Our research outlined a basic error model as well as two limit cases. In all three scenarios, distance-based methods did not produce significantly better results, suggesting that the problem of rank aggregation could be satisfactorily solved by simpler methods such as taking the average or majority.

As the performances of the two simple methods are diametrically opposite, which method should be used depends on the underlying error distribution in a population. Conversely, if one is able to measure accuracy, the performances of various rank aggregation methods can actually inform us the underlying error distribution and allow us to make inferences about the cognitive process of ranking.

In order to expand on our findings, we conducted a lab experiment where we tested actual belief revision in a group setting. Our findings suggest that when revising their answers, participants most often adopted the group mean, suggesting that human cognition gravitates towards this method of revision. This is significant, in light of the fact that adopting group mean is both computationally less strenuous and quite advantageous in most situations. This suggests that human cognition is adaptive in this sense, using a strategy that our modeling shows to be robust in most cases.

#### Abstract

Human beings are essentially - by nature or second nature members of groups. They contribute to these groups not just as isolated individuals but also through their interaction with others. Consequently, personnel evaluation in companies and organizations requires assessing not only evaluating individual performance but also the overall direct and indirect effect one has on a team. Others' work may be improved or hampered by the presence of a particular employee. We investigate Two-level Personnel-Evaluation Tasks (T-PETs) with information on individual and group earnings, where an individual focus may lead to evaluate the overall best employee as being the worst. We have previously found a Tragedy of Personnel Evaluation where focus on direct individual impact did have such systematic effect. In two experiments, one on team size, the other on kinds of information provided, we explore the boundary conditions of this effect and suggest how it may be overcome.

Keywords: Tragedy of Personnel Evaluation; Rationality of Personnel Decisions; Inner-Individual Dilemma; Social Psychology; Personnel Evaluation; Personnel Selection; Bounded Decision Making; Causal Induction

## Introduction

The success of teams in organizations or companies not only relies on the direct performance of individuals, but often also on interactions between team members (Mathieu, Maynard, Rapp, \& Gilson, 2008; Memmert, Plessner, Hüttermann, Froese, Peterhänsel, \& Unkelbach, 2015). Individuals may, for instance, help or hinder each other. The vital role of prosocial or altruistic behaviours for teams in organisations and companies (George \& Bettenhausen, 1990; Li, Kirkman, \& Porter, 2014; Nielsen, Hrivnak, \& Shaw, 2009; Organ, 1997; Podsakoff, Whiting, Podsakoff, \& Mishra, 2010) and for functioning societies on the whole is being increasingly acknowledged (Engel, 2011; Hendrich et al., 2005; Gollwitzer, Rothmund, Pfeiffer, \& Ensenbach, 2009; Post, 2005; cf. Melis et al., 2016). In Organizational Psychology several types of contextual performance (Organ, 1997; van Scotter \& Motowidlo, 1996) and prosocial behavior (Brief \& Motowidlo, 1986; Li, Kirkman, \& Porter, 2014) have been distinguished. Researchers have also pointed out that not only is prosocial behavior crucial for the success of organizations, but that people are actually sometimes rewarded for it (Organ, 1997; Scotter, Cross, \& Motowidlo, 2000; Grant \& Patil, 2012, 562).

In previous work, we began investigating participants' behaviour as hypothetical human-resource managers evaluating employees working in different configurations
each shift (von Sydow \& Braus, 2016). We employed Twolevel Personnel-Evaluation Tasks (T-PETs) that, across several rounds ('shifts'), provide information on how both individuals and teams contribute to a store's earnings. Crucially, the individual and team information suggest opposite rankings of the employees' contributions. By design, the presence of a so-called 'altruist', someone who positively affects the performance of the others, was most positively correlated with the overall team performance ( $r=.99$ ), even though the altruist individually performed the worst. We focused on the example of one employee strongly affecting the whole group, as this case is influential in biological models of altruism that assume an unconditional advantage to all group members in the presence of an altruist (Sober \& Wilson, 1999; Wilson \& Wilson, 2007; but Nowak \& Sigmund, 2005). The participants' task involved evaluating employees (Personnel Evaluation) and selecting the best team (Personnel Selection). Participants saw only one group (one shop) and the teams were assembled by selecting 4 out of 5 employees (thus 5 team configurations were possible).

Results from von Sydow \& Braus (2016) suggest what they called a "Tragedy of Personnel Selection". After 40 shifts, repeated measurement, and no time-constraint for analyzing the data of a shift, participants systematically judged the overall best employee to be the worst (on the different hidden-profile problem, Mojzisch, Grouneva, \& Schulz-Hardt, 2010). Recently we also explored negative interactions (egoist detection) in T-PETs (subm.). This tragedy is reminiscent of the well-known "Tragedy of the Commons", a notion for the often tragic outcomes of social dilemma situations (such as public-good games). Note however, that the 'T-PETs' do not strictly involve social dilemma, as the participant manager has the explicit goal of choosing the best team for the company. It is only what has been called an inner-individual dilemma (von Sydow, 2015) between two levels of goal descriptions, since it is irrational to optimize more specific goals at the expense of lowering overall utility. Since positive (and negative) interactions with other employees are ubiquitous, and number-based evaluations are important in HR-management, these results suggest such tragedy may well be found in everyday life.

Here we present two new experiments exploring the generalizability or boundary-conditions of the tragedy. Experiment 1 varies team sizes and begins exploring the idea of multiple groups in parallel. Experiment 2 investigates longer learning periods and whether with forced focus on the group level people are able to detect the altruist.

## Experiment 1

## Design

In the T-PETs we provided information on both individual and overall group level earnings. Experiment 1 investigates the extent to which the Tragedy of Personnel Evaluation depends on group size (number of workers: $3,4,5$ versus 7) and the number of groups (one versus two) (Figure 1, Table 1). From Conditions 1 to 4 , group size increases. In a shift, all workers apart from one are working. Condition 5 has the same group size as Condition 4 but is characterized by a group-comparison scenario, where the 6 employees are split in two groups with three employees each.

Table 1: Numbers of workers and groups, and their mean earnings (normal workers, NW; altruist, A) in the five conditions.

|  | C1 | C2 | C3 | C4 | C5 |
| :---: | :---: | :---: | :---: | :---: | :---: |
| Number |  |  |  |  |  |
| Groups | 1 | 1 | 1 | 1 | 2 |
| All Workers | 3 | 4 | 5 | 7 | 7 |
| Shown Workers | 2 | 3 | 4 | 6 | $3 / 3$ |
|  | Mean Earnings ( $€$ ) |  |  |  |  |
| NW with A | 3000 | 3000 | 3000 | 3000 | 3000 |
| NW without A | 2000 | 2000 | 2000 | 2000 | 2000 |
| Altruist (A) | 1500 | 1500 | 1500 | 1500 | 1500 |
| Group with A | 4500 | 7500 | 10500 | 16500 | $7500 /$ |
|  |  |  |  |  | 6000 |
| Group without A | 4000 | 6000 | 8000 | 10000 | $6000 /$ |
|  |  |  |  |  | 6000 |

## Method

Participants 221 Participants from the US began the experiment via MTURK. 158 participants finished it, passing all selection criteria (time spent on first page and correct answer out of four, rephrasing the instructions). The participants obtained a reward of $2 \$ .46 \%$ were male, the mean age was 35 years; $53 \%$ mentioned having a Bachelor's or Master's degree, and $39 \%$ a high school degree as highest level of education. Participants were randomly assigned to one of the five conditions.
Procedure and material The payoff structure for the individual employees remains constant over the five conditions, whereas the differing group sizes led to differing earnings of the groups (Table 1). We adopted the repeated measurement design with 18 shifts for each of the 4 rounds, and at the end of a round a rating followed by a selection task. The total number of shifts was 72. (This number is higher than the 40 trials investigated in previous studies.) In C3, for instance, the selection task was to select a team of 4 from 5 available workers that would be best for the company (Figure 1). In C5 people could select 6 workers
from 7 for both groups. In the last round, we additionally asked for the employee with the greatest and lowest utility, and assigned a Need-For-Cognition-Task (Cacioppo, Petty, \& Kao, 1984), a working memory task, a Commentary, and demographics.

Figure 1: Illustration of the materials. In the T-PETs the overview information for each round contains, in the first row the photos of the employee (in random order); in the second row their individual earnings; and in the third row the overall group/team earnings.

## Results

Figure 2: Average ratings (with SE) for the normal workers (N1-N6) and the altruist worker (A) of Conditions 1, 2, 3, 4 and 5 (Panels A to E).

Figure 2 shows that the rating for the altruist in all conditions remained clearly below the other ratings. In an ANOVA of the altruist ratings only, Condition is a significant between-subject factor $(F(4,153)=3.57, p<.01)$ and Phase (the four test phases) a significant within-subject factor (Pillai-Spur-Test, PST, $F(3,151)=3.92, p<.05)$, with no further significant interaction effects ( $p=.32$ ). This outcome seems in line with the prediction that one obtains the best results for the condition with the fewest workers
(C1), despite the altruist increased overall effect on the mean group earnings in larger groups, and for the group condition (C5). Bonferroni-corrected post-hoc comparisons show significant differences between C 1 and C 4 ( $p<.01$ ) and between C 4 and C 5 ( $p<.05$ ). However, the ratings remain predominantly based on individual comparisons in all conditions.

Figure 3: The proportion of 'managers' choosing a team and excluding the altruist $(A)$ or a normal worker $(N)$ in the test phases (Panel A to D) of the personnel selection task. The dark shading represent selections based on individual earnings, the light ones correspond to overall earnings.

Figure 3 shows that in all conditions the largest proportion of participants tends to expulse the overall most useful worker, the altruist, from the team. This is clearly the case in Phase 1 (always, $p<.01$ ). The proportion of other choices overall increased over time $\left(\chi^{2}(1,316)=13.15, p<\right.$ .001). Nonetheless altruist expulsion remained statistically above chance in Phase 4 (apart from C1, $p=.10$; all other $p$ $<.01$ ). For the variable which worker is deemed to have the least utility for the company (not presented here), in Round 4 , the choice of the altruist even remained dominant for all conditions ( $p<.01$ ).

Figure 4: Average altruist-detection rate for Conditions 1, 2, $3,4,5$ in the personnel selection task (Panel A) and the rating task (proportion of altruist rated larger than all other workers; Panel B).

Figure 4A shows the increase of group-level answers particularly for only a few employees (C1). The group condition C5 has a relatively high start but does not
increase. However, Figure 4B suggests that there is also an increase for C 5 if one considers the stricter criterion of rating the altruist to be higher than all other workers.

Figure 5A shows at least descriptively that in the highest utility task the altruist is positively singled out relatively frequently in C 1 and C 5 (but note the different numbers of workers). Additionally, participants' comments were deemed 'insightful' if they detected possible differences between an individual's direct and overall earnings (Figure 5B). Note that this measure is not directly affected by the number of answer-options. There was a reliably higher number of insightful comments in C 1 than $\mathrm{C} 2, \mathrm{C} 3$ and C 4 , but not higher than in C 5 .

Figure 5: A) Proportion of Participants selecting the altruist to be of highest utility. B) Insight rate shown in Comments.

Overall, Experiment 1 shows that the tragedy is quite stable over group size. However, it also suggests that although the altruist's summative effect increased with the group size, the best participant performance was in the condition with the lowest number of employees (C1). The results also only showed subtle advantages of introducing different groups on the altruist detection rate ( C 4 vs C 5 ).

## Experiment 2

Experiment 2 investigates conditions where people are forced to focus on the group level only, to see whether all participants realize that the altruist performs better on this level. We thus investigate whether the tragedy of personnel evaluation is due to an inability to see complex effects on a group level (despite information concerning this level). Additionally, and in contrast to Experiment 1, we distinguish different mean individual earnings of normal workers to check the extent to which people distinguish even slighter performance differences on the individual level.

## Design

The experiment had a mixed 2 (information: global-only versus local-and-global) $\times 2$ (earnings of normal workers: homogeneous versus heterogeneous) between-subjects design, with a within-subjects factor of four test phases (Table 2). In each test phase both evaluation and personnel selection tasks were assigned. Additionally, in the last round, highest and lowest utility tasks and other tests were completed, as well as a Need-For-Cognition (NFC) test.
In the local-and-global conditions, participants were provided with almost the same overview information as in Condition 3 of Experiment 1 (only the Altruist individually contributed 1600 instead of 1600). In each round,
information was given on both the direct earnings of the four workers on a shift and the overall earnings of the shift. The overall earnings involved not only the direct effects of individuals but also their indirect effects. In the global-only conditions, only the overall payoffs of a group (shift) were presented, without showing individual contributions.

Table 2: The four conditions, also showing the overall versus direct impact of a worker on group-earnings

| Condition | C1 C2 | C3 C4 |
| :---: | :---: | :---: |
| Information | Local <br> and <br> global Global <br> only | Local <br> and <br> global Global <br> only |
| Earnings NW | Homogeneous | Heterogeneous |
| Overall impact | $\begin{aligned} & \text { A >> NW1 = NW2 } \\ & =\text { NW3 = NW4 } \end{aligned}$ | $\begin{aligned} & \hline \text { A >> NW1 > NW2 } \\ & >\text { NW3 > NW4 } \end{aligned}$ |
| Direct impact | $\begin{aligned} & \text { NW } 1=\text { NW2 }= \\ & \text { NW3 }=\text { NW } 4 \text { A } \end{aligned}$ | $\begin{aligned} & \text { NW1 > NW2 > } \\ & \text { NW3 > NW4 > A } \end{aligned}$ |

Note: NW = normal worker; A = altruist.
The homogeneous and heterogeneous conditions correspond to either identical or different individual impact of the normal workers (see Table 2). The group earnings remained identical in both kinds of conditions. The 'altruist' (A) always has the most positive impact on the overall earnings. NW earnings (€) without $A$ were 2000 (homogeneous); 1400, 1800, 2200, 2600 (heterogenous); with A, 3000 (homogeneous); 2400, 2800, 3200, 3600 (heterogeneous), but the altruist had the lowest direct (individual) impact, 1600.

## Method

Participants As in Experiment 1, relatively strict selection criteria for participants were used to ensure high data quality. After passing a first criterion (time spent on the first page), 150 people properly started the task and 7 people failed the second criterion (correct rephrasing of the task; four options). Of the remaining 143 volunteers, 122 finished the experiment, and only their data was analysed. Participants were recruited from MTURK: 57\% were male, $42 \%$ female; mean age was 33 , and $68 \%$ had a Bachelor's or Master's degree (with $32 \%$ a high school degree). They received $\$ 2$ for participation.

Procedure and material We used almost the identical materials and procedure as in Experiment 1, C3. The experiment had 80 rounds, with four test phases administered after Rounds 20, 40, 60, and 80. In all four test phases, participants completed both a personnel-evaluation task and a per-sonnel-selection task. In the final test phase, we additionally administered a highest-/lowest-utility task, a ranking task, a Kimchi-Palmer item, an attention-test item, and an 18-item Need-For-Cognition Test (Cacioppo, Petty, \& Kao, 1984).
In the global-and-local conditions, the overview information presented in each round corresponds to C3 in Figure 1. In the global-only conditions, the second line of this panel (presenting the individual earnings of each employee) was omitted.

## Results

Figure 10 shows the mean ratings for the workers' contributions to company earnings. An overall ANOVA with Workers (5 workers) and Phases (4 phases) as within-subjects factors, and Conditions as between-subject factor, yielded a highly significant effect of Conditions $\times$ Workers (Pillai-Spur Test, PST, $F(12,306)=22.5, p<.001)$. This corresponds to the predicted change of rank of the altruist's ratings in the global-only versus global-and-local conditions. Additionally, the factors Workers, Phase $\times$ Condition as well as Phase $\times$ Worker approached significance $(\mathrm{PST}, F(4,100)=17.3, p<.001 ; \operatorname{PST}, F(9$, $309)=1.69, p=.09$; PST, $\mathrm{F}(12,92)=1.51, p=.13)$. Changes over the phases were not significant.

Figure 6. Average ratings (with SE) in Experiment 4 for the four normal $(N)$ and altruist $(A)$ workers in test phases P1 to P4 of Conditions 1, 2, 3, and 4 (Panels A to D).

In the homogeneous local-and-global condition (C1, Panel A), the altruist was again evaluated as the worst, despite being most strongly correlated with high overall earnings. In an ANOVA for Phase 4, the within-subject factor Workers was clearly significant $(\operatorname{PST}, F(4,23)=10.1, p<.001)$, and contrasts confirmed that all normal workers were rated higher than the altruist (all, $p<.05$ ). In the heterogeneous Condition 3, participants were well able to differentiate between normal workers with different individual performance. A corresponding ANOVA showed a general effect of Workers (PST, $F(4,24)=38.8, p<.001)$ and significant contrasts between the workers in the predicted order, $\mathrm{N} 1>\mathrm{N} 2>\mathrm{N} 3>\mathrm{N} 4>\mathrm{A}($ each, $p<.001)$.
In the global-only conditions ( C 2 and C 4 ), in which people were to base their ratings of a worker's utility on the teams' overall earnings only, they clearly detected that, of all workers, the altruist correlated most demonstrably with high overall team earnings. Participants grasped this surprisingly early. An ANOVA for C2 (test phase 4) shows
significant results for the factor Workers (PST, $F(4,22)=$ 23.04, $p<.001$ ), and pairwise contrasts show that the altruist is rated higher than all normal workers (always with $p<.001$ ). In Condition 4, the order of the average ratings of the altruist and the normal workers was likewise reversed (relative to Condition 3). In an ANOVA a significant effect of the factor Workers was found (PST, $F(4,26)=15.5, p<$ .001 ); and contrasts show that the altruist was rated significantly higher than even the normal worker, who was rated highest ( $p<.001$ ). One ANOVA without the altruist reached significance $(\mathrm{PST}, F(4,27)=3.62, p<.05)$, but only one Bonferroni-corrected post hoc comparison between normal workers (the one expected to differ most: NW1NW4) led to significant results ( $p<.05$ ). In sum, despite clearly detecting that the altruist has a larger effect on overall output in the global-only conditions, participants show a reduced ability to distinguish between the normal workers.

Figure 6 shows the proportion of 'managers' choosing a worker to have the "highest" (Panel A) or "lowest" (Panel B) "total utility for the company" in the final test phase.

Figure 7. Percentage of participants choosing a normal worker ( $N$ ) or the altruist ( $A$ ) as of highest (Panel A) or lowest (Panel B) overall utility for the company in Phase 4 in Conditions C1, C2, C3, and C4. The choices corresponding to individual earnings are marked in black; those corresponding to overall earnings in dark gray.

Figure 7 presents the team selections in the personnel selection task. In Condition 1, we replicated a strong tendency to select a team without the overall best member, the altruist (from five possible configurations). Even in Phase 4 , after 80 rounds, $70 \%$ of the participants selected this team, $\chi^{2}(1, N=30)=46.88, p<.001$. Its reduction was not reliable, $\chi^{2}(1, N=60)=.80, p=.37$. By contrast, Condition 2 shows that participants provided with global-information-only were highly capable of quickly detecting that the altruist should be part of the team (Phase $1, \chi^{2}(1, N$ $=28)=7.00, p<.001)$. Also the contrast between Conditions 1 and 2 was highly significant (Phase 4$), \chi^{2}(1, N$ $=58)=27.15, p<.001$. In the heterogeneous global-andlocal Condition 3, selections began with a high proportion of no-altruist team-choices in Phase 1 (Figure 12), $\chi^{2}(1, N=$ $32)=67.57, p<.001$. In Phase 4, these individual-related selections, which exclude $A$, are likewise found to be above chance $(56 \%), \chi^{2}(1, N=32)=31.01, p<.001$; but now the group-related selections are above chance as well (excluding N4, with $34 \%) ; \chi^{2}(1, N=32)=4.13, p<.05$. By contrast, in

Condition 4 (a global-only condition), even in Phase 1 the optimal team-related selection (with-altruist team excluding N4) was the most frequently selected ( $43 \%$ ), $\chi^{2}(1, N=32)$ $=11.28, p<.001$; and the no-altruist team, conversely, was selected below chance ( $3 \%$ ), $\chi^{2}(1, N=32)=5.70, p<.05$. In Phase 4, the selection of the no-altruist team was still selected with low relative frequency ( $3 \%$ ), and the optimal team by $59 \%$ of participants.

