearly demonstrate unsupervised associative learning in pigeons using the same general stimuli and response options used in our earlier work in pigeons'
supervised category learning. One must appreciate, however, that supervised learning tasks are not altogether free from the influence of unsupervised learning. When correct responses are made and positive feedback is given, a statistical regularity is enforced which can strengthen the stimulus-response bond on correct-choice trials. What most strikingly distinguishes supervised from unsupervised learning is therefore likely to be what happens on incorrectchoice trials; here, weakening or pruning of stimulusresponse bonds can further direct responses to the correct choice option. Just such independent evidence was provided in the research of Roembke et al. (2016).

What remains to be determined is why-during the supervised phase-pigeons in the Consistent Pairings group were reluctant to peck the color pattern that had earlier been paired with the object image. Further work is underway to make that determination.

#### Abstract

There is contradictory evidence on whether speech production gets impaired or enhanced when people are restrained from gesturing. There is also very little research on how this effect can change with aging. The present study sought evidence for these by asking young and elderly adults to describe two different routes on a map in spontaneous speech and when gestures were prohibited. We found that elderly adults produced more spatial language when they were restricted to use gestures compared to their spontaneous speech, whereas young adults produced comparable levels of spatial language in both conditions. Young and elderly adults used comparable levels of gestures in their spontaneous route descriptions. Yet, only young adults' gesture use correlated positively with their spatial language production. Thus, the results of gesture prohibition on speech production are different for young and elderly adults.

Keywords: gesture restriction; speech production; aging; spatial language

## Introduction

People produce spontaneous gestures as they speak. Gestures improve communication as listeners understand a spoken message better when it is accompanied by a visible gesture (Hostetter, 2011). This enhanced communication might arise because gestures provide an image that is particularly informative about the spatial or motor aspects of the message that are not easily encoded in speech. That is, gestures, especially the ones accompanying spatial or motor information, improve communication (Alibali, 2005). Apart from the effects on the listener, gestures also benefit speakers. Gestures can directly convey imagistic components of thought due to the isomorphism between spatial-motor images and representational gestures. This
might be helpful for speakers describing spatial-motor events (Church \& Goldin-Meadow, 1986). The current study investigates the role of gesturing on the use of spatial language in a spatial task in young and elderly adults. We examined the relation between gesture and speech to address two questions: (1) How does people's use of spatial language change when they are restricted from using gestures in a spatial task? (2) How does aging influence the link between gesture production and spatial language use?

## How does gesture restriction affect speech production?

There are multiple accounts suggesting that gesturing benefits speakers as they speak (e.g., Kita, 2000; Krauss, Chen, \& Gottesman, 2000; Melinger \& Levelt, 2004). However, these accounts differ in the proposed mechanism for this benefit in speech. The Information Packaging Hypothesis (Kita, 2000) states that gestures help speakers to organize and package visual-spatial information into the linear and segmented units of language. Forming an image of the referent by gesturing might induce attention on the specific properties of that image, thus, helping speakers to break their rich spatial representations into units that are codable in speech. According to this model, when people are restricted from gesturing while talking about spatial information, people have difficulty in organizing their rich spatial-motor ideas into the units of language. As a result, they produce less spatial information in their speech compared to the cases in which they can spontaneously produce gestures. Indeed, Rimé and colleagues (1984) found that when people are restricted from gesturing, their speech contained less vivid descriptions. In line with the Information Packaging Hypothesis, when producing motor descriptions (e.g. how to tie a shoe), people who were free
to produce gestures used more semantically rich verbs referring to key elements in motoric descriptions (Hostetter, Alibali, \& Kita, 2007).

Another account, the Lexical Access Hypothesis, suggests that gestures might facilitate speech to retrieve words especially when expressing spatial information (Hadar \& Butterworth, 1997; Krauss, Chen, \& Gottesman, 2000). One prediction of this account is that if speakers are restricted from gesturing, they will have problems in retrieving the correct words particularly when they describe spatial-motor events. Thus, in line with Information Packaging Hypothesis, this account argues that speech will be impaired in the absence of gesture use. Many studies support this account (Krauss, 1998; Rauscher, Krauss, \& Chen, 1996). For example, Hostetter, Alibali, and Kita (2007) found that speakers who were restricted from gesturing started their speech with more connectors such as "and" compared to speakers who were free to use gestures when describing motoric events. The disfluencies observed in the absence of gesture is more evident in spatial contents. When restricted from gesturing, speakers were found to be speaking slower when talking about spatial information compared to the nonspatial aspects of a cartoon (Krauss, 1998). Also, speakers produced higher proportion of filled pauses (e.g. um, uh) when they could not gesture, indicating that they had difficulty in accessing the lexical items.

Another account suggests that speakers use gestures to supplement and/or complement their speech (Melinger \& Levelt, 2004). It is easier to convey the imagistic properties of spatial-motor events with gestures in a more global manner compared to speech (see also Kita, 2000). Yet, according to this account, speakers use speech and gesture concurrently; but if a gesture expresses necessary information, then, that information can be omitted in speech. For instance, Melinger and Levelt (2004) found that speakers who produced iconic gestures representing the spatial relations omitted the required spatial information from their speech more compared to speakers who did not gesture. Also, when restricted from gesturing, speakers used more spatial language when describing the spatial relations between objects (Graham \& Heywood, 1975).

Although all three accounts state that gesturing not only benefit communication of the listener but also of the speaker, they diverge on the mechanism of this benefit. They also propose different predictions on how speech will be affected in the absence of gesture use. The Information Packaging Hypothesis and the Lexical Access Hypothesis predict that speech will be impaired when speakers are restricted from gesturing, whereas the third account by Melinger and Levelt (2004) suggests that speech and gesture work as two different channels of expression, mutually
compensating each other. Thus, speech can be enhanced in the absence of gesture use.

## How does aging affect gesture production?

Although the effect of aging on communication has been studied considerably in the literature, the impact of aging on gesture use has received less attention. Studies investigating the effects of aging on gesture show that production (Cohen \& Borsoi, 1996), imitation (Dimeck, Roy, \& Hall, 1998), and comprehension (e.g., Cocks, Morgan, \& Kita, 2000) of gestures are all impaired by aging.

Aging can either affect cognition globally or increase problems in specific components of the cognitive system, such as working memory and spatial integration in visual processing (Andersen \& Ni, 2008; Copeland \& Radvansky, 2007). People with poor visual-spatial working memory and spatial transformation ability used more representational gestures (Chu, Foulkes, Meyer, \& Kita, 2014). Thus, it is possible that elderly people use fewer representational gestures in spontaneous speech due to problems in their working memory system. Cohen and Borsoi (1996) found that in an object description task, elderly adults produced fewer descriptive (i.e., representational) gestures compared to young adults; however, the use of non-descriptive (i.e., beat) gestures did not differ between young and elderly adults. These findings were interpreted as a specific consequence of reduced use of visual imagery in elderly people. No difference in the description quality of speech was found as a function of age. This study, in contrary to the Information Packaging Hypothesis (Kita, 2000), suggests that the less frequent use of gestures did not impair speech in elderly. Feyereisen and Harvard (1999) also investigated the production of representational and beat gestures in different description contents varying the likelihood of generating mental images. Elderly adults used fewer representational gestures when they talked about visuospatial content generating more mental imagery, whereas the use of beats for low mental imagery events was comparable between young and elderly.

The findings on the gesture use of elderly adults are not conclusive. Although elderly adults less frequently use representational gestures in spontaneous speech in spatial contents, the effects of gesture restriction on their speech is unknown. To our knowledge, no study has investigated how the effects of gesture restriction on speech, particularly spatial information, differ between young and elderly adults.

## The Present Study

The purpose of the present study is to further understand the effects of gesture restriction on speech production as a function of aging. We asked young and elderly adults to
describe two different routes on a directional map task without mentioning gesture use (i.e., spontaneous gesture production) and by prohibiting them from gesturing.

First, in line with the previous studies (e.g., Feyereisen \& Harvard, 1999; Cohen \& Borsoi, 1996), we expect that elderly adults would use fewer gestures compared to young adults when spontaneously describing the routes on the map. If gestures facilitate speech production by either helping speakers to organize and package visual-spatial information into units of speech (as suggested by the Information Packaging Hypothesis) or helping them to retrieve words (as suggested by the Lexical Access Hypothesis), then we would expect that young and elderly adults should use more spatial language in the gesture unrestricted condition compared to the gesture restricted condition. However, when we consider the already sparse use of gestures in elderly, we might also observe no difference between spatial language use in spontaneous speech and gesture restricted conditions in elderly adults. If, on the other hand, gesture helps speakers by easily conveying information that is not necessarily available in speech (Melinger \& Levelt, 2014), then, young adults should use more spatial language when restricted from gesturing compared to spontaneous speech. However, if elderly adults use fewer gestures compared to young adults, then elderly adults would use more spatial language in spontaneous speech compared to young ones and use comparable levels of spatial language across spontaneous speech and gesture restriction conditions.

## Method

## Participants

Twenty young ( $M_{\text {age }}=20.3, S D=2.18$, range: $18-22,9$ females) and 19 elderly ( $M_{\text {age }}=62, S D=7.17$, range: 52-78, 15 females) adults agreed to participate in the experiment in exchange for course credit or $\$ 10$ for an hour. All participants were right-handed and native English-speakers. Before the sessions, they were provided with a written, informed consent in accordance with the policies of the University of Pennsylvania's Institutional Review Board.

## Stimuli and Procedure

Participants were asked to describe two different routes (Route 1 vs. Route 2) on a San Diego Zoo Map in two different counterbalanced conditions in a quiet room with an individual setting (see Figure 1). All participants were seated on an armless chair to promote gesturing. The map was printed on an A1 size cartoon ( $594 \times 841 \mathrm{~mm}$ ) so that the routes were visible to the participants. The large and unnecessary identification signs were erased and targets were circled in pink to make finding them easier on the
map. Two routes (Route 1 vs. Route 2) were created. Route 1 was from a landmark at the bottom left to another landmark at the top right. Route 2 was the other diagonal route; from a landmark at the top right to another landmark at the bottom left. The map was present throughout the session and the experimenter held the map for the participant to describe the routes.

Figure 1: San Diego Zoo Map
In the first condition (spontaneous gesture condition; SG), participants were asked to describe the path they would take to go from one pink-circled landmark to another. In this condition, they were given no specific information about the use of speech or gesture. In the second condition (gesture restricted condition; GR), however, they were asked to sit on their hands and explain how they would continue from a different marked landmark to another just with speech. Participants always completed the SG condition first and GR condition second not to make them aware of the gesture use in the SG condition. However, the order of routes (Route 1 vs. Route 2) on the map was counterbalanced across different conditions. Sessions were videotaped for further coding.

## Coding

Speech. Participants' speech was transcribed verbatim in both conditions by a native English speaker. For each condition, we first calculated the number of utterances coded as the units of speech bounded by silence. Next, we coded three different spatial information in speech: (1) direction describing the course of movement in relation to other objects (e.g., down, south), (2) street names (e.g., Hippo trail or Parkway), and (3) landmarks (e.g., restaurant). Participants' frequency of using each spatial information in speech was calculated. We also calculated a composite speech score that was the sum of all spatial information in speech.

Gesture. Participants' use of spontaneous co-speech gestures was coded in SG condition. A change in the path of hand movement determined a new gesture. We coded three different gestures: (1) pointing (e.g., pointing at a landmark on the map), (2) tracing (e.g., continuously moving the finger or hand on the map to show the route), and (3) iconic (e.g., moving the hand off the map to represent a direction).

We also calculated a composite gesture score that was the total of all 3 specific gesture types. Both speech and gesture were coded by the first author.

## Results

Young and elderly adults did not differ in the total number of utterances in $\mathrm{SG}(F(1,37)=.77, p>.05)$ and $\mathrm{GR}(F(1$, 37) $=.04, p>.05)$ conditions, and the total trial duration it took to describe the routes in $\operatorname{SG}(F(1,37)=.30, p>.05)$ and GR $(F(1,37)=2.99, p>.05)$ conditions. There was also no gender difference in the total number of utterances in $\operatorname{SG}(F(1,37)=.57, p>.05)$ and $\operatorname{GR}(F(1,37)=1.13, p$ $>.05)$ and, the total trial duration in $\mathrm{SG}(F(1,37)=.19, p>$ $.05)$ and $\operatorname{GR}(F(1,37)=.31, p>.05)$ conditions. Thus, we merged gender for further analyses.

To see if the order of the routes (Route 1 first vs. Route 2 first) influenced the number of utterances used and the duration of describing the routes, we conducted 2 separate mixed ANOVA with total number of utterances (SG vs. GR conditions) and total trial duration (SG vs. GR conditions) as within subject variables and the order of routes (R1 first vs. R2 first) as the between subject variable. There was an interaction between the number of utterances and the order of the routes, and between the trial duration and the order of the routes, $F(1,37)=7.59, p<.01$ and $F(1,37)=6.69, p<$ .02 , respectively. Participants produced more utterances and spent more time in GR ( $M=10.25$ and $M=78.35$ seconds, respectively) compared to $\mathrm{SG}(M=6.35$ and $M=39.80$ seconds, respectively) only when they completed the second route (R2) in GR condition. Thus, for further analyses, we used normalized scores, obtained by the total number of utterances (i.e. raw scores) divided by the number of utterances for each subject in the respective condition. For the next analyses, we used Bonferroni adjusted alpha levels in pairwise comparisons for multiple hypotheses testing and applied Greenhouse-Geisser correction when sphericity assumption was violated (see Tables 1 and 2 for the mean raw scores)

## Speech Analyses

First, we conducted a mixed ANOVA with composite speech score ( SG vs. GR conditions) as within subject variable and group (young vs. elderly) as the between subject variable to see if total spatial information used in speech from SG to GR conditions differed between young and elderly. There was a main effect of the condition on the composite speech scores, $F(1,37)=27.68, p<.001$. However, this main effect was qualified by interaction, $F$ (1, 37) $=7.07, p<.05$. Young participants $(M=2.18)$ used more spatial information compared to elderly ( $M=1.42$ ) in SG condition. However, no difference was found for the use
of spatial information between young ( $M=2.58$ ) and elderly ( $M=2.62$ ) participants in GR condition. In addition, elderly adults used more spatial information in GR compared to SG, whereas young participants produced comparable spatial information in speech in SG and GR conditions (see also Table 1 for raw scores). Thus, even though young adults used similar spatial information in both conditions, when gesture use was restricted, elderly adults' use of spatial information increased.

To see if specific spatial information used in speech (street name, landmark or direction) in SG to GR conditions differed between groups, we conducted a $2 \times 2 \times 3$ mixed ANOVA with group (young and elderly adults) as the between subject variable and condition (SG and GR) and specific spatial information (street name, landmark, and direction) as within subject variables. There was a main effect of condition, $F(1,37)=27.68, p<.001$ and an interaction of condition by group, $F(1,37)=7.07, p<.02$. As reported earlier, elderly, on average, used more spatial information in GR compared to SG conditions, whereas young produced comparable levels of spatial information in SG and GR conditions. There was also a main effect of the specific type of spatial information, $F(2,74)=16.35, p<$ .001. Regardless of the condition, all participants used more direction information $(M=.99)$ compared to street name ( $M$ $=.60)$ and landmark $(M=.61)$ information in speech. No other interactions among spatial information, group, or condition were found, $p s>.05$.

Table 1: Mean raw speech scores for each condition (SG and GR) and group. The values in parentheses are standard errors of mean.

|  | Young |  | Elderly |  |
| :---: | :---: | :---: | :---: | :---: |
|  | $\boldsymbol{S G}$ | $\boldsymbol{G R}$ | $\boldsymbol{S G}$ | $\boldsymbol{G R}$ |
| Number of Utterances | 9.6 | 9 | 7.3 | 9.5 |
|  | $(2.2)$ | $(1.5)$ | $(1.4)$ | $(1.7)$ |
| Composite Speech | 18.0 | 21.1 | 11.6 | 21.4 |
| Score | $(3.5)$ | $(2.6)$ | $(2.9)$ | $(2.6)$ |
|  |  |  |  |  |
| Direction in speech | 8.3 | 9.3 | 5.6 | 9.3 |
|  | $(1.9)$ | $(1.5)$ | $(1.2)$ | $(1.4)$ |
| Landmark in speech | 5 | 6.5 | 3.5 | 7.0 |
|  | $(1.3)$ | $(1.0)$ | $(1.1)$ | $(1.2)$ |
| Street Name in speech | 4.7 | 5.2 | 2.4 | 5.2 |
|  | $(0.6)$ | $(0.5)$ | $(0.8)$ | $(0.6)$ |

## Gesture Analyses

There was no difference in the total number of gestures produced by young and elderly participants, $F(1,39)=$ $1.15, p>.05$. We conducted a mixed ANOVA with different gesture types (pointing, iconic and tracing) as the within subject variable and group (elderly vs. young) as the between subject variable. There was a main effect of gesture
type, $F(1.20,44.34)=46.59, p<.001$. There was also a marginally significant interaction between gesture type and group, $F(1.20,44.34)=3.79, p=.051$. Both young and elderly adults used more tracing gestures ( $M=.80$ and $M=$ 1.23, respectively) compared to pointing ( $M=.29$ and $M=$ .16 , respectively) and iconic gestures ( $M=.06$ and $M=.06$, respectively). However, the difference between pointing and iconic gestures was only significant for young adults, $M_{\text {diff }}=$ $.23, p<.01$. Elderly adults produced comparable number of pointing and iconic gestures, $M_{d i f f}=.10, p>.05$.

Table 2: Mean raw gesture scores. The values in parentheses are standard errors of mean.

|  | Young | Elderly |
| :---: | :---: | :---: |
| Composite Gesture Score | 8.4 | 7.3 |
|  | $(1.6)$ | $(1.2)$ |
| Pointing Gestures | 2.5 | 1.2 |
|  | $(0.6)$ | $(0.3)$ |
| Tracing Gestures | 4.9 | 5.9 |
|  | $(0.9)$ | $(1.0)$ |
| Dynamic Gestures | 1 | 0.2 |
|  | $(0.5)$ | $(0.2)$ |

## Gesture \& Speech Analyses

Young adults' total number of gestures and spatial language positively correlated in both $\operatorname{SG}(r=.54, p<.05)$ and GR ( $r$ $=.70, p<.01$ ) conditions. There was also a positive correlation for spatial language use in SG and GR conditions ( $r=.58, p<.01$ ) in young adults. The total number of gestures did not correlate with spatial language use in SG ( $r=-.42, p>.05$ ) and GR ( $r=.01, p>.05$ ) conditions in elderly adults. Moreover, the spatial language use in SG and GR conditions did not correlate in elderly adults as well, $r=.08, p>.05$.

## Discussion

This is one of the first studies investigating how the effects of gesture restriction on speech production differ with aging. We asked whether gesture prohibition impair or enhance spatial speech production of young and elderly adults. Our results showed that the effects of gesture restriction on the production of spatial language differed between young and elderly. Even though elderly and young adults produced comparable number of gestures in spontaneous speech condition, gesture restriction increased the use of spatial information in speech only for elderly adults. Overall, younger individuals produced more spatial language and the use of gestures correlated with their use of spatial information.

In the first task when people were allowed to gesture, young and elderly individuals produced similar number of
gestures. This result contradicts with the previous findings that showed evidence for decreased amount of gestures in elderly adults (Cohen \& Borsoi, 1996; Feyereisen \& Harvard, 1999). However, the majority of the gestures used by young and elderly adults in our study were nonrepresentational (e.g. tracing and pointing gestures). Since the map was present throughout the experiment, this might trigger the frequent use of pointing to the map (i.e. pointing gestures) or continuously moving finger on map to trace the route (i.e. tracing gestures). When people are asked to talk about an object from memory, they use more representational gestures compared to a condition where the object of interest is present when they talk about it (Wesp et al., 2001). Thus, the sparse use of iconic gestures might lead us not to find any difference between young and elderly adults in the use of representational gestures.