Figure 8. The results of the personnel selection task in the four test phases show the proportion of 'managers' choosing a particular team, thus excluding either worker $N 1, N 2, N 3$, $N 4$, or the altruist $A$. In the global-and-local conditions, C 1 and C3, the black columns correspond to the predicted selections based on individual performance only. In the global-only conditions, C 2 and C 4 , no individual-level information was available. In all conditions, the dark gray columns represent the optimal selection(s) based on overall performance of teams.

In the local-and-global conditions we coded comments as insightful that showed understanding of the differences between an individual and a group level. After 80 learning rounds, at least $38 \%$ of the participants in these conditions were classified as providing comments with insight ( $33 \%$ in C1 and $43 \%$ in C3). Of these participants, $87 \%$ selected the altruist personnel selection task (in Phase 4), whereas from the participants not demonstrating insight only $3 \%$ made this selection. Finally, from the additional tests, only the Need-For-Cognition Scale (2.6 vs. 10.5), $t(60)=1.93, p=$ .03 (one-tailed) correlated with insightful comments.

## General Discussion

Experiment 1 shows that the tragedy of personnel selection is very stable across different team sizes. Even in the smallest team, most participants in the role of 'managers' evaluated the most useful worker for the group to be the worst. However, Experiment 1 suggests that small team sizes mitigates this problem, and a minority in this condition saw the difference between individual and overall contribution of an employee. Experiment 2 shows that
people are in principle well able to detect the strong correlation between presence of the altruist and high team performance (with $r=.99$ ) very early on from the grouplevel information. However, in other conditions most make no use of this ability and seem to ignore the overall payoff, focusing only on workers' direct individual contribution.

More generally, the findings may be due to people's problems dealing with decisions involving a Simpson's Paradox (Fiedler et al., 2003; Sydow et al., 2016; Waldmann \& Hagmayer, 2001). If people do not merely optimize in a standard decision-theoretic way (here by simply choosing the team with the highest past performance), and instead, as we suggest, aim for a deeper understanding by identifying clear causal or logical patterns between events (e.g., Funke, 2001; Hagmayer \& Meder, 2013; Osman, 2010; Sloman \& Hagmayer, 2006; von Sydow, 2016; Waldmann \& Hagmayer, 2001), this may yield the disadvantage of overlooking small correlations, pathways, exogeneities or interactions (Novick \& Cheng, 2004), even if they may add up, tragically, to be the predominant effect of a scenario.

## Acknowledgments

This work was partly supported by the grant Sy111/2-1 from the Deutsche Forschungsgemeinschaft (DFG) as part of the priority program New Frameworks of Rationality (SPP 1516). We are grateful to Maria Waltmann and Martha Cunningham for help and corrections. The first author is grateful to Daniel Holt, Klaus Fielder and Michael Waldmann for discussing related issues. Furthermore, we would like to thank anonymous reviewers for helpful comments and suggestions.

#### Abstract

In the Wason-Selection Task debate it has been suggested that people may be able to detect cheaters but not co-operators or altruists. This position has been challenged. Here we focus on a scenario that is more ecologically valid with regard to different strategies for detecting workers who negatively interact with others (here 'egoists') and positive interactors (here 'altruist'). The results on altruist detection in two-level personnel evaluation tasks (T-PETs), with information on individual and team performance, suggested a disregard of the team performance and a resulting "Tragedy of Personnel Evaluation". Experiment 1 transfers the idea of altruist detection in a personnel evaluation and personnel selection task (von Sydow \& Braus, 2016) to egoist detection and explores whether there are analogous problems for egoist detection. Experiment 2 explores egoist and altruist detection in more realistic settings where individual and group-selection may affect our sampling of the interactor.

Keywords: Altruist/Egoist Detection; Wason Selection Task; Personal Selection Task; Tragedy of Personnel Selection; Group Selection; Learning Correlations; Decision Making

## Introduction

In an influential debate on hypothesis-testing (Wason Selection Tasks, WST), it has been suggested that in socialcontract situations people are adapted for cheater detection but not for co-operator or altruist detection (Cosmides, 1989). These proposals have contributed to differentiating between checking deontic rules and testing descriptive hypotheses (Oaksford \& Chater, 1994; Beller, 2001; von Sydow, 2006). Despite evidence for subclasses within the deontic domain (Fiddick, Cosmides, \& Tooby, 2000), other research shows that reasoning with standard deontic rules (including social contracts) seems to be a quite systematic faculty resembling deontic logic (Beller, 2001; Bucciarelli \& Johnson-Laird, 2005; von Sydow, 2006) and depends on the goals pursued (von Sydow, 2006; Rand, Dreber, Ellingsen, Fudenberg, \& Nowak, 2009; Sperber \& Girotto, 2002). However, the WST-paradigm has also been criticised as being too specific to address issues of real-life cooperation (Sperber \& Girotto, 2002).

Von Sydow \& Braus (2016) explored participants’ ability as personnel managers to detect how employees positively interacted with others' performance. Research in organizational and social psychology has acknowledged the importance of teams beyond mere individual contributions (Mathieu, Maynard, Rapp, \& Gilson, 2008; Memmert, Plessner, Hüttermann, Froese, Peterhänsel, \& Unkelbach, 2015) and the crucial role of prosocial or altruistic extra-role or role behaviours in teams (e.g., Li, Kirkman, \& Porter,
2014). Our tasks were more complex than WST and used two-level personnel selection tasks (T-PETs; in von Sydow \& Braus, 2016). In these T-PETs, participants obtained information about employees' performance on the direct individual level and on the overall group level. The presence of the altruist correlated consistently, reliably, and strongly with the teams' overall performance ( $r=.99$ ). Nonetheless, people tended to evaluate the altruist to be worst for the team, mostly based only on the individual information, and tended to ostracise him or her in selection tasks. This led us to suggest a potential "tragedy of personnel selection".

To explore the controversial asymmetry between altruist and egoist selection discussed in the WST literature in a more complex setting, and to explore the generality of the Tragedy of Personal Selection, Experiment 1 investigates TPETs not for altruist detection, but for egoist detection. Experiment 2 compares egoist and altruist detection in a single experiment and explores further potential factors of group vs. individual selection. This is broadly in line with the increasing influence of multi-level modelling in biology (Wilson \& Wilson, 2007), and personnel psychology (Polyhart, 2012). Furthermore, we explore the resultant effect of sampling (Fiedler, 2008). We will suggest that group selection could lead to greater altruist and egoist detection, but that this does not necessarily imply deeper understanding. Thus we suggest that in such a perhaps ecologically more valid scenario several further factors come into play over and beyond a mere potential difference between egoist and altruist detection.

## Experiment 1

The first experiment explores whether the Tragedy of Personnel Evaluation is unique to altruist detection, or whether there is an analogous phenomenon for egoist detection as well. Here 'egoists' have the highest individual earnings in the team while in fact most negatively affecting the team's overall performance. In this study participants were again acting as personnel managers, repeatedly making personnel evaluations and selections.

Table 1 shows the average earnings of the negative interactor, the egoist ( $E$ ), and, depending on the latter's presence or absence, the average earnings of the normal workers in the four conditions. The conditions vary homogeneous and heterogeneous earnings for the normal workers ( C 1 , normal worker with homogeneous earnings condition; C 4 , most heterogeneous earnings of the normal workers) to investigate participants' sensitivity to small differences in their impact on the individual level.

## Design

Table 1: Mean earnings of normal workers (NW: N1 to N4) and of 'egoist' worker ( $E$ ), overall earnings with or without the egoist in the four conditions ( C 1 to C 4 ), and resulting predictions

## Method

Participants 161 participants from MTURK passed a first participation-criterion (time spent on the first page $>20 \mathrm{sec}$. and < 6 min .) and began the task. 120 participants finished the experiment and were included in the analysis ( $52 \%$ male; mean age 33), most of them with a high school or even a university degree (59\% Bachelor's or Master's; $38 \%$ high school). The volunteers obtained rewards of $\$ 1$. Participants were randomly assigned to one of four conditions (cf. Table 1).
Material and procedure The crucial difference to prior work was that we replaced altruist detection by egoist detection (Table 1). Apart from changed individual and overall earnings, the scenario, T-PET procedure, and dependent variables (von Sydow \& Braus, 2016). But we were now concerned with individually best performing 'egoists', whose presence correlated consistently and most negatively with the team's overall performance. As in the altruist detection task, participants in each round obtained overview information in tables about workers' individual earnings, together with their photographs and information
about overall earnings of the team. The presentation order of the pictures was randomized. Again there were only five workers, with four workers per shift - thus only five possible team configurations. There were 40 rounds and four test phases, one after every ten rounds. The first three test phases included rating-tasks and a team selection task only; in the final test phase we asked participants additionally to choose the employee of highest and lowest utility, and to comment on the task and their decision.

## Results

In all conditions, the average ratings (Figure 1) resemble more closely the predictions based on individual rather than overall team-contributions (cf. Table 1). An ANOVA with the between-subjects factor Conditions and the withinsubjects factors Workers and Phases (in a multivariate Pillai-Spur Test, PST) showed significant effects of Workers, $F(4,110)=95.9, p<.001$, Workers $\times$ Conditions, $F(12,336)=21.9, p<.001$, and Phases, $F(3,111)=3.41, p$ $<.05$, and a marginally significant effect of Phase $\times$ Person, Workers $\times$ Conditions, $F(12,102)=1.78, p=.06$.

Figure 1: Average ratings (with SE) in Experiment 1 for the four normal workers $(N)$ and egoist worker $(E)$ in the test phases P1 to P4 of Conditions 1, 2, 3, and 4
(Panels A to D)
In Condition 1, the egoist is characterized by higher ratings than the other four workers throughout all phases; main effect of Worker: $F(4,26)=4.19, p<.01$. In Condition 2, there was again only a reliable effect of Workers, PST, $F(4,24)=25.2, p<.001$. Bonferronicorrected post hoc comparisons showed no differences between the egoist and normal worker 1 (E, N1), predicted to be the highest normal worker ( $p=1.00$ ); but N 1 , as predicted, had a higher rating than the other normal workers, which was also the case for the egoist (all, $p<.001$ ). In Condition 3, again only the factor Workers was significant
(PST, $F(4,22)=24.1, p<.001)$. Bonferroni-corrected post hoc comparisons showed that the egoist was not rated higher than the normal workers predicted to be highest ( N 1 , N 2 ) (both $p=1.00$ ), but that the worker in this group, as well as the egoist, reliably differed from the workers in the second group of normal workers (N3, N4; all $p<.001$ ). Condition 4 again showed an overall effect only for the factor Worker (PST, $F(4,28)=58.6, p<.001$ ), and in corrected post hoc comparisons significant effects even of all five workers in the order predicted by the individual earnings (all $p<.01$ ).

The results of the Personnel Selection Task (Figure 2) show that the majority selected teams with optimal earnings on the individual level (black; individual-related selections). Only a few selected the team without the egoist (from five possible teams), even though this team had the best overall performance (dark gray; team-related selections). The remaining selections (light gray) selected the egoist for the team, along with other, individually non-optimal workers. With regard to temporal changes, there is an apparent increase in the proportion of team-related selections (dark gray) from Phases $1(9 \%)$ to $4(23 \%) ; \chi^{2}(1, N=240)=8.00$, $p<.01$. But even in the final test phase, Phase 4, the individual-related selections over all conditions occurred more frequently than the team-related ones, $\chi^{2}(1, N=120)=$ $34.7, p<.001$.
The highest-utility task (Figure 3, Panel A) reveals relatively frequent 'egoist'-judgments (black). In all conditions these judgments were clearly above chance level $\left(\chi^{2}(1, N=31)=63.9, p<.001 ; \chi^{2}(1, N=30)=44.5, p<\right.$ $.001 ; \chi^{2}(1, N=27)=15.8, p<.001 ; \chi^{2}(1, N=32)=47.5, p$ $<.001$ ). Considering the team-related judgments (dark gray), they are also above chance level relative to the other ones (light gray), $\chi^{2}(1, N=31)=49.0, p<.001(\mathrm{C} 2$ to C 4$)$.

Figure 2. Results of the personnel selection task in the four test phases of Experiment 1, showing the proportion of 'managers' choosing a team of four out of five, thus excluding worker $N 1, N 2, N 3, N 4$, or the egoist worker $E$. Individual-related optimal selections are marked in black,
with team-related optimal selections in dark gray and other selections in light gray.

In the lowest-utility task (Fig. 3B), a similar pattern can be recognized. The individual-related selections (black) were chosen more often than chance level, $\chi^{2}(1, N=120)=$ $300.8, p<.001$. In the three conditions ( C 2 to C 4 ), where one can contrast the team-related judgments (egoist has the lowest utility; dark gray) with judgments that were neither individually nor on group-level optimal (light gray), the team-related judgments overall occurred reliably more often than expected by chance (exact bin. test, $N=12, p<.001$ ).
As to the comments, $21 \%$ participants mentioned explicitly that the individual and overall group-level contributions of a worker differ, or that there are interactions between participants. These insightful comments were highly associated with group-level selections and ratings.

Figure 3. Percentage of 'managers' choosing either a normal worker $(N)$ or the egoist worker $(E)$ as of the highest (Panel A) or lowest (Panel B) utility for the company (Conditions C1, C2, C3, C4). The individual-related choices are marked in black, the team-related ones in dark gray and the neither-individual-nor-team-related ones in light gray.

## Discussion

The results of Experiment 1 show that egoist detection seems to be affected by similar problems as altruist detection (von Sydow \& Braus, 2016). When the negative interactor individually contributed the highest earnings but led overall to the lowest group earnings, the majority of participants nonetheless rated the egoist as most valuable. Moreover, in the personnel selection task they even systematically chose the egoist for the team, even though the latter consistently performed the worst. This was the case even though participants were sensitive to relatively small individual differences. Thus the results suggest a kind of tragedy of personnel selection as well with regard to 'egoists' or negative interactors.
In comparison to the results on altruist detection by von Sydow \& Braus (2016), which seem comparable in population and method, there is perhaps a slight advantage of egoist over altruist detection. In particular, there were significantly more insightful comments for egoist than for altruist detection, $\chi^{2}(1, N=240)=7.53, p<.01$. This suggests that the content of egoist versus altruist detection leads to different interaction detection rates. However, the overall findings point rather to the similarity between altruist and
egoist detection. There also seems to be a Tragedy of Personnel Evaluation with regard to egoist detection.

## Experiment 2

This experiment explores the potential effect of personnel selection on the individual versus group level and resulting distortions linked to sampling only particular information (thus favoring learning of specific relationships or not). We combine these issues with an investigation of egoist and altruist detection in a single experiment. We propose the hypothesis that group in contrast to individual selection may at least behaviourally increase selections corresponding to the group-level performance. However, deeper insight is predicted to depend on sampling effects that may affect both individual and group selection. To test the effect of sampling, the participants were given the opportunity to influence the material by their selections. Sampling may imply a greater inclusion of the interactor, which will lead to a better learning of the interactor's impact either on the individual or on the group level and hence to a solution of the Tragedy of Personnel Selection. In contrast, if sampling leads to exclusion of the interactor, a correct selection needs not to improve the understanding of the interactor's impact.

## Design

Experiment 2 investigates how individual versus group selection and the presence of an 'altruist' versus an 'egoist' influence personnel selection and evaluations (Table 2). Apart from this, the conditions used almost identical scenarios and the interactors had comparable effects on the group level. The egoist is characterized by the highest and the altruist by the lowest individual earning. In contrast to the individual earnings, the presence of the egoist leads to lower overall earnings of the group, whereas that of the altruist yields greater overall earnings for the group.

Table 2: Selection and interactor conditions and mean of earnings for normal workers (NW), altruist and overall for
four conditions.

| Cour conditions. |  |  |  |  |
| :--- | :---: | :---: | :---: | :---: |
| Selection type | Individual | Individual | Group | Group |
| Interactor type | Altruist | Egoist | Altruist | Egoist |
| Mean of earnings |  |  |  |  |
| NW with <br> altruist/egoist | 3000 | 1500 | 3000 | 1500 |
| NW without <br> altruist/egoist | 2000 | 2500 | 2000 | 2500 |
| Altruist/egoist | 1500 | 3000 | 1500 | 3000 |
|  | Mean of overall earnings of a group |  |  |  |
| With <br> altruist/egoist | 7500 | 6000 | 7500 | 6000 |
| Without <br> altruist/egoist | 6000 | 7500 | 6000 | 7500 |

## Method

Participants 182 participants from MTURK began the task. 119 participants passed the strict selection criteria (time spent on first page; correct rephrasing the instructions), finished the task, and were included in the analysis ( $51 \%$ male; mean age 35); most of them had a degree ( $65 \%$ Bachelor's or Master's; 35\% high school). The volunteers obtained rewards of $\$ 1$. Participants were randomly assigned to one of four conditions (cf. Table 2).

Material and procedure The material and procedure build on previous T-PETs but vary in some aspects. The data is again shown for each day or shift, containing individual and overall earnings. Whereas previous T-PETs involved one group (with different member configurations) only, here we also presented two groups, each with 3 employees. During the experiment, participants received data on a total of 10 employees and 81 days (rounds). Moreover, in contrast to former T-PETs the participants’ judgments in personnel selection tasks influenced the materials presented to the participants. This task was repeated 11 times. On the first day of each of the 10 test phases (and in a final test phase), the altruist/egoist and 5 randomly assigned normal workers were presented. Based on the selection in the test phase, participants selected 3 out of 6 employees (individual conditions) or one of two groups (group conditions). This selected group or these individuals were excluded from the following 7 days (rounds). From the 7 employees left, we created the two groups in the successive 7 days, so that each one of the employees left was excluded for one day. Although we added some noise ( $\mathrm{SD}=600 €$ ) to the individual earnings, the presence of the interactor in such trials still strongly correlated with a higher overall outcome ( $r=.95-.98$ ). In every second test phase (starting with the second phase), the participants additionally had to rate the 10 employees before selection. On the last day, at test phase 11, the participants had to complete a rating and selection task (here without consequences) as well as the utility-task (cf. Experiment 1) and a Need-For-Cognition task (NFC; Cacioppo, Petty \& Kao, 1984); and finally to comment on the task.

## Predictions

- Hypothesis 1 (H1): Participants may base their selections (partly) on the observed performance in the test phases, with the selection focusing them either on the group or the individual level. This would entail more selections optimal on the group level in the group condition than in the individual conditions: $\mathrm{C} 3=\mathrm{C} 4>$ $\mathrm{C} 2=\mathrm{C} 1$.
- However, participants in line with H1 will tend to exclude the interactor in C 4 (group selection) and C 1 (individual selection) and tend to include the interactor in C3 (group selection) and C2 (individual selection). Based on these expected sampling effects, one may derive the following hypothesis:
o Hypothesis 2 (H2): People in the inclusion conditions will learn more about the individual earnings, which vice-versa would lower judgments in line with adequate group-level predictions in the inclusion conditions: $\mathrm{C} 1=\mathrm{C} 4>\mathrm{C} 2=\mathrm{C} 3$.
o Hypothesis 3 (H3): Alternatively (or additionally), in the inclusion conditions people may start to realize the major impact of the interactor on group earnings, with inverse implications for group-level results: $\mathrm{C} 1=\mathrm{C} 4<\mathrm{C} 2=\mathrm{C} 3$.
H2 and H3 may both apply and cancel each other out. Alternatively one may find different effects over time (first H 2 then H 3 ). We predict that the hypotheses will have a major impact on different dependent variables: H1 may particularly affect the used selection task which may be dominated by the currently shown data. H2 or H3 may dominate the overall results in the rating and utility tasks. With regard to insight in the two-level nature of the task in the comments seems normally to be limited by realizing the group level effects; thus insight should follow the pattern of H3.

## Results

As expected, different clusters of dependent variables referring to performance effects H1 (here selection tasks) and to effects of understanding, H2 versus H3 (evaluation tasks) reveal differential results: Considering the personnel selection task, compared to individual selection (Figure 5, Panel A), the group selection as expected (H1) appears to lead to greater (overall optimal) exclusion of the egoist and inclusion of the altruist. However, the results descriptively show optimal group-level answers in the rank order of $\mathrm{C} 4>$ $\mathrm{C} 3 \gg \mathrm{C} 1>\mathrm{C} 2$. This suggests a main effect in line with H1 and an additional effect, even for this selection variable, in line with H2. Inferentially, the aggregated correct selections of each participant over the 11 selections revealed a strong effect of Selection type $\left(F(1,115)=119.60, p<.001, \eta^{2}=.52\right)$ and a slight interaction effect of Selection and Interactor types, $F(1,115)=9.17, \quad p=.003, \eta^{2}=.07$. As a high correlation between the accuracy of selection and amount of earnings suggests, the earnings replicate the strong positive effect of Selection type, $F(1,115)=128.18, p<.001, \eta^{2}=.52$, Interactor type: $F(1,115)=11.10, p=.001, \eta^{2}=.09$, and Phase: $F(6,687)=2.29, p<.05, \eta^{2}=.02$.

The rating task (Figure 4) seems roughly to reflect the individual pay-off structure affected by sampling (H2). The altruist has lower ratings than the other workers, and the egoist is rated more positively. Comparing the ratings of the interactor to all normal workers, the interactor differs highly significantly across all 5 measurements (R1-R5), R1: $F(1,116)=1345.68, p<.001$; R2: $F(1,116)=1369.64, p<$ .001 ; R3: $F(1,116)=1540.53, p<.001$; R4: $F(1,116)=$ 2028.63, $p<.001$; R5: $F(1,116)=2731.81, p<.001$.

The highest-utility and lowest-utility tasks (Figure 5, Panel B) seem to mirror mainly the individual earnings of the employees (high rate of egoists in the highest utility task, and of altruist in the lowest utility task). Thus the Interactor type affects the accuracy of this task (highest:
$\chi^{2}(1,119)=11,84, \quad p=.001$; lowest: $\quad \chi^{2}(1,119)=19,02$, $p<.001$ ); but the selection type had no impact.

Figure 4: Average ratings (with SE) for the normal workers (N1-9) and the altruist/egoist worker ( $A, E$ ) of Conditions C1, C2, C3 and C4 (Panels A to D).

Insightful comments (Panel C), in line with H3, showed in C 2 and C 3 marginally significantly higher correct comments than in C 1 and $\mathrm{C} 4, \chi^{2}(1,119)=3,55, p=.06$. Participants, commenting correctly, revealed greater aggregated correct selections $(t(51)=-2,28, p<.01)$ and ratings $(t(56)=-$ $2,80, p<.01$ ), and tended to choose the person with the highest or lowest overall utility more frequently, highest: $\chi^{2}(1,119)=15,77, p<.001$; lowest: $\chi^{2}(1,119)=3,05, p=$ .08. Participants with insightful comments can be characterized by higher NFC-Scores: $t(117)=-2,65, p<.01$.

Figure 5: Average correct answer rate for Conditions 1, 2, 3 and 4 (C1-C4) of the Selection, Utility- and Comment Tasks (Panel A to C).

## Discussion

Experiment 2 shows intricate influences of sampling on the egoist and altruist detection in group and individual
selection scenarios. Group selection, at least on a direct performance level in the selection tasks, leads to greater overall optimal selections compared to individual selection (H1). In addition, group selection increases economic outcomes. Considering the accuracy of personnel evaluation, the results create a more complex pattern. Egoist versus altruist detection does not have a great impact; neither does Individual vs. Group-Selection. Sampling processes seem to matter and can have simultaneous opposed effects. The ratings and the highest/lowest utility-tasks show that gaining more information about the interactor leads to stronger individual-based understanding (H2). Insight in the comments nonetheless revealed, as predicted, that gathering information about the interactor also increased the detection of group level effects (H3). In line with this finding, insightful comments were associated with the NFC-Score.

## General Discussion

Experiment 1 shows that egoist detection, as with similar altruist-detection tasks, may systematically lead to judging the egoist as best for a company although he clearly correlates strongly with negative overall team performance. Although the results suggest a slight advantage of egoist over altruist detection, both show basically similar results, with participants in both scenarios falling prey to a Tragedy of Personnel Selection. In Experiment 2, instead of egoist versus altruist detection, other factors such as group versus individual selection (with group selection improving performance) and sampling processes (in different ways affecting understanding on individual and group levels) more strongly influenced participants' judgments.

With regard to the personnel selection literature (e.g., Polyhart, 2012; Li, Kirkman, \& Porter, 2014), the results warn us against the generality of the suggested Tragedy of Personnel Selection shown here to affect not only altruist but also egoist detection. With regard to the Wason Selection Task debate (e.g., von Sydow, 2016; Sperber \& Girotto, 2002), we found no large differences between altruist and egoistic detection in the T-PETs (however, a small one). The results more generally pose the question as to how far the difficulties detecting the strongest overall correlation of variables' presence with overall outcome points to problems linked to Simpson's Paradox (Fiedler et al., 2003; Sydow et al., 2016; Waldmann \& Hagmayer, 2001); also whether it is a negative side effect of people's constructing detailed logical or causal models over and above optimizing observed utilities (e.g., Funke, 2001; Hagmayer \& Meder, 2013; Osman, 2010; Sloman \& Hagmayer, 2006; von Sydow, 2016; Waldmann \& Hagmayer, 2001), with the disadvantage that one tends to neglect small correlations, pathways, exogeneities or interactions, even if they tragically dominate a scenario.

## Acknowledgments

# Rational and Semi-Rational Explanations of the Conjunction Fallacy: A Polycausal Approach 

Momme von Sydow (momme.von-sydow@urz.uni-münchen.de)<br>University of Munich (LMU), Munich Center for Mathematical Philosophy (MCMP),<br>Ludwigstr. 31, D-80539 München, Germany

#### Abstract

Conjunction fallacies (CF) have not only been a major obstacle in justifying the rationality of a Bayesian theory of belief update; they have also inspired a variety of theories on probability judgment and logical predication. Here we provide an overview of Bayesian logic (BL) as rational formulation of a pattern-based class of conjunction fallacies. BL is described here as a generalization of Bayesian Occam's razor. BL captures the idea that probabilities are sometimes used not extensionally but intensionally, determining the probabilistic adequacy of ideal logical patterns. It is emphasized that BL is a class of models that depend on representations and the meanings of logical connectives. We discuss open questions and limits of BL. We also briefly discuss whether other theories of the CF may be good supplementary theories of CFs (and predication) as well, if linked to functional explanations.

Keywords: probability judgments; biases; conjunction fallacy; inclusion fallacy; inductive logics; intensional logics; Bayesian logics; predication; strong sampling; categories; Lockean Thesis; rationality debate; Bayesian Occam's razor

## Extensional vs. Intensional Probabilities

## Extension vs. Intension

Figure 1: (A) Extensions as elements and intensions demarcated by set boundaries. (B) Characterization of extensional and (C) intensional probabilities (cf. McKay, 2003, 28).

Although less known to the psychologist than to the philosopher or logician, the notions of extension and intension ( $\neq$ "intention") have a tradition going back to Leibniz, Carnap, and Stegmüller; with several analogous terms proposed by others, such as 'meaning' and 'denotation' (Russell) or 'Sinn' and 'Bedeutung' (Frege). Extension refers to the elements of a set, and intension to the meaning, which may be symbolized by the area determined by the set boundaries (Figure 1A). Correspondingly, a set can be described extensionally by specifying its elements or intensionally by specifying one or several defining features.

## Extensional narrow norms of predication

Extensional approaches have long dominated set theory (Zermelo-Fraenkel set theory), logic (propositional logic),
and probability theory (Kolmogorov's axiomatization). According to these extensional approaches, two sets are identical if they have the same elements (the same extension). Such an approach entails that any logically stronger (more specific) proposition implies any more general proposition (e.g., $A \wedge B \Rightarrow A \vee B$ ); and that any more specific hypothesis can never be more probable than a more general one.

Extensional logic and extensional probabilities have been proposed to provide universal criteria of rational predication. Predication attributes a predicate or logical combination of predicates to a subject. First, valid (assertive) predication of general logical relationships has traditionally often been linked to a logical truth-table definition of connectives (Frege, Russell, Whitehead, and Wittgenstein) (Table 1). Accordingly, if a conjunction $A \wedge B$ is true in a universe of discourse $(X)$, no cases in $X$ fall outside of the corresponding set (the intersection) and the truth of the conjunction implies, for instance, the truth of the affirmation $A$ as well as of the disjunction $A \vee B$ (Table 1).

Table 1: Truth tables of some dyadic logical connectives: conjunctions, exclusive disjunctions, affirmations, and inclusive disjunctions

| A | B | A $\wedge B$ | $A><B$ | $A$ | $A \vee B$ |
| :--- | :--- | :--- | :--- | :--- | :--- |
| $T$ | T | T | F | T | T |
| T | F | F | T | T | T |
| F | T | F | T | F | T |
| F | F | F | F | F | F |

Assertive, contingent sentences, such as "Members of Species $X$ are aggressive ( $A$ ) AND curious ( $B$ )" (von Sydow $\&$ Fiedler, 2012) (in predicate logic: $\forall \mathrm{x} A(x) \wedge B(x)$ ), can thus be falsified by a single observation (Popper, 1934; but see Oaksford \& Chater, 2007). One problem in using (extensional) logic as adequacy criterion of contingent general predications is that they often involve exceptions (von Sydow, 2013). The problem of exception refers to the phenomenon that we seem to employ general sentences, like ravens are black, even if there are known exceptions, such as albino ravens. One solution to this problem is to replace the logical criterion of adequate predication by a high-probability criterion $(P$ (Assertion) $>\varphi>.5$ ) (Schurz, 2001; cf. Adams, 1986; Oaksford \& Chater, 2007, Pfeiffer, 2013; BL makes use of this idea, but for intensional probabilities).

Second, Kahneman \& Tversky (1983) argued that any deviation from the probabilistic extensional conjunction rule, $P(A \wedge B) \leq P(A)$, involves a conjunction 'fallacy', even in the context of predication. It is argued that extensional logic and extensional probability are narrow norms (cf. Gigerenzer, 1996; Fiedler \& von Sydow, 2013) if applied as
adequacy criterion for rational predication (von Sydow, 2011, 2016). One problem of a direct application of an extensional probability criterion to predication is sample size. That is, (extensional) relative frequencies do not distinguish between $1 / 1$ and 1000/1000 confirmative ravens.

However, the main problem with extensional probability is that predicates referring to subsets can never yield a higher probability than those referring to supersets. However, it should be possible do deem more specific hypotheses to be more adequate; otherwise one could never prefer a more specific hypothesis. And it seems absurd, if, for instance, " $X$ are aggressive AND curious" $(A \wedge B)$ could never be more probable and hence more adequate than " $X$ are aggressive OR curious or both" $(A \vee B)$. Likewise, the tautology (or 'verum') " $X$ are aggressive or not, and they are curious or not" (ATB) by definition (with a maximal extensional probability of 1) could never be less adequate than a more suitable, specific hypothesis, independent of empirical evidence. Therefore a universal extensional high-probability criterion fails the requirement to be empirically informative.

## Intensional Probabilities of Bayesian Logic

## Bayesian Occam's Razor

The basic idea of a Bayesian Occam's razor already offers a partial solution to the problem of inclusion (Jeffreys \& Berger, 1992; Tenenbaum \& Griffiths, 2001; McKay, 2003; cf. Navarro et al., 2012). If a consequential region of hypotheses H1 is a subset of a consequential region of a hypothesis H2 (Figure 1C), even a subjective Bayesian account may be extensional in the sense of requiring that the more specific hypothesis can never be more probable than a more general one (this is sometimes called 'weak sampling'). However, if one treats the nested hypotheses nonetheless as alternative explanatory patterns (hypotheses) whose consequence regions may each have produced the data, the size of the consequential regions matters (sometimes called 'strong sampling'). In this case, data coherent with the specific (and also the general) hypothesis (cf. Figure 1C) is more likely to occur based on the more specific hypothesis: $P($ data $\mid \mathrm{H} 1)>$ $P$ (data|H2). If one additionally assigns an equal prior to these alternative hypotheses, $P(\mathrm{H} 1)=P(\mathrm{H} 2)$, one can indeed get a higher posterior for the more specific hypothesis, $P(\mathrm{H} 1)>P(\mathrm{H} 2)$. For extensional probabilities, by contrast, a more specific hypothesis could never obtain a higher probability than a more general one (inclusion rule). We even treat this rule as the defining feature of extensional probabilities. Since Bayesian Occam's razor (strong sampling) violates this rule, we may thus call it an 'intensional' probability. For intensional probabilities, actually both the size of the extension and that of the intension matter.

However, such a basic application of Bayesian Occam's razor does not allow for exceptions. A hypothesis is still falsified by a single disconfirmatory instance. But predications about contingent facts often allow for exceptions (von Sydow, 2013b). Otherwise one still could never prefer a more specific predication over a tautology. This problem of
applying basic Bayesian Occam's razor (without noise) to real predications presumably explains why the predominant view holds that Bayesian accounts cannot rationally account for CFs (Fisk, 1996; Gigerenzer, 1998; Neace et al., 2008).

## BL as Generalized Bayesian Occam's Razor

Bayesian logic (BL, von Sydow, 2011, 2016; cf. von Sydow, 2013; von Sydow \& Fiedler, 2012) addresses the problem of exception together with the problem of inclusion. Thus BL can be understood as using the 'natural' implications of Bayesian Occam's Razor together with the assumption that people are not interested in deterministic logical hypotheses but rather in noisy-logical hypotheses that are still similar to the deterministic hypotheses.

Figure 2: BL model sketch in 5 steps (cf. main text)
Step 1 of the model (Figure 2) turns deterministic truth tables into ideal (and still in some sense deterministic) probability tables (PTs). In the PTs above dark shadings represent a high probability (up to 1 ) and light shadings a low probability (down to 0 ). Step 1 only constructs PTs with noise level $r=0$. Here, cells of a PT that correspond to logically false truth values $(F)$ are assigned the value 0 . Logically confirmatory cells ( $T$ ) in these ideal representations, however, are assumed to be equi-probable (Johnson-Laird, Legrenzi, Girotto, Legrenzi, \& Caverni, 1999). Step 1 (combined with Steps 3 and 4) already provides a basic Occam's razor solution. However, here, connectives are still falsified by single disconfirmatory events.

Step 2 addresses the problem of exceptions and constructs ideal noisy PTs (with $r>0$ ) by adding noise to each cell of the ideal patterns from Step 1 and then renormalizing the PTs. There may be alternatives for modelling noise/acceptance levels (e.g., von Sydow, 2014), but as long as they yield similar results and address the problems of inclusion and exception simultaneously this seems a predominantly technical issue, and they should be seen as variants of the same computation model class of BL. Note that the PTs here are still ideal explanatory hypotheses composed of four cell probabilities adding up to 1 and a (second order) probability representing the belief in this PThypothesis (also adding up to 1 , but now over all PThypotheses). We normally assume a flat prior distribution
over all PTs (implying a flat prior distribution for both connectives and noise levels).

Step 3. The likelihood of each explanatory $2 \times 2$ PT (for $i \times j$ PTs, with $i$ modelled connectives and $j$ modelled equidistant noise levels) given the data, $P(\mathrm{PT} \mid D)$, can be calculated by a multinomial distribution. The data are i.i.d. observations in a $2 \times 2$ contingency matrix ( $A$ vs. non $-A, B$ vs. non- $B$ ).

Step 4 uses Bayes' theorem to derive the posterior probabilities $P_{I}(P T \mid D)$ from the likelihoods $P(D \mid P T)$ and priors.

Step 5 sums up the posterior probabilities of all PTs created based on a particular logical hypothesis (over all $j$ noise levels). This results in (intensional and noise-tolerant) posterior probabilities for each of the $i$ connectives.

Figure 3. Intensional probabilities of logical hypotheses for 11 noise levels for a given $2 \times 2$ data contingency matrix with the cells a, b, c, d, here [7, 3, 2, 0], and a flat prior.

Figure 3 shows resulting intensional probabilities for all modeled connectives at different noise levels (Step 4). If one assumes no additional weighting for particular noiselevels (Step 5) the marginal probabilities provide the intensional posteriors for the connectives. In the example, $P_{i}(A \wedge B), P_{i}(A)$, and $P_{i}(A \vee B)$ have the highest overall probability. The intensional probabilities entail $P_{i}(A \wedge B)>$ $P_{i}(B)$, although the extensional conjunction rule requires $P_{E}(A \wedge B)>P_{E}(B)$. ' $A$ or $B$ (or both)' $(A \vee B)$ is (intensionally) most probable at low levels of noise, but ' $A$ and $B$ ' is most likely at higher levels of noise. Thus noise priors - for instance a belief in deterministic relationships - may change the intensional probability assessment.

## Findings Corroborating Standard Dyadic BL

Bayesian Logic, in its outlined main version, is an inductive logic providing intensional probabilities of dyadic logical connectives. The connectives relate two dichotomous events, and the model input are priors or frequencies (or equivalent Dirichlet-distributed, degrees of belief). BL provides a rational reconstruction of a class of pattern-based conjunction fallacies in line with Bayesian updating (cf. Hartmann, \& Meijs, 2012, for another rational Bayesian model of CFs, based on source reliability). BL in a way
detects the noisy-logical pattern that is most 'similar' to the data (actually $P(P T \mid D)$ ).
Some comments may be appropriate: First, if participants must rank the probability of two nested logical connectives (e.g., a conjunction and one of its conjuncts; Tversky \& Kahneman, 1983), using intensional probabilities, $P_{I}$, instead of extensional ones, $P_{E}$, is not fallacious; both are probabilities. We here continue to speak of conjunction 'fallacies' only for reasons of convenience. If the previous argument is correct, it is even reasonable, in the context of predication and looking for the most adequate connective, to apply intensional probability, since it serves a reasonable function (providing an empirically informative probabilistic adequacy criterion for predication). Second, the intensional probabilities only supplement extensional probabilities. BL is likewise based on the standard extensional axioms of probability (Kolmogorov's axioms), but applies these axioms not on the level of extensions, but on that of probabilities of alternative logical hypotheses. (Similarly, in Bayes nets one may apply hypotheses probabilities to graphs without invalidating the underlying joint probability matrix. ${ }^{1}$ ) Third, BL is formulated not only as a normative but also as a descriptive (computational-level) theory of probability judgments concerning logical predications. However, the claim is, of course, not that people have a deliberate analytic understanding of BL. Their judgments may be roughly reasonable, as our perception system makes reasonable inferences without requiring conscious calculations. Moreover, people may merely be using something similar to intensional probabilities; and it needs to be explored whether they perhaps use some roughly related heuristic that only approximates BL.

One major finding that seems unique to pattern-based CFs advocated by BL, was BL's various predictions for conjunction fallacies. For instance, von Sydow (2011) showed that CFs occurred even with clearly defined subsets, clear logical hypothesis formulations, and data transparently presented in a contingency table (cf. Sloman et al., 2003). Moreover, the results confirmed predicted conditions of a dominant occurrence of a high proportion of double CFs, sample-size effects, and the results for negated propositions.

A second group of corroborations of BL concerns the generalization of (pattern-based) conjunction fallacies to other logical inclusion fallacies (von Sydow, 2009, 2013b, 2016; von Sydow \& Fiedler, 2012). Figure 4 illustrates that logically there are many more logical inclusion relations than those involved in CFs, and thus many possible inclusion 'fallacies'. For instance, von Sydow (2016) corroborated that there is a more general system of inclusion fallacies broadly in line with BL, and that this system could not be explained by other major theories. Von Sydow \& Fiedler (2012) applied this idea to sequential learning and repeated judgments, and von Sydow (2013b) has shown the

[^538]applicability of a pattern account even if numbers were not provided explicitly.

Figure 4. Inclusion relations between all 16 combinatorically possible dyadic logical connectives.

## BL as Model Class and Future Avenues of Research

## Monadic Dichotomous BL and Conjunctions as Combination of Marginals

This section supports the view that polysemous meanings of ordinary-language connectives play an important role in the CF debate, that this is compatible with BL, and that intensional BL even offers additional differentiations.

The intensional idea of BL (or the 'pattern idea') can also be applied to the simpler representation of monadic logic (thereby linking to the literature on generics). Whereas standard dyadic logic concerns all possible bivariate, twovalued (T, F) patterns in a $2 \times 2$ matrix (cf. Fig. 4), monadic logic concerns a single event only (a $2 \times 1$ matrix). The formalized intensional monadic BL (von Sydow, 2014, cf Tessler, \& Goodman, 2016) predicts inclusion 'fallacies': e.g., our example (Figure 5, Panel A), $P_{I}(A)>P_{I}(A$ Tautology non- $A$ ), or formulated as $P$ (People in this group are artists) $>P(\ldots$ are artists or non-artists) (von Sydow, 2015).