Our results showed that elderly adults used more spatial language when they were restricted from gesturing compared to spontaneous speech, whereas young adults produced comparable levels of spatial language in both conditions. The higher use of spatial language when gesture use was restricted in elderly adults is compatible with the account suggesting that gestures are used to supplement and/or complement the speech. That is, when gestures convey the imagistic properties of spatial events, this information can be omitted from speech (Melinger \& Levelt, 2004; Graham \& Heywood, 1975). Our results, however, did not find support for the Information Packaging Hypothesis (Kita, 2000) or the Lexical Retrieval Hypothesis (Hadar \& Butterworth, 1997; Krauss, Chen, \& Gottesman, 2000). On the other hand, our findings from young adults did not support any of accounts regarding the relation between speech production and gesture restriction. For young adults, gesture restriction did not affect their spatial speech production. However, we found that the gesture and speech production were positively correlated in young adults. Thus, young adults, who produced more gestures (possibly high in spatial skills) could use more spatial information overall.

Why does gesture restriction influence only elderly adults' speech? We cannot answer this question with certainty, but state some possible explanations. First, people's general verbal skills could be related to their gesture use. Hostetter and Alibali (2007) found that people with low verbal skills produced gestures to facilitate their speech, yet people with high verbal skills only supplemented their speech with gestures. Thus, elderly individuals who had high verbal skills could produce more spatial information in a gesture prohibited context. This does not necessarily explain the difference between young and elderly adults, which require future studies to find
answers. Second, not only verbal abilities, but also spatial skills (e.g., Chu \& Kita, 2011; Chu et al., 2014) or working memory and spatial integration in visual processing (Andersen \& Ni, 2008; Copeland \& Radvansky, 2007) could play a role in how people benefit from gestures. Increased problems in working memory and visual-spatial problems might particularly be a problem in the elderly group. Again, we did not examine the participants' spatial skills or working memory in the current study, hence we cannot make a conclusion regarding this issue. Future studies should investigate skill differences between these age groups to draw stronger conclusions. Also, the composition of our two different age groups in terms of sex might create a problem in the interpretation of findings. Finally, even though we told everyone not to gesture, it is possible that some people might have moved other body areas such as lips, eyes or parts of the body (Rimé et al., 1984).

Taken together, the present study provided new evidence for the role of gesture restriction on spatial language use from young and elderly adults. Surprisingly, we did not find detrimental effects of gesture prohibition on spatial language use in either groups. On the contrary, elderly people benefited from not using gestures. These findings suggest that gestures might serve different purposes for young and elderly people in the context of spatial language use.

#### Abstract

Subjective duration estimates are positively related to the magnitude of various non-temporal stimuli (e.g. Xuan et al., 2007). Our study investigated whether temporal and spatial magnitude information conveyed by linguistic stimuli would affect perceived duration in a temporal reproduction task. We used time-related words referring to different exact durations (e.g. second; Experiment 1), and spatial-temporal metaphors (e.g. long), referring to indistinct temporal as well as spatial magnitudes (Experiment 2). In both experiments, participants over-reproduced the shorter target duration ( 2.4 s ) and underreproduced the longer target duration (4.8 s). In Experiment 1, participants under-reproduced the longer target duration more when they saw "week" in the training and "year" in the reproduction. Yet, we did not observe the same semantic magnitude effect in other word pairs either in Experiment 1 or 2. Overall, we did not find supporting evidence for magnitude information conveyed by language affecting subjective time estimates.

Keywords: time perception; language

## Introduction

The perception of time is a key feature of many biological and behavioral processes. Although accurate timing is essential to many daily tasks, substantial evidence shows that the subjective experience of time is not perfectly isomorphic to physical time (Zakay, 1993). Rather, perceived durations are contracted or dilated depending on many factors, including changes in non-temporal stimulus properties.

In this study, we investigated how perceived durations are modulated by temporal magnitude information provided in the medium of language.

## The Interaction Between Non-Temporal Stimulus Magnitude and Perceived Duration

Subjective duration estimates are positively related to the magnitude of various non-temporal stimuli presented in
different modalities. In visual domain, duration judgments were observed to be longer for larger numbers (Xuan et al., 2007; Oliveri et al., 2008; Vicario, 2011), stimulus size (Ono \& Kawahara, 2007), stimulus luminosity (Goldstone, Lhamon \& Sechzer, 1978), and complexity (Schiffman \& Bobko, 1974). For example, people were more accurate and faster when classifying the duration of smaller magnitude numbers presented for a shorter time (congruent trials) than smaller magnitude numbers presented for a longer duration (incongruent trials) in a Stroop-like paradigm (Xuan et al., 2007). The effect of stimulus size on perceived duration has also been documented in many studies (e.g.,Ono \& Kawahara, 2007; Xuan et al., 2007; Rammsayer \& Verner, 2014). For example; when categorizing the durations of stimuli of different sizes by pressing one of four keys (" 1 " for short and " 4 " for long) in a temporal categorization task, people perceived larger visual stimuli as lasting longer compared to smaller visual stimuli of an equivalent duration (Ono \& Kawahara, 2007).

Although the studies cited above each investigate the effects of non-temporal magnitude information on perceived duration, to our knowledge, no study so far has investigated the effects of the temporal magnitude (i.e. duration) implied by word stimuli on time perception. If there is an effect of magnitude on subjective time estimations, then we should be able to see the same effect of magnitude information derived from the semantic representations activated by linguistic stimuli. However, how semantic representations of duration and magnitude information encoded by individual words interact with the representation of duration is mostly unknown.

## Interaction Between Language Processing and Low-Level Sensory/Perceptual Processing

A growing body of research investigating the interaction between language and perceptual processing suggests that semantic representations activated as we process linguistic stimuli affect the content-specific domain of low-level
sensory and perceptual processing (Glenberg, Kaschak, 2002; Zwaan, 2004; Kaschak et al., 2005). According to theories of embodied language processing, comprehension involves the perceptual and motor simulation of the situation described in the linguistic input. Thus, the comprehension of words referring to a particular modal event should interact with low-level perceptual processing of that event (Barsalou, 1999; Glenberg \& Kaschak, 2002; Zwaan, 2004; Kaschak et al., 2005). Many behavioral studies have provided evidence for an interaction between comprehension and perceptual processing, suggesting that higher-level semantic knowledge influences low-level sensory processing in visual perception (e.g. Spivey et al., 2001; Stanfield \& Zwaan, 2001; Zwaan, Stanfield \& Yaxley, 2002).

While the effects of language-activated semantic information on cognitive processing across a range of domains has been investigated, the effects of temporal magnitude representations activated by duration words and metaphors on the content-specific area of perceptual processing, namely duration perception, has not been studied. The present study aimed to fill this gap, in order to provide evidence informing both the duration perception and language processing literatures. To this end, in two experiments, we investigated how participants' reproduced duration estimations of a target interval are modulated when presented as different word types: 1) distinct temporal magnitudes (i.e. duration words; e.g. week vs. year) or 2 ) indistinct magnitudes or durations (i.e. spatial-temporal metaphors; e.g. long vs. short).

## Experiment 1

In Experiment 1, we investigated how words referring to different exact durations (e.g. second, year) affect duration estimations. We hypothesized that when the word in training refers to a shorter duration compared to the word presented in the reproduction (e.g. seeing the word "second" in the training and "minute" in the reproduction), participants would under-estimate (i.e. over-reproduce) the target interval and vice versa. We did not expect any systematic difference in reproduced duration estimations when participants are presented with the same words in both reproduction and training.

## Method

## Participants

Twenty-five Koç University students (16 females, $\mathrm{M}_{\text {age }}=21.7$ ) agreed to participate in exchange for course credit. We discarded one female subject because her average coefficient of variation (CV) was high (average CV across conditions $=.51$ ). All experiments were approved by the Institutional Review Panel for Human Subjects of Koç University.

## Task and Stimuli

We used a temporal reproduction task. In this task, we asked participants to reproduce a given target duration by pressing a pre-designated response button to approximate the target duration as closely as possible.

At the beginning of a trial, a word ("training word") was visually presented for one of two different target intervals ( 2400 ms or 4800 ms ). At the end of the target interval, a blank screen was presented for 1 second, followed by a fixation cross presented for a random interval between 500 ms and 1500 ms . Participants were then instructed to initiate the reproduction interval by pressing the space bar. Upon pressing the spacebar, another word ("reproduction word") appeared at the center of the screen, remaining for the entirety of the reproduction interval. The interval ended when the reproduction was perceived as temporally equivalent to the target and the participant released the spacebar. Following the termination of the reproduction interval, the next trial was presented after a random interval between 1000 and 2000 ms .

In Experiment 1, we chose four words referring to different exact durations in Turkish: saniye ("second"), dakika ("minute"), hafta ("week") and sene ("year"). There were two conditions presented in two different sessions. In Condition 1, the words appearing in training and reproduction were different (different word pairs). In this condition, we created two-word pairs out of these four words: ("second") vs. ("minute") and ("week") vs. ("year"). The order of the words also changed. Thus, in some trials participants saw the word referring to the shorter duration during training (e.g. "week" in training and "year" in reproduction) and vice versa (e.g. "year" in training and "week" in reproduction), making four different training word - reproduction word pairs. In Condition 2, however, the same word appeared both in the training and the reproduction intervals (same word pairs). Thus, in this condition, four words appeared both in training and reproduction (e.g. "week" in training and "week" in reproduction, etc.).

## Procedure

All words were presented at the center of the screen, printed in white on a black background. There were 30 presentations for each training word-reproduction word pair at each of the target durations. Hence, in each session, for two target durations and four word pairs, there were 240 experimental trials. We also added 24 trials ( $10 \%$ of the experimental trials) in which the target words appeared for a random interval between 500 and 5000 ms . We added them in order to avoid participants to habituate the two target intervals and label them as "short" and "long" durations throughout the experiment. the selected target intervals as "short" and "long" durations. Thus, in each session, there were 264 trials in total, 240 of which were used in the analyses. All trials were presented randomly. Additionally, to verify that participants looked at the screen, we asked them to report the last word they saw on the screen on 12
randomly selected trials. Participants who could not correctly identify the words three or more times were discarded from analyses (Only one participant in Experiment 2 was discarded on this front). Each participant completed the two sessions and the order of the sessions was counterbalanced across participants. Each experimental session lasted $50-60$ minutes and was separated by a minimum of 1 and a maximum of 5 days.

## Results

For every participant, we calculated the normalized reproduced time (i.e. the reproduced duration divided by the target duration) and averaged those scores for each word pair-target duration combination. Also, for each participant, we calculated the coefficient of variation (CV; i.e. standard deviation of each condition divided by its mean) for each condition. Reproduced intervals that were greater than three times, or smaller than one third of the target duration were excluded from the analyses. Also, the mean normalized reproduction scores and CVs that were above and below three standard deviations of the sample mean for any of the word pairs for a specific target duration were treated as outliers and excluded from further analyses.

The mean normalized reproduction times across target durations for second vs. minute and week vs. year can be found in Table 1. This table presents the over-reproduction of the 2.4 s duration and an under-reproduction of 4.8 s duration regardless of the word pair type (same vs. different) or the specific word pairs used.

Table 1: Mean normalized reproduction scores for two word pairs across two target durations. The first word in the pair is the one that was presented in training, and the second one during reproduction. The values in parentheses are the standard errors of the mean.

|  | 2.4 s | 4.8 s |
| :---: | :---: | :---: |
| second - minute | $1.19(.05)$ | $.84(.03)$ |
| minute - second | $1.21(.06)$ | $.84(.03)$ |
| second - second | $1.22(.05)$ | $.89(.03)$ |
| minute - minute | $1.22(.06)$ | $.86(.03)$ |
| week - year |  |  |
| year - week | $1.20(.05)$ | $.62(.03)$ |
| week - week | $1.15(.04)$ | $.83(.04)$ |
| year - year | $1.20(.05)$ | $.88(.03)$ |
|  | $1.18(.05)$ | $.87(.04)$ |

There was no effect of sex (all $p \mathrm{~s}>.19$ ) and the order of the conditions (all $p s>.18$ ) in any of the word pair-target duration combinations. Also, there was no interaction between sex and the session order (all $p s>.22$ ).

In Condition 1, we conducted three-way repeated measures ANOVA. The results showed that word pairs, $F$
$(1,20)=116.56, p<.001$, target duration, $F(1,20)=$ $110.72, p<.001$, and the order of the word referring to the shorter duration, $F(1,20)=40.60, p<.001$, had significant main effects. However, these main effects were qualified by an interaction between all three repeated factors, $F(1,20)=$ 49.66, $p<.001$. Further comparisons showed that, for week vs. year, reproduced durations were greater when week was given in reproduction ( $M=.80$ ) compared to training ( $M=$ .60 ) only when they were presented for 4.8 s .
In Condition 2, we conducted a two-way repeated measures ANOVA and found a main effect of the target duration, $F(1,21)=73.35, p<.001$, and the same word pairs, $F(3,63)=4.38, p=.007$. Pairwise comparisons showed that the mean normalized reproduced durations were greater for 2.4 s for all same word pairs compared to $4.8 \mathrm{~s}\left(M_{\text {diff }}=.34, p<.001\right)$. However, there were no significant differences between any of the same word pairs when we consider Bonferroni adjusted alpha levels of .008 per test (.05/6) in the pairwise comparisons. There was also no interaction between target duration and same word pairs, $F(3,63)=1.50, p=.22$.
To investigate the difference between the same and different word pairs, we averaged the mean normalized scores for the same and different word pairs separately and conducted a two-way repeated measures ANOVA. The results showed only a main effect of target duration, $F$ (1, 19) $=92.18, p<.001$. There was no difference between same and different word pairs, $F(1,19)=3.09, p=.095$ or the interaction between word pair type and target duration, $F(1,19)=3.26, p=.087$.

A two one-way ANOVA with all word pairs regardless of the word pair type (same vs. different) and the order of the shorter duration as repeated measures and CV scores as dependent measure was conducted separately for each target duration. For 2.4 s , there was no significant effect of word pair on CV scores, $F(4.14,95.18)=1.30, p=.25$. However, for 4.8 s , there was a main effect of word pair, $\mathrm{F}(7,161)=$ $78.65, p<.001$. Pairwise comparisons revealed that CVs were greater when participants saw "week" in the training and "year" in the reproduction compared to all other word pairs in 4.8 s (all $M_{\text {diff }}>.173$, all $p \mathrm{~s}<.001$ ). To see whether variability in perceived durations differed between Condition 1 and 2, we computed grand total CVs for same and different word pairs separately for each target duration and conducted a two-way repeated measures ANOVA. Results revealed a main effect of the target duration, $F$ ( 1 , 19) $=92.18, p<.001$. The CVs were greater for $2.4 \mathrm{~s}(M=$ 1.172) compared to $4.8 \mathrm{~s}(M=.806)$. There was no main effect of the word pair type (same vs. different), $F(1,19)=$ $3.09, p=.095$ and no interaction between two, $F(1,19)=$ $3.26, p=.087$.

In sum, in Experiment 1, we found that regardless of the word pair type and specific order, participants overreproduced the target duration of 2.4 s and under-reproduced 4.8 s . We also found that participants under-reproduced 4.8 s more when they saw "week" in the training and "year" in the reproduction compared to all word pair conditions. The

CV was also greater for that word pair ("week-year") compared to all other.

## Experiment 2

In Experiment 2, we investigated how words implying both a temporal magnitude as well as a spatial magnitude modulated duration estimations. To this end, we employed quantifiers that can refer metaphorically to different indistinct durations as well as spatial magnitudes (i.e. the size of an object; e.g. long vs. short). Our hypotheses were same as with Experiment 1.

## Method

## Participants

Twenty-five Koç University students (14 females, $\mathrm{M}_{\mathrm{age}}=21$ ) agreed to participate in exchange for course credit. One male participant was discarded because he did not pay attention to the experiment and one female participant was discarded because her mean normalized reproduced scores were outliers in 10 out of the 16 conditions.

## Task, Procedure \& Stimuli

The task and the procedure were identical to Experiment 1, except for the word stimuli used in the task. In Experiment 2, we used spatial adjectives and adverbs that are used as spatial-temporal metaphors referring to indistinct durations. We chose four words: uzun ("long"), klsa ("short"), geniş ("wide") and dar ("narrow"). In Condition 1, participants were trained with a spatial-temporal adjective and presented with the antonym of that word in the reproduction phase. We created 2 word pairs: "long" vs. "short" and "wide" vs. "narrow". The order of the words was reversed in this condition. In Condition 2, participants saw the same spatialtemporal adjective both in training and reproduction.

## Results

We used the same exclusion criteria as in Experiment 1. The averaged mean normalized reproduced intervals for short vs. long and narrow vs. wide for each target interval can be found in Table 2. Visual inspection of Table 2 suggests the over-reproduction of 2.4 s and an under-reproduction of 4.8 s in both word pairs.

Table 2: Mean normalized reproduction scores for two word pairs across two target durations. The values in parentheses are the standard errors of the mean.

|  | $2.4 \boldsymbol{s}$ | $\mathbf{4 . 8 ~ s}$ |
| :---: | :---: | :---: |
| short - long | $1.30(.05)$ | $.85(.02)$ |
| long - short | $1.30(.05)$ | $.86(.02)$ |
| short - short | $1.18(.04)$ | $.83(.03)$ |
| long - long | $1.20(.04)$ | $.83(.03)$ |

|  | $2.4 \boldsymbol{s}$ | $\mathbf{4 . 8 ~ s}$ |
| :---: | :---: | :---: |
| narrow - wide | $1.30(.05)$ | $.88(.02)$ |
| wide - narrow | $1.27(.04)$ | $.86(.02)$ |
| narrow - narrow | $1.21(.04)$ | $.81(.03)$ |
| wide $\boldsymbol{-}$ wide | $1.23(.05)$ | $.82(.03)$ |

Neither sex (all ps > .12) nor the order in which participants attended the two conditions (all ps > .09) affected the normalized reproduction scores in any of the word pair-target duration combinations. Also, there was no interaction between sex and the session order in any of the conditions (all $p \mathrm{~s}>.15$ ).

For Condition 1, we conducted a three-way repeated measures ANOVA. The results revealed only a main effect of target duration, $F(1,19)=122.96, p<.001$. The mean normalized reproduction scores were greater in 2.4 s ( $M=$ 1.29) compared to $4.8 \mathrm{~s}(M=.86)$ for all different word pairs. There were no main effects of the specific word pair (short vs. long and narrow vs. wide), $F(1,19)=.286, p=$ .599 , or the order of the shorter duration, $F(1,19)=.147, p$ $=.706$. Also, there was no interaction between all three repeated factors, $F(1,19)=.013, p=.910$.

For Condition 2, our analysis revealed only a main effect of target duration, $F(1,20)=69.56, p<.001$. Pairwise comparisons showed that the mean normalized reproduced durations were greater in $2.4 \mathrm{~s}(M=1.18)$ compared to 4.8 s ( $M=.81$ ). There was no main effect of the same word pairs, $F(3,60)=2.095, p=.110$. There was also no significant interaction between same word pairs and target duration, $F(3,60)=2.39, p=.078$.

We conducted two separate two-way repeated measures ANOVA with the averaged mean normalized reproduced durations for the same and different word pairs for each target duration. The results showed only a main effect of target duration, $F(1,17)=87.54, p<.001$. There was no significant difference between the averaged normalized reproduced durations for same and different word pairs, $F$ $(1,17)=2.70, p=.119$. Also, there was no interaction between two repeated factors, $F(1,17)=.999, p=.334$.

With participants' CV scores, we conducted a two-way repeated measures ANOVA with all word pairs and the target duration as the two repeated factors and the CVs as the dependent measure. The results showed a significant effect of target duration, $F(1,22)=35.338, p<.001$. Pairwise comparisons revealed that CVs were greater in 2.4 s ( $M=.260$ ) compared to $4.8 \mathrm{~s}(M=.213)$. There was no difference between any word pair, $F(3.31,72.83)=.639, p$ $=.607$. However, these results were qualified by an interaction between two, $F(7,154)=2.674, p=.012$. The follow-up multiple t-tests show that, when we consider Bonferroni adjusted alpha levels (.05/8 =.0062), CV scores were greater in 2.4 s in word pairs "long-short" $(M=.271)$, "wide-narrow" ( $M=.276$ ), "short-long" $(M=.259)$, "narrow-wide" $(M=.265)$, "wide-wide" $(M=.252)$ and "narrow-narrow" ( $\mathrm{M}=.255$ ) compared to the target
duration of 4.8s ( $M=.207, .204, .201, .211, .208, .218$; respectively).

In sum, in Experiment 2, we found an over-reproduction of 2.4 s and an under-reproduction of 4.8 s regardless of the word pair conditions, as in Experiment 1. However, we did not find any difference in mean normalized reproduced duration between any of the word pairs. We also found that CVs were greater in 2.4 s compared to 4.8 s for all four different word pairs as well as two of the same word pairs ("short" and "wide").

## General Discussion

In this study, we asked how language affects time perception. Specifically, we investigated how the temporal magnitude (Experiment 1; duration words) and spatialtemporal magnitude (Experiment 2; spatial-temporal metaphors) implied by words influenced subjective time estimates as assessed in temporal reproduction task. We hypothesized that increasing the magnitude conveyed by words from training to reproduction would lead to the overreproduction of the target duration, and vice versa. We found that (1) in two experiments, participants overreproduced 2.4 s and under-reproduced 4.8 s , regardless of the implied temporal / spatial magnitude of words (Figure 1 and 2), (2) CVs were greater in 2.4 s compared to 4.8 s in both experiments, and (3) participants' reproduced durations were smaller and CVs greater when they saw "week" in the training and "year" in the reproduction in 4.8 s compared to all other conditions in Experiment 1. Last, (4) we did not find any systematic effect of the temporal/spatial magnitude implied by words on perceived duration in both experiments.

The over-reproduction of 2.4 s and the under-reproduction of 4.8 s in our current study are in line with Vierordt's Law (for a review see Lejeune \& Wearden, 2009) and found in many timing studies in the literature across multiple timing tasks (e.g., Karşılar \& Balcı, 2016). This migration effect, which is the regression of duration estimates toward the mid-range of the target duration series, is likely due to the fact that all word pair-target duration conditions were presented randomly (i.e. interleaved) rather than in blocks.

We also detected a trend that CVs were greater for 2.4 s compared to 4.8 s . According to Weber's Law, although the variation of the reproduced duration increases proportionally with the to-be-timed intervals, these results might be best explained by an additive source of variability due to experimental manipulations (other than duration) in addition to the proportional one due to timing mechanism itself (e.g. generalized form of Weber's Law).

In Experiment 1, we found that the word pair week-year was under-reproduced more when presented for 4.8 s compared to all other word pairs. It means that participants thought of the target duration of 4.8 s as shorter when "week" in the training was followed by a word implying a larger temporal magnitude, like "year". However, we did not see the same effect in other exact duration word pairs in

Experiment 1 and spatial-temporal metaphor pairs in Experiment 2. This might be due to the larger temporal magnitude difference between these two words compared to the other word pair. Furthermore, the opposite effect was not observed for the year-week pair suggesting an asymmetrical form of time warping (see also Karşılar \& Balc, 2016). Further investigation is needed to determine if this effect is reliable.

Overall, we could not find supporting evidence for the effect of language on time perception. Both temporal magnitude and temporal/spatial magnitude information conveyed by words did not affect perceived duration (other than the word pair of week-year in 4.8s). Yet, it should be noted that there is no hypothesized model for the interaction between time perception and language. Thus, the current study is an exploratory one. However, in a recent study, Bottini and Casasanto (2010) investigated the effects of implicit spatial length information encoded in different object nouns (e.g. cigarettes, clothesline, footpath) on perceived duration and found a positive effect of spatial magnitude information conveyed in linguistic medium on time perception. Object nouns with relatively shorter implicit spatial lengths (e.g. cigarette) were remembered as appearing for shorter durations compared to nouns with longer implicit spatial lengths (e.g. footpath) despite each being presented for the same amount of time. However, we did not find the same kinds of effects. It is interesting when we consider that we used direct spatial magnitude information in Experiment 2, rather than an implicit one as in Bottini and Casasanto (2010). One possibility for falling short to replicate the findings of this study might be that the previously documented effects of magnitude on time perception are only for spatial and numerical magnitude (i.e. non-temporal) and not for temporal magnitudes. In other words, those findings might be present only for crossdomain effects. In the current study, however, we tested the impact of duration magnitude on duration perception, which is a within-domain interaction. Yet, in Experiment 2, we used spatial-temporal metaphors that implied both temporal and spatial magnitudes. One reason for the null effect in this experiment concerns the everyday use of spatial -temporal metaphors. Space and time are so intertwined that spatial adjectives are commonly understood as temporal concepts, especially in the context of a time reproduction task (Lakoff \& Johnson, 1980).

Another possible explanation for not finding data to support our hypothesis in both experiments, concerns the nature of our to-be-timed stimuli. Larger, more complex, and intense stimuli expand perceived duration (Eagleman, 2008). One mechanism for this effect is the modulation of attention and arousal by the non-temporal properties of the to-be-timed stimulus. For example, intense negative sounds expand subjective duration since they heighten physiological arousal (Mella et al., 2011). Also, apart from emotional valence, attentional modulation by highly dynamic stimuli might affect duration perception. For example, Karşılar and Balcı (2016) found that higher motion
coherence in a highly dynamic moving dot array may capture more attention to the non-temporal properties of the stimulus at the expense of attention to the timing task itself. This may result in the over-reproduction of a target interval when the coherence level is increased from training to reproduction. However, our stimuli were not emotionally arousing nor attention capturing. Also, magnitude was not inherently perceptible in the to-be-timed stimuli, but implied by words. Concrete, visual magnitude information presented as an inherent property of the external stimuli might affect perceived duration by better directing attentional resources to stimulus properties.

Last, the task we used might not be the most sensitive for exploring the possible effects of language on perceived duration. Other tasks, like temporal bisection (Allan \& Gibbon, 1991) or categorical timing (Wearden, 1992) that force participants to decide on whether the perceived target duration is shorter or longer compared to a reference interval, might better detect differences between conditions due to its specificity to perceptual time in future studies.

In sum, the current study did not support the hypothesis that temporal and spatial magnitude information conveyed by linguistic stimuli influences subjective duration estimations. Limitations of the current study and the absence of an hypothesized model to be rejected prevent strong conclusions, but higher-order linguistic representations may not reliably interact with a low-level domain like interval timing across experimental paradigms.

# Action and actor gaze mismatch effects during spoken sentence processing 

Dato Abashidze (dato.abashidze@hu-berlin.de)<br>CITEC, Department of Linguistics, Bielefeld University, Germany<br>Psycholinguistics, Humboldt University of Berlin, Germany

#### Abstract

Eye tracking research on situated language comprehension has shown that participants rely more on a recent event than on a plausible future event during spoken sentence comprehension. When people saw a recent action event and then they listened to a German (NP1-Verb-Adv-NP2) past or futuric present tense sentence, they preferentially looked at the recent event target over another plausible target object (that might be involved in a future action) independent of tense. This preferential inspection persisted even when future events and futuric present sentences were much more frequent within the experiment, or when a gaze cue biased towards the future action target. The present experiments extend this line of research by introducing incongruence (in Experiment 1 a past tense verb mismatched the recently seen action and in Experiment 2 an actor gaze cue mismatched the past tense sentence condition). Can the verb-action and the gaze-sentence mismatches eliminate the recent-event inspection preference? Would participants recall information in post-experimental memory tests better for matches (the futuric present tense condition) than mismatches (the past tense condition)? Results revealed inspection of the recent event target as participants processed the verb-action mismatch (Exp 1) and actor gaze incongruence (Exp 2). However, the gaze (but not the verb-action) incongruence eliminated the overall recent event preference in the NP2 region. The memory tests also showed some evidence for a reversal of the recent-event preference.

Keywords: Eye-tracking; spoken sentence comprehension; visual world paradigm; recent-event preference; eventsentence incongruence; actor gaze mismatch

## Introduction

Every day people see or hear about events in the world and effortlessly integrate language with what they see. Although previous research has examined how people understand language referring to events, little is known about how we interpret reference to a preceding event context in relation to language about future events. Previous research has revealed that both visual and linguistic context can rapidly guide the listeners' visual attention (e.g., Chambers, Tanenhaus, Eberhard, Filip, \& Carlson, 2002; Tanenhaus, Spivey-Knowlton, Eberhard, \& Sedivy, 1995) and expectations about events. For example, cues to event tense provided by the utterance can help comprehenders in developing expectations about future events (e.g., Altmann \& Kamide, 1999; Kamide, Scheepers, \& Altmann, 2003). At the same time, listeners tend to prioritize recently inspected event depictions (Knoeferle \& Crocker, 2007), or real-world event portrayals (over expectations of future events) when both recent and future events could, temporarily, relate to an utterance (Abashidze, Knoeferle, Carminati, \& Essig, 2011; Knoeferle, Carminati, Abashidze, \& Essig, 2011). We present two eye-tracking ex-
periments that are situated in the context of these extant findings. The present experiments examine to which extent the priority accorded to recent (vs. future) events in interpreting an utterance holds up when we weaken the congruence between the recent event and the unfolding utterance. To this end, we created mismatches between the recent event context (the action) and (the verb in) an unfolding utterance (Experiment 1) / an actor's gaze behavior (Experiment 2).

## The robustness of the recent-event preference

A number of studies have provided evidence for an attentional behaviour that has been dubbed the 'recent event preference' (e.g., Abashidze et al., 2011; Knoeferle \& Crocker, 2007): In Experiment 2 by Abashidze et al. (2011) participants saw a person performing an action (e.g., sugaring strawberries) and then they listened to either a past tense sentence (Der Versuchsleiter zuckerte kürzlich die Erdbeeren, 'The experimenter recently sugared the strawberries') or a futuric present tense sentence (Der Versuchsleiter zuckert demnächst die Pfannkuchen, 'The experimenter will soon sugar the pancakes'). During the sentence they saw the person in a static position and two objects on the table in front of him (e.g., pancakes and strawberries, i.e., Fig 1-B). After the sentence presentation a second event showed again a sugaring action (the 'future' action) but this time on the other object (e.g., sugaring pancakes). While participants listened to the sentence, their eye gaze to the two potential targets (of the recently seen action, and of a potential future action) were monitored. Results showed that participants preferentially inspected the recent event target (i.e., the strawberries) over the other plausible future event target. This happened even during the futuric present tense sentence, and they shifted gaze to the pancakes (the plausible future event target) only as it was mentioned. Follow-up studies examined this issue by increasing the number of the future events and of futuric present tense sentences up to $88 \%$ (Abashidze, Carminati, \& Knoeferle, 2014), by having the actor gaze at the targets before their mention (Abashidze, Knoeferle, \& Carminati, 2015), and by moving linguistic cues that could bias against the recent-event preference to the sentence beginning (Abashidze \& Chambers, 2016). Despite these strong visual and linguistic cues in favor of the future event target, these experiments replicated the overall recent event preference.

## The impact of incongruence and gaze cues

In language processing research, many studies have employed picture-sentence incongruence and verification as a
method. Experiments using this method have found that participants are sensitive to the incongruence, so that they responded faster to congruent than incongruent picturesentence pairs (Carpenter \& Just, 1975; Underwood, Jebbett, \& Roberts, 2004). In an eye-tracking study by Knoeferle and Crocker (2005) participants were presented with depicted scenes and either matching or mismatching np1-verb-advnp 2 sentences. The authors found an incongruence effect in the verb and adverb regions. Participants were faster reading these sentence regions in the congruous than incongruous condition (see also related findings on gender stereotype effects in a picture-sentence verification task by Rodríguez, Burigo, \& Knoeferle, 2015). Further studies used the sentence-picture verification procedure while participants were presented with positive and negated sentences (Glenberg, Robertson, Jansen, \& Johnson-Glenberg, 1999). Results showed that pictures matching the presented sentences (even when the sentences were negated) elicited faster responses than pictures mismatching the sentences. In addition, another cue that has been shown to rapidly influence comprehension (and guide participants' visual attention even when it was incongruous with language) is a speaker's gaze (e.g., Hanna \& Brennan, 2007; Kreysa \& Knoeferle, 2013; Staudte, Crocker, Heloir, \& Kipp, 2014).

The present experiments relied on incongruence in verbaction relations and an actor's gaze (to the future target) as a way to stress-test listeners' preference of inspecting the target of a recent action. The causes underlying the preferential inspection of the recent event are unclear. Perhaps the preferential inspection is guided by the verb. The verb could be linked to representations of the recently inspected action and its location, prompting participants to shift gaze to the location of the action when they encounter the verb. If so, then a match between the recent event and the sentence referring to it could boost the attention towards the recent event. By contrast, a mismatch between the visual and linguistic information could reduce the recent event preference. Alternatively, what we see is a general recency effect (i.e., participants inspect the object that is the target of the recent action, independent of verb meaning). If this were the case, then a mismatch between the recent action and the verb should not interfere with the recent-event preference but a gaze cue (e.g., the actor shifting gaze during the verb to the future target object) might diminish a recency effect and direct the listener's attention to the future target object.

## The present experiments

Given that incongruence has been shown to influence participant' eye-movements and their reaction times during picturesentence verification tasks, two eye-tracking studies examined to which extent incongruence could bias against the recent-event preference. In Experiment 1, the verb of the past (but not futuric present) tense sentences mismatched the recent action. In Experiment 2, the actor began to inspect the future target object at verb onset in the past tense sentences. We tested to what extent these incongruences will reduce the
preferential inspection of the recent event target during the verb. At this point people could realize that the verb does not match the action they saw in Exp 1 and notice that the actor shifts his gaze towards the future target from the verb onset while the past tense sentence refers to the recent event target in Exp 2. In both experiments the experimental trials were incongruent in the past tense condition only. These experiments used the design from Abashidze et al. (2011, Exp 2), presented above, with one factor, viz. tense (past vs. futuric present). If the recent event preference is sensitive to the incongruence between the recent event and either the past tense sentence $(\operatorname{Exp} 1)$ or the actor's gaze $(\operatorname{Exp} 2)$, then we should see a decrease in looks to the recent event target starting from the verb region. Can the congruence in the futuric present tense increase the inspections towards the future event target and override the preferential inspection of the recent event? The incongruence in the past tense might strengthen the congruence in the futuric present tense condition (e.g., Glenberg et al., 1999).

After the eye-tracking session, participants took part in a gated-memory (Exp 1) and a memory (Exp 2) test. Previous studies reported a better recall of the future event (Abashidze et al., 2015, Exp 1) which was not in agreement with the gaze data; however, other findings revealed a better recall of the recent events (Abashidze et al., 2014, Exp 1 and 2), and a better recall of the past tense sentence (Abashidze et al., 2015, Exp 2) underscoring the recent-event preference in the gaze data. If the incongruence affects the recent-event preference and the incongruence effects are long-lasting, then we might see a reduced recall performance for recent compared with future events in the memory test. Alternatively, the incongruence does not affect the recent-event preference and / or its effects are short-lived, in which case we might see better recall of recent than future events.

## Experiments 1 and 2: Methods

## Participants

Thirty-two native German University students in each experiment (aged 18 to 32) with normal or corrected-to-normal vision gave informed consent and received 6 Euros each for their participation. The study was approved by an ethics vote (Experiment 1: Bielefeld University ethics committee, Experiment 2: DGfS).

## Materials and design

The current experiments used the experimental sentences from Abashidze et al. (2014, see Table 1). All sentences ( $N=24$ ) had the structure NP-VERB-ADV-NP and two native German speakers recorded them. The sentences were in two tense conditions and referred either to a recently seen event or a plausible future event. In one condition, the verb was in the present tense and a time adverb (demnächst, 'soon') indicated the futuric present tense condition (Table 1b). In the other condition, the verb was in the simple past, and a time adverb (kürzlich, 'recently') indicated the past tense condi-
tion (Table 1a). The critical sentences employed only regular German verbs in which the verb was tense ambiguous up to but excluding the word-final phoneme which disambiguated towards the simple past in the past tense condition. As we can see in Table 1, the experiments used two sentences for each tense condition. With this counterbalancing we ensured that each object was once the target of the recent and once the target of the future event. The critical words in a sentence were matched for spoken syllables and lemma frequency within an item (Baayen, Piepenbrock, \& Gulikers, 1995).

Experiment 1 also used the videos from Abashidze et al. (2014) for futuric present tense sentences. These videos ( $M_{\text {duration }}=5015$ ) showed an actor sitting at a table in front of two objects (e.g., strawberries and pancakes, one on the left and one on the right; both of the objects can be sweetened). We additionally recorded new videos (for the recent events). For example, instead of sugaring strawberries, a first video presented the actor tasting the strawberries (see Fig 1A), and the verb in the past tense sentence (translated literally: 'The experimenter sugared recently the strawberries') never matched the recent action. By contrast, the futuric present sentence always matched the future event (see Fig 1-C).

In Experiment 2, for each experimental trial, participants saw a short video before and after hearing a sentence about a person performing an action. For the incongruence, we used the gaze videos from Experiment 2 by Abashidze et al. (2015). For instance, when participants listened to a past tense sentence they saw a video of the actor shifting his gaze towards the future event target (i.e., pancakes) from the onset of the verb, where it remained until the end of the sentence (the gaze cue mismatched the referential past tense sentence). By contrast, in the futuric present tense condition no gaze cue was present. Participants saw a snapshot from the last frame of the first video showing the actor in a static position looking straight ahead (i.e., see Fig 1-B). In both experiments the incongruence biased against the recent event preference.

In addition to the experimental items we created 36 filler sentences. To balance the incongruence across/within experiments, 12 fillers in Experiment 1 featured an incongruence between the futuric present verb and future event. Similarly, 12 fillers in Experiment 2 showed the actor looking at the recent event target during a futuric present sentence. In both experiments, recent and future events appeared equally often.

Thus, both experiments manipulated 1 factor: sentence tense (past vs futuric present); in half of the trials the sentence was in the past tense and in the other half in the futuric present tense (see Table 1 for counterbalancing). The resulting four lists used a Latin square design. Each experimental list contained every critical item in only one condition and all fillers. Each subject saw an individually pseudo-randomized version of one of the four experimental lists.