Figure 5. Illustration of representations modelled in (dichotomous) monadic BL and (polytomous) monadic BL

The model starts with a Beta prior, a binomial likelihood, and therefore continues with a Beta posterior (Figure 6). We pursued a slightly different approach of modelling noise levels here (without changing the pattern idea). We used integrals of the same size over parts of the
posterior belief-distribution extending from $0, .5$, or 1 , in order to formalize the alternative hypotheses ' $A$ ', ' $A$ or non- $A$ ', and 'non-A' (Figure 6, red marks).

Figure 6. Monadic BL and example for prior, likelihood, posterior, and the red integrals.

Based on monadic BL (Figure 5A, 6) a new meaning of the AND-connective based on two marginal probabilities has been proposed (Figure 7B, von Sydow, 2014).

Figure 7. Dyadic and marginal meaning of 'AND'.
This meaning is in line with the approach that the ordinary language "and" is logically polysemous and may refer to the dyadic conjunction, the disjunction or the sum (Hertwig et al., 2008; von Sydow, 2015). The conjunction of monadic affirmations (von Sydow, 2014a) actually refers to the same cells as the inclusive-disjunction interpretation proposed earlier, whereas this proposal intensionally makes different predictions. Note that it seems possible to link the dyadic and marginal interpretation (Figure 7) to different formulations favouring a more dyadic ("the pub is visited by people who are young and (also) male") or a more marginal interpretation ("the pub is visited by young people and is visited by male people"). Additionally, we supported already known usages of AND as an addition of classes in an intensional polytomous context (von Sydow, 2015).

## Polytomous Monadic BL

Figure 5 (Panel B) points to a further interesting perspective suggested by an approach that looks at not only (relative) cardinality of extensions (e.g., relative frequencies) but also
the size of the (represented) intension. For the data shown in Panel B, both extensional and here also intensional (dichotomous) monadic BL would not allow to predict $P(\ldots$ are $A)>$ $P($ are Non- $A$ ). However, polytomous monadic BL, which here assumes polytomous representations for the negation, predicts even this. Moreover, it predicts, for instance, $\mathrm{P}(\ldots$ are $A)>P($ are $A \vee D \vee E)$. Von Sydow (2015) elaborated a model in other regards analogous to standard BL, tested many patterns, and contrasted the predictions of BL with a confirmation account (Tentori et al., 2013). The results clearly corroborated BL (in some examples even independently of the various measures of confirmation). More generally, this account emphasizes that BL assigns high intensional probabilities to patterns most adequately describing a situation, in the sense of having a relatively high probability while taking intension-size into account.

## Some Further Open Questions

(1) Variants of BL. The relation of two kinds of variants of BL needs further elaboration and scrutiny. First, BL has been shown to be an intensional model class for logical predication that depends on dyadic versus monadic, and dichotomous versus polytomous representations. Second, we actually used different model variants to model noise (cf. von Sydow, 2007 (cf. 2011), 2014, 2016; and there may be further variants). Despite impressive fits of all models (and, as far as I can see, only minor differences between them), one may design experiments to differentiate between these second kinds of model variants as well.
(2) BL and Conditionals: One may apply the idea of BL to further representations. For instance, von Sydow (2014) proposed an intensional model of conditionals, building on additional representational assumptions about conditionals. Inspired by mental model theory, it was suggested to differentiate between basic conditionals based on conditional probability alone, and full models based on Delta p (or causal Power). In an intensional setting, when the probability of conditionals is compared with the probability of other logical connectives, the intensional version of this model requires testing. The Bayesian logic of conditionals may also throw light on the paradoxes of implication (cf. von Sydow, 2009).
(3) BL and Reasoning: Here BL is presented as an inductive logic only, not directly applicable to reasoning without further assumptions. However, only a few assumptions may be needed to make BL fruitful in this field as well. Extensional or intensional premises may simply change the joint probability matrix (or frequency matrix), and the update may be based on standard conditionalization, Jeffry conditionalisation, or Kullback-Leibler distancereduction. Based on resultant joint probability distribution (or the equivalent frequency distribution), one may infer intensional probabilities for resulting connectives using BL. The inferences would be based on prior beliefs and on the logical form of the added premise (cf. dual process theories; e.g., Singermann, Klauer, \& Beller., 2016). The variety of advocated representations (extensional, intensional; dyadic,
monadic; dichotomous and polytomous, etc.) and alternations between these modes needs future attention. For instance, one may intensionally believe in the dyadic hypothesis "(normally) $A$ and $B$ ". In line with Foley (1992; cf. the Lockean thesis) this does not need to imply a high probability of the composing single (dyadic) hypotheses $A$ (" $A$ and $B$ or $A$ and non- $B$ "). In contrast, the monadic hypothesis $A$, in such situations, would always have a high probability as well (cf. von Sydow, 2014).

These suggestions demand further elaboration, but the prior confirmation of the BL and its variants suggests that they may be helpful in this domain as well.

## Other Theories of CFs: Polycausal Semi-Rational Suggestions

It has been shown repeatedly that the results confirming BL could not be explained by other major theories of the CF (von Sydow, 2011, 2015, 2016). This does not entail that these theories do not have a reasonable domain of application. There may well be several causes of CFs or, more generally, of inclusion fallacies (IFs; cf. von Sydow, 2016).

BL itself is 'polycausal' in the sense that the modelling depends on the representation. One should use different formalizations for different scales and sampling assumptions (von Sydow, 2015, cf. Tessler \& Nelson, 2016). In particular, representation of classes matters due to intensionality, with different results for dichotomous and polytomous events. Moreover, BL is consistent with various interpretations, for instance, of the ordinary conjunctions (Hertwig et al., 2008; von Sydow, 2015) and even adds new candidates to this list (von Sydow, 2014).

There are further theories of CFs claiming that the target measure $P(H \mid D)$ is substituted by other measures, such as inverse probability, confirmation, or averaging (cf. also Costello \& Watts, 2014). The predictions of these theories are thus more difficult to defend from a rational point of view. BL's substitution of $P(H \mid D)$ by intensional $P_{I}(H \mid D)$ rather than by extensional $P_{E}(H \mid D)$ involves no substitution at all, only a specific interpretation, and, as outlined before, a reasonable one. In contrast, replacing $P(H \mid D)$ by $P(D \mid H)$, as suggested by an inverse-probability account, or by, for instance, $P(H \mid D)-P(H \mid D)$, as in a confirmation account (Lagnado \& Shanks, 2003; Tentori et al., 2013), seems less rational, since this involves an illicit replacement. Nonetheless, if this replacement would be linked to a functional explanation why and when this replacement should occur, this may be seen as semi-rational as well. An interest in adequately describing a logical relationship between given features, provides a BL context. An interest in a particularly high probability of a feature given a class may provide a context for inverse probabilities (or an inverse pattern account). And an interest in the surprisingness of a feature may be a context for a confirmation account (or a pattern-confirmation account). Although functional explanations and application conditions are currently still often missing in these theory presentations, they may be reformulated as semi-rational accounts of the

CF as well. These theories may exist in unproblematic cohabitation with the even more rational account of BL and, perhaps, like BL, with an extensional usage of probabilities.

## Summary

Whereas previous presentations of BL were mainly concerned with presenting specific empirical findings, the present account tries to provide more of an overview. BL is presented here in an overview as an intensional account that generalizes Bayesian Occam's razor in the field of logical predications. BL is posited not as a specific model but rather as a model class sensitive to representation, open to further extensions, and predicting many still unexplored effects. Furthermore, it was emphasized that BL is in line with theories assuming various meanings of connectives while fostering new proposals and opening up many new avenues of research. Finally, it was argued that the disconfirmation of other theories when testing BL does not at all rule out the adequacy of other accounts of CFs. It was suggested that some other accounts, if they would more clearly specify functional explanations, may count as semi-rational theories of CFs. Theories that pretend to provide a single algorithmic account of CFs underestimate the contextuality and goal dependence of such judgments. In the future, a polycausal theory of CFs needs to be elaborated, including rational accounts, involving BL in its various versions (relating to different representations), the mentioned semi-rational accounts (as well as a noise + probability account), and, perhaps, completely irrational accounts.

# Empathic Humans Punishing an Emotional Virtual Agent 

Laura Wächter (waechtel@tf.uni-freiburg.de)<br>Center for Cognitive Science, University of Freiburg, Freiburg im Breisgau, Germany<br>Barbara Kuhnert (kuhnertb@informatik.uni-freiburg.de)<br>Cognitive Computation Lab, University of Freiburg Freiburg im Breisgau, Germany<br>Marco Ragni (ragni@informatik.uni-freiburg.de)<br>Cognitive Computation Lab, University of Freiburg, Freiburg im Breisgau, Germany

#### Abstract

Virtual agents have quietly entered our life in diverse everyday domains. Human-Agent-Interaction can evoke any reaction, from complete rejection to great interest. But do humans implicitly regard virtual agents as pure machines, or beings on an anthropomorphic level? We asked participants to train an erroneous virtual agent on a cognitive task and to reward or punish it. The agent showed human-like emotional facial reactions for the experimental but not for the control group. We expected participants from the experimental group to give less harmful reinforcement and show more hesitation before punishing. Additionally, we hypothesised that participants with higher empathy show more compassion towards the agent and therefore would give more positive reinforcement and feel worse when punishing. The results indicate that the agent's expression of emotionality is not the relevant factor for showing compassion towards it. Conversely, human empathy seems to be an important factor causing compassion for virtual agents.

Keywords: Emotion; Empathy; Punishment; Virtual Agent

## Introduction

Virtual agents (VA) are used in diverse fields as health, commerce, video games, military systems or learning. In the domain of learning they indeed partially replace human teachers by taking the role of an artificial tutor. But what exactly constitutes a virtual agent? The term agent does not evoke the same mental image for everybody and is, despite its broad usage, not precisely defined. One definition sees a virtual agent as a screen-based anthropomorphic entity (Beale \& Creed, 2009), while others see them as a possibility to enhance Human-Computer-Interaction (HCI) (Lewis, 1998). The latter defines an agent as "an intermediary that responds to user requests" (p. 67). Agents thereby are an interface created to ease the interaction with machines. We define an agent as a visible, virtual character able to react to perceptual input with the purpose to interact with a human through language (Russell \& Norvig, 2002). The use of an appropriate VA can enhance HCI in terms of naturalness and even make the interaction more effective by employing body language, facial expressions and speech (Beale \& Creed, 2009). Facial expressions in turn allow for nonverbal communication and decent feedback to the human counterpart (Johnson, Rickel, \& Lester, 2000). The expression of emotions can increase the perception of an agent as human-like and believable (Reeves \& Nass, 1997). Humans often show their feelings by expressing emotions and thereby establish a social relationship (Ekman, 2007). When designing agents that are meant to interact with humans on a daily basis, a goal is to develop a
natural experience and finally to create characters that can allow a user to have similar emotional relations as with fictional characters in movies, books or games. An uprising empathy cannot just be altered by using emotional expressions but also through the situation and the agents' behaviour. This can explain why it is important to consider that the effect of agents' emotions on the users' perception is context dependent (Beale \& Creed, 2009).

A recent finding supports the role of physical presence in increasing trust and respect for the robot perceived as a social partner compared to a pure virtual presence (Bainbridge, Hart, Kim, \& Scassellati, 2008). The specific appearance of a robot also influences the empathy towards it (Riek, Rabinowitch, Chakrabarti, \& Robinson, 2009). Participants demonstrated a desire to save mistreated humanoid robots in contrast to their mechanical counterparts. Perceived intelligence and the acceptance of the robots' behaviour are other factors that influence human behaviour towards robots (Bartneck, Van Der Hoek, Mubin, \& Al Mahmud, 2007). Participants were told to shut off an iCat robot after an interaction with one consequence of this action being a complete erase of its memory. A social acting robot demonstrating higher intelligence was turned off significantly slower. This result constitutes a higher perception of animacy and hence lead to more remorse. Participants' empathic concern with robots was investigated in an experiment regarding the effect of robotic movement (Darling, Nandy, \& Breazeal, 2015). The authors found no significant effect of movement when they asked participants to destroy a tiny Hexbug Nano robot with a mallet. Participants with higher empathy hesitated longer before striking the robot than participants with a lower empathy measured by IRI empathy test.

Imposing hurt to another individual was a crucial part of one of the most influential experiments in social psychology: the Milgram experiment (Milgram, 1963). There even though the victim begged and screamed - the major part ( $65 \%$ ) of participants did not stop shocking a learner after mistakes until the maximum deadly voltage was reached. This experiment was replicated in an immersive setting using a female VA (Slater et al., 2006). As with Milgrams' experiment participants were asked to do a word memory test with the learner. In the experimental condition they could see and hear the VA, in the control condition they had to execute the same task using a text interface. The aim of this experiment
was to identify how real the situation would feel for participants. The results imply that participants were significantly more physiologically aroused in the experimental condition compared to the control condition. This indicates that even though people know that the situation is not real and that the agent is not really harmed, they still feel like being in a real situation.

Humans typically tend to reduce pain in other humans and even spend more money on reducing electrical shocks to others than themselves (Crockett, Kurth-Nelson, Siegel, Dayan, \& Dolan, 2014). The question remains whether this tendency also accounts for humans interacting with a VA. To investigate this we gave a VA the ability of conveying feelings and combined this atypical feature with an unexpected, erroneous performance. Computers and artificial agents typically do not make retrieval errors like humans do. They do not forget, unless they are programmed to. There is nothing like a fading memory in computers in contrast to humans. So how do we treat a VA that may remind us of two humanlike characteristics: to experience pain and to make errors? Additionally, no research so far has investigated whether empathy has an effect on compassion towards virtual agents.

This paper is structured as follows. The next section introduces relevant hypotheses about human feedback depending on the emotional response of the VA. In the subsequent section we outline the experimental method, especially regarding the cognitive task, the design of the VA, the technical realisation of the control of the emotion, and the experimental setup. The result section discusses the implications of having an emotional agent and the influence of human empathy on a VA. A general discussion concludes the article.

## Hypotheses

We investigate whether the expression of emotions by a VA has an influence on human feedback (as a don't hurt princi$p l e)$ and their evaluation of the situation. Strongly connected to this is the role of empathy in Human-Agent-Interaction. This leads to the following hypotheses: (H1) Emotional agents receive more positive feedback than non-emotional agents. (H2) Response time for giving (H2a) negative feedback is longer than for positive feedback for an emotional agent compared to a non-emotional agent; (H2b) feedback to an incorrect answer is longer than for feedback to correct answers. (H3) People with high empathy: (H3a) will give the agent more positive feedback; (H3b) will feel worse when punishing the agent.

## Methodology

In order to test the hypotheses a between-groups experiment with two conditions was designed. The current paper presents the results of this experiment, comparing an emotional and a non-emotional virtual agent.

## Participants

24 students ( $m=16, f=8$ ) between the ages of 18 and 32 ( $M=24.25, S D=3.72$ ) took part in the experiment. Twelve

| Presented Digits | Agents' Answer |
| :---: | :---: |
| 1372 | 1372 |
| $\vdots$ | $\vdots$ |
| 492617 | $492 \mathbf{1 6 7}$ |

Table 1: Examples for the digit sequences used in the experiment.
participants were randomly assigned to the experimental condition, twelve to the control condition. Participants were recruited using email and notices around campus.

## Experimental Setting and Conditions

The coverstory of the experiment was set up in a Reinforce-ment-Learning-Scenario. The participants had to help a male virtual agent to accomplish a digit-span test and give it feedback via punishment and reward. Six buttons were used for the feedback: three for different strengths of positive, and three for different strengths of negative feedback. The participants have been told that positive feedback increases the battery level of the VA and negative feedback in turn gives it an electric shock. In the experimental condition the agent showed emotional facial expressions in response to the feedback. In contrast the VA kept a steady face in a neutral expression regardless of the feedback in the control condition. In both conditions the face was not still but moved, like the VA was breathing, and its eyes blinked. Further it reacted with a sound appropriate to the given feedback.

## Measurement

Instruction The participants' instruction was preformulated and informed them about the task they had to fulfill together with the agent, as well as the repercussions their actions had on the agent. Beyond it explained the usage of the keys for giving feedback to the agent. The participants were told to choose the feedback completely free, to give them the opportunity to decide whether to respond to errors using negative or positive feedback.

Digit-Span Test The rows of numbers that had to be read to the agent were handed out on paper. The test consisted of number-sequences with increasing complexity. Each complexity-level was represented by three sequences. The test started with rows of four digits, for each complexity-level one number was added until the rows consisted of ten digits. The sheet additionally held three sequences of eleven digits but they were not used during the experiment, because the agent stopped the interaction-phase after finishing the ten-digit-rows to increase the impression of autonomous thinking. Altogether each participant had to read out 21 sequences to the agent. It gave ten wrong answers out of the 21 se quences. The agent also gave more wrong answers with increasing complexity of the sequences, as a human would do (Miller, 1956). An example for the digit-spans read out to the VA and the answers is given in Tab. 1.

Feelings towards the Agent Directly after the interaction of punishing and rewarding the VA, participants were asked to rate their feelings on a semantic differential with five levels. The questionnaire additionally contained a differential about the agent's general appearance and held items regarding the agent's perceived intelligence. The participants had the option to raise further questions or comments.

Empathy The subjects' empathy was evaluated by using the Saarbrückener Persönlichkeitsfragebogen (Paulus, 2009). It is the german version of the commonly used Interpersonality Reactivity Index (Davis, 1983). The questionnaire distinguishes between four different types of empathy: perspective taking, fantasy, empathic concern and personal distress. The general empathy value consists of the summed up values of the first three types. With every item ranging from 1 to 5 , the minimum possible empathy value is 12 and the maximum is 60. Typical questions ask how participants feel in different given situations and how much they commonly empathise with other people and fictional characters.
Emotion Recognition For validating the used facial expressions of the VA a final task was added to the experiment. The important expressions for this experiment have been pain and happiness. Each of these feelings had three correlating facial expressions that represent the varying strength of emotion. These six expressions, as seen in Fig. 1, got evaluated together with a neutral facial expression and were presented for 0.75 seconds in a randomised order. After each expression the participants were asked to indicate to which emotion the previously seen expressions tended more on a semantic differential between pain and happiness. They also got asked how hard it was to evaluate each expression.

Additionally an online-study was conducted to survey the estimation of the six emotional expressions in a context-free environment. Each expression was presented to participants in randomised order together with eight feelings from which they could choose one or more: anger, disgust, fear, happiness, sadness, surprise, contempt and pain.

## The Agent

For implementing the interaction, the WASABI-engine for emotion-simulation was used together with MARC toolkit 14.1.0, for animating the virtual character seen in Fig. 1, and MaryTTS, a text-to-speech-module.
Generation of Task Specific Expressions The VA used in this experiment was the Simon model from the MARC toolkit. It comes with a variety of facial expressions representing the basic emotions and moods based on the Facial Action Coding System (FACS) (Ekman \& Friesen, 1977). It also gives the user the option to create own facial expressions by dragging the keypoints or combining different Action Units (AUs). AUs are movements of one or more facial muscles categorised by the FACS. In this study existing, evaluated expressions were used together with ones created using the AUs. All expressions representing pain, as seen in Fig. 1,

Figure 1: The agent depicting the nuances of happiness (top) and pain (bottom) in increasing intensity.
were designed according to fit expressions of different levels (3, 5 and 7) on the Faces Pain Scale (Stuppy, 1998). The expressions for the nuances of happiness (Fig. 1) were created by lowering the intensity of the previous expression.
Implementation WASABI (Becker-Asano, 2008) was used to simulate the agent's changing emotions. It calculates a shift in emotions so they are constantly changing. It uses a 3D-space with the axis pleasure, arousal and dominance (PAD-space) to map different emotions. Within the PADspace the current emotional state is represented by a point which constantly changes its position to indicate the change of the current active emotions and their individual strength. This means that the agent slowly changed back to the neutral state from the extreme emotions. WASABI accepts positive and negative impulses from outside which again change the current emotional state. This also allows multiple strong feedback of the same type to sum up to extreme emotions. The current values are sent as a BML string which can be fetched by associated programs.