## Procedure

An Eyelink 1000 eye-tracker recorded participants’ eye movements. After a successful 9-point calibration, the experiment began. Participants were asked to inspect the scene

Figure 1: Sequence of events of a typical experimental trial for Experiment 1

and to listen carefully to the sentences. As in the previous studies by Abashidze et al. (2011), on a given trial, a participant first saw a video of a person (the actor) performing one action before the sentence (e.g., tasting strawberries for Exp 1 and sugaring strawberries for $\operatorname{Exp} 2$ ); then participants saw a static photo (see Fig 1-B). 700 ms after the onset of the static photo, a sentence was presented via the loud speakers either in (a) the past tense or (b) the futuric present tense (see Table 1). In Experiment 1 (experimental items), the past tense verb did not match the recent event; but the verb of the futuric present matched the future event (shown after the sentence had ended). In Experiment 2, during the past tense sentence the actor directed his gaze towards the future event target from verb onset (the gaze cue mismatched the past tense sentence and its NP2 referent). However, during the futuric

present sentence participants saw the actor in a static position throughout the sentence (as in Experiment 1, see Fig 1-B). 700 ms after the sentence had ended, participants saw a video of the actor performing the second action event (e.g., sugaring pancakes, Fig 1-C, both experiments). Post-experiment, participants completed a gated memory test in Experiment 1 and a memory test in Experiment 2 (Fig. 2). At the end, they were debriefed. Each experiment lasted approximately 50-55 minutes.

## Memory tests

Experiment 1 tested participants' later memory of the linguistic information and Experiment 2 examined participants' later memory of the visual information. Experiment 1 shows an example sentence as presented in the gated memory test in a 3-stage procedure (Fig 2, Exp 1). At the first stage, participants saw only the first noun phrase and the verb stem and had to verbally complete the verb tense. The second stage added the temporal adverb, and they had to recall the second noun phrase. If they were unable to do so, they received a further prompt at the third stage and had to select the correct referent out of three objects. Two of these were from that sentence trial and the third was a distractor from another filler item.

Figure 2: An example of a sequence of stages in the gated memory test, $\operatorname{Exp} 1$ and display for the memory test, $\operatorname{Exp} 2$

For the memory test in Experiment 2, we created two snapshots of the first and second video of each experimental item, i.e., showing the experimenter performing one of the two actions (Fig 2, Exp 2). The two snapshots associated with each item were combined into one display and shown to participants. Two versions were created in which the respective location of the two pictures was counterbalanced and participants responded with a button press. Above the picture, one of two questions appeared:
(a) Welche Aktion wurde VOR dem Satz durchgeführt?
"Which action was performed before the sentence?"
(b) Welche Aktion wurde NACH dem Satz durchgeführt? "Which action was performed after the sentence?"

## Experiments 1 and 2: Analyses and results

## Eye tracking

For the eye-tracking data we divided each experimental sentence into three time regions, (the verb, the adverb and the NP2). Each word region lasted from its onset to the onset of the following word region and NP2 ended at sentence offset. The measure of interest was inspection of the recent and future target objects. Because looks to one of the objects implied fewer looks to the other target objects, we computed mean log gaze probability ratios for the recent relative to the future target $(\ln (P($ recent target $) / P$ (future target $))$ ). A score of zero indicates that both targets are inspected equally often; a positive value means more looks to the recent event target; a negative value means more looks go to the future event target (see Knoeferle et al., 2011).

For the inferential analyses, we performed separate ANOVAs on the mean log ratio averaged for each condition (past vs. futuric present) and word region by participants and by items respectively. The independent variable was tense, with two levels, past and future tense. We tested the significance of the intercept overall (a positive intercept represents a preference of inspection of the recent event target).

In Figure 3, the dotted lines indicate the past tense condition and the solid lines indicate the futuric present tense condition. As we can see, the incongruence influenced target inspection during sentence comprehension. In Experiment 1, participants decreased their attention towards the recent event target at the end of the verb region (i.e., following the mismatch); however both lines (in the mismatching past and matching futuric present tense) remain above zero, meaning that people continued to preferentially inspect the recent (vs. future) event target. In Experiment 2, the preferential looks towards the recent event target lasted until the middle of the adverb region in both tense conditions. Interestingly, despite the incongruent gaze in the past tense condition, participants' attention towards the recent event target persisted until sentence end but decreased as the target was mentioned.

A noticeable difference between Experiment 2 and Experiment 1 is thus that the gaze incongruence (but not the verbaction incongruence) seems to have prompted participants to decrease their attention to the recent target object during NP2. At the end of the NP2 (the name of the recent event target), participants inspected the recent and future event targets equally often in the past tense condition (unlike in Experiment 1).

ANOVAs revealed a tense effect in the NP2 region in Experiment 1 and in the Adverb and NP2 regions in Experiment 2, reflecting that tense modulated the listeners' looks to the recent (vs. future) event target. The grand mean (i.e., the mean of both conditions / the intercept) was positive in all regions in Experiment 1 and in the Verb and Adverb regions in Experiment 2, which indicates an overall recent-event preference (significant intercept in all the ANOVAs by region). Thus, Experiment 1 replicated the overall preference to look at the recent event target in all three word regions indepen-

Figure 3: Mean log gaze probability rations ( $\ln (P$ (recent target) $/ P$ (future target))) by condition from verb onset for Exps 1 and 2

dent of tense condition, whereas Experiment 2 did not reveal a significant intercept in the last word region (NP2), suggesting the gaze incongruence eliminated the overall recent event preference in the NP2 region. Furthermore, a post-hoc two-way ANOVA on the mean log gaze ratios of the NP2 region revealed a tense effect and a marginal experiment effect but no interaction. This experiment effect suggests that the gaze incongruence not only eliminated the overall recent event preference but also marginally decreased participants’ attention towards the recent event target in Experiment 2 compared with Experiment 1.

## Memory tests

Gated memory test We calculated the percentage of correct responses by conditions. Participants correctly answered questions from all three stages on average with $61 \%$. They correctly recalled $54 \%$ at stage one, which is more accurate than at stage two with $40 \%$. Importantly, the highest accuracy emerged at stage three ( $89 \%$ ). Subjects recalled the futuric present sentence (match) better than the past tense sentence (mismatch). Logistic linear mixed effect (LME) analyses showed a marginal tense effect at stage $1(p<.08)$ and a fully significant tense effect at stage $2(p<.02)$, indicating higher accuracy for the futuric present than past tense sentence condition. Memory test In Experiment 2 we calculated the percentage of correct answers in indicating the event targeted in the image. Participants correctly answered questions on average with $61 \%$. They were slightly more accurate in recognizing the future (matching) events ( $60 \%$ ) than the recent (mismatching) events (59\%). The LME analyses did not reveal any significant difference in recalling the recent versus future events.

## Discussion

Across two experiments, we examined the recent-event preference (e.g., Abashidze et al., 2014; Knoeferle et al., 2011) and stress-tested it with two types of incongruence (verbaction and the actor's gaze to the future target in the past tense condition).

We had predicted that if the recent event preference were guided by the verb, then participants' overall preference to inspect the recent event target should disappear when they realize that the recent action mismatched the verb in meaning (this did not happen, Exp 1). Analyses of the data from both eye-tracking experiments did not show an early preferential inspection (during the verb and adverb) of the future event target but rather corroborated participants' preference to gaze at the recent event target. It is possible that the effect of the verb-action incongruence was weak since the past tense sentence, while mismatching at the verb, did mention the correct event target. Perhaps for this reason, inspection of the recent event target persisted during the Adverb and increased during NP2 in the past tense sentences of Experiment 1.

Furthermore, if a recency effect underlies the recent-event inspection preference and more generally object inspection, then an incongruent actor's gaze to the future target (as the most recent cue) should have guided the listeners' attention to that target during the verb and adverb for the past tense sentences, which did not happen; rather participants preferentially inspected the target of the past event i.e., in line with the sentence tense and the recent-event preference.

While previous studies revealed an immediate gaze effect in a congruent environment (at around $300-500 \mathrm{~ms}$ after its onset, e.g., Kreysa \& Knoeferle, 2013), participants in Experiment 2 fully decreased their inspection of the not-gazedat recent event target only at sentence end (i.e., after mention of the target), thus ignoring that the actor gazed at the future target from verb onset. This suggests a strong reliance on the recently-seen event and a relatively slow effect of the actor's gaze when it had to compete with the preceding action event referenced by the verb. Although the gaze mismatch eliminated the overall recent event preference in the NP2 region of Experiment 2, a between-experiment comparison of the same word region did not reveal a fully significant experiment effect between Experiment 1 and 2. The two types of incongruence hence did not differ reliably in the extent to which they disrupted the recent event preference at sentence end. For the Adverb region, however, between-experiment analyses clarified that participants were more likely to inspect the recent event target in Experiment 2 than 1, corroborating that gaze did not immediately modulate this inspection preference. Tense effects in the Adverb and NP2 regions in Experiment 2 (compared with only the NP2 region in Experiment 1) revealed that the gaze incongruence (and the actor's attention to the future event target) did boost the integration of tense after the verb in Experiment 2 compared with 1.

The post-experiment memory tests results in Experiment 1 did not agree with the overall recent event preference in the
gaze data (recall was reliably better for the futuric present tense sentences, in conflict with the recent event inspection preference (see also Abashidze et al., 2015)). In Experiment 2 , no reliable difference in recall emerged for the recent versus future events, suggesting short-lived effects of the gaze mismatches. The better recall of the futuric present condition in Experiment 1 could be explained if we assume that the congruent recent events and linguistic information evoked more in-depth processing and increased attention to the stimuli that then also benefitted the later recall of event information.

In conclusion, the incongruences in the past tense sentences did not reduce the overall recent event preference immediately (during the verb and adverb in both experiments); but at least actor gaze incongruence did eliminate the overall preference eventually, in the NP2 region of Experiment 2 and it boosted the tense effects. What these results suggest is that the recent-event inspection preference it robust, and that it is not entirely dependent upon verb reference or cue recency. The recall accuracy in Experiment 1, by contrast, suggests that the verb-action mismatches affected short-term memory of the events. Gaze mismatches, by contrast, seem to have had immediate effects in the sense that they boosted tense effects but they neither reduced the overall inspection preference more than verb-action mismatches at NP2, nor did they modulate recall of the stimuli.

## Acknowledgments

# It's Time: Quantifying the Relevant Timescales for Joint Attention 

Drew H. Abney (dhabney@indiana.edu)<br>Linda B. Smith (smith4@indiana.edu)<br>Chen Yu (chenyu@indiana.edu)<br>Department of Psychological and Brain Sciences<br>Indiana University, Bloomington, IN 47405 USA

#### Abstract

The study of the coordination of attention, a term called joint attention (JA), has resulted in a better understanding of the dynamics and development of communication. Despite the important insights gained from studying JA, there is little consensus regarding the specific components that are included in operationalizing JA. The present work explored a parameter space of JA during a dyadic naturalistic toy play task between 9-monthold infants and their parents. We systematically measured the temporal properties of two components commonly used to operationalize JA: the duration of continuous alignment of parent and infant visual fixations and the flexibility of fluctuations of attention. The results show that very brief bouts of JA are important predictors for vocabulary development. The results from this work provide new insights into the specific properties used to operationalize JA and point to the importance of considering multiple timescales of behavior that make up JA.

Keywords: joint attention; communication; development; language development; methodology

## Introduction

Human interaction consists of behaviors that occur across multiple timescales. When an infant interacts with a parent, physiological rhythms are coordinated within a 1 s timescale (Feldman, Margoi-Cohen, Galli, Singer, \& Louzoun, 2011), vocalizations at a 3 s timescale (van Egeren, Barratt, \& Roach, 2001; Harder et al., 2015), and leader-follower dynamics of vocalizations fluctuate across a 10s-temporal window (Abney, Warlaumont, Oller, Wallot, \& Kello, 2016). Infants and their parents also coordinate their attention onto objects, a coordinative behavior called joint attention. The achievement of joint attention emerges early in the first year of life (Scaife \& Bruner, 1975), and has been shown to be a fundamental component of communicative skills ranging from the development of language to social competencies (Mundy \& Newell, 2007). The main goal of the current paper is to determine the relevant timescales for joint attention during infancy.

The empirical study of joint attention was initiated by the seminal work of Scaife and Bruner (1975) observing that infants could follow the direction of a partner's gaze within the first year, and that this behavior increased in frequency with age. Since Scaife and Bruner's original findings, decades of research have led to important theoretical and empirical contributions to areas of psychology ranging from
basic questions and connections about attentional processes (Corkum \& Moore, 1995; Mundy, Card, \& Fox, 2000), to whether or not joint attention is critical for language development (Baldwin, 1995; Tomasello, 1988; Akhtar \& Gernsbacher, 2007), and has led to proposals about the origins of theory of mind (Baron-Cohen, 1991) and communication (Tomasello, 2010).

Although the overall consensus is that joint attention is an important ability, there is less agreement and consistency regarding how joint attention is defined and operationalized. For example, in Scaife and Bruner's (1975) original work, a positive joint attention behavior was coded if an infant (a) looked in the same direction as the experimenter without (b) intervening looks elsewhere within (c) 7s of the experimenter's look. In another example, Bakeman and Adamson (1984) coded behavior as a coordinated joint engagement state if the infant (a) actively coordinates his or her attention with another person and an object for (b) a particular duration with (c) only brief attention shifts to other objects for less than 3s. Finally, Tomasello and colleagues (Tomasello \& Todd, 1983; Tomasello \& Farrar, 1986) defined joint attention as when (a) infant and parent both visually attended to the same object for (b) at least 3 s with (c) only brief looks elsewhere. Table 1 provides an abbreviated review of the timescales used to operationalize
joint attention for studies focused on the relationship between joint attention and language.

In free-flowing parent-infant everyday interaction, joint attention is embedded in a stream of free-flowing activity in which parents both react to and attempt to control toddlers' behaviors and in which toddlers react to, direct, and sometimes ignore parents as they pursue their own goals. In those naturalistic contexts, we know that adults generate on average 3 eye fixations per second (Hayhoe, Shrivastava, Mruczek, \& Pelz, 2003) and we also know, from our recent head-mounted eye tracking studies, infants generate lots of short looks in toy play (Yu \& Smith, 2016). That means the exquisite real-time "dance" of social interactions require effective adjustments within the dyad and socially coordinated shifts in attention have to be resolved in fractions of a second. In this context, it is possible that joint attention spans multiple timescales, displaying important variability at short timescales and also at longer timescales.

The specific goal of the current paper is to investigate the relevance of two key parameters used to operationalize joint attention that have varied considerably across research groups: the duration of continuous alignment of parent and infant visual fixations and the flexibility of fluctuations of attention. We refer to the former parameter as minimum joint duration and the later parameter as minimum duration. For minimum joint duration, we varied the duration to estimate joint attention across micro-level (e.g., 500 ms ) and macro-level (e.g., 10s) timescales. We focused on two aspects of this manipulation. First, we investigated how properties of joint attention, like mean duration, frequency, and proportion, varied across the minimum joint attention dimension. Importantly, we were also interested in how minimum joint duration affected how many dyads in our sample exhibited joint attention at a particular timescale. For example, it is possible that some infant-parent dyads do not exhibit any macro-level joint attention bouts, which would require us to omit them from subsequent analyses. For minimum duration, we first kept the parameter fixed at 0 ms to simulate coding schemes that only identified a JA bout as continuous visual alignment on a target object with no looks elsewhere (Study 1) and then manipulated the parameter to allow for brief fluctuations of attention less than 300 ms (Study 2).

Second, we asked how different values of minimum joint duration impacted the predictive value of joint attention. Previous research has observed that joint attention correlates with concurrent - and predicts future - vocabulary size (Baldwin, 1995; Tomasello \& Farrar, 1986; Tomasello \& Todd, 1983; Smith et al., 1988; Carpenter et al., 1998; Morales et al., 2000; Mundy, Sigman, \& Kasari, 1990). Therefore, to determine how minimum joint duration affects the predictive value of joint attention for vocabulary size, in Study 3, we estimated joint attention for different values along the minimum joint duration dimension for 9-month infants and their parents, and tested whether joint attention across various timescales predicted future vocabulary size.

## Methods

## Participants

26 parent-infant dyads participated ( 15 female and 11 male). The mean age of infants was 9.21 months ( $S D=0.23$ ). Parent reports of vocabulary were collected three and six months later when the infants were 12 months and 15 months.

## Stimuli

Six toys (car, cup, and train; duck, plane, and boat), organized into two sets of three were used. Each toy in the two sets had a unique uniform color (red, blue, green).

## Stimuli

Parents and their infants sat across from each other at a table $(61 \mathrm{~cm} \times 91 \mathrm{~cm} \times 64 \mathrm{~cm})$. The infants sat in a custom highchair and the parents sat on the floor. Both infants and parents wore head-mounted eye trackers (positive science, LLC). The head-mounted eye-tracking system includes two cameras: (1) An infrared camera that is placed just below and is pointed to the right eye that records eye images, and (2) A scene camera that is placed low on the forehead and is pointed outwards captures the user's first-person view ( $90^{\circ}$ visual field). Each eye tracking system recorded egocentricview video and gaze direction ( $\mathrm{x}-$, y -coordinates) in that view, sampled at 30 Hz . Another camera ( 30 Hz ) was mounted above the table and provided a bird's eye view of the dyadic interaction (see Yu \& Smith (2013) for additional technical details).

## Procedure

Parents and infants were fitted with the eye-tracking gear (see Figure 1). Once the eye-tracking gear was securely affixed to the participants, a calibration phase was completed. To collect calibration points for each eyetracker, an experimenter directed the infant's attention toward a toy that was only used for calibration while another experimenter recorded the moment the child attended to the location of the toy. This procedure was repeated 15 times with the calibration toy played in various locations on the tabletop. A similar procedure was used to calibrate the parent's eye tracker. The calibration procedure took approximately five minutes.

Once the calibration phase was complete, an experimenter placed one of the object sets on the table and the first play trial began. During object play, parents were instructed to engage with their infant as they naturally would. After approximately 60 seconds of play, an experimenter swapped out the objects with the second set of objects, and the second trial began. This procedure was repeated and dyads completed up to four trials for a total of six minutes of play. Not all dyads completed the full play session. Twenty-four dyads completed all four trials and two dyads completed three trials, for a total average playtime of five minutes, eight seconds.

Figure 1: (A) A dual eye-tracking set-up. (B) Sample infant and parent ROI streams.

## Data Processing

Eye-tracking software yielded scene camera footage with crosshairs superimposed, this footage was then sampled at a rate of 30 frames per second. Using an in-house coding program, trained coders annotated frame-by-frame the target of gaze. Three regions of interest (ROIs) were defined for the three objects. ROIs were manually coded frame-byframe from a first-person view video. An ROI was annotated when a cross-hair overlapped on any portion of an object or face. To assess reliability, a second coder coded a randomly-selected $10 \%$ of the frames with $95 \%$ agreement.

Figure 2: Operationalizing joint attention bouts using minimum duration and minimum joint duration.

## Joint Attention Parameters

Two parameters were used to determine joint attention: minimum joint duration and minimum duration (see Figure 2). Minimum joint duration is the temporal duration of continuous alignment of parent and infant fixations on a particular object ROI. Minimum duration is the temporal duration of brief looks elsewhere other than the joint attention ROI, e.g., another object, partner's face. Previous research has incorporated this component into various coding schemes, sometimes allowing for brief looks elsewhere, and for other coding schemes, not allowing the flexibility of brief looks. For Study 1 , we keep this parameter fixed at 0 ms to not allow for brief looks
elsewhere. In other words, all joint attention bouts estimated for this study only included simultaneous and continuous fixations from infant and parent. For example, in Figure 2, Bout 1 (blue object) would not be considered a JA bout because there is a brief look from the parent to the infant's face (pink). Bout 2 (red object) would be considered a JA bout because (1) the infant's and parent's fixations were on the same object (red object) for longer than a particular duration set in our parameter exploration and (2) the fixations were continuous with no brief fixations elsewhere.
In Study 2, we manipulated the minimum duration parameter to equal either 0 ms or 300 ms . To return back to the example in Figure 2, when minimum duration equals 300 ms , Bout 1 (blue object) would now be considered a JA bout because the brief look from the parent to the infant's face (pink) is shorter in duration than 300 ms .

## Exploration of Joint Attention Parameter Space

To explore the parameter space of minimum joint duration, we created six different temporal durations for minimum joint duration $(500 \mathrm{~ms}, 1 \mathrm{~s}, 2 \mathrm{~s}, 3 \mathrm{~s}, 5 \mathrm{~s}$, and 10 s$)$. The other parameter we manipulated was minimum duration, and varied this parameter as either 0 ms or 300 ms . In Study 1, we fixed the minimum duration parameter to 0 ms , and explored the minimum joint duration parameter across all six duration. In Study 2, we explored a combination of a subset of the minimum joint duration parameter ( 500 ms and 1 s ) and the minimum duration parameter ( 0 ms and 300 ms ).

## Properties of Joint Attention Bouts

In Study 1, we estimated joint attention bouts across the minimum joint duration parameter space for each of the 26 infant-parent dyads. Thus, for each dyad, we had 6 joint attention streams. In Study 2, we estimated joint attention bouts across the limited minimum joint duration parameter and the minimum duration parameter, equating to 4 joint attention streams across the parameter space combinations. For each joint attention bout stream, we estimated three properties: proportion ( $\%$ of time in joint attention), frequency (rate $/ \mathrm{min}$ ), and average bout duration. To determine how many dyads with at least one joint attention bout in each parameter space value, we calculated a parameter-level measure as the percentage of the sample (26 dyads) that yielded at least one joint attention bout in a particular parameter value. In Study 3, we explored how joint attention proportion estimates across the minimum joint duration parameter space at 9 -months of age predicted vocabulary size at 12 and 15 months of age.

## Vocabulary Size

Infants and parents returned to the laboratory at ages 12and 15 -month to complete the MacArthur-Bates Communicative Development Inventory (Fenson et al., 1994). We used total receptive vocabulary as our measure of vocabulary scores at each age.

## Study 1

We first investigated the properties of joint attention bouts across parameter space. We conducted a linear mixedeffects model (Baayen, Davidson, \& Bates, 2008) to examine the effects of minimum joint duration on the joint attention bout properties (proportion, frequency, and average bout duration). We included dyad membership as a random slope with the maximally permitted random intercept. Because only one dyad had at least one joint attention bout longer than the minimum joint duration parameter at 10 s , we excluded the 10 s duration from the minimum joint duration parameter in subsequent analyses (see Figure 3).

Figure 3: Joint attention properties across minimum joint duration parameters. Error bars reflect 95\% CIs.

For joint attention rate, there was a significant effect of minimum joint duration ( $\beta=-.0009, S E=0.00007, p<.001$ ), suggesting that as minimum joint durations increased, the rate of joint attention bouts (per minute) decreased. When increasing the minimum joint duration parameter from the shortest duration reflecting the micro-level timescale, 500 ms ( $M_{\text {rate }}=4.99, S E_{\text {rate }}=.39$ ), to the frequently-used timescale in previous literature, 3000 ms ( $M_{\text {rate }}=1.07, S E_{\text {rate }}=.11$ ) (see Table 1; Bakeman \& Adamson, 1994; Carpenter et al., 1998; Tomasello \& Todd, 1983; Tomasello \& Farrar, 1986), we observed a $78 \%$ decrease in JA bout rate.

As expected, for mean joint attention duration, there was a significant effect of minimum joint duration ( $\beta=.001, S E=$ $0.00003, p<.001$ ), suggesting that as minimum joint durations increased, the mean duration of joint attention bouts increased.

Similar to what was observed for rate, for joint attention proportion, there was a significant effect of minimum joint
duration ( $\beta=-.0001, S E=0.00002, p<.001$ ), suggesting that as minimum joint durations increased, proportion decreased. When increasing the minimum joint duration parameter from $500 \mathrm{~ms}\left(M_{\text {proportion }}=.16, S E_{\text {proportion }}=.02\right)$ to 3000 ms $\left(M_{\text {proportion }}=.07, S E_{\text {proportion }}=.01\right)$, we observed a $53 \%$ decrease in JA proportion.

Calculating the percentage of dyads with at least one joint attention bout for a particular parameter space value provides a metric of how the sample size changes as a function of parameter value choices. Considering that investigations of joint attention utilize properties of joint attention bouts, we interpret this value below $100 \%$ for a particular combination to be suboptimal for the study of joint attention. Inspection of these estimates yielded some important observations. Estimates decreased as the duration of the minimum joint duration parameter increased. At 2 s , the amount of dyads with at least one JA bout dropped below $100 \%$ and at 5 s , only approximately $50 \%$ of the sample had at least one joint attention bout. This is an important observation because it points to a particular timescale, 2-3s, when the behavior of interest, joint attention, does not occur for some dyads in a sample.

We have established that after a particular timescale, 2-3s, the amount of dyads producing at least one bout of joint attention drops considerably with increases in the minimum joint duration parameter.

## Study 2

To investigate the potential combinatory effects of both minimum joint duration and minimum duration, we estimated JA bouts across the minimum duration parameter ( 0 ms and 300 ms ) and a subset of the minimum joint duration parameter dimension ( 500 ms and 1000 ms ). Our parameter space therefore consisted of 4 possible combinations of the two parameters. We chose these parameters because (1) in Study 1, we observed $100 \%$ of the dyads had at least one JA bout for the 500 ms and 1000 ms minimum joint duration values and (2) 300 ms as a value for the minimum duration parameter has been used in previous research to allow for flexibility in the fluctuations of attention (Yu \& Smith, 2013, 2016).

Consistent with Study 1, for joint attention rate, there was a significant effect of minimum joint duration ( $\beta=-.0004$, $S E=0.00003, p<.001$ ), suggesting that as minimum joint durations increased, rate of joint attention bouts increased. There was no significant effect of minimum duration ( $\beta=.0001, S E=0.0004, p=.76$ ) nor was the interaction significant $\quad(\beta=.0000001, \quad S E=0.0000006, \quad p=.78)$, suggesting, despite allowing for brief attentional flexibility (minimum duration $=300 \mathrm{~ms}$ ) compared to no flexibility (minimum duration $=0 \mathrm{~ms}$ ), joint attention rate remained the same (see Figure 5).

Mean joint attention duration increased as minimum joint duration increased ( $\beta=.002, S E=0.0001, p<.001$ ), but there was no significant effect of minimum duration ( $\beta=-.0002$,
$S E=0.0004, p=.75$ ) nor was the interaction significant ( $\beta=.00000003, S E=0.0000006, p=.56$ ). Mean joint attention proportion decreased as minimum joint duration increased ( $\mathrm{b}=-.0005, S E=0.00004, p<.001$ ), but there was no significant effect of minimum duration ( $\mathrm{b}=.00005, S E=$ $0.0001, p=.74$ ) nor was the interaction significant ( $\mathrm{b}=$ $.00000005, S E=0.0000002, p=.81)$.

Figure 5: Joint attention properties across minimum joint duration and minimum duration parameters. Error bars reflect 95\% CIs.

## Study 3

We analyzed the relationship between joint attention proportion estimates across the minimum joint duration parameter space at 9 -months of age and vocabulary size at 12 and 15 months of age. From the previous analyses, we know that increases in minimum joint duration lead to decreases in the amount of joint attention bouts and also the proportion of joint attention bouts. It is possible that even though joint attention proportion decreases, the overall variability still predicts vocabulary size. Alternatively, it is also possible that decreases in joint attention proportion also reduces the likelihood that the variability of joint attention proportion covaries with later vocabulary size. Table 2 shows the correlation results across parameter space values for joint attention proportion at 9 months and vocabulary size at 12 and 15 months. As observed in previous analyses, the amount of dyads with proportion estimates varies across the parameter space. Therefore, it is important to note the varying degrees of freedom of the correlations across the parameter space values.

There are a few important observations from this analysis. First, the pattern of correlations between joint attention proportion and vocabulary size does not vary across 12 months to 15 months. This suggests that the predictive value of joint attention at 9 months extends into the second year of life. Second, the results suggest that after exceeding a minimum joint duration of 3 s , joint attention is no longer predictive of language development. This is an important
finding because it strengthens the argument that the relevant timescales for joint attention, and subsequent predictive value for language development, include durations shorter than 3 seconds. We will discuss the implications of this result in the Discussion section.

Table 2: Summary of correlation coefficients (degrees of freedom in parentheses) between JA proportion and 12- and

15-month vocabulary size across the Minimum Joint
Duration parameter.

| Minimum Joint Duration | 12 months | 15 months |
| :--- | :--- | :--- |
| 500 ms | $.58(24)^{* * *}$ | $.54(24)^{* * *}$ |

## Discussion

The present study investigated the relevant timescales for joint attention in infant-parent naturalistic free-play. To answer this question, we explored a parameter space consisting of two frequently used components implemented to operationalize joint attention: minimum joint duration and minimum duration. Across three studies, we observed a collection of important results that provide insight into the consequences of choosing specific parameters for operationalizing joint attention. First, the observation of joint attention behavior drops precipitously when the duration of continuous alignment of parent and infant visual fixations (minimum joint duration parameter) extends longer than $\sim 3 \mathrm{~s}$. Second, allowing for brief fluctuations of attention away from the target object (minimum duration parameter), does not appear to impact the overall properties of joint attention. Third, the predictive value of joint attention for language development reduces in strength when joint attention bouts shorter than 3 s are omitted from analysis.

Perhaps the most important observation from this study was that when we only included joint attention bouts exceeding 3 seconds, the properties of joint attention changed significantly: rate and proportion of joint attention bouts were reduced by $50 \%$ or more. Furthermore, only including joint attention bouts exceeding a 3 -second duration resulted in the loss of predictive value of joint attention for vocabulary size. Taken together, these results suggest that a purely macro-level approach to the study of joint attention can lead to a loss of important variability that captures the phenomenon of joint attention.

We also observed that the inclusion of a parameter that affords brief fluctuations of attention to parts of the visual environment other than the target object does not significantly affect the properties of joint attention. It is
important to point out that we limited this analysis to only a subset of the minimum joint duration parameter in order to include all joint attention bouts longer than 500 ms and 1000 ms . It is possible that the inclusion of macro-level values of minimum joint attention (e.g., 500 ms ) and longer values of minimum duration - extending the duration of fluctuations of attention - would affect the joint attention properties beyond nominal differences. We plan to attend to this question in more detail in subsequent research.

Investigations of joint attention provide unique insights into the development and dynamics of human communication. The present study focused on an important methodological and theoretical question: what are the relevant timescales for joint attention? Our results, generated from a deductive technique to explore different areas of the parameter space of joint attention, suggest that the inclusion of micro-level temporal specifications of joint attention (e.g., <3s) is important for capturing a more vibrant picture of joint attention.

## Acknowledgments

#### Abstract

For a language learner, any new word is a pseudoword. A pseudoword is a string of of letters or phonemes that sounds like an existing word in a language, though it has no meaning in the lexicon. On the other hand, speakers are well aware of permissible phonemes, their frequencies and collocations in their language due to the phonotactics inherent in the language. For example, saktal is a pseudoword in Turkish, whereas szyan is not, due to Turkish phonotactics. This study investigates the relationship between pseudoword letter formation and eye movement characteristics in reading. In particular, we examine the role of Turkish vowel harmony, middle-word consonant collocation, and word-initial and word-final consonants on eye movements with adult native speakers reading sentences that involve predesigned Turkish pseudowords. The results of an experiment with 34 participants are indicative of the role of pseudoword formation on a set of eye movement parameters.

Keywords: Consonant collocations; Eye movements, Pseudowords; Reading; Turkish; Vowel harmony.

## Introduction

If native speakers of English are asked to judge the acceptability of the words, wug, toysion, or craphen, they are likely to rate them as acceptable. Similarly, Turkish speakers may judge talar as a possible Turkish word though they hear it for the first time. These are all pseudowords, which sound like existing words in a language, without semantic content.

Pseudowords are commonly used as experiment stimuli in research in psychology, linguistics, neuroscience, and cognitive science. They are especially useful when researchers aim at overcoming likely effects of semantics in the experiments. Phonological well-formedness of words (Hammond, 2004), morphological productivity (Anshen \& Aronoff, 1988), language development (Dabrowska, 2006), judgment of semantic similarity (MacDonald \& Ramscar, 2001), vowel harmony (Pycha, Novak, Shosted \& Shin, 2003), machine learning for orthography (Testolin,

Stoianov, Sperduti \& Zorfib, 2015), neuroimaging of reading (Mechelli, Gorno-Tempini \& Price, 2003), and dyslexia (Grainger, Bouttevin, Truc, Bastien \& Ziegler, 2003; Houpt, Sussman, Townsend \& Newman, 2015) have been among the major topics that have been studied through the use of pseudowords as experimental stimuli. Pseudowords have been employed to test models of word and letter perception, such as the interactive activation model of context effects in letter perception (McClelland, \& Rumelhart, 1981).

Previous studies have revealed that native speakers seem to make their judgments by using a probable combination of sounds (Hammond, 2004; Shademan, 2007), the cooccurrence of syllables or consonant collocations locally (Hay, Pierrehumbert \& Beckman, 2004), non-locally (Finley, 2012; Frisch \& Zawaydeh, 2001; Koo \& Callahan; 2011), or through nucleus-coda combination probabilities (Treiman, Kessler, Knewasser, Tincoff \& Bowman, 2000). Accordingly, the acceptability judgments of pseudowords are connected to orthographic neighborhood (e.g., Davis, 2010, see Rayner, Pollatsek, Ashby, Clifton Jr., 2012, for a review), which takes into account the relative positions of consonants and vowels (Perea \& Lupker, 2004), as well as letter position coding through adjacent bigrams (Seidenberg \& McClelland, 1989) and open bigrams of letters (Whitney, 2001).

For Turkish, a language with shallow orthography, it has been shown that some of the properties that characterize pseudowords can be captured from a written corpus in parallel to native speakers' judgment (Kilic, 2014). Against this background, the present study first employs corpusbased frequencies for the formation of pseudowords according to a set of criteria, including the relative positions of consonants and vowels in pseudowords. Then we investigate pseudoword processing by locating the pseudowords in sentential contexts and having native speakers read them in sentential contexts. The underlying approach is that we capture eye movement characteristics as
an indicator of word processing, which may enrich our knowledge about word processing by providing data that go beyond response time (cf. lexical decision tasks). In other words, we propose that sentential pseudoword reading, as we name it, has the potential to contribute to our understanding of word processing through the study of the relationship between subword characteristics of pseudowords and eye movement parameters.

Three dominant experimental factors that have been found to influence eye movement characteristics in reading are word length, frequency and sentential predictability (Rayner, Sereno \& Raney, 1996; Rayner, 1998; Rayner, Pollatsek, Ashby, Clifton Jr., 2012). In the present study, we controlled word length by forming pseudowords of six letters. Using pseudowords allowed us to ignore sentential predictability and word-level frequency as factors for experimental control. Instead, we focused on subword frequencies that are specified by the combinations of the letters that form six-letter pseudowords. We studied three specific types of combinations by designing high-frequency and low-frequency letter bigrams for experimental purposes:

- Vowel combinations that follow vowel harmony
- Middle-word consonant collocation
- Word-beginning and word-end consonants

Silent reading is under the influence of inner speech. If a pseudoword is hard to speak out loud, it is also hard to read silently. In this study, we hypothesize that these three variables will affect pseudoword reading in Turkish as high frequency ensures easy pronunciation, whereas low frequency of these variables lead to difficult pronunciation. It is also expected that adjacent dependencies will have a strong influence on pseudoword reading. In the following section, we present an overview of these characteristics of word structure in Turkish.

## The Turkish Language

Turkish is an agglutinating language, read from left-to-right, with a considerably shallow orthography using 8 vowels and 21 consonants derived from the Roman Alphabet (Göksel \& Kerslake, 2005; Lewis, 2000). The description of Turkish word structure depends on morphophonological constraints. The continuation of a morpheme and the selection of the corresponding morph are determined by the preceding morph. The final vowel in the preceding morph affects the form of the vowel in the incoming morpheme (Turkish vowel harmony). Similarly, the final consonant in the most recent morph causes some changes on the first consonant of the next morpheme (Assimilation).

While a morpheme with a vowel is concatenated to a string in Turkish, its vowel is modified with respect to the roundedness and backness properties of the most recent vowel in the string as in (1).
at-lar
horse-Plu
horses
kedi-ler
cat-Plu
cats
okul-lar school-Plu schools

This is not an immediate dependency because diphthongs and consecutive vowel collocations are usually not allowed in Turkish. When the corpus frequencies are investigated, it is seen that the frequencies of words containing $a \ldots a$ or $e \ldots i$ as substrings are higher than the frequencies for the words with $l \ldots \ddot{u}$ or $o \ldots e$. In other words, frequencies mimic vowel harmony. Similarly, some immediate consonant collocations are more frequent than others due to assimilation as shown in (2) for the ablative case marker -DAn.

$$
\begin{array}{lll}
\text { ev-den } & \text { et-ten } & \text { yatak-tan }  \tag{2}\\
\text { house-Abl } & \text { meat-Abl } & \text { bed-Abl } \\
\text { from house } & \text { from meat } & \text { from bed }
\end{array}
$$

Accordingly, some consonant collocations, such as $v d$, $t t$, and $k t$, are more frequent than $v t$, $t d$, and $k d$. These are infrequent but not zero frequencies because there are exceptions to assimilation as well as vowel harmony.

Another salient aspect of Turkish word structure is word boundary. Some letters, e.g., $k, g, d, z$ and $y$, are observed more frequently than, e.g., $c, g, r, v$, and $f$ in word-initial or word-final position. Even Turkish words in root forms mostly follow the regularities briefly exemplified above. In this study, word-initial and word-final boundaries are treated as a single variable (either low or high frequency letters at both boundaries) to keep the stimuli size manageable and the experiment duration reasonable.

The present study examines the effects of the aforementioned three major aspect of word formation in Turkish, namely the frequency of vowel combinations that follow vowel harmony (henceforth, vowel harmony collocation), the frequency of middle-word consonant collocations (henceforth, consonant collocation), and the frequency of word-beginning and word-end consonants (henceforth, word boundary collocation) on eye movement characteristics in sentential reading. These three variables are assumed to be binary variables with either high frequency or low frequency in a $2 \times 2 \times 2$ design. A total of 80 pseudowords were created as experimental stimuli. The letter bigram frequencies were obtained from the METU Turkish Corpus (Say, Zeyrek, Oflazer \& Ozge, 2002). All pseudowords had the same template of vowels (V) and consonants (C) shown in (3).

## (3) $\mathrm{C}_{1} \mathrm{~V}_{1} \mathrm{C}_{2} \mathrm{C}_{3} \mathrm{~V}_{2} \mathrm{C}_{4}$

Low-frequency or high-frequency vowel collocations, i.e. $\mathrm{V}_{1} \mathrm{~V}_{2}$, were selected, where high-frequency pairs of $\mathrm{V}_{1} \mathrm{~V}_{2}$ followed the rules of Turkish vowel harmony. Similarly, high-frequency and low-frequency pairs were selected for the consonant collocation $\mathrm{C}_{2} \mathrm{C}_{3}$, and for the word boundary
collocation $\mathrm{C}_{1} \mathrm{C}_{4}$. Below, we present the experiment, its methods, materials and the results obtained.