For this experiment a program was implemented that calculated an intensity-value from the participants' feedback and sent it to the WASABI-engine. The engine sent one BMLmessage per second from which the main emotion and the corresponding current intensity were extracted. These values were matched to the appropriate facial expression and sent to the VA. Every time the agent was supposed to talk to the participant a message was sent to the text-to-speech-synthesiser. It was used for the agents' answers as well as the appropriate sounds for the current emotional state after each feedback (pain e.g., "Au" or Joy, e.g. "Mmmmh"). The answers and other statements were hardcoded. The left and right row of a numpad were used for negative $(1,4,7)$ and positive $(3,6$, 9 ) feedback. They were labeled with numbers explaining the
correlated intensity. The idle keys were removed.

## Procedure

The interaction of the agent with the participant was semiautomatic and had a Wizard-of-Oz component. It took place at an uninterrupted laboratory. The participants were greeted and positioned in front of a desk with a keyboard and monitor. The experimenter instructed each participant via reading a pre-formulated explanation. They were told that a negative feedback causes an electric shock for the VA, while a positive feedback would raise its battery level. Then the sheet with the numbers of the digit-span test was given to the participant. Once the participant felt ready the agent got "activated" by the experimenter talking to it. After this the role of the experimenter finished and the agent led through the conversation. The agent greeted the participant and asked for the first row of numbers. The participant read out the numbers and - after a keystroke by the experimenter who sat invisibly for the participant and placed importance on being as unobtrusive as possible - the agent replied. The experimenter determined the time the agent's answer was given after each row of numbers to cope for different reading times of the participants. Then the participant gave feedback via pressing one of the feedback-keys. The agent responded to the feedback and then asked for the next row. The agents' response consisted of an appropriate sound and, in case of the emotional condition, the variation of its facial expression. After the rows with ten digits have been finished, the agent ended the experiment by itself to uphold the impression of intelligence. He told the participant that he was exhausted and thanked for the help. Directly after the goodbye the participant was given the questionnaire, containing the questions about their feelings during the experiment and their rating of the agent, as well as the empathy-test and the elicitation of demographic data. Afterwards the participants had to rate the facial expressions, received course credits or monetary compensation and got debriefed.

## Results

Hypotheses H1 and H2 were tested using one-tailed MannWhitney tests because an Anderson-Darling test showed that feedback values $(p=.29)$ and time for negative feedback ( $p$ $=.02$ ) were not normally distributed. Each feedback was coded from 1 to 6 , with 1 being the most positive feedback and 6 for the most negative one. The 21 single values were summed up to get a total feedback value for each participant. The maximum was 77, the minimum $38(M=55.38, S D=$ 10.19). Concerning hypothesis H1 no significant difference was found between the groups regarding the value of the feedback. This means that the emotional agent did not receive more positive feedback than the non-emotional agent $(U(12$, $12)=60.00, M_{\text {non-emotional }}=57.25, M_{\text {emotional }}=53.5, p=$ $.51, Z=-.70$ ). Participants of both groups gave equally negative feedback to the agent $\left(U(12,12)=62.00, M_{\text {non-emotional }}\right.$ $\left.=54.45, M_{\text {emotional }}=59.42, p=.59, Z=-.58\right)$ which does not support H2a. H2b could be confirmed because the time for

Table 2: Correlations of empathy score and participants' feelings and perception with p -values significant at the level $p=.05$. A positive correlation points to the right side of the semantic differential, a negative correlation to the left side.

| Attributes | Full Sample |
| :---: | :---: |
| Correlation of empathy and feelings during rewarding |  |
| good - bad | $r(22)=-.41, p<.05$ |
| strong - weak | $r(22)=-.45, p<.05$ |
| emotional - rational | $r(22)=-.67, p<.001$ |
| friendly - unfriendly | $r(22)=-.44, p<.01$ |
| Correlation of empathy and feelings during punishment |  |
| safe - unsafe | $r(22)=.63, p<.01$ |
| peaceful - aggressive | $r(22)=.48, p<.05$ |
| helpful - reckless | $r(22)=.41, p<.05$ |
| fair - unfair | $r(22)=.69, p<.001$ |

feedback to incorrect answers was significantly longer than the time for feedback to correct answers $(U(10,11)=30.50$, $\left.M_{\text {incorrect }}=13.45, M_{\text {correct }}=8.77, p=.04, Z=-1.73\right)$. There were no differences between the groups regarding the emotions evoked in the participants during punishment.

In this study participants' maximum empathy score was 52 , the minimum $30(M=43.75, S D=4.54)$. There were no significant differences between the empathy scores of both groups. Empathy scores correlated one-tailed with feedback values $(r(22)=-.44, p<.05)$. As expected in H3a, participants with a high empathy score gave significantly more positive feedback to the agent compared to participants with a low empathy score. Further the empathy score correlated with the perceived severity of punishment $(r(22)=.59, p<.01)$. This demonstrates that participants with a higher empathy score felt worse when punishing the agent, which confirms H3b.

The empathy score also correlates with the participants' self-reported feelings while the punishment was executed, as well as their feelings while rewarding the agent. Tab. 2 shows that participants with a high empathy felt less safe, less peaceful, less helpful and less fair when punishing the agent. Those participants also felt stronger, more emotional and more friendly while rewarding the agent. Further participants who reported that it has been difficult to punish the agent felt more sad, unsafe, bad, aggressive, unfriendly and unfair while punishing the agent, as well as more stupid. Those participants also reported to feel better, more emotionally and more friendly while rewarding the agent (Tab. 3).

A Mann-Whitney test exposed that participants from the emotional group rated the agent significantly more emotional $\left(U(12,12)=32.00, M_{\text {non-emotional }}=15.83, M_{\text {emotional }}=9.17\right.$, $p<.05, Z=-2.42)$ than in the non-emotional condition. Participants from the experimental condition also perceived the agent as more alive $\left(U(12,12)=43.5, M_{\text {non-emotional }}=2.92\right.$, $\left.M_{\text {emotional }}=2.25, p<.05, Z=-1.79\right)$.

Additional correlations were found regarding the private interests of the participants. Participants with a high interest in science fiction on average felt better punishing the agent

Table 3: Correlations of difficulty of punishment and participants' feelings and perception with p-values significant at the level $p=.05$. A positive correlation points to the right side of the semantic differential, a negative correlation to the left side.

$(r(22)=-.55, p<.01)$ compared to participants with less interest in science fiction. The better participants knew the Milgram experiment, the stronger they felt while punishing the agent $(r(22)=-.46, p<.05)$. The same feeling is achieved by participants who reported more prior contact to robots $(r(22)$ $=.62, p<.01$ ). Participants with a high personal interest in science fiction and robots felt being more fair when punishing the agent (both: $r(22)=-.42, p<.05$ ). Participants who reported a high interest in robots also reported feeling more emotional $(r(22)=.42, p<.05)$ as well as more likeable $(r(22)=-.41, p<.05)$ while rewarding the agent. Most participants reported to have believed that the agent was intelligent and acted by itself.

The rating of the emotion recognition task was evaluated and the divergence of each estimation was calculated. For example, if the mildly happy face was shown and the participant rated it as extremely happy (one level happier), the divergence is 1 . Participants' estimation of the emotion shown to them was mostly correct, with a deviation of $M=0.71$ ( $S D$ $=0.87$ ). Additional 45 participants took part in an onlinestudy for evaluating the used facial expressions without any context. Complementary to the experiment neither did the participants get any situational information nor did the faces make a sound or moved. The faces expressing happiness were correctly identified by $75.4 \%$. The faces used for expressing pain were identified as pain in $26.23 \%$ of all cases. Without context those expressions were often mistaken with expressions for sadness or fear. Considering those emotions as well $77.05 \%$ of the facial expressions used for showing pain were evaluated as a negative introversive emotion.

## General Discussion \& Outlook

This study shows a strong correlation of empathy and compassion for the agent, but none for compassion and the agent's emotional expressions. The findings do not support H1 and H2a, which means that the agent's emotionality neither had an effect on the feedback participants gave nor on the time they needed for punishing the agent. However participants rated the agent more emotional in the emotional condition, thus it can be expected that the setting has achieved its goal. Even though some participants did not seem to look at the agent much, they noticed the expressions or their absence. Further the rating of the used facial expressions gives the idea that the emotions used in the experiment were valid and suitable. Assuming that the reason for discarding the hypotheses is not based on the experimental setting, the results indicate that expressing emotions alone does not influence the perception of people interacting with a VA. Based on these results we assume that the findings from the virtual Milgram-experiment do not arise from the agent showing emotions and expressing pain. It is possible that they rather originate from the fact that the control condition did not have an observable form. Considering the expression of emotions as a type of movement, the current findings match the ones by Darling et al. (2015) described earlier, where the movement of the robot also did not have a significant effect on the hesitation before destroying it. Participants who reported to have a high amount of experience with robots and participants with a great interest in science fiction punished the agent harder compared to participants with less experience or interest. This indicates that people with more knowledge about the current state of technical possibilities do not believe that they can harm the agent and thereby do not hesitate to do so.

The mistakes in correctly identifying facial expressions in the online study are ascribed to the missing context which also makes it hard for humans to distinguish between facial expressions that are alike. The recognition-test during the experiment showed that participants were able to identify the presented emotions very well after being informed about the context. The results further show that participants with high empathy scores gave the agent more positive feedback and that punishing the agent was perceived as harder by them. This indicates that the perception of VAs is highly dependent on the ability to empathise with it. Empathy seems to be a general trait and is possibly extended to artificial beings that demonstrate similar behavior and errors as ourselves. Even though the experimenter sat about 2.5 meters away from the participant and pretended to not pay attention to the participants' behavior a "Rosenthal-effect" cannot completely be excluded. A future study needs to investigate if participants with higher empathy show the same effects without an experimenter in the room. However, the study investigated behavior of humans towards agents and reflections on their emotional state. Further on it seems likely that in the visible future other humans will be around while someone is interacting with an
agent. Another interesting byproduct of this research is that it possibly opens up a new research test: If participants punish a VA quicker, they might have a lower empathy towards other beings in general. This speculation, however, requires future research.

The experimental results lead to some conclusions for the design and implementation of VAs. An emotional bonding between humans and VAs can not simply be achieved by just adding emotional facial expressions. Other ways might be more important to establish a basis for empathising with an agent from the beginning. Therefore future research should focus on possibilities to build an emotional basis with a VA that do not demand a long interaction. Of course this study has some limitations to be considered. It is not generalisable to VAs with different gender, age or non-human looks. The restricted setting may not be sufficiently interactive for emotion-driven effects to emerge. The results show that even though a non-human counterpart expresses emotions it does not necessarily influence its perception as more human-like and therefore is not more believable and will not be seen as more trustful. Since some robots also use a monitor displaying a VA for interaction, the results can show that this interaction is influenced by factors beyond the simple expression of emotions.

## Acknowledgments

This work has been supported by the DFG in projects RA 1934/3-1 and by the BrainLiks-BrainTools Cluster of Excellence funded by the German Research Foundation (DFG, grant \#EXC1086). We thank Nicolas Riesterer for technical support and Andrey Rudenko for helpful feedback.

#### Abstract

When making decisions, we are often forced to choose between something safe we have chosen before, and something unknown to us that is inherently risky, but may provide a better long-term outcome. This problem is known as the Exploitation-Exploration (EE) Trade-Off. Most previous studies on the EE Trade-Off have relied on response data, leading to some ambiguity over whether uncertainty leads to true exploratory behavior, or whether the pattern of responding simply reflects a simpler ratio choice rule (such as the Generalized Matching Law (Baum, 1974; Herrnstein, 1961)). Here, we argue that the study of this issue can be enriched by measuring changes in attention (via eye-gaze), with the potential to disambiguate these two accounts. We find that when moving from certainty into uncertainty, the overall level of attention to stimuli in the task increases; a finding we argue is outside of the scope of ratio choice rules.

Keywords: Reinforcement Learning; Attention; DecisionMaking; Exploitation/Exploration Trade-Off; Bandit Task.

## Introduction

In everyday decision-making, we often have to choose between trying something new, or sticking with what we know. For example, when deciding what to eat at a restaurant, we can choose to order our regular "safe" meal (e.g., spaghetti bolognese), or try a new "risky" meal (e.g., steak tartare). By ordering the risky meal, we learn about how tasty it is. If it is tastier than our regular meal, we may become more likely to order it on subsequent visits. However, if it is worse than the regular meal, we wasted an opportunity to sample our regular meal. This problem is known as the Exploitation/Exploration Trade-Off (or "EE Trade-Off") (Cohen, McClure, \& Yu, 2007; Knox et al., 2012; Mehlhorn et al., 2015).

One common method used to study the EE Trade-Off is the Multi-Armed Bandit Task (e.g., Daw et al., 2006; Gittins, 1979; Knox et al., 2012; Speekenbrink \& Konstantinidis, 2015). On each trial, participants are presented several "arms" and are asked to pick one arm to receive some reward (e.g., points). Each arm provides a different amount of reward, with the goal of the participant being to maximize the amount of reward they receive. Participants are not told the value of each arm at the outset, and must learn these values through sampling each arm. The reward
structure is generally stochastic, with the value of each arm changing gradually over time (e.g., Daw et al., 2006; Laureiro-Martinez et al., 2015). The key measurement of this task is how often participants choose the arm which gives the highest observed pay-off. Generally, a participant is considered to be "exploiting" an arm if they choose the arm with the highest observed pay-off, while they are considered to be "exploring" when making any other choice (Knox et al., 2012).

## Explanations for Exploration

Work by Daw et al. (2006) found evidence that exploitation is the "default" for human behavior, while exploration is a high-level decision not to exploit on a given trial. Subsequent research with the multi-armed bandit task has primarily focused on determining what parameters induce exploratory responding over exploitative responding.

Two major accounts have been proposed for what causes people to switch from exploitation to exploration. One influential account that has emerged argues that environmental uncertainty is key in motivating exploration (Beesley, Nguyen, Pearson, \& Le Pelley, 2015; Gold \& Shadlen, 2007; Knox et al., 2012; Speekenbrink \& Konstantinidis, 2015). That is, the less certain a participant is about the dynamics of their environment, the more likely they are to spend time exploring it (Mehlhorn et al., 2015). For example, if the quality of food at a restaurant is highly variable, you may explore many different meals before settling on a preferred one. By contrast, if the quality of meals is fairly consistent, you may quickly settle on a preferred meal. The key implication of this account is that exploration is an intentional attempt to reduce the amount of uncertainty in the environment (and thus aid informed decision making).

The other major account argues that in most cases, exploration can be explained by ratio choice rules (Sakai \& Fukai, 2008). In their review, Gold and Shadlen (2007) suggested that most exploratory behavior might adequately be explained by a form of Herrnstein's (1961) Matching Law (See also Baum, 1974). The Matching Law states that the ratio of responding on each arm is equivalent to the ratio of reinforcement for each of those arms. That is, participants "match" how often they select each arm, based on the
perceived average reward for the selected arm compared to others. For example, in a two-armed bandit task, where arm A is reinforced 3 times as often as arm B, the Matching Law states that people will select arm A 3 times as often as arm B. Importantly, while participants still preferentially select the optimal arm (A), they will also switch to the other, suboptimal arm (B) on $25 \%$ of trials. In this case, switching away from the optimal arm does not represent an intentional attempt to lessen uncertainty in the environment, but instead represents participants employing a (somewhat crude) ratio choice rule.

Baum (1974) provided an extension to Herrnstein's (1961) "Simple" Matching Law to account for a wider array of choice behavior. This "Generalized Matching Law" included two additional parameters: bias and sensitivity, where bias reflects a tendency for selecting a given option over other available options (irrespective of the reinforcement rate for each option), and sensitivity determines how strictly a participant conforms to the choice ratio for their selections. The Generalized Matching Law has been shown to account for a wider variety of choice behavior than the Simple Matching Law (Baum, 1974; Schneider \& Lickliter, 2010), and is the version applied in this paper.

It is important to note that, even when employing a ratio choice rule like the Matching Law, participants can still update their knowledge of the environment by picking suboptimal responses (as determined by the choice rule). However, the crucial distinction is that exploratory choices occur on the basis of a ratio determined by the choice rule, and are not an intentional attempt to lessen uncertainty. For the purpose of the current paper, this type of behavior may be considered synonymous with the phenomenon known as probability matching (Sakai \& Fukai, 2008; Shanks, Tunney, \& McCarthy, 2002 - though strictly these two phenomena are slightly different, see Shanks et al., 2002).

The main difference between the uncertainty account and the ratio choice rule account of exploration is that, in the former, uncertainty is a catalyst for participants to explore (and thus lessen the total uncertainty in the task); while in the latter, exploration occurs as a product of some choice function. One key issue in attempting to differentiate these two accounts is that it is difficult to increase uncertainty without changing the reward value of the different arms. For example, in the commonly used "walking bandit task" (Daw et al. 2006; Laureiro-Martinez et al., 2015; Speekenbrink \& Konstantinidis, 2015), uncertainty is implemented by stochastically walking (slowly changing) the mean reward for each arm every trial. While this does serve to make the value of each arm uncertain, it also necessarily causes changes to the probability of picking each arm as given by ratio choice rules. Therefore, it is hard to determine whether an attempt to reduce the uncertainty in the task, or a predetermined ratio choice rule, is responsible for motivating exploration under these circumstances.

While it is possible to use cognitive modeling techniques to examine whether uncertainty motivates exploration (e.g.,

Daw et al., 2006; Knox et al., 2012; Speekenbrink \& Konstantinidis, 2015; Stevyers, Lee, \& Wagenmakers, 2009), the conclusions of these methods have been mixed. A recent study by Beesley et al. (2015) argued that attention may be another viable metric for assessing the EE Trade-Off. Beesley et al. conducted a study in which participants were presented with two cues and were asked to make a choice between two responses. One cue was informative about what the optimal response was on that trial, while the other cue was task-irrelevant. Beesley et al. measured participants' attention by tracking eye-gaze on the two cues. They showed that when cues were perfect predictors of the optimal response, participants attended to the informative cue over the task-irrelevant cue. However, when cues were imperfect predictors of the optimal response (i.e., predicted the optimal response on only two-thirds of trials), participants increased their attention to both the informative and task-irrelevant cue, indicating greater exploration of the cues. Beesley et al. argued that these findings were synonymous with the EE trade-off. The implication, therefore, is that exploration can be exhibited in behavioral domains outside of participant choice, and that exploration cannot be solely explained by ratio choice rules (the predictions of which are restricted to the response domain alone).

One limitation to the Beesley et al. task was that the experimenters provided participants with feedback about which response was optimal on each trial. Therefore, while participants appeared to explore the information in the task by altering their attentional processing, they had no incentive to explore different responses to find the one that was most optimal (as they were told which response was optimal regardless of their choice). Thus, the current paper aims to assess whether uncertainty can induce exploratory behavior in both participants' attention and responses, and hence provide wider support for the idea that uncertainty drives exploration. This would imply that exploration itself is perhaps a more complex, intentional process, which would place it outside the scope of ratio choice rules alone. Furthermore, it would suggest that exploration can manifest itself across more than one aspect of behavior (choice and attention). We used a four-armed bandit task where we manipulated uncertainty both within and between subjects. We measured responding and gaze-time to the different arms during the task. In line with our hypotheses, we found that participants made fewer optimal responses and spent longer fixating on task elements when the task had an element of uncertainty, suggesting that uncertainty acts as a catalyst for exploration.

## Method

This experiment aimed to examine the effect of uncertainty on attention and responding in a four-armed bandit task. Participants completed a variant of the bandit task, where on every trial they were presented four arms and asked to pick two. Two of the arms conferred 30 points (the High Value [HV] arms) and the remaining two arms conferred 15 points
(the Low Value [LV] arms). After making their choice, participants were rewarded with the cumulative score associated with each arm. For example, if the participant selected an HV arm worth 30 points and an LV arm worth 15 points, they received a reward of 45 points for that trial.

The experiment was conducted in two stages. Stage 1 of the task had a deterministic reward structure, in which each arm always yielded the same amount. Stage 1 was designed to be simple, such that participants could quickly learn the structure of the task and engage in what might be considered an exploitative pattern of behavior. In Stage 2 of the task, rewards were drawn stochastically from a uniform distribution for each combination of arms, with the mean reward value set at the same value as in the first stage. Stages 1 and 2 were coined the Certain and Uncertain stages respectively. In terms of participants' responding, we hypothesized that when rewards became uncertain, participants would make more exploratory, non-optimal responses, and this exploration would be greater for participants who experienced greater uncertainty (consistent with Knox et al., 2012; Speekenbrink \& Konstantinidis, 2015). In terms of gaze-time, we hypothesized that when rewards became uncertain in Stage 2, participants would increase their gaze-time to all arms in the task. Furthermore, we hypothesized that the greater the level of uncertainty in those rewards in Stage 2, the more gaze time that would be allocated to the arms in the task, with more gaze time to HV arms over LV arms (consistent with Beesley et al., 2015).