## Experiment

Thirty-four university students at Middle East Technical University (METU), Turkey, participated in the experiment (18 female and 16 male university students, mean age: 23.59, SD: 5.04). The participants were asked to read silently 80 single-line sentences displayed separately on a computer screen while their eye-movements were recorded by an EyeLink 1000 Hz desktop eye tracker. Each sentence included one pseudoword, which was located around the middle of the display. The stimuli were shown in random order. Simple true/false questions were asked randomly after some screens to ensure active engagement of the reader with the task. 20 random and simple true/false questions, which were about words other than the pseudowords in the sentences, were asked as well in order to ensure that the participants had been actively reading. The experiment was conducted in single sessions. Each session took approximately 40 minutes. The participants were paid 25 TL (approximately 6\$) as an incentive for participation.

## Material

A total of 80 pseudowords of the form $\mathrm{C}_{1} \mathrm{~V}_{1} \mathrm{C}_{2} \mathrm{C}_{3} \mathrm{~V}_{2} \mathrm{C}_{4}$ were formed for the eight categories (cf. $2 \times 2 \times 2$ design of highand low-frequency bigrams) by using orthographic frequencies obtained from the METU Turkish Corpus. Frequency was specified as a binary variable, with either high or low values. For example, if the frequency of a consonant bigram is above the mean of the frequencies of all possible bigrams, it was assumed to be a high consonant collocation frequency for selecting $\mathrm{C}_{2} \mathrm{C}_{3}$. Otherwise, it was assumed to be a low frequency consonant collocation. Similarly, high-frequency and low-frequency bigrams were selected for the word boundary collocations $\mathrm{C}_{1} \mathrm{C}_{4}$, and for the vowel harmony collocations $\mathrm{V}_{1} \mathrm{~V}_{2}$. We did not distinguish between onset and offset frequencies while studying the bigrams in the corpus to keep the experiment design simple. Below, we present more detail about the three types of collocations.

Turkish Vowel Harmony Collocation ( $\left.V_{1} \mathbf{V}_{2}\right)$. Since Turkish has eight vowels, $8 \times 8$ vowel bigrams were produced and their frequencies were calculated from the METU corpus. The vowels might have zero or more intervening characters in between. For example, while $a \ldots a$ is a very frequent vowel substring, $l \ldots \ddot{u}$ is an unlikely one. We calculated all available vowel bigrams. The highfrequency bigrams represented Turkish vowel harmony, whereas the ones with low frequency were due to the words that were exceptions to vowel harmony.

Consonant Collocation ( $\mathbf{C}_{2} \mathbf{C}_{3}$ ). Turkish has 21 consonants. Therefore, $21 \times 21$ bigrams from $b b$ to $z z$ were produced by calculating their bigram frequencies from the corpus. For example, $m l$ is much above the average of all possible
bigram frequencies while $f v$ is very rare in the corpus. Accordingly, high-frequency consonant collocations and low-frequency consonant collocations were identified for forming the pseudoword consonant collocations of the form $\mathrm{C}_{2} \mathrm{C}_{3}$. In contrast to vowel harmony collocations, only adjacent bigrams were calculated for consonant collocation since $\mathrm{C}_{2} \mathrm{C}_{3}$ is an adjacent-bigram collocation.

Word Boundary Collocation ( $\mathbf{C}_{1} \mathbf{C}_{4}$ ). The frequency values of the $21 \times 21$ bigrams, from $b \ldots b$ to $z \ldots z$, were produced from the 21 consonants in Turkish and their word boundary frequencies were calculated from the corpus. Since $C_{1} C_{4}$ is not an adjacent-bigram collocation, we allowed intervening characters between the first character of words and the last character when calculating the bigram frequencies. For example, $k$ is a frequent word-initial boundary while $z$ is a frequent word-final boundary in Turkish, making $k \ldots . z$ a frequent word boundary pattern, whereas $f \ldots b$ is a very rare word boundary co-occurrence in Turkish.

Since each of the three independent variables can be either high or low frequency, eight ( $2 \times 2 \times 2$ ) groups, each of which had ten representative pseudowords, were formed. Eight samples from the 80 -pseudoword set are shown in Table 1.

Table 1: Pseudoword groups and representative samples

|  | $\mathbf{V}_{\mathbf{1}} \mathbf{V}_{\mathbf{2}}:$ Low |  | $\mathbf{V}_{\mathbf{1}} \mathbf{V}_{\mathbf{2}}:$ High |  |
| :--- | :---: | :---: | :---: | :---: |
|  | $\mathbf{C}_{\mathbf{2}} \mathbf{C}_{3}:$ | $\mathbf{C}_{\mathbf{2}} \mathbf{C}_{\mathbf{3}}:$ | $\mathbf{C}_{\mathbf{2}} \mathbf{C}_{\mathbf{3}}:$ | $\mathbf{C}_{\mathbf{2}} \mathbf{C}_{\mathbf{3}}:$ |
|  | Low | $\mathbf{H i g h}$ | $\mathbf{L o w}$ | $\mathbf{H i g h}$ |
| $\mathbf{C}_{\mathbf{1}} \mathbf{C}_{\mathbf{4}}:$ Low | vöfvac | nindüd | lagşav | remliv |
| $\mathbf{C}_{\mathbf{1}} \mathbf{C}_{\mathbf{4}}:$ High | töjkur | köndız | hupşar | kadraz |

$\mathrm{V}_{1} \mathrm{~V}_{2}$ : Vowel harmony frequency
$\mathrm{C}_{2} \mathrm{C}_{3}$ : Consonant collocation frequency
$\mathrm{C}_{1} \mathrm{C}_{4}$ : Word boundary frequency
The pseudowords were located around the center of 80 meaningful and different sentences of similar length (63 to 65 characters). For avoiding likely effects of the orthographic features of the neighbor words, the pre-target word was fixed in the sentences: The word "aslinda" (English 'actually'), which is a very frequent Turkish adverb was consistently used as the single pre-target word. For preventing parafoveal information intake from the posttarget word, we used the frequent Turkish bigram bi- such that all the post-target words started with this same bigram (cf. Lima \& Inhoff, 1985). A sample sentence is shown in (4), where GEN is the genitive marker, PLU is the plural marker, NEG is the negative marker, PASS is the passive marker, and PAST is the past tense marker in Turkish. The target pseudoword is underlined.
(4) Siz-in mektuplar aslında köndız bitmez dendiği için Your-GEN letter-PLU indeed köndız end-NEG say-PASS for dağıtılmamış.
distribute-PAST-NEG.

In (4), the target word is the pseudoword köndız. It has a low-frequency vowel harmony collocation $\mathrm{V}_{1} \mathrm{~V}_{2}$, in this case $\ddot{o} l$; a high-frequency consonant collocation $\mathrm{C}_{2} \mathrm{C}_{3} n d$; and a high-frequency boundary collocation $\mathrm{C}_{1} \mathrm{C}_{4} \mathrm{kz}$. (sample sentences are provided in the Appendix).

## Results \& Discussion

We calculated a set of eye movement measures, as listed below.

- First fixation duration is the duration of the first fixation on the first-pass reading of the target pseudoword.
- First pass gaze duration is the sum of individual fixation durations in the first-pass reading of the target pseudoword. In other words, the entire word is an area-of-interest and this value represents the total time spent by a participant before his/her gaze left the word for the first time.
- First pass fixation count is the sum of individual fixations in the first-pass reading of the target pseudoword. The first-pass reading covers all the fixations on the word without leaving it. If the eye shifts from a pseudoword to another word on its right, the first pass is over. If the eye shifts from a pseudoword to another word on its left, the first pass is over, as well.
- Regression in count is the number of regression fixations that return to the target pseudoword after the first-pass reading. If the gaze re-fixates on a previously fixated word, but this time from its right, this is called Regression-in.

The mean values for those eye movement parameters, for the eight pseudoword categories are shown in Table 2.

Table 2: Mean values for eye movement parameters on target pseudowords

|  | $\mathrm{V}_{1} \mathrm{~V}_{2}$ : Low |  | $\mathrm{V}_{1} \mathrm{~V}_{2}$ : High |  |
| :---: | :---: | :---: | :---: | :---: |
|  | $\begin{aligned} & \mathrm{C}_{2} \mathrm{C}_{3} \text { : } \\ & \text { Low } \\ & \hline \end{aligned}$ | $\begin{aligned} & \mathrm{C}_{2} \mathrm{C}_{3}: \\ & \mathrm{High} \\ & \hline \end{aligned}$ | $\begin{aligned} & \mathrm{C}_{2} \mathrm{C}_{3}: \\ & \text { Low } \\ & \hline \end{aligned}$ | $\begin{aligned} & \mathrm{C}_{2} \mathrm{C}_{3}: \\ & \text { High } \\ & \hline \end{aligned}$ |
|  | First Fixation Duration (ms) |  |  |  |
| $\mathrm{C}_{1} \mathrm{C}_{4}$ : Low | 265.97 | 253.67 | 259.58 | 253.72 |
| $\mathrm{C}_{1} \mathrm{C}_{4}$ : High | 259.74 | 247.01 | 274.45 | 258.06 |
|  | First Pass Gaze Duration (ms) |  |  |  |
| $\mathrm{C}_{1} \mathrm{C}_{4}$ : Low | 467.97 | 435.13 | 454.60 | 390.80 |
| $\mathrm{C}_{1} \mathrm{C}_{4}$ : High | 426.58 | 360.19 | 431.32 | 331.75 |
|  | First Pass Fixation Count |  |  |  |
| $\mathrm{C}_{1} \mathrm{C}_{4}$ : Low | 1.86 | 1.86 | 1.84 | 1.66 |
| $\mathrm{C}_{1} \mathrm{C}_{4}$ : High | 1.76 | 1.57 | 1.71 | 1.40 |
|  | Regression in Count |  |  |  |
| $\mathrm{C}_{1} \mathrm{C}_{4}$ : Low | 1.27 | 1.29 | 1.18 | 1.22 |
| $\mathrm{C}_{1} \mathrm{C}_{4}$ : High | 1.23 | 1.28 | 1.28 | 1.34 |

We also calculated the averages for eye movement measures for the six-letter, legitimate words of the form CVCCVC in the sentences (excluding the sentence-initial word, the sentence-end words, and post-target words). We found nine words as such, in the stimuli sentence set. Table 3 shows the mean values, which can be taken as a baseline for comparison with the pseudoword values.

Table 3: Mean values for eye movement parameters on legitimate words

| First Fixation Duration (ms) | 201.65 |
| :--- | :--- |
| First Pass Gaze Duration (ms) | 237.33 |
| First Pass Fixation Count | 1.20 |
| Regression in Count | 1.20 |

The data in Table 3 are not sufficiently representative due to the limited number of words. On the other hand, the values in Table 3 are close to the average values obtained for sixletter words in another study with a richer data set (Acartürk, et al., in preparation). Therefore, we believe that these values can be conceived as close to representative mean values.

## Analyses

Four three-way ANOVAs were run on the data from 34 participants to examine the role of vowel harmony collocation, consonant collocation and word boundary collocation on the following eye movement measures in sentence reading: First Fixation Duration, First Pass Dwelling Time, First Pass Fixation Count, and Regression in Count. No significant three-way interaction was observed between the variables and these measures $(F(1,33)=.266$, $p=.61, \quad \eta^{2}=.001 ; \quad F(1,33)=.002, \quad p=.97, \quad \eta^{2}=.000$; $F(1,33)=.208, p=.65, \eta^{2}=.006 ;$ and $F(1,33)=.000, p=.99$, $\eta^{2}=.000$ respectively). However, there were significant twoway interactions and single effects, as presented below.

First Fixation Duration. Consonant collocation frequency had a significant effect on the first fixation duration, $F(1,33)=8.428, p<.05, \eta^{2}=.20$. As the frequency of the collocated consonant bigram decreased, the average duration of the first fixation on the pseudoword significantly increased, and vice versa.

First Pass Gaze Duration. A statistically significant interaction was found between consonant collocation frequency and word boundary collocation frequency, $F(1,33)=4.608, p<.05, \eta^{2}=.12$. In other words, the effect of consonant collocation is greater in the high-frequency wordboundary collocation condition than in the low-frequency word-boundary collocation condition, and the effect of word-boundary collocation is greater in the high-frequency consonant collocation condition than in the low-frequency consonant collocation condition.

First Pass Fixation Count. There was a statistically significant interaction between consonant collocation frequency and word boundary collocation frequency, $F(1,33)=4.341, \quad p<.05, \quad \eta^{2}=.12$, similar to the finding obtained for the gaze duration. This means that if the frequency of consonant collocation is high, then word boundary collocation frequency has an effect on the first pass fixation count, such that if the word boundary collocation frequency changes from high to low, first pass fixation count increases. If both the consonant collocation frequency and the word boundary collocation frequency change, the effect is stronger.

Regression in Count. A statistically significant interaction was obtained between vowel harmony collocation frequency and word boundary collocation frequency, $F(1,34)=5.002$, $p<.05, \eta 2=.13$, without an interaction with consonant collocation frequency. In particular, when the consonant collocation frequency is high, pseudowords with high word boundary collocation frequency gets more re-fixations from its right if the vowel harmony collocation frequency is also high. This effect disappears if the dominant variable, the consonant collocation, becomes infrequent.

## Discussion and Conclusion

Our findings revealed mixed results. This indicates the need for further research on pseudoword reading in Turkish. In particular, the findings for the first fixation durations showed that the consonant collocation frequency is the dominant aspect that influences eye movements in reading, since low frequency consonant collocations result in longer fixation durations and vice versa. The frequency of consonant collocations also significantly interacts with the frequency of word boundary collocations, according to the findings obtained for the first pass fixation count and first pass gaze duration, showing that when they both have low frequency, a higher number of first pass fixation count and a longer first pass gaze duration is observed. Finally, the regression-in-count findings suggest that when the consonant collocation frequency is already high, regressionin counts increase when the vowel harmony collocation frequency and the frequency of word boundary collocations are also high. It is likely that this is because pseudowords of this type look like real words. This might have caused the participants to assume misreading a known word, which was followed by re-fixations after the first pass.

In reading research, the first fixation duration on a word is usually conceived as the most valuable indicator of word recognition, since it can be seen as a reflection of the initialstage processes in word recognition (Rayner, 1998). The second fixation on a word (viz. refixation), further fixations on the same word and regression fixations reveal more complex processes than word recognition, such as syntactic and semantic processes at a sentential-level. Accordingly, at this stage, our findings indicate the frequency of the middleword consonant allocation as a dominant factor that
influences pseudoword reading in Turkish. We also believe that the sentential pseudoword reading paradigm has the potential to enrich our knowledge about word processing with higher ecological validity compared to alternative approaches, such as lexical decision tasks and naming tasks.

## Appendix

Below we present sample stimuli for each combination of vowel harmony collocation $\mathrm{V}_{1} \mathrm{~V}_{2}$, middle-word consonant collocation $\mathrm{C}_{2} \mathrm{C}_{3}$, and boundary word collocation $\mathrm{C}_{1} \mathrm{C}_{4}$, respectively. H is used for high frequency, and L is used for low frequency. Pseudowords are underlined for demonstration.

## $V_{1} V_{2}$ is high, $C_{2} C_{3}$ is high, $C_{1} C_{4}$ is high

- Kaldırmaya çabalasan aslında biylen birden yere düşüp kırılmazdı.
- Mirası harcamasaydım aslında sirden binası şimdi çoktan bitmişti.
$V_{1} V_{2}$ is high, $C_{2} C_{3}$ is high, $C_{1} C_{4}$ is low
- Hasan cebindeki parayı aslında niyled birimi olarak düşünüyordu.
- Son yılın modası aslında lirdev birası ile karides pişirmekmiş.
$\mathbf{V}_{1} V_{2}$ is low, $C_{2} C_{3}$ is high, $C_{1} C_{4}$ is high
- Sizin mektuplar aslında köndız bitmez dendiği için dağıtılmamış.
- Dün Emine'nin nişanlısı aslında bındül binayı bulamadı gerçekten.
$V_{1} V_{2}$ is low, $C_{2} C_{3}$ is high, $C_{1} C_{4}$ is low
- Radyonun sesini açarsan aslında nındüd bizden sonuçları öğrenir.
- Şu kediler sokakta aslında ü̈lrıv birini bulup sürtünüyorlarmış.
$\mathrm{V}_{1} \mathrm{~V}_{2}$ is high, $\mathrm{C}_{2} \mathrm{C}_{3}$ is low, $\mathrm{C}_{1} \mathrm{C}_{4}$ is high
- Yarın deniz kenarında aslında bıgvıl birini izleyerek eğlenecek.
- Baharda sigara içmek aslında sagșan binası çevresinde yasaktır.
$V_{1} V_{2}$ is high, $C_{2} C_{3}$ is low, $C_{1} C_{4}$ is low
- Bu bölgedeki kuşların aslında lagşav birini korkuttuğu söylenir.
- Fizik dersi haricinde aslında revşev bilimi konusundan bahsetti.
$V_{1} V_{2}$ is low, $C_{2} C_{3}$ is low, $C_{1} C_{4}$ is high
- İstatistik dersinde aslında söcșun birden bütün verileri bozmuş.
- Hastaneye sabah gelenler aslında töjkır birini görmek istiyorlar.
$V_{1} V_{2}$ is low, $C_{2} C_{3}$ is low, $C_{1} C_{4}$ is low
- Doğa resimlerinde aslında löcșuv binası betimlemelerini kullanır.
- Cuma gecesi televizyonda aslında şobçüc birini izleyerek uyudum.

# Children's familiarity preference in self-directed study improves recognition memory

#### Abstract

In both adults and school-age children, volitional control over the presentation of stimuli during study leads to enhanced recognition memory. Yet little is known about how very young learners choose to allocate their time and attention during self-directed study. Using a recognition memory task, we investigate self-directed study in low-income preschoolers, who are at an age when attention, memory, and executive function skills rapidly develop and learning strategies emerge. By pre-exposing children to some items before self-directed study, we aimed to discover how familiarity modulates their study strategies. We found that children showed a preference for studying pre-exposed items. Overall, items studied longer led to increased recognition of those items at test. We also compared recognition task performance and strategies with measures of cognitive control skills, finding that children's selective attention skills support recognition performance. These findings may inform both theory and educational intervention.

Keywords: active learning; recognition memory; executive function; attention; cognitive development

## Introduction

Children learn through active exploration of their environments. They ask questions, test hypotheses, and probe novel or confounding objects that could shed new light on how the world works (Schulz \& Bonawitz, 2007). Recent research in cognitive science suggests that schoolage children learn better when allowed to control the content and timing of information flow compared to passively receiving information (Partridge, McGovern, Yung, \& Kidd, 2015; Sim, Tanner, Alpert, \& Xu, 2015). Little is known, however, about how self-directed information gathering develops during preschool ages, a time of great plasticity in the neural networks that support executive function, attention, and memory (Blair \& Raver, 2015). Understanding patterns in young children's active information gathering and examining the mechanisms through which self-directed control affects learning may inform cognitive science as well as educational initiatives, particularly for low-income preschoolers at higher risk of poor learning outcomes (Ursache, Blair, \& Raver, 2012).

Episodic memory is one ability that has been found to benefit from active learning. Memory is aided by topdown, meta-cognitive control processes, such as when learners prioritize study of items close to mastery and
avoid content that is already learned or that is too difficult to master (Markant, Ruggeri, Gureckis, \& Xu, 2016). Bottom-up influences of cognitive control can also support episodic memory. In adult recognition memory tasks with self-paced study, alignment of stimulus exposure with attentional resources improved later recognition (Markant, DuBrow, Davachi, \& Gureckis, 2014). These active control behaviors enhance representations and strengthen associative networks, both of which help to encode and retrieve experienced stimuli (Markant et al., 2016).

Voss and colleagues (Voss, Galvan, \& Gonsalves, 2011; Voss, Gonsalves, Federmeier, Tranel, \& Cohen, 2011) examined how adults' study patterns influence the benefits of active encoding for recognition memory. They tasked participants with memorizing a set of objects arranged in a $5 \times 5$ grid. A moving window allowed only one object to be visible at a time, with control over the window given to the participant during active blocks. During yoked blocks, participants watched the window move according to the recorded movements of a previous participant. Importantly, the yoked condition allowed the authors to distinguish the effects of active control over and above the visual stimulus information experienced during study. They found both an overall active study advantage, as well as benefits to particular study patterns. Recognition improved when objects were studied for longer duration and revisited within a short time frame, but the benefits of these study features were only found in active and not yoked conditions.

Ruggeri, Markant, Gureckis, and Xu (2016) adapted the Voss et al. paradigm to examine study patterns during active encoding with school-age children. They found that 6 -to 8 -year-olds had better recognition memory when given volitional control over the presentation of stimuli during study, as compared to being yoked to study sequences generated by other children. Moreover, the recognition memory advantages of self-directed study were present following a one-week delay. In contrast to Voss et al.'s findings in adults, school-age children showed generalized benefits of certain study patterns on their memory encoding: participants had improved recognition memory in both active and passive conditions for items visited often and studied longer (Ruggeri
et al., 2016). The authors suggest that children benefited in both conditions from attentional cues (red outlines that indicated which object would be presented for study next). For school-age children, attentional cueing appears to support benefits of longer study even in the yoked condition. This finding is consistent with previous research showing that even subtle opportunities to coordinate the learner's attentional state to incoming information (i.e., by giving learners control over when the next stimulus appears) can improve episodic memory (Markant et al., 2014).

These studies suggest that multiple levels of control may enhance memory from an early age, but the developmental course of these processes remains unclear. One possibility is that the effects of active encoding vary based on the maturation of the neural networks that support volitional control, working memory, and attention. These neural networks undergo tremendous growth during the preschool years, leading to meaningful individual differences in children's attention and self-regulatory control (Blair \& Raver, 2015). These cognitive control skills support school readiness, and are targeted for intervention to close income-based early achievement gaps (Ursache et al., 2012). Little is known about the effects of active encoding on recognition memory at preschool ages. Young children's variability in attentional control may make study duration and attentional coordination particularly critical factors for active encoding. Developing cognitive control skills may also affect children's metacognitive ability to strategically allocate study effort based on their current familiarity with the materials.

This study examines whether low-income preschoolers use active control to engage in strategic study during a recognition memory task. If so, what patterns of sampling emerge, and how do these patterns change with varied stimulus familiarity? Another gap in the research literature is whether individual differences in young children's control skills influence the effects of active sampling on encoding. This study addresses these questions by examining active memory performance in a large sample of low-income preschoolers. We use a novel extension of the Ruggeri et al. (2016) task design that varies stimuli pre-exposure, as well as a battery of well-validated executive function and attention measures.

## Experiment

## Methods

Participants Ninety-four 5-year-olds from low-income backgrounds were recruited and tested as part of a school readiness study run in collaboration with two Head Start preschool centers. An additional 16 participants were tested but excluded due to incomplete data due to experimenter error or connectivity problems, or because of difficulty understanding task instructions. Children were tested in their preschools by trained assessors. Administration of the tasks was divided over two testing
days scheduled within one week of each other. EF and attention tasks were administered on day 1 , and lasted about 5 minutes each for a total of 15 minutes. The recognition memory task was administered on day 2 and lasted about 10 minutes.

## Memory Task

Materials Stimuli were taken from Ruggeri et al. (2016), which included 149 color line drawings of animals and objects that are used frequently by children younger than 5 -years-old in everyday conversations (MacWhinney \& Snow, 1985). Items were randomly sampled from the stimulus set and presented in a series of 4 x 3 grids. Stimuli not presented during the practice or study phases were randomly sampled in the test phase and used as novel foils. The task was presented on a touchscreen laptop, with timing and choice data logged to a database via psiTurk (Gureckis et al., 2015).

Procedure The task was presented as a simple memory card game (see Figure 1). Children were instructed to study a grid of images on the touchscreen tablet, presented initially "face-down" as empty rectangles. Children could "turn cards over" by touching the empty rectangle to reveal the image underneath. Later, they were asked to recognize studied items presented among novel distracter images. The design and procedure closely followed described in Ruggeri et al. (2016), with a key design modification: this version experimentally manipulates the pre-exposure of items during the study phase in order to examine the role of exposure on children's active study behavior.

Practice phase. Children were presented with a 2 x 2 practice grid. Half the items on the grid were simultaneously revealed during a pre-exposure phase that lasted 6 s while the other half remained face down, and children were instructed to "Remember these pictures!" The practice study phase ( 30 s ) followed, with all cards presented face down. Children were told to tap the cards they wanted to see. Once a card was touched, the image underneath was revealed until the child "tapped" off by touching the image again, or touched another card. Only one item was revealed at a time. Next the untimed test phase presented a $3 \times 2$ grid showing all 4 items in the study phase as well as 2 additional novel distracter items, in random grid locations. Children were instructed to touch all the "old" pictures they saw before, and not touch the "new" pictures. A red box appeared around each item when selected, and was toggled off if tapped again. Children were not restricted in how many or few items could be selected during the test phase. Once children indicated that their selections were complete, the assessor praised correct answers and gave feedback on incorrect answers. The practice phase could be played 1 to 3 times with different stimuli. If the child was unable
to understand directions, the task was ended.
Study phase. The study phase consisted of 3 blocks, each presenting a $4 x 3$ grid of randomly sampled images. The procedure is similar to that described in the practice phase. Simultaneous pre-exposure of half the items lasted 2 s per item ( 12 s in the two half pre-exposed blocks, and 24 s in the all pre-exposed block) before cards were turned over and the child could then actively select and turn over cards to study for 36 s . This shorter duration of the active study phase (as compared to Ruggeri et al., 2016) was chosen to enhance the potential effect of pre-exposure on search behavior. The 3 study grids were presented consecutively before the test phase.

Test phase. The test phase consisted of 6 blocks. Each $4 x 3$ test grid was a random sample drawn without replacement from a pool of 72 stimuli, including the 36 included in the study phase along with 36 novel images. The number of old items in each grid ranged from 0 to 12 (randomly chosen) in order to minimize strategic responding based on the proportion of items selected within each block. All 36 studied stimuli and all 36 novel stimuli were presented only once at test. Children were instructed to "Touch the pictures you remember!" and not to select new pictures. Once the child indicated that they were done with selection, the assessor prompted. "Are you sure you touched only the pictures you saw before and not any new pictures?" If the child said yes, the assessor advanced to the next test grid. If the child answered no, the assessor reminded them to choose only "old" pictures seen before.

Both hit rate (proportion of studied items correctly selected as "old") and correct rejection rate (proportion of novel items correctly not selected) were calculated. In addition, total study time per item and study repetitions per item was computed for pre-exposed vs. non-preexposed items and conditions.
Executive Function and Attention Tasks Attention Network Test. The Attention Network Test (ANT; Rueda et al., 2004) is a well-known behavioral measure thought to map onto the neural networks supporting attentional control. The child version of the ANT presents either a single fish or a horizontal row of five fish. Children are instructed to feed the center fish by pressing a blue box in the lower corners of either side of the screen indicating in which direction the central fish is swimming. Children are asked to ignore the flanker fish pointing either in the same (congruent) or opposite direction (incongruent) as the target middle fish. Mean accuracy and reaction time are computed.

Visual Search Task. The Visual Search task (Steele, Karmiloff-Smith, Cornish, \& Scerif, 2012) measures the ability to select relevant stimuli (targets) while ignoring distracters (non-targets). Children are presented with a search display on the touch screen monitor. Each display contains 90 items, made up of 20 targets (animals) and

Figure 1: Each study phase of the experiment was preceded by pre-exposure of half (6) or all (12) of the items, for 2 s per item (i.e., 12 s in the two half-pre-exposed conditions and 24 s in the all-pre-exposed condition). All three cycles of pre-exposure and study were completed before the six screens of testing were performed.

70 non-targets (objects). Children are instructed to find animals, which are replaced with a star when successfully touched. The task ends when a total of 18 correct responses is reached, or 40 responses are made overall. Mean search speed (time between touches), and number of errors are recorded.

Continuous Performance Test. The Continuous Performance Test (CPT; (Steele et al., 2012) measures the ability to sustain attention for a prolonged period without distraction. In this version, the child is instructed to touch the screen as soon as an animal appears. One hundred pictures are randomly presented one at a time, including 20 presentations of the target stimuli (animals) and 80 presentations of nontarget stimuli (objects). Each stimulus appears on the screen for 300 ms followed by a blank screen for 1250 ms . In addition to response time, number of missed responses to targets (omission error) and incorrect touches to distracters (commission error) are recorded.

Digit Span. Digit Span is a widely used executive function task that assesses children's working memory. Children are instructed to repeat number sequences of sequentially longer length in forward and backward conditions. Total number of correct responses per condition is recorded. Children in this sample were largely unable to repeat sequences backwards, so only performance on the forward condition are used here.

## Results

Data from 94 participants were analyzed with respect to recognition (selection) of studied items (i.e., hit rate), correct rejection of unstudied items, and the number of
repetitions and total study time for studied items. Participants' mean hit rate (HR) was 0.65 , and the mean correct rejection (CR) rate was 0.56 .
Study Behavior Studied items were selected for study on average 1.78 times (median: 1 ; maximum: 10). The mean study time for old items was 3037 ms (median: 2067 ms ). Table 1 shows the distribution of how many times children repeated study items and cumulative study time per item (median, mean, and SD). Children most often studied items a single time (38.6\%), but it was not uncommon to study an item twice ( $22.6 \%$ ) or even three times ( $10.6 \%$ ). A surprising number of items ( $23.4 \%$ ) were not actively selected for study at all, and these were well-distributed among the participants, who left a median of 6 of the 36 items unstudied (mean 8.3, bootstrapped $95 \%$ confidence intervals: $(6.8,10.1)$ ).

| Reps | Median Time | Mean Time | SD | N |
| ---: | ---: | ---: | ---: | :--- |
| 0 | 0 ms | 0 ms | 0 ms | 783 |
| 1 | 1,452 | 2,443 | 3,137 | 1,307 |
| 2 | 2,305 | 3,371 | 3,331 | 766 |
| 3 | 2,860 | 3,528 | 2,413 | 360 |
| 4 | 3,645 | 4,491 | 2,891 | 121 |
| 5 | 5,069 | 6,622 | 5,028 | 37 |
| $>5$ | 5,467 | 6,984 | 5,552 | 8 |

Table 1: Statistics of study repetitions and time (ms).

Pre-exposure Effects To investigate the impact of pre-exposure on study time and repetitions, we fit mixedeffects regression models to separately predict triallevel study time and study repetitions (both scaled and centered to $[-1,1]$ ) for only the blocks with half preexposed items. Subject was included as a random factor, and item pre-exposure as a binary predictor ( R syntax: Study Time $\sim$ Preexp + (1|Subject) and Repetitions $\sim$ Preexp + (1|Subject). Shown in Table 2 , the regression predicting study time found a significant positive intercept ( $\beta=0.19, Z=5.02, p<.001$ ). Moreover, there was a significant positive effect of preexposure ( $\beta=0.11, Z=2.23, p<.05$ ), indicating that pre-exposure led to increased study time. ${ }^{1}$ On average, pre-exposed items in these conditions were studied for 3477 ms , whereas the hidden items were studied for 3001 ms . Shown in Table 3, the regression predicting study repetitions found a significant positive intercept ( $\beta=0.32, Z=5.58, p<.001$ ). There was a positivelytrending effect of pre-exposure $(\beta=0.07, Z=1.88$, $p=.06$ ), suggesting that pre-exposed items may be selected more often for study. On average, pre-exposed items in these conditions were selected 1.80 times, while the hidden items were selected 1.65 times.

[^259]|  | $\beta$ | SE | $Z$-score | $p$-value |
| :--- | ---: | ---: | ---: | ---: |
| Intercept | 0.185 | 0.037 | 5.016 | $p<.001^{* *}$ |
| Pre-exposed | 0.112 | 0.050 | 2.233 | $p<0.05^{*}$ |

Table 2: Regression predicting study time.

|  | $\beta$ | SE | $Z$-score | $p$-value |
| :--- | ---: | ---: | ---: | ---: |
| Intercept | 0.315 | 0.057 | 5.578 | $p<.001^{* * *}$ |
| Pre-exposed | 0.070 | 0.037 | 1.884 | $p=0.06$. |

Table 3: Regression predicting study repetitions.

Recognition Accuracy To investigate the impact of pre-exposure, repetitions, and study time on recognition performance, we fit two logistic mixed-effects regression models to the item-level accuracy data for old stimuli, separating study time and repetitions since they are correlated. Subject was included as a random factor, and study repetitions and study time (scaled and centered to $[-1,1])$ were included in their respective models as fixed, continuous predictors, allowed to interact with item preexposure, a binary predictor ( R syntax for study time model: Correct ~ Preexp * Time + (1|Subject); and substitute Reps for Time in the other model).

In the study repetitions model, there was a significant positive intercept, showing that participants were more likely to correctly recognize rather than miss the old items ( $\beta=0.95, Z=5.16, p<.001$ ). There was a significant positive effect of study repetitions $(\beta=0.52$, $Z=4.19, p<.001$ ), showing that studying items more often led to higher recognition of those items. There was also a significant positive effect of pre-exposure ( $\beta=0.27, Z=2.37, p=.02$ ), showing that pre-exposure increased the likelihood of correctly recognizing an old item. Finally, there was a significant negative interaction of pre-exposure and repetitions $(\beta=-0.31, Z=2.23$, $p=.03)$ : with pre-exposure, there was less accuracy benefit of more study repetitions. Figure 2 shows the mean hit rate as a function of pre-exposure and study repetitions, along with the relative frequency of each level of repetitions.

In the study time model, in addition to a significant positive intercept, $(\beta=1.05, Z=5.83, p<.001)$, there was a significant positive effect of study time ( $\beta=0.36, Z=3.19, p=.001$ ), showing that studying items longer led to increased recognition of those items. There was also a positively-trending effect of preexposure ( $\beta=0.21, Z=1.92, p=.06$ ), suggesting that pre-exposure may increase their chance of recognizing old items. Finally, there was a significant negative interaction of pre-exposure and repetitions $(\beta=-0.29$, $Z=2.32, p=.02$ ), showing that pre-exposure lessens the accuracy benefit of longer study time.

The AIC of the study repetition model was 2712.8, and the AIC of the study time model was 2722.6, making the

Figure 2: Items that were studied more often had higher hit rates, but most items were not studied more than one or two times. (Not pictured: participants were at chance for unstudied 'old' items.)
relative likelihood of the study time model 0.007 . Thus, although both models have similar interpretations, the repetitions model provides a better account of the data.

Self-directed Memory and Executive Function We next examined the link between behavior in the selfdirected memory task and the various attention and executive function (EF) measures using three mixed-effects regression models to predict item-level ( $\mathrm{N}=2,770$ ) 1) recognition accuracy, 2) study time, and 3) study repetitions for old items. All three models included subject as a random factor, and the following EF measures (scaled and centered to $[-1,1]$ ) as fixed predictors: working memory, visual search errors, visual search reaction time, commission errors, and omission errors, and ANT accuracy and RT (R syntax: Correct ~ + EFvar1 + EFvar2 + . $+(1 \mid$ Subject $)$ ).
For the logistic model predicting recognition accuracy, besides a significant positive intercept ( $\beta=0.77$, $Z=4.35, p<.001)$, there was a negatively-trending coefficient for visual search errors ( $\beta=-0.41, Z=-1.92$, $p=.05$ ). All other predictors were insignificant ( $p$ 's $>.1$ ). In summary, this suggests that fewer visual search errors, an index for selective attention skills, is associated with increased recognition.

The model predicting study time (log-transformed, scaled and centered to $[-1,1]$ ) found a positive coefficient for visual search time ( $\beta=0.05, Z=2.11, p=.03$ ), with all other predictors insignificant ( $p$ 's $>.1$ ). This indicates that participants with longer visual search times also spent longer studying items during the study phase.

The model predicting study repetitions (with a Poisson linking function) found no significant predictors in the EF measures.

## Discussion

The present study examined low-income preschool children's study behavior in a self-directed recognition memory task, and compared 5 -year-olds' active study behaviors to patterns found in older samples in previous literature. We next examined if stimuli pre-exposure affects active encoding. Finally, we explored how individual differences in executive function and attention skills may influence study strategies and recognition.

First, we found that children were above-chance at recognizing old items and correctly rejecting new items, indicating that they can meaningfully engage in a developmentally-complex paradigm requiring selfdirected study. We found increased recognition accuracy for items with greater repetitions, and for items with greater study time, replicating classic repetition effects from both traditional (experimenter-directed) recognition memory experiments, as well as self-directed versions (e.g., Voss et al., 2011a; Voss et al., 2011b).

Second, we found that pre-exposure significantly increased study time, suggesting a preference to allocate study effort to familiar material at the outset of study. Pre-exposed items were also more likely to be recognized, but this effect appeared to overlap with other helpful study behaviors. For pre-exposed items, both repetitions and study time showed less benefit to recognition compared to items without pre-exposure. Thus, although children use their familiarity with items to guide their study, they appeared to benefit more generally from stimulus exposure, be it through passive pre-exposure or active selection (i.e., increased study time or repetitions). Ruggeri et al. (2016), finding similar results for 6 - to 8 -year-olds who had better recognition memory in both active and yoked conditions for items visited often and studied longer, suggested that children in yoked conditions were able to benefit from attentional cueing, allowing them to coordinate their attention with the presentation of new information. Notably, we found that preschoolers benefited from passive pre-exposure, which provides no attentional cueing. These findings suggest that duration of stimuli exposure alone may be particularly important for memory encoding at preschool ages.

Third, we found that greater recognition accuracy was predicted by both fewer visual search errors and longer visual search response times in a developmental selective attention task. These data suggest that selective attention skills support children's active study during preschool, a period of neurocognitive plasticity in systems that support attention, executive function, and memory (Blair \& Raver, 2015). While it may be surprising that longer visual search time supports recognition memory, it is important to note that these behav-
ioral measures often exhibit a speed-accuracy trade off (Davidson, Amso, Anderson, \& Diamond, 2006). Young children who search more carefully may be slower to respond but more successful in encoding stimulus information. The relation between stimuli pre-exposure and increased study time suggests that one possible study strategy for children is to focus attention on familiar items. As attentional focus is a more effortful and limited resource at this young age, children may benefit from allocating study time to known items. Prioritizing study of items close to mastery is a learning strategy described in Metcalfe's zone of proximal development framework (Metcalfe, 2011). In this framework, optimal learning strategies should focus on the easiest possible as-yetunlearned items, as focus on items too difficult may be maladaptive and potentially disheartening. In this task, the difficulty of unexposed items to encode is unknown until they are "turned over" and revealed, whereas young children have time during pre-exposure to evaluate preexposed item difficulty and engage attentional resources. Continued experimental investigation is needed to better understand the role of attention skills and search strategies on young children's active encoding.