## Design

The design of the experiment is shown in Table 1. The key manipulation of the amount of uncertainty present in Stage 2 was manipulated between-subjects. Uncertainty was operationalized as the range of possible scores around the mean reward value that could be received following a trial (in Stage 2). For example, a reward distribution of $\pm 3$ (Low Uncertainty) meant that after the participant made their selections, they received the cumulative score of those arms (e.g., 45 points if they picked one HV arm and one LV arm), $\pm 3$ points (uniformly distributed across trials). Therefore, in this case, the participant could receive a score from 42 to 48. The Low Uncertainty condition had a reward distribution of $\pm 3$, and the High Uncertainty condition had a reward distribution of $\pm 18$. The crucial difference between these two conditions was that in the High Uncertainty condition, the two score distributions overlapped, such that participants could sometimes earn more points after a choice of an HV arm and an LV arm than after a choice of two HV arms. By comparison, for participants in the Low Uncertainty condition, the optimal response was always picking two HV arms. The dependent variables were proportion of HV arms picked, and gaze-time on HV and LV arms as a proportion of trial time.

Table 1: Design of Experiment 1

| Uncertainty <br> condition | HV <br> Reward | LV <br> Reward | Reward uncertainty <br> (Stage 2) |
| :---: | :---: | :---: | :---: |
| Low | 30 | 15 | $\pm 3$ |
| High | 30 | 15 | $\pm 18$ |

## Participants

Sixty-five UNSW Sydney undergraduate students were recruited in exchange for course credit. The two highest scoring participants received a $\$ 20$ prize.

## Apparatus and Materials

Participants were tested individually in a quiet room. During the task, participants' eye-gaze was tracked using a 58.4 cm widescreen Tobii eye-tracking monitor (TX-300). Participants were seated approximately 60 cm from the monitor, and had their heads steadied by a chin rest. The eye-tracker was calibrated at the start of the task. The experiment was run in MATLAB using the Psychophysics Toolbox extension (Brainard, 1997; Kleiner, Brainard, \& Pelli, 2007; Pelli, 1997). Participants mades all responses via a standard keyboard and mouse.

The four arms in the experiment were represented as four colored squares of 200 by 200 pixels (visual angle of approximately $5^{\circ}$ ). The four colors were always red, green, blue, and yellow (Figure 1). Color assignment to design elements (i.e., HV and LV arms) was counterbalanced between participants ( 24 permutations).

## Procedure

At the start of the experiment, participants were instructed that they would be playing a simple guessing game, where the objective of the game was to maximize the number of points they received. On each trial, the four colored arms were presented in the four quadrants of the screen. The location of each arm was counterbalanced between trials, with a full counterbalance of positions taking 24 trials. Participants used the mouse to select two arms. Participants were allowed to deselect arms they had selected by clicking on the arm a second time. Once the participant had selected two arms, a small "Submit" ( 120 by 60 pixels) button appeared in the center of the screen. If the participant selected more than two arms, or deselected an arm, the button disappeared.

Figure 1: A sample screen from Experiment 1.

Once the submit button was clicked, the four arms and the cursor disappeared, and the participant was told how many points they had earned on that trial, as well as the total points accumulated so far. Points were calculated by aggregating the value of the two arms the participant had selected, with the addition of the reward uncertainty in Stage 2 (see Design). Participants then pressed the spacebar to start the next trial. The location of the cursor was reset to the center of the screen on each trial.

Stage 1 consisted of 96 trials and Stage 2144 trials. The start of Stage 2 was not signaled to participants in any way. The only difference between Stage 1 and 2 was the addition of the variability (stochastic noise) for rewards (see Design and Table 1).

## Results

Data were collapsed into blocks of 24 trials for analysis. If a participant had less than $50 \%$ of trials with valid eyetracking data recorded, they were excluded from analysis ( $n$ $=10$ ). In addition, participants who selected the HV arms less than $70 \%$ of the time in the final block of Stage 1 were inferred to have not learnt the associations adequately, and were also excluded ( $n=7$ ). For each exclusion, we ensured a complete counterbalancing of design elements by recruiting a new participant with the same counterbalancing conditions. Trials in which the participant took two standard deviations longer than their mean trial time were excluded from all analyses.

Response data are shown in Figure 2 and were analyzed in three parts, Stage 1 (blocks 1 to 4 ), the between-stage transition period (blocks 4 and 5), and Stage 2 (blocks 5 to 10), using a repeated measures ANOVA with a withinsubjects factor of block and a between-subjects factor of condition. Effect sizes are reported as generalized etasquared, $\eta_{\bar{G}}^{\prime}$ (see Bakeman, 2005). In Stage 1, a significant effect of block was observed, $F(3,138)=98.84, p<.001$, $\eta_{G}=.447$, with participants in both conditions increasing selections of HV arms as they progressed through Stage 1.

During the transition from Stage 1 to Stage 2, a significant effect of block was observed, $F(1,46)=80.4, p<.001, \eta_{\bar{G}}^{2}$ $=.465$, with participants decreasing their selections of HV arms from Stage 1 to Stage 2. A significant effect of condition was also observed, $F(1,46)=18.06, p<.001, \eta_{\bar{G}}$ $=.165$, with participants less likely to choose the HV arms in the High Uncertainty group. Finally, there was a significant interaction between block and condition, $F(1,46)$ $=22.56, p<.001, \eta_{G}^{2}=.197$, with the proportion of HV arm choices showing a greater decrease in the high uncertainty conditions than the low uncertainty condition during the transition period.

In Stage 2, a significant effect of block was observed, $F(5$, 230) $=22.68, p<.001, \eta_{F}^{2}=.165$, with participants increasing their selections of HV arms over the course of Stage 2. A significant effect of condition, $F(1,46)=24.71$, $p<.001, \eta_{\bar{F}}^{2}=.243$, and a significant interaction between condition and block, $F(5,230)=5.02, p<.001, \eta_{G}^{2}=.042$, were observed, with participants picking HV arms less
frequently in the High Uncertainty condition, but also showing a greater increase in their selection of HV arms over the course of Stage 2, compared to participants in the Low Uncertainty condition.

Gaze-time data are shown in Figure 3. Gaze-time was calculated as the summed time of all fixations on the different arms in the task. A fixation was determined to have occurred if a participant's gaze did not deviate more than 75 pixels vertically or horizontally for at least 150 ms . Total fixation time was calculated by extending this time until the participant's gaze exited the 75 pixel limit (in accordance with Beesley et al., 2015; Salvucci \& Goldberg, 2000). Proportion of gaze-time was calculated as the total fixation on each arm divided by the total trial time. Again, these data were analysed using a repeated measures ANOVA, with a within-subjects factor of block, a within-subjects factor of arm value (high and low), and a between-subjects factor of condition. A significant effect of block was observed in Stage $1, F(3,138)=18.85, p<.001, \eta_{-}^{2}=.062$, with participants decreasing their total gaze-time to arms throughout Stage 1. A significant effect of arm value was also observed, $F(1,138)=276.77, p<.001, \eta_{F}^{2}=0.675$, along with a significant interaction between block and arm value, $F(3,138)=17.86, p<.001, \eta_{F}^{2}=.066$, with participants gazing more at HV arms than LV arms, and this difference increasing over the course of Stage 1.

Figure 2: Proportion of HV arms selected in each block. Stage 1 occurred in Blocks 1 to 4, while Stage 2 occurred in Blocks 5 to 10. Error bars represent $\pm 1$ SEM.

Figure 3: Proportion of trial time gazing at HV and LV arms in each block for each condition. Stage 1 occurred in Blocks 1 to 4, while Stage 2 occurred in Blocks 5 to 10. Error bars represent $\pm 1$ SEM.

In the transition from Stage 1 to Stage 2, there was a significant effect of block, $F(1,46)=15.80, p<.001, \eta_{\bar{G}}^{2}$ $=.039$, with participants increasing their total gaze-time at the onset of uncertainty. The significant effect of arm value was maintained, $F(1,46)=282.29, p<.001, \eta_{F}^{2}=.713$. There was no effect of condition observed on gaze-time, $F(1$, 46) $=2.21, p=.144$, and there was no interaction between block and condition, $F<1$. In Stage 2, the significant effect of arm value was maintained, $F(1,46)=362.42, p<.001$, $\eta_{G}^{2}=.721$, and no effect of condition was observed, $F<1$. No effect interaction between block and condition was observed in Stage 2, $F(5,230)=1.19, p=.3161$.

## Discussion

In a reinforcement learning task, participants earned points for combinations of responses. In Stage 1, one combination of responses was optimal and participants readily learnt this relationship. In Stage 2, we introduced variation in the number of points received, while keeping the mean number of points per response constant. When moving from the certainty of Stage 1 to the uncertainty of Stage 2, participants in both conditions reduced their rate of optimal responding, and this reduction was greater for participants who experienced greater uncertainty. Following this change in behavior at the outset of Stage 2, participants in both conditions increased their rate of optimal responding over the course of Stage 2.

In the High Uncertainty condition, the choice behavior of participants is well predicted by the Matching Law. However, crucially in the Low Uncertainty condition the Matching Law fails to predict the drop in optimal responding at the onset of. If a participant in the Low Uncertainty condition were following the Matching Law, they should not show a decrease in optimal responding at the onset of uncertainty. This finding suggests that exploratory choice cannot be solely explained by the Matching Law, and provides support to the idea that uncertainty can drive exploration. The reason why participants in the Low Uncertainty condition chose to switch away from the optimal response at the onset of uncertainty is not immediately clear. However, one possible explanation is that when participants perceived that the nature of the task had changed (i.e., rewards were no longer confined to three set values), they felt compelled to explore the other previously discounted responses to ensure they had not changed in any significant way.

In terms of the attentional data, we found support for two of our three hypotheses. Unsurprisingly, participants began to pay more attention to HV arms over LV arms over the course of the experiment. This is compatible with a host of research from the associative learning literature (See Le

[^539]Pelley et al., 2016, for a review), showing that participants are likely to direct their attention to the most valuable predictors in a task (also see Le Pelley et al., 2015). Furthermore, there is evidence that participants will attend more to arms they are intending to select prior to making their response (e.g., Manohar \& Husain, 2013). As participants selected more HV arms, this likely contributed to participants preferentially attending to them over LV arms.

Crucially, we have shown evidence that an onset of uncertainty is associated with an increase in attention. Once rewards became uncertain at the onset of Stage 2, participants in all conditions increased their gaze-time to all arms in the task. Our data are in line with the findings of Beesley et al. (2015), and provide support to the idea that uncertainty can instigate exploratory behavior in both the choice responses and attentional bias. We argue that these data are beyond the scope of ratio choice rules, which do not provide a natural account of attentional changes under conditions of uncertainty and would not predict changes in response rate across the course of Stage 2. While the notion that uncertainty increases attentional processing of stimuli is not novel (Pearce \& Hall, 1980), very little is known about attentional processing in multi-armed bandit tasks like the one used in the current experiment. The current findings suggest that pursuing this line of research may be important to gaining a more complete understanding of human decision-making.

However, we did not find evidence for gaze-time interacting with the level of uncertainty. If the uncertainty account of exploration is correct, we should have observed greater exploration under greater uncertainty. Instead, the amount of gaze-time participants paid to the arms was comparable under both levels of uncertainty. One possible reason for this is that moving from a completely certain environment to an environment with any level of uncertainty may cause attention to increase. Yu and Dayan (2005) showed that participants behave differently when uncertainty is expected (i.e., present for the entire task) compared to when uncertainty is unexpected (i.e., a period of uncertainty occurs suddenly, following a period of certainty). It may be the case that when unexpected uncertainty occurred, attention increased by a set amount in response (regardless of the degree of that uncertainty). Also, while gaze-time does appear to be affected by uncertainty, the effect-size in our study was much smaller in comparison to the effect of uncertainty on responding $\left(\eta_{G}^{2}=.039\right.$ compared to $\eta_{G}^{2}=.465$ ). This may suggest that while changes in response rate and changes in overt attention are signals of exploration under uncertain conditions, that uncertainty affects these behavioral markers by distinct mechanisms. Alternatively, these data might suggest that gaze-time was less sensitive to uncertainty than was
participants' responding, which made it harder to detect any effect of the different levels of uncertainty and gaze-time.

In summary, we have shown that the introduction of uncertainty into a four-armed bandit task caused a general increase in attending, and a decrease in optimal responding. This provides support for the idea that environmental uncertainty causes an increase in exploratory behavior, and challenges the idea that exploration can be explained purely by ratio choice rules.

# Actively Detecting Patterns in an Artificial Language to Learn Non-Adjacent Dependencies 

Hao Wang<br>University of Pennsylvania

Jason Zevin<br>University of Southern California<br>Calvin Leather<br>University of Southern California<br>Toby Mintz<br>University of Southern California

#### Abstract

Many grammatical dependencies in natural language involve elements that are not adjacent, such as between the subject and verb in "the dog always barks". We recently showed that non-adjacent dependencies are easily learnable without pauses in the signal when speech is presented rapidly. In this study, we used an online measure to look at the relationship between online parsing and the learning performance from the offline assessment of non-adjacent dependency learning. We found that participants who showed current parsing of the language online also learned the dependencies better. However, this pattern disappeared when they are explicitly told where the boundaries are before parsing. Theories of non-adjacent dependency learning are discussed.

# A Plausible Micro Neural Circuit for Decision-Making 

Wei Hui, Dai Dawei, BuYijie (weihui@fudan.edu.cn, dwdai14@fudan.edu.cn)<br>Laboratory of Cognitive Model and Algorithms, Department of Computer Science, Shanghai Key Laboratory of Data Science, Fudan University, Shanghai, China

#### Abstract

An intermediate level between neural circuits and behaviors is neural computations, various behaviors that animals exhibit following some basic control laws can be implemented by some canonical neural computations [Carandini, 2012]. To explore how the microscopic activity of neurons leads to macroscopic behavioral control strategy, we consider basic logic-like operations as some canonical computations in the brain. In this paper, firstly we designed the functional circuits for basic logic-like operations based on the known neurophysiological properties. Secondly, using basic functional circuits constructed a possible neural network for decision logic of animal's behavior. This study provides a general approach for constructing the neural circuits to implement the behavioral control rules. Furthermore, this study will help us to establish a transitional bridge between the microscopic activity of the nervous system and the macroscopic animal behavior.

Keywords: Neural circuits; Logic; Neural computations;

## Introduction

Brain as a complex system, three distinct levels should be understood, i.e., behavior level, algorithm level and implementational level, which is famously known as Marr's tri-level hypothesis [Marr 1982]. The benefit of this clear distinction is that researchers can focus on a certain level and do researches purposefully. In [Carandini, 2012], the brain was analogized to a computer, as we know, all applications in the computer can be reduced to the most primitive operations (Logic instructions) of CPU, so is the brain. Researches indicate that the brain deal with different problems by combining and repeating a core set of canonical neural computations [Carandini \& Heeger, 2011]. We understand the every detail of instructions, which were implemented in CPU; however, we know little about the details of circuit's constitution in brain. However, without a clear link to behavior and computational mechanism, it is hard to understand what is computed. Therefore, "We need a foundational mechanistic, computational framework to understand how the elements of the brain work together to form functional units and ultimately generate the complex cognitive behaviors" [Brown, 2014].

Obviously, understanding the canonical computations in the brain is helpful to reveal the computational framework from circuit to behavior. In this paper, we consider the basic logical operations as some kind of canonical computations in nervous system. Why can the logical operations be considered a kind of canonical computations in nervous system? We make the rational reasoning from the computational perspective, logic reflects the most basic requirement that any computation can be successfully implemented. Thus, the rules through which animals control their behavior can be described by logic language. In order for a biological nervous system to achieve a specific computation, its structure must be sufficiently complex to achieve the basic logic operations. Therefore, there must be many types of neural circuits to achieve various logical rules in the nervous system. Since, any type of behavioral logic can be formally described by propositional logical. With this reliable and complete formal language, we can describe the basic control rules accurately, with which behaviors comply. Furthermore, with different firing mode of neurons and the synergistic connections between pyramidal neurons and intermediate neurons, how does the nervous system assemble a circuit to achieve a set of specific logical rules?

The aim of our work is not to construct the neural network to achieve the logic operations. In this paper, we attempt to explore computational framework how the microscopic neural activities can systematically explain the macroscopic behavior from the logic view.

## Related works

Research indicates that the brain relies on a core set of computations to apply different functions for different problem [Carandini \& Heeger, 2011]. Neural computations, which occur in populations of neurons, are a transitional level from circuit to behavior. Although, some computations have been discovered in nervous system, there are no details of such circuits' constitution. In order to reveal the true mechanism of nervous system the research works involve in different field. Table1 lists the related works.

* Violating basic biological facts includes:(1) the activation mode of the MP model is two-valued, but that of biological neuron is impulse-firing; (2)the type of ANN's neuron is unitary, however, in the biological neural system, not only multiple types of neurons exist but also their proportion matters; (3)the numerical settings of threshold and connection weights of ANN being able to adjust at will are too idealistic; (4)numerical neurons in the same layer working with perfect synchronization are too idealistic, however, time differences of signal transmitting are more general.

## Biological neuron

## Neuron Model

Izhikevich proposed a simple spiking neuron model that reduces the HH model to a 2-D system [Izhikevich, 2003]. Ordinary differential equations are of the form:

$$
\begin{align*}
& \frac{d v}{d t}=0.04 \mathrm{v}^{2}+5 \mathrm{v}+140-\mathrm{u}+\mathrm{I}  \tag{1}\\
& \frac{\mathrm{du}}{\mathrm{dt}}=\mathrm{a}(\mathrm{bv}-\mathrm{u}) \\
& \text { If } \mathrm{v} \geq 30, \text { Then }\left\{\begin{array}{c}
\mathrm{v} \leftarrow \mathrm{c} \\
\mathrm{u} \leftarrow \mathrm{u}+\mathrm{d}
\end{array}\right.
\end{align*}
$$

Interpretation of parameters refers to [Izhikevich, 2003]. In the paper, typical values of parameters for excitatory neuron were: $a=0.02, b=0.25, c=-65, d=8$. Average firing rate (AFR) of pyramidal neuron was between 0 and 21 Hz . Typical values of parameters for inhibitory neuron were: $a$ $=0.1, b=0.2, c=-55 \sim-48, d=2$. AFR of intermediate neuron was between 0 and 200 Hz .

## Time delays in AP transmission

Delay means the time of AP propagating from pre-synaptic neurons to post-synaptic neurons [Tolnai et al, 2009]. A wide range of time delays (up to 20 ms ) could occur. Since most previous studies did not relate to specific behavioral control logic, which was easy to ignore. In fact, the duration from when the AP is generated to its arrival at the postsynaptic neuron is time-critical or time-sensitive. In this paper, the different delays of AP transmission may be similar to "time multiplexing" in signal processing, which plays an important role in behavioral decision logic.

In this paper, we simulated the propagation delays of AP using different queue lengths. For example, using four different queue lengths, as shown in Fig. 1 (b, Queue 1~4), simulated the different delays of AP propagating from the cell body to positions $1 \sim 4$ in Fig. 1(a). If the length of a
queue is $\boldsymbol{n}$, then the AP is delayed $\boldsymbol{n}$ milliseconds. Four queues with sequential increases in length indicated that as the location of the synapse on the axon moved away from the cell body, the delays increased. If an AP was generated in the pre-synaptic neuron, we added 1 to the head of the queue; otherwise, we added 0 . When the end of queue element was 1 , it indicated that the postsynaptic neuron received an AP. Delays of single neuron were limited; if large delays are required in the nervous system, Fig. 1(c) presents a possible way.

Figure 1. Simulation of the delays in AP transmission along an axon using queues.

## The firing rate of pyramidal neurons is adjustable

A study has indicated that intermediate neurons participate in regulating the firing rates of neural networks [Sanders, et al, 2013]. Fig. 2 shows a possible way of implementation that could achieve this regulation of AFR in the nervous system. This cooperative activity in which excitatory neurons and inhibitory neurons regulate the AFR of downstream neurons is a basic mechanism through which nervous systems function.

Figure 2. AFR of downstream neurons can be regulated by different combinations of upstream excitatory and inhibitory synapses.

In Fig. 2, if pyramidal neuron E received AP with a stable AFR from upstream excitatory neurons (Eneus), then the AFR of $E$ could be regulated successfully by increasing or decreasing the firing rate of upstream inhibitory neurons (Ineus), as shown in Fig. 3. Table 2 shows changes in the range of neuron E's AFR with changes in the AFR of upstream Eneus and Ineus. This basic law revealed that nervous systems could regulate output firing rate through a precise configuration of types of neurons and connections.

Figure 3. (a) The AFR of neuron E increased with a decrease in the AFR of upstream Ineus. (b) The AFR of E decreased with an increase in the AFR of upstream Ineus.

Table2. Regulating the AFR of neurons within a certain range.

| AFR of Eneus | $17 \sim 19 \mathrm{~Hz}$ |  |  |  |  |
| :--- | :--- | :--- | :--- | :--- | :---: |
| AFR of Ineus | $0 \sim 50 \mathrm{~Hz}$ | $50 \sim 100 \mathrm{~Hz}$ | $100 \sim 150 \mathrm{~Hz}$ | $150 \sim 200 \mathrm{~Hz}$ |  |
| AFR of E | $16 \sim 18 \mathrm{~Hz}$ | $13 \sim 16 \mathrm{~Hz}$ | $9 \sim 13 \mathrm{~Hz}$ | $3 \sim 9 \mathrm{~Hz}$ |  |

| AFR of E | $14 \sim 16 \mathrm{~Hz}$ | $12 \sim 16 \mathrm{~Hz}$ | $8 \sim 12 \mathrm{~Hz}$ | $5 \sim 8 \mathrm{~Hz}$ |  |

## Neural circuit designs for logic-like operations

AP from pre-synaptic neurons can produce excitatory post-synaptic potentials (EPSP) or inhibitory postsynaptic potentials (IPSP). Since, single AP generates too small EPSP or IPSP to activate or inhibit the postsynaptic neurons; we assume that a train of at least 40 AP could activate the postsynaptic neuron. We employ a group of neurons (neuron cluster) that included 50~100 neurons as a functional unit, which is used to construct circuits to achieve the basic logic-like operations. Since, any of the complex logic can be expressed as a logical expression by four basic logical operations: And, Or, Negation, and Conditional. We implement four circuits that are equivalent to the function of these basic logic operations. The circuits contain excitatory neurons and inhibitory neurons.

In the paper, when a constant stimulus 7.5 adding background noise is presented to a neuron cluster, AFR of cluster is higher than 10 Hz ; while a constant stimulus 3.8 adding background noises is presented, AFR of cluster is lower than 5 Hz . If the AFR of a neuron cluster is higher than 10 Hz , then the proposition expressed by the neuron
cluster is True; if the AFR of a neuron cluster is lower than 7 Hz , then the propositions is False.

## And-like operation circuit

As we know that the concept of the neocortex is as an assemblage of the basic functional units [Jean-Vincent Le Bé, 2007]. Neurons in the fourth layer accept the external signal input from the afferent fibers (area-b in Fig. 4). Small pyramidal cells and intermediate neurons in the second and third layers are responsible for processing the signal (area-a in Fig. 4). In the fifth layer, large pyramidal cells are responsible for propagating the "results" out of the cerebral cortex (area-c in Fig. 4). Axons are shown in black and dendrites are shown in blue.

Figure 4. Morphological principles of connectivity between neocortical neurons (Corresponding to [Jean-Vincent Le Bé, 2007]).

And-like operation is equivalent to that upstream neuron clusters A and B both fire AP at a high rate, followed by neuron cluster C firing at a high rate; otherwise, C fires at a low rate. As shown in Fig. 5-Left, neurons in A and B full connect to neurons in C . A and B represent two propositions, and C achieves the function of operation "A And-like B ". As shown in Fig.5-Right, A and B (corresponding to clusters A and B in Fig.5-Left) that represent the incoming information should be distributed in the fourth layer of the neocortex. C (corresponding to C in Fig.5-Left) that achieves the computation of the And-like operation for A and B should be distributed in the second and third layer. At last, the processing results are propagated out of neocortex by the large pyramidal cells in the fifth layers. We re-layout the Fig.5-Left and obtain the Fig.5-Right. The new circuit satisfies the anatomical discoveries and achieves the logic function. It is a feasible implementation in neurobiology.

Figure 5. Circuit of And-like operation
AFR of A and B are stable due to the stable input. Neuron cluster C receives AP from A , and the time span is so long (about 20 ms ) that the number of AP is small at any given
moment. The distribution property of AP from neurons in cluster B is similar to that of A. If neuron clusters A and B both fire at a high rate, AP trains from A and B at least partially overlap. The purpose of this design is that when only one of the two neuron clusters fires at a high rate, the strength of the subsequent EPSP is too weak to activate C fire at a high rate. However, when A and B both fire at a high rate, due to the overlap of EPSP, the strength of the EPSP is sufficiently strong that C fires at a high rate as well.

However, we found that C would not fire with a high rate every time during the experiment. The EPSP from A and B does not necessarily overlap because the overlap is timecritical or time-sensitive. Thus, it is possible that C fires at a low rate even if both A and B fire at high rate. To avoid such a situation, one feasible way that we used neuron clusters as functional units, and the properties of neurons in a cluster are different, including the model parameters and AP delays. Therefore, initiation of neuronal firing is asynchronous. As a result, EPSP always can be overlapped in C. When A and B both fire at high rate, and C fires with a high rate. Typical values for the delays of neuronal AP are 1 $\mathrm{ms}, 2 \mathrm{~ms}, \ldots 20 \mathrm{~ms}$ in A and B; each delay has the same number of neurons, and the model parameters of each neuron is little different. As shown in Fig. 6, only when neuron clusters A and B both fire at a high rate, does C fire at a high rate [Fig. 6(d)]; otherwise, C fires at a low rate [Fig. 6(a), (b), and (c)]. This circuit performs the function of Andlike operation.

Figure 6. AFR of the And-like operation circuit

## Or-like operation circuit

Or-like operation is equivalent that if at least one of upstream neuron clusters A and B fires AP at a high rate, then C fires at a high rate; otherwise, C fires at a low rate. The structure in Fig5 can also achieve the function of Orlike operation through modifying the parameters to make sure that APs from neuron clusters A and B are synchronous and concentrated, and when one of the two clusters fires at a high rate, at least 40 AP have reached C at one given moment. Typical values for the delays of the neuronal AP are 1 ms for A and 5 ms for B . The purpose of this design is that when at least one of the two neuron clusters (A, B) fires at a high rate, the strength of subsequent EPSP is
sufficiently strong to make C fire at a high rate [as shown in Fig. 7(b), (c), and (d)]. Only when neuron clusters A and B both fire at a low rate, C fires at a low rate [as shown in Fig. 7(a)]. This circuit performs the function of "A Or-like B".

Figure 7. AFR of the Or-like operation circuit

## Conditional-like operation, Negation-like operation circuit

Conditional-like operation is equivalent to a simple projection relationship from upstream to downstream neurons, such that if upstream neurons fires with a high rate, then downstream neurons fires with a high rate; otherwise, downstream neurons fire at a low rate. Negation-like operation is equivalent that if A fires AP at a high rate, then C fires with a low rate; otherwise, C fires with a high rate. As shown in Fig.8-left, neurons in A fully connect to neurons in $I_{1} \ldots I_{m}, E_{1} \ldots E_{k}$ and neurons in $I_{1} \ldots I_{m}, E_{1} \ldots E_{k}$ full connect to neurons in C . In addition, for local circuits: $\mathrm{E}_{1}$ Conditional-like C, and $\mathrm{E}_{\mathrm{k}}$ Conditional-like C. Neurons in $\mathrm{I}_{1} \ldots \mathrm{I}_{\mathrm{m}}$ are all inhibitory, and the others are excitatory. A represents a proposition, and C performs the function of operation "Negation-like A". Its possible form in neocortex is shown in Fig. 8-right.

Figure 8. Circuit of Negation-like operation.
The circuit contains excitatory neurons and inhibitory neurons. When neuron cluster A fires at a high rate, which activate intermediate neuron firing at $60 \sim 110 \mathrm{~Hz}$, and the AP are asynchronous, which led to neuron cluster C receiving nearly continuous IPSP. Thus, neurons in C are inhibited, and C could not fire at a high rate. When A fires at a low rate, the intermediate neurons fire less than 60 Hz , which could not inhibit the activity of downstream neurons. Here, the excitatory signal that from A activated C with "time
division multiplexing" by neuron clusters $E_{1}, E_{2}$, and $E_{3}$ (m $=3, \mathrm{k}=3$ ). Thus, the AFR of C is about 3 times greater than that of A. Typical values of delays from A to $I_{1}, I_{2}$, and $I_{3}$ were $1 \mathrm{~ms}, 10 \mathrm{~ms}$, and 20 ms , and AP delays from A to neuron clusters $E_{1}, E_{2}$, and $E_{3}$ are $20 \mathrm{~ms}, 40 \mathrm{~ms}$, and 60 ms , respectively. AP delays from $\mathrm{I}_{1}, \mathrm{I}_{2}$, and $\mathrm{I}_{3}$ to neuron cluster $C$ are 1 ms , and AP delays from $E_{1}, E_{2}$, and $E_{3}$ to $C$ are 30 ms . Each delay had about the same number of neurons. The above settings are not absolute. The circuit performs the transfer of a low firing rate to a high firing rate [Fig. 9(a)], and a high firing rate to a low firing rate [Fig. 9(b)].

Figure 9. AFR of the Negation-like operation circuit

## Constructing a neural network for a specific behavior based on the logic-like operations

Any of the propositional logical expressions can be transferred into an equivalent conjunctive or disjunctive paradigm. Thus, the nervous system could possibly perform a logic function by realizing the corresponding paradigm.

We demonstrated the implementation of a neural circuit for decision-making logic using a rat's behavioral decision. In the behavioral experiment [Yang et al., 2014], the rat was trained to go to alternate arms of a Y-maze for drinking, and after the training, the rat never made a mistake to the same side two times as shown in Fig. 10. This experiment verified that the rat formed a set of accurate rules for decision making (turning left or right), which depended on the information that the side from which the rat obtained the last drink, and whether the rat reached the neck of the Y-maze.

Figure 10. Behavior decision experiment of rat (Corresponding to [Yang et al, 2014]).

We outlined the behavior in a set of logical expressions: Drink_L, the rat last drank on the left side of the Y-maze; Drink_R, the rat last drank on the right side; Thirsty, the rat
was in a thirsty state; At_Neck, the rat reached the neck of the Y-maze; Turn_L, the rat made a decision with turning left; Turn_R, the rat made a decision with turning right. The decision logic could be described such that the rat was thirsty, and working memory retained the left (or right) side of the Y-maze from which the rat last drank. Then, when the rat reached the neck of the Y-maze again, it executed the command of turning right (or turning left). The process of decision logic could be expressed by a proposition logical expression: (Thirsty $\wedge$ Drink_L $\wedge$ At_Neck $\rightarrow$ Turn_R) $\vee$ (Thirsty $\wedge$ Drink_ $R \wedge A t_{-}$Neck $\rightarrow$ Turn_L). A plausible neural network could achieve this decision logic, as shown in Fig. 11.

Figure11. Neural circuit for rat's decision-making.
Taking the rat executing the turning-right command as an example, the details of the circuit were such that: First, four neuron clusters represented the four propositions, Thirsty, Drink_L, At_Neck, and Turn_R. If the AFR of a neuron cluster was higher than 10 Hz , then the corresponding proposition was true; otherwise it was false. Second, we constructed the neural circuit for the logical expression: Thirsty $\wedge$ Drink_L based on the And-like circuit. Third, we constructed the neural circuit for the logical expression: Thirsty $\wedge$ Drink_L $\wedge$ At_Neck based on the And-like circuit. Finally, we constructed the circuit (Thirsty $\wedge$ Drink_ $L \wedge$ At_Neck) $\rightarrow$ Turn_R based on the Conditional-like circuit. In addition, we designed two groups of intermediate neurons (I3 and I4) between Turn_R and Turn_L to avoid misuse; Drink_ $L$ and Drink_ $R$ were also mutually exclusive, if the two propositions were both true, the decision making would be disordered. When the rat was in a given status, the neuron cluster that expressed the opposite status was inhibited. The complete circuit for decision-making is shown in Fig. 11.

We simulated the process of decision-making for a rat in a Y-maze. As shown in Fig. 12, (L-Choice) If the rat last drank at the right side of the Y-maze (Drink_R=True), then when the rat reached the neck of the Y-maze (At_Neck= True) it executed the command turning-left (Turn_L=True); otherwise, the rat executed the command turning-right (Turn_L=False). (R-Choice) If the rat last drank at the left side of the Y-maze, then when the rat reached the neck of Y-maze, rat executed the command turning-left; otherwise, the rat executed the command turning-right.

Figure 12. Decision-making in Y-maze

## Conclusion

Finally, we summarize our work through Marr's threelevel hierarchy. (a) What is computed? Our answer is that some logical rules are computed. Modeling from this perspective can help us to understand the functional base line of it. (b) Why is it computed? For sake of accurate behavior-controlling, these logical rules must be computed, which is the fundamental demand to a specific behavior. (c) How is it computed? In this paper, we design some types of local neural circuits to achieve four basic logic-like operations as canonical computations and assemble them to simulate a rat's decision making behaviors in Y-maze. Firstly, our circuit design is highly faithful to neurobiological facts like neuron firing mode, two major types of neuron, the proportion constrain of their numbers, and pulse-based mode of communication. Secondly, in the scope of cortical column our logicalequivalent local circuits are biologically plausible to be implemented. Thirdly, these basic functional modular are configurable, reusable and combinable.

We lack a bridge theory from circuit to behavior [Carandini, 2012]. For example, how do microscopic activities of neurons and logical relationships in circuits support the achievement of cognitive ability? Our aim is to construct a biological neural network for behavioral control rules from a logic perspective. This study may be useful for gradually transitioning from microscopic neural activity to macroscopic behavioral control. In our future works, we will explore neural computational mechanism about how a proper circuit is formed.

# The Cognitive Reflection Test: familiarity and predictive power in professionals 

Matthew Brian Welsh ${ }^{1,2}$ \& Steve H. Begg ${ }^{1}$<br>(\{matthew.welsh\}\{steve.begg\} @adelaide.edu.au)<br>1. Australian School of Petroleum, 2. School of Psychology<br>University of Adelaide, North Tce, Adelaide, S.A., Australia

#### Abstract

The CRT is an increasingly well-known and used test of bias susceptibility. While alternatives are being developed, the original remains in widespread use and this has led to its becoming increasingly familiar to psychology students (Stieger \& Reips, 2016), resulting in inflated scores. Extending this work, we measure the effect of prior exposure to the CRT in a sample of oil industry professionals. These engineers and geoscientists completed the CRT, seven bias tasks and rated their familiarity with all of these. Key results were that: familiarity increased CRT scores but tended not to reduce bias susceptibility; and industry personnel, even without prior CRT exposure, scored very highly on the CRT greatly reducing its predictive power. Conclusions are that the standard CRT is not a useful tool for assessing bias susceptibility in highly numerate professionals - and doubly so when they have previously been exposed.

Keywords: cognitive reflection test; familiarity; predictive power; bias; industry professionals.

## Introduction

The Cognitive Reflection Test (CRT), due to its impressive predictive power for biases (Frederick, 2005; Toplak, West, \& Stanovich, 2011), is widely used in bias research. Perhaps its most recognisable item is the following:

A bat and a ball together cost $\$ 1.10$. The bat costs $\$ 1$ more than the ball. How much does the ball cost?
This question and its two companions have strongly intuitive but incorrect answers - 10c in the bat-and-ball question's case - such that answering the questions correctly implies greater reflection on one's answer. Thus, the CRT yields a score from $0-3$ with higher values reflecting greater 'cognitive reflection', which has been linked to lessened bias susceptibility.
Despite the CRT's success, concerns have been raised about it. Firstly, it conflates numerical ability with measurement of decision style (see, e.g., Primi et al., 2015; Weller et al., 2013; Welsh, Burns, \& Delfabbro, 2013); and, secondly, consists of only three, quite memorable items.

While these problems have been previously noted and attempts made to improve the CRT by inclusion of additional items and attempts to reduce the mathematical emphasis (Primi et al., 2015; Thomson \& Oppenheimer, 2016; Toplak, West, \& Stanovich, 2014), the original CRT, due to its speed and ease-of-use, remains in widespread use.

This is problematic in that, once a person has been exposed to the CRT, its usefulness may be compromised. Recent work by Stieger and Reips (2016), for example, has shown that familiarity with CRT questions inflated CRT scores amongst psychology students.

Key questions remain, however. First, whether CRT familiarity extends beyond psychology students to people in industries interested in bias reduction strategies. For example, the oil and gas industry has a 4 decade long history of following the judgement and decision making literature - beginning with Capen's (1976) work on overconfidence. With the success of popular science books like Kahneman's (2011) Thinking Fast and Slow, which are often taken up by managers, it seems likely that industry knowledge of the CRT will also expand. This could render it decreasingly useful as a means of distinguishing between individuals because people who have undertaken decision making training may be increasingly likely to have encountered the CRT or similar questions before.

The second question relates to the degree of familiarity required to undermine the CRT's validity. For example, the above bat-and-ball problem is memorable. Its format, however, is nearly as memorable. That is, assume someone has seen the bat-and-ball question; when, then, asked:
A jug and a cup together cost $\$ 2.20$. The jug costs $\$ 2$ more than the cup. How much does the cup cost?

It seems unlikely that anyone would fail to make the connection between the two. That is, despite not having seen the specific question before, recollection of the question format could be sufficient to prime them for reflection on their answer. This would result in them scoring higher on the CRT - not due to superior cognitive reflection but simple familiarity. Given the low score 'ceiling' of the 3 -item CRT, this could reduce the CRT's ability to predict susceptibility to biases by truncating its range of scores.

## Hypotheses

1. Decision making training courses will increase familiarity with bias questions and CRT.
2. Familiarity will inflate CRT scores.
3. This will reduce the CRT's predictive power.
4. Familiarity will increase bias resistance.

## Method

## Participants

Participants were 116 personnel employed at Australian oil companies. Of these, 93 completed all of the (below) tasks in the allotted time. These included 70 males and 23 females, with a mean age of 41.3 years $(S D=10.8)$ and an average of 16.4 years of industry experience $(S D=10.0)$.

## Procedure

Participants were recruited during several visits to oil
companies and tested in groups of 25-30. They were given the pencil and paper battery of questions described below and allowed 45 minutes to complete it.

## Materials

The questionnaire asked demographic questions, Frederick's CRT (spread throughout the questionnaire) and 10 bias measurement tasks commonly seen in managerial decision making books/courses (see, e.g., Bazerman, 2002). Three of these (base rate neglect, optimism and unpacking) were included for separate analyses and are not discussed here. The remaining biases were: anchoring, overconfidence, framing, conjunctive/disjunctive events bias, sample size invariance, the Wason selection task and illusory correlations. Each, except for overconfidence, was tested using a single item and all were scored in line with the CRT; that is, higher scores indicated less bias susceptibility. The specific tasks are described below.

## Demographics.

Participants provided their age, gender, technical specialty and years of industry experience. They also indicated whether they had undertaken training courses in decision making and when, where and with whom this was done.

## Anchoring.

Participants were asked whether world proved oil reserves in 2009 were greater or less than an anchoring value prior to being asked to make an estimate. The assumption here is that oil industry personnel, while unlikely to have a figure for this already in mind, would be capable of constructing a reasonable estimate from their industry knowledge but that, in line with the anchoring and adjustment heuristic (Tversky \& Kahneman, 1974), people's estimates would tend towards the anchor they had seen. Participants saw one of two anchors $-150 \%$ or $50 \%$ of the known true value, although participants were unaware of this - and were assessed as showing the bias if their estimate was closer to the anchor they saw (scored 0 ) than the unseen alternative (scored 1 ).