This study is a first step in examining the effects of executive function and attention on low-income preschool children's active learning. We found that selective attention supports recognition memory, but measures of inhibitory control and working memory were not significant unique predictors. One possibility is that demands of the recognition memory task were particularly dependent on visual search and attentional focus skills. Future experimental studies should aim to tease apart how various cognitive control skills might contribute to different types of active learning tasks. A limitation to this study is that the narrow range of socio-economic status (SES) for our sample may limit generalizability of the findings. Notably, long-term exposure to chronic stress associated with poverty has been found to have negative consequences on children's selective attention and memory (McEwen, 2000). Thus, examining mechanisms that support active encoding may be particularly important for understanding the effects of poverty on early learning. We are planning additional data collection with a higher income cohort to examine relations between SES, cognitive control skills, and active encoding. Future work may also seek not only to measure children's self-directed study strategies, but to improve them via intervention.

#### Abstract

Recent Machine Learning systems in vision and language processing have drawn attention to single-word vector spaces, where concepts are represented by a set of basic features or attributes based on textual and perceptual input. However, such representations are still shallow and fall short from symbol grounding. In contrast, Grounded Cognition theories such as CAR (Concept Attribute Representation; Binder et al., 2009) provide an intrinsic analysis of word meaning in terms of sensory, motor, spatial, temporal, affective and social features, as well as a mapping to corresponding brain networks. Building on this theory, this research aims to understand an intriguing effect of grounding, i.e. how word meaning changes depending on context. CAR representations of words are mapped to fMRI images of subjects reading different sentences, and the contributions of each word determined through Multiple Linear Regression and the FGREP nonlinear neural network. As a result, the FGREP model in particular identifies significant changes on the CARs for the same word used in different sentences, thus supporting the hypothesis that context adapts the meaning of words in the brain. In future work, such context-modified word vectors could be used as representations for a natural language processing system, making it more effective and robust.

Keywords: Neural Networks; FGREP; Concept Attribute Representation theory; fMRI; Context; Meaning; Semantics; Embodied Cognition

## Introduction

Recently, Deep Learning systems of vision and natural language processing (NLP) have drawn special attention into single-word vector spaces. They are able to extract low level features in order to recognize concepts (e.g. cat), but they are incapable of forming an abstract notion of the concept (symbol). In general, these models build semantic representations from text corpora where words that appear in the same context are likely to have similar meanings (Harris, 1970; Landauer \& Dumais, 1997, Burgess, 1998; Baroni et. al., 2010). However, such representations lack intrinsic meaning, which means sometimes even different concepts may appear similar. This problem has driven
researchers to develop new componential approaches, where concepts are represented by a set of basic features, or attributes, based on textual and perceptual input. (Bruni, et al., 2012; Silberer \& Lapata, 2014, Vinyals et. al., 2015). However, even with their multimodal embedding space, such vector representations fall short from symbol grounding.

In contrast, embodiment theories of knowledge representation (Regier, 1996; Landau et al., 1998, Barsalou, 2008) provide a direct analysis in terms of sensory, motor, spatial, temporal, affective, and social phenomena. Further, these theories can be mapped to brain networks. Recent fMRI studies helped identify a distributed large-scale network of sensory association, multimodal and cognitive regulator systems linked with the storage and retrieval of conceptual information (Binder et al., 2009). This network was then used as a basis for Concept Attribute Representation (CAR) theory, an embodiment theory that enumerates semantic features of concepts and grounds them in brain networks (Binder et al., 2009, 2011 and 2016).

An intriguing challenge to such theories is that concepts are dynamic, i.e. word meaning depends on context and recent experience (Pecher, Zeelenberg, \& Barsalou, 2004). For example, a pianist would invoke different aspects of the word piano depending on whether he will be playing in a concert or moving the piano. When thinking about a coming performance, the emphasis will be on the piano's function, including sound and fine hand movements. When moving the piano, the emphasis will be on shape, size, weight and other larger limb movements.

This paper focuses on addressing these challenges based on the CAR theory. The main idea is that different attributes in CARs can be weighted differently depending on context, i.e. according to how important each attribute is in that context. More specifically, neutral CARs of words are first used to form an expected fMRI pattern of a subject reading a sentence. That pattern is compared to an actual fMRI image. Two techniques, multiple linear regression and a FGREP neural network, are then used to determine how the CARs would have to change to account for the actual fMRI
pattern. These changes represent the weighting in context; it is thus possible to track the dynamic meanings of words by tracking how the weighting changes across contexts.
Experiments with available fMRI data show that the approach is feasible, demonstrating meaningful differences for e.g. human communication vs. noise from a machine; dangerous storm vs. dangerous person; live mouse vs. dead mouse. These changes are principled and could be captured e.g. by a neural network. It might then be possible to create them dynamically, and form as a basis for a more robust and grounded natural language processing system.

The CAR theory is first reviewed below, and the sentence fMRI and word representation data described. The methods for determining semantic changes, i.e. multiple linear regression and FGREP, are then presented, followed by an analysis of the results.

Figure 1: Perceptual Grounding. CARs are composed of a list of known modalities that relate to specialized sensory, motor and affective brain processes, systems processing spatial, temporal, and casual information, and areas involved in social cognition. They capture aspects of experience central to the acquisition of abstract and concrete event as well as object concepts.

## Concept Attribute Representation Theory

CARs represent the basic components of meaning defined in terms of known neural processes and brain systems (Binder, 2016). They relate semantic content to systematic modulation in neuroimaging activity. And are therefore not limited to the classical sensory-motor dimensions of most embodied theories.

CARs are composed of a list of well-known modalities that correspond to specialized sensory, motor and affective brain processes, systems processing spatial, temporal, and casual information, and areas involved in social cognition. They capture aspects of experience central to the acquisition of event and object concepts (both abstract and concrete).

These attributes were selected after an extensive body of physiological evidence based on two assumptions: (1) all aspects of mental experience can contribute to concept acquisition and consequently concept composition; (2) experiential phenomena are grounded on neural processors representing a particular aspect of experience (Figure 1).
These aspects of mental experience model each word as a collection of a 66 -dimensional feature vector that captures the strength of association between each neural attribute and
the word meaning. An example is shown in Figure 2. For a more detailed account of the attribute selection and definition see Binder et al. (2009, 2011 and 2016).

## Data Collection and Preprocessing

Two existing data sets were used in this study: fMRI images of sentences and CARs obtained via Mechanical Turk.

## Neural Images

The stimuli shown to subjects consisted of a list of 240 every day written sentences prepared in the Knowledge Representation in Neural Systems (KRNS) project (Glasgow et al., 2016). The sentences are composed by three to nine words from a set of 242 words ( 141 nouns, 39 adjectives and 62 verbs). Eleven subjects took part in this experiment producing 12 repetitions each. Participants viewed the sentences word by word while in the scanner. The data was acquired by the Center for Imagining Research of the Medical College of Wisconsin (Anderson et al., 2016). The fMRI data was preprocessed and transformed into a single sentence fMRI representation per participant (by averaging all the repetitions), with a final selection of 396 voxels per sentence on a scale from 0.2-0.8, for further use in the computational models.

Figure 2: Bar plot for CAR 66 semantic features. The attribute ratings represent the basic features of chair. Given that this concept is an object, gets low weightings on human-related attributes: face, speech, social, and emotion and strong on visual, shape, touch, manipulation, and some others.

## Semantic Vectors

The semantic attribute ratings were collected thru Amazon Mechanical Turk for each of the 242 words (e.g. family, hospital, chair, small, green, laughed, listened, walked). In a scale of $0 . .6$, the participants were asked to assign the degree to which a given concept is associated to a specific type of neural component of experience (e.g. "To what degree do you think of a chair as having a fixed location, as on a map?"). Approximately 30 ratings (all attributes for each word) were collected. After averaging all the ratings and removing outliers, the final attributes were transformed to unit length yielding a collection of 66-dimensional feature vector that captures the weights of association between each neural attribute and the 242 words. Note that in this manner, the richness and complexity of representations is based on intrinsic meaning of each word, and not on word co-occurrence (Figure 2).

## Data Preparation

The data set did not include fMRI images for words in isolation, a technique developed by Anderson et al. (2016) was adopted to approximate them. The voxel values for words were obtained by averaging all fMRI images for the sentence where each word occurred. Thus, the vectors include a combination of examples of that word along with other words that appear in the same sentence (context). Because of the limited number of combinations, some of these became identical, and were excluded from the dataset.

Given the final set of 237 sentences and 236 words (138 nouns, 38 adjectives and 60 verbs), the next step was to identify pairs of sentences with differences on word meanings such as live mouse vs. dead mouse, good soldier vs. soldier fighting, built hospital vs. damaged hospital, and playing soccer vs. watching soccer. This collection will allow the computational models to evaluate distinctive attribute representations and consequently adjust the baseline meaning of a word to convey the effects of context and conceptual combination.

A collection of 77 such sentences, with different shades of meaning for verbs, nouns and adjectives, as well as different contexts for nouns and adjectives was assembled. This collection will be used as Words of Interest (WoI) for the analysis of context in the experiments (Table 1).

Table 1: Contrasting Sentences. Eight sentences from the collection of the 77 contrasting sentences. Here, for instance, the verb kicked is used in two different contexts, playing with a ball (as in Soccer) vs. breaking the door (as an aggressive behavior).

| SEMANTIC <br> CONTRAST | SENTENCES |
| :--- | :--- |
| GOOD | 94 The soldier delivered the medicine during the flood. |
| AGGRESSIVE | 112 The soldier kicked the door. |
| PLAY <br> (SOCCER) | 239 The artist kicked the football. <br> 62 The boy kicked the stone along the street. |
| BREAK | 112 The soldier kicked the door. |
| BAD PEOPLE | 119 The dangerous criminal stole the television. <br> 152 The mob was dangerous. |
| NATURE | 99 The flood was dangerous. |

## Computational Models

A new technique is proposed in this section for analyzing data imaging. It is grounded on the CAR theory and implemented using Multiple Linear Regression (LReg) and the FGREP neural network (Forming Global Representations with Extended BP; Miikkulainen \& Dyer, 1991). The main idea is to predict sentence fMRI by mapping CARWord to SynthWord (fMRI) (top of Figure 3). The SynthWord is then combined by averaging to form SyntSent for the predicted sentence. Next, the SynthSent is compared to the actual fMRISent (middle of Figure 3). The differences are included by modifying the SynthWord that map to fMRISent and by modifying the CARWord that map to the modified SynthWord (bottom of Figure 3). The resulting CARWord indicate how word meaning change across sentences.

Figure 3: General System framework and data flow. Mapping CARWord to SynthWord (top). Then SynthWord is combined by averaging to form SyntSent and to be compared to the actual fMRISent (middle). Invert the process to modify the CARWords via SynthWord revised (bottom). The Revised CARWord includes different word meaning across sentences.

## Multiple Linear Regression

At the word level, Multiple regression (LReg) is used to learn the mapping between CARWord and SynthWord voxels. The training set has attribute vectors of words as independent variables and the corresponding SynthWord vectors as the dependent variable, predicting one voxel at the time. Similarly, at the sentence level, the training contains assembled sentences (SynthSent) as independent and the corresponding Observed fMRISent as the dependent variable. Once the prediction error is calculated, LReg is inverted (which is possible because it is linear), to determine what the CARWord values should have been to make the error zero.

## Neural Network with FGREP

It is possible that the linear prediction based on LReg is not powerful enough to account for the context effects. Therefore, a nonlinear approach based on neural networks is tested as well. A neural network is trained to map CARWord to SynthWord, which are then averaged (as before) into a prediction of the sentence SynthSent (Figure 4). The prediction error is used (through backpropagation) to train the network.

After training, this network is used to determine how the CARWords should change to eliminate the error. That is, for each sentence, the CARWords are propagated and the error is formed as before, but during backpropagation, the network is no longer changed. Instead, the error is used to change the CARWords themselves (which is the FGREP method---Forming Global Representations through Extended backPropagation; Miikkulainen et al., 1991). This modification can be carried out until the error goes to zero, or no additional change is possible (because the CAR values are already at their max or min limits).

Figure 4: The FGREP model to account for context effects. Propagate CARWord to SynthWord. Compose SynthSent by averaging the words into a prediction of the sentence. Compare SynthSent against Observed fMRISent. Backpropagate the error with FGREP for each sentence, freezing network weights and changing only CARWord. Repeat until error reaches zero.

Training the neural network requires as input the 236 CARWord 66-dimensional vectors (W1, W2, W3) and as target, the equivalent corresponding 396-dimensional SynthWord vector (W'1, W'2, W'3). The network then learns a general mapping of words across all sentences. This mapping is then utilized in the FGREP phase to change the CARWord for each different sentence separately (Figure 4). As the last step, the changes in the semantic attributes are analyzed according to the CAR theory for each affected sentence. At this point, due to scarcity of data this is a manual process verifying that the changes made sense.

## Results

The two approaches LReg and FGREP were evaluated in a preliminary experiment of distinguishing between the different meanings of the verb listened. LReg was found to be inadequate in this task and therefore in two subsequent experiments, focusing on the the adjective dangerous and in the noun mouse only the FGREP approach was used. The analysis was performed on the individual subjects for which the fMRI data in general was most consistent.

## Different contexts for the verb "listened "

Both models were used in this experiment to compare the contrasting meanings of HUMAN COMMUNICATION vs. NOISE FROM A MACHINE for the word listened as expressed in 89: The mayor listened to the voter, 92: The lonely patient listened to the loud television. The left side of Figure 5 shows the results for LReg between the original and transformed CARs. Although the CARs adjusted in all sentences, the changes were small and unprincipled, unable to characterize the difference between human communication versus noise from a machine. In contrast, the outcome for FGREP resulted in context-dependent
changes as shown, for sentences 89 and 92 in the right side of Figure 5.

CARs in Sentence 89 presented salient activations in human-related attributes like Face, and Body, Audition, and Speech, as well as Human, Communication, and Cognition, presumably denoting human verbal interaction. For Sentence 92, high activations on Vision, Bright, Color, Pattern, Large, Shape, Complexity, Touch, Temperature, Weight, Scene, Near, Harm, Unpleasant, Happy, and Angry describe a loud and large object such as a television. These results suggest that the linear mapping that LReg performs is not powerful enough to capture context, but the nonlinear mapping of FGREP is. The following experiments therefore both used the FGREP method for this task.

## Different contexts for the adjective "dangerous"

This experiment compared the contrasting meanings of NATURE vs. BAD PEOPLE for the word "dangerous", as expressed in 98: The flood was dangerous, 118: The dangerous criminal stole the television. Figure 6 shows the differences resulting from the FGREP method. As with the verb listened, context-dependent changes did emerge.

CARs in Sentence 98 present changes on activation for Large, Motion, SOMS attributes Texture and Weight, and event attributes Time, Short, and Caused, reflecting moving water. The attributes Toward, Harm, Unpleasant, and the emotion of Angry, represent the experiential and personal nature of danger. Conversely, Sentence 118 shows high activation for Vision, Complexity, Face, and Speech, because they represent human types and roles such as a criminal. Motor attribute Lower Limb as well as evaluation attributes Benefit, Angry, Disgusted, and Fearful can be associated with a dangerous act by a criminal. The FGREP method, therefore, was largely able to differentiate between

Figure 5: Results for the word listened in two contrasting sentences. LReg (left) did not capture context. All changes were insignificant to characterizing the context-dependent representations. The green line shows the original CARs for comparison. FGREP (right) did grasp context. The CARs for Sentence 89 have increased activations in human-related attributes like Face and Body, Auditory attributes, as well as Human, Communication and Cognition. In contrast, Sentence 92 activations on Vision, Color, Large, Shape, Complexity, Touch Temperature, High sound, and Unpleasant, depict a loud object such as a television.
the contrasting relevant dimensions of dangerous act of nature and humans.

## Different contexts for the noun "mouse"

This experiment compared the contrasting meanings of DEAD vs. ALIVE for the word mouse as expressed in sentences 56: The mouse ran into the forest, 60: The man saw the dead mouse. Figure 7 shows the differences resulting from the FGREP method, which are again systematic and meaningful.

Figure 6: FGREP results for the adjective dangerous across two contrasting sentences. CARs in Sentence 98 changed activation for Large, Motion, Texture and Weight, Time, Short, and Caused, reflecting moving water. The attributes Toward, Harm, Unpleasant, and Angry, represent the experiential nature of danger. Sentence 118 shows high activation for Vision, Complexity, Face, and Speech, because they represent human types and roles. Lower Limb, Benefit, Angry, Disgusted and Fearful can be associated

CARs in Sentence 56 have increased activation for Vision, Motion, Complexity, High, and Sound, possibly suggesting animate properties of the live mouse. Upper Limb, spatial attributes Path and Away, and event attributes Time, Duration, Short, and Consequence, symbolize activity such as running. Emotions of Fearful and Surprised may well be associated with seeing a live mouse. In contrast, Sentence 60 shows increased activation for Temperature, Weight, and Smell, as well as emotions Sad, Angry, Disgusted and Fearful, which may be associated to the dead mouse. These changes indicate different aspects of mouse in two contrasting contexts.

## Discussion and Further Work

The experiments in this paper suggest that different aspects of word meaning are activated in different contexts, and it is possible to see those changes in the corresponding fMRI images. These changes are likely to be nonlinear: The linear mapping approach (regression) tends to muddle them, but a nonlinear mapping (FGREP neural network) can tease them apart.

This result is remarkable considering that the dataset was not originally designed to answer the question of dynamic meaning. In particular, having fMRI images for isolated words available, instead of having to synthesize them, should amplify the observed effects significantly. It should also be possible to include sentences with contrasting contexts systematically, thus increasing the number of possible observations, and making it possible to identify differences in a more comprehensive manner.

With such a larger dataset, it should be possible to characterize changes across multiple sentences. Different kinds of changes may occur in nouns, adjectives, and verbs, and there are likely to be interactions between them. Moreover, the semantic changes can vary from individual to individual. As the first step, only single subjects were analyzed in this paper. In the future, the analysis can be
extended to more subjects, identifying which changes are consistent across subjects, and which ones are more individualistic. For instance, the subject in experiment 3 was Sad that the mouse was dead; another subject could show a different emotion.

After formulating such principles, the next step would be to utilize them in building artificial natural language processing systems. It may be possible to train e.g. a neural network to predict how meaning changes in context. Such a network could be then used as a part of an engineered natural language processing system, dynamically modifying the vector representations for the words to fit the context. Such a system should be more effective and more robust in its inference, and match human behavior better.

Figure 7: FGREP results for the noun mouse across two contrasting sentences. CARs in Sentence 56 increased activation for Vision, Motion, Complexity, High, and Sound, presumably to indicate the animate properties of the live mouse. Upper Limb, Path, Away, Time, Duration, Short, and Consequence, suggest activity such as running. In contrast, Sentence 60 shows increased activation for Temperature, Weight, and Smell, as well as Sad, Angry, Disgusted and Fearful, which can be associated to the dead mouse. These changes indicate different aspects of mouse in two contrasting contexts.

## Conclusion

Concepts are dynamic; their meaning depends on context and recent experience. In this paper, word meaning was represented as a collection of attributes (CARs), grounded in observed brain networks. Multiple Linear Regression analysis and a nonlinear FGREP Neural Network were used to understand how the CARs could change to construct the actual sentence representations seen in fMRI images. Preliminary results suggest that there are indeed systematic changes in CARs, and they make sense in each sentence context. These changes could only be seen in the FGREP analysis, suggesting that they are likely to be nonlinear. In the future, such changes could be characterized more fully and used to make artificial natural language systems sensitive to context.

## Acknowledgments

We would like to thank Jeffery Binder (Medical College of Wisconsin), Rajeev Raizada and Andrew Anderson (University of Rochester), Mario Aguilar and Patrick Connolly (Teledyne Scientific Company) for their work and valuable help regarding this research. This work was supported in part by IARPA-FA8650-14-C-7357 grant.