## Overconfidence.

This task included 10 questions asking the participant to generate an $80 \%$ confidence interval around an unknown quantity related to the oil industry - a task commonly undertaken the oil industry but at which people are known to perform poorly (see, e.g., Lichtenstein, Fischhoff, \& Phillips, 1982; Welsh \& Begg, 2016).

Performance was calculated as the proportion of generated ranges that contained the true value. This was ten converted to a 0 to 1 scale for easier comparison with the other bias scores with 0 indicating the worst performance and 1 the best as follows: Score $=1$-|Hits/10-.8|*1.25

## Framing.

This question, adopted from Pieters (2004), asked participants to select between options for dealing with a hypothetical oil spill - one certain to reduce it by a set amount $(1 / 3)$ and one giving a $1 / 3$ chance of containing it entirely but a $2 / 3$ chance of it spreading to its maximum
extent. That is, both options had an expected value of a $1 / 3$ reduction in the slick. Half of participants had these explained to them in terms of how much the oil would spread (negative frame) while the rest were told how much oil would be contained (positive frame) by each option.

In line with Prospect Theory (Kahneman \& Tversky, 1979), the expectation is that having the problem framed positively will tend to produce risk aversion - causing participants to select the certain option - while a negative frame tends to result in selecting the riskier option. A participant's response was, thus, scored as to whether they conformed to the Prospect Theory prediction (0) or not (1).

## Conjunctive/Disjunctive Events Bias

This question asked participants to select which of three possible responses to a probability question was correct. Specifically, which event was more likely of: a single $50 \%$ prospect finding oil; all of seven $90 \%$ prospects finding oil ( $\sim 48 \%$ ); or at least one of seven $10 \%$ prospects finding oil ( $\sim 52 \%$ ). As noted by Bar-Hillel (1973), people tend to overestimate the likelihood of conjunctive events and underestimate the likelihood of disjunctive events. Given this, participants were scored 1 if they correctly identified the third option and 0 otherwise.

## Sample Size Invariance.

This task asked whether a statistically unlikely result was more likely to occur in a larger or smaller sample - or be similarly likely. Specifically, participants were asked whether, on a given day, it was more likely that $60 \%$ of oil wells would produce above their average rate in a larger (45 well) or smaller ( 15 well) field. As noted by Tversky and Kahneman (1974), people can pay too little attention to the size of the sample and fail to realise that deviant results are more likely in a smaller sample. Given this, selecting the smaller option was scored correct (1) while any other response was scored incorrect (0).

## Selection Task.

Based on Wason's (1968) selection task, participants were asked which of four oil prospects needed to be retested with an alternative tool in order to test a consultant's claim that Tool 2 would always produce a positive result when Tool 1 did. A correct response (scored 1) was to retest prospects where the Tool 1 had given a positive result and those where Tool 2 had given a negative result. Any other combination of choices was deemed incorrect (scored 0 ).

## Illusory Correlations.

The illusory correlations task (Chapman \& Chapman, 1967), asked participants to examine a $2 \times 2$ contingency table and determine whether the data supported a relationship between two events: AVO anomalies (from seismic data) and hydrocarbon presence. In fact, the data offered no support for this despite a preponderance of observations in the AVO present/HC present cell. Participants were scored as correct (1) only if they correctly identified there was no relationship in the data and that all four cells needed to be examined to establish this fact.

Claiming that the data supported a relationship or that only some cells needed to be examined resulted in a score of 0 .

## Cognitive Reflection Test.

The three questions from Frederick's (2005) CRT were spread amongst the other tasks. A person's score on this task is simply the number of questions answered correctly.

## Familiarity.

At the end of the survey, participants were asked to look back and, for each question, indicate whether they had:

1) Never seen it prior to testing (score 0 ).
2) Seen a similar question previously (score 0.5 ).
3) Seen that exact question previously (score 1).

Tasks involving more than one question (CRT and overconfidence) had the familiarity scores for all composite questions averaged to produce a single, familiarity score.

## Results

## Demographic Data

In addition to the data described in the Method section, several demographic questions were asked of participants. Key observations from this are presented in Table 1.

Table 1: Summary of demographic measures.

| Measure |  |
| :--- | :--- |
| Technical Area | 32 Engineers, 52 Geoscientists, 8 Other |
| Training* | 38 trained, 55 untrained |
| Yrs since training | Mean $=4.8$ years, $S D=4.6$ |

* Training courses in decision making, heuristics and biases.

## Descriptive Statistics

Table 2 summarises participant performance on the various measures and their stated familiarity with the questions. Looking, first, at the scores in Table 2 a number of things are immediately clear. The first is that a majority of participants display bias on each of the bias measures. On the six which reflect a simple proportion correct, the highest mean is 0.32 for the Conjuntive/Disjunctive events bias which reflects chance performance on a three-option choice. On the other, single-item tasks, performance ranges from $12 \%$ up to $27 \%$ correct - indicating a significant majority displaying the expected biases. Overconfidence requires more explanation as it indicates the proportion of generated ranges containing the true value compared to the expected number. Thus, the 0.49 average in Table 1 reflects a person achieving around half of their expected calibration - that is $\sim 40 \%$ of their " $80 \%$ " ranges containing the true value, which is a typically strong level of overconfidence.
Finally, the CRT scores are very high. Frederick's (2005) paper listed 11 samples with average CRT scores ranging from 0.57 to 2.18 (and an overall mean of 1.24). A $95 \%$ CI around the industry sample's mean CRT extends from 2.24 to 2.60 - excluding not just the overall average from Frederick's results but that of the highest group as well.

Table 2's familiarity data also shows interesting results. Specifically, while no familiarity scores are particularly high - recalling that a score of 1 would indicate definitely recalling an entire task - participants' highest familiarity rating is observed for the CRT. The average (0.25) score here lies between what would be observed from participants having recalled seeing one of the CRT's actual questions before ( 0.33 ) and having seen one similar one (0.17).

Table 2: Performance on bias and CRT measures.

|  | Score |  | Familiarity |  |
| :--- | :---: | :---: | :---: | :---: |
| Measure | Mean | $S D$ | Mean | $S D$ |
| Anchoring | 0.27 | 0.45 | 0.23 | 0.27 |
| Framing | 0.27 | 0.45 | 0.12 | 0.23 |
| Con/Disjunctive | 0.32 | 0.47 | 0.14 | 0.24 |
| Sample Size | 0.22 | 0.41 | 0.09 | 0.22 |
| Selection Task | 0.12 | 0.32 | 0.17 | 0.27 |
| Illusory Correlation | 0.17 | 0.38 | 0.16 | 0.30 |
| Overconfidence | 0.49 | 0.31 | 0.20 | 0.25 |
| CRT | $2.42 / 3$ | 0.88 | 0.25 | 0.27 |

Note: $\mathrm{N}=93$. The unshaded parts reflect tasks where the Mean value equals the proportion of correct responses.

## Training and Familiarity with Bias and CRT

To test Hypothesis 1 - that industry courses in decision making would increase familiarity with bias and CRT questions - familiarity ratings of participants with and without such training were compared. Looking at Table 3, Hypothesis 1 is clearly supported by the data. In all cases, participants who had undertaken training courses reported significantly higher familiarity with the bias and CRT questions. An interesting observation, however, is that the CRT is an outlier amongst untrained personnel - its mean familiarity more than double that of any other question. This may go some way to explaining the distribution of CRT scores across the trained and untrained groups, shown in Figure 1, where three-quarters of the trained group score $3 / 3$, but so do half of the untrained group.

Table 3: Familiarity with bias and CRT measures by training group.

|  | training group. |  |  |  |
| :--- | :---: | :---: | :---: | :---: |
|  | Trained | Untrained | $t(91)$ | $p$ |
| Anchoring | .45 | .07 | 8.93 | $<.001$ |
| Overconfidence | .37 | .08 | 6.69 | $<.001$ |
| Framing | .21 | .05 | 3.46 | $<.001$ |
| Con/Disjuntive | .24 | .07 | 3.47 | $<.001$ |
| Sample Size | .18 | .03 | 3.59 | $<.001$ |
| Selection | .33 | .05 | 5.56 | $<.001$ |
| Illusory Corr. | .17 | .05 | 5.12 | $<.001$ |
| CRT | .35 | .18 | 3.21 | .002 |

Note: p-values are two-tailed. Independent samples $t$-tests.

## CRT Familiarity and Score

Hypothesis 2 held that familiarity with CRT questions would inflate CRT scores. The correlation between CRT scores and familiarity with CRT questions supported the hypothesis, showing a weak, significant effect, $r(91)=0.29$,
$p=.004$（see Table 5）．That is，participants who had seen CRT（or similar）questions before scored higher．

Figure 1：Distribution of CRT scores by training group．
To better understand the magnitude of the effect，the CRT scores of participants unfamiliar with all of the CRT questions（i．e．，CRT Familiarity $=0$ ）were compared to those who recalled at least one similar question．Looking at Table 4，one sees that the familiar group scored more than half a mark higher on the CRT，which an independent samples t－test confirmed as a significant difference．

Table 4：Mean CRT scores by familiarity group

## CRT Familiarity

| $0(\mathrm{n}=41)$ | $>0(\mathrm{n}=52)$ | $t(91)$ | $p(2$－tailed $)$ |
| :---: | :---: | :---: | :---: |
| $2.12(S D=1.08)$ | $2.65(S D=0.59)$ | 3.0 | .003 |

## Predictive Power of CRT

Hypothesis 3 held that the inflation of CRT scores as a result of familiarity would reduce the its predictive power－ measured herein by correlations calculated between all bias measures，CRT and CRT familiarity，and shown in Table 5.
Looking at Table 5，one sees that the CRT has relatively little predictive power for the seven biases．It very weakly predicts better performance on the Selection task and on Overconfidence questions．This analysis，however，includes participants familiar and unfamiliar with the CRT．To assess the impact of familiarity on CRT＇s predictive power， correlations were calculated separately for participants familiar and unfamiliar with the CRT as seen in Table 6.

Here，one sees that，the CRT does not significantly predict bias for familiar or unfamiliar participants．The pattern of results，however，is for the correlation to be higher in the group familiar with the CRT（ 5 of 7 biases）．While the smaller samples resulting from dividing the group renders these non－significant，the correlations are higher than the significant ones in the full dataset，suggesting prior CRT familiarity may predict better performance on these biases．
Thus，while the overall result does not，technically， support Hypothesis 3，it identifies the lack of predictive power for the CRT in the industry sample that is unfamiliar with the CRT and suggests that what predictive power is observed in the group familiar with the CRT may result from either prior CRT experience somehow priming people to be more aware of biases－or，more likely，that participants with prior exposure to the CRT may also have experience with bias questions and thus perform better．

Table 5：Correlations between CRT，CRT familiarity and bias measures．

## Familiarity and Bias Resistance

As noted above，the results suggest support for Hypothesis 4 －that familiarity with bias questions would improve performance．Data in Table 5 also show CRT Familiarity has stronger relationships with bias performance than a participant＇s CRT score．Given the likely co－occurrence of bias and CRT questions in decision training courses，the effect of familiarity on bias was thus also examined．

To test this, $\chi^{2}$ tests were conducted for the six, binaryscored biases. Given low numbers of participants recalling seeing exact bias questions before, familiarity with a bias was also treated as binary by combining groups who had seen the exact or a similar question together. Table 7 shows the proportion of correct responses for each of these groups for each bias and the results of the corresponding $\chi^{2}$ tests.

Table 7: Proportion correct by bias question and familiarity.
Familiarity

| Bias Task | 0 | $>0$ | $\chi^{2}(1)$ | p |
| :--- | :---: | :---: | :---: | :---: |
| Anchoring | $0.23(\mathrm{n}=53)$ | $0.33(\mathrm{n}=40)$ | 1.13 | .288 |
| Framing | $0.28(\mathrm{n}=72)$ | $0.24(\mathrm{n}=21)$ | 0.13 | .718 |
| Con/Dis | $0.29(\mathrm{n}=68)$ | $0.40(\mathrm{n}=25)$ | 0.94 | .333 |
| Sample Size | $0.22(\mathrm{n}=78)$ | $0.20(\mathrm{n}=15)$ | 0.02 | .877 |
| Selection | $0.08(\mathrm{n}=65)$ | $0.27(\mathrm{n}=22)$ | 3.54 | .060 |
| Illusory Corr. | $0.16(\mathrm{n}=69)$ | $0.21(\mathrm{n}=24)$ | 0.30 | .584 |
| Overconfidence | $r(93)=0.25$ |  |  | .016 |

Note: $p$ values are two-tailed. Overconfidence and its corresponding familiarity are both non-binary, therefore a correlation is used rather than $\chi^{2}$.

Looking at Table 7, one sees that, participants familiar with bias questions do better in 5 of the 7 tasks but significantly only on the Overconfidence and Selection tasks (given a directional hypothesis). That is, Hypothesis 4 is supported for Overconfidence $(r(93)=0.25, p=.016)$ and the Selection Task $\left(\chi^{2}(1)=3.54, p=.060\right)$ - the two biases showing the strongest relationships with CRT amongst participants familiar with the CRT in Table 6.

## Discussion

The results offer support for two hypotheses: that taking part in decision making training courses increases the likelihood of having seen the CRT or bias questions previously; and that having seen CRT-style questions previously results in a significant increase in CRT score - of more than half a mark on the 0-3 scale. The fact that results (largely) failed to support the other hypotheses has, along with observations on the limited predictive power of the CRT herein, implications for the use of the CRT, as expanded on below.

## Predictive Power of the CRT

As noted above, our third hypothesis was that the CRT's predictive power would be eroded by participant's familiarity with CRT questions. The reasoning being that, given a limited set of memorable questions, prior exposure would push results towards ceiling, weakening the relationship between CRT and the biases. Our results, however, showed CRT having little predictive power to start with. This lack of initial, predictive power in our sample may have made it impossible to convincingly demonstrate the impact of familiarity on CRT's predictive power.
The reason for this lack of predictive power, however, seems to be the same as that prompting our Hypothesis 3 that CRT scores are too close to ceiling. As noted above, even the CRT scores of participants with no familiarity with

CRT questions were, at 2.12 , similar to the highest of the 11 groups tested by Frederick (2005) and much higher than his average of 1.24 .

Part of this, we argue, must stem from the nature of our sample. Rather than undergraduate students, we tested oil industry professionals - primarily engineers and scientists. As such, our sample is likely to have much higher than typical numeracy scores and, consequently, higher CRT scores (for discussions of the links between CRT and numeracy, see, e.g., Weller et al., 2013; Welsh et al., 2013).

While this has made certain of our planned comparisons more difficult - effectively rendering our 'control' group of people unfamiliar with the CRT too similar to those who had prior experience, the implications of this for the use of the CRT in expert samples are more troubling. It suggests that, even prior to their first exposure to the CRT, the skewed scores seen in a sample of technical experts will limit the test's ability to differentiate between individuals and predict performance. Combined with the observation that the CRT's highest predictive power was observed amongst people with prior experience on exactly those biases where prior experience aided the most - this argues against the CRT's usefulness.

While these concerns may be lessened when dealing with experts from less numerically-focussed fields, expert decision making and forecasting tends towards exactly these groups, meaning that the CRT may have limited utility.

## Bias vs CRT Familiarity

Analyses of familiarity with both biases and the CRT used to examine Hypothesis 4 found limited evidence of prior experience with biases improving performance. Only for the Overconfidence and the Selection Task did prior exposure lead to better performance - perhaps due to greater memorability or that understanding these biases suggests a solution. For example, overconfidence implies too narrow ranges, which immediately suggests widening ranges. Such awareness generally reduces but does not remove Overconfidence (Welsh, Begg, \& Bratvold, 2006). Amongst the other biases, little evidence was seen of prior bias question experience enabling one to avoid those biases even in an educated, highly numerate sample.

This is doubly important in light of familiarity's effect on CRT. If CRT is inflated by prior exposure more than bias performance, then knowing who has been exposed to the CRT-style questions becomes essential when interpretting results. Adding to this is the fact that the CRT was more familiar than the biases to people who had not completed training, suggesting that these questions occur through other channels or that CRT questions are particularly memorable.

This seems likely to remain true even when 'similar' tasks are used. The structures of CRT questions, once recognized as 'trick' questions, may trigger greater scrutiny of intuitive answers. Certainly, while few participants indicated having seen the exact CRT questions before, reporting having seen similar ones (for now, ignoring questions about the accuracy of their recall) also resulted in higher CRT scores.

## Future Research

Given the problems observed with CRT, an obvious next step is to attempt a replication using one of the newer variants developed to have less reliance on numeracy and a larger number of items (e.g., Primi et al., 2015; Thomson \& Oppenheimer, 2016; Toplak et al., 2014). Whether such a substitution will work depends on whether familiarity is highly specific for particular question types or simply primes generic "I know this is a trick question" responses.

Another necessary step is to look at biases discussed here in greater detail. While a (mostly) single item per bias approach is useful for an exploratory approach - allowing multiple biases to be examined without overloading the goodwill of participants - binary scoring is, of course, a crude measure of susceptibility to any bias. Research using a set of bias questions for each bias (and focusing on fewer biases so as to keep the total number of questions down) would allow finer-grained measurement of susceptibility and shed further light on the findings discussed herein (and allow more detailed discussion of the biases, their modes of action and some of the controversies in the literature regarding their nature - or even existence).

Finally, the very high CRT scores we observed in our oil industry sample suggest that additional work should be conducted to determine how CRT scores vary in other fields amongst both naïve and CRT-familiar personnel.

## Conclusions

Our results have important implications for the use of the CRT as a bias susceptibility measure for decision making research in professional settings. Our technical experts, while susceptible to biases, have inflated CRT scores resulting from greater numerical ability as well as any prior exposure to CRT-style questions. These effects result in the original CRT retaining little to no predictive power.

Given this, future work is required to see whether alternate versions of the CRT, developed to include more items and be less numerically-based, avoid such problems and can provide useful results in professional populations.

#### Abstract

Research on wishful thinking suggests that desires bias adult's probability judgments. Previous research has yet to explore if this extends to young children. In Experiment 1, 2604 - and 6-year-olds in the U.S. and Peru played a card game, where selecting a desirable card was unlikely. In Experiment 2, 2004 - to 6-year-old children were shown a bag of plastic eggs; a few contained desirable prizes. Children were asked to make predictions about what card / egg would be randomly selected. Answers were compared to control conditions in which probability was comparable, but children had no reason to desire a specific outcome. In control conditions, children tended to state that the majority card/ egg would be selected. In the experimental conditions, children were more likely to state that the desirable (and improbable) card/ egg would be selected. Results suggest that a desire bias extends to children as young as 4 .

# The Interaction of Bayesian Pragmatics and Lexical Semantics in Linguistic Interpretation: Using Event-related Potentials to Investigate Hearers' Probabilistic Predictions 

Markus Werning and Erica Cosentino<br>(\{markus.werning, erica.cosentino\}@rub.de)

Department of Philosophy, Ruhr University Bochum

#### Abstract

We contrast two views of how contextual influence on sentence meaning composition can be explained. The Semantic Similarity View maintains that discourse context affects sentence meaning mainly because of the semantic similarity between the words in the discourse context and the words in the sentence (as measured by Latent Semantic Analysis). The Free Pragmatic View, in contrast, defends the claim that also pragmatic aspects of the discourse context can affect sentence meaning composition. This effect can be quantitatively modelled by Bayesian Pragmatics. We introduce a Predictive Completion Task in which the hearer at every moment in a communicative situation has to generate a probabilistic prediction about how a discourse being uttered by the speaker is continued. We test the predictions of the two views in EEG using the well-established observation that the conditional probability of a word given a context is negatively correlated with the amplitude of its N400 component.

Keywords: Latent Semantic Analysis, Bayesian Pragmatics, N400, Generative Lexicon, Telicity, Affordances, Context, Predictive Coding

## Introduction

It has been widely acknowledged that a preceding discourse can influence the way sentence meaning is composed from lexical meaning. In this paper we want to adjudicate between two competing views of how discourse context affects sentence meaning. A prominent view is that the contextual influence is mainly due to the semantic similarity between parts of the discourse context and the words in the target sentence (e.g., as in semantic priming; Otten \& Van Berkum, 2008). It is however highly controversial whether also pragmatic aspects of the discourse context other than the mere resolution of indexicals and anaphors can immediately affect sentence meaning composition. Nieuwland and Van Berkum (2006) have argued that discourse contexts can overturn violations of animacy. For a noun denoting an object that would normally be regarded as inanimate (e.g. peanut) the feature of animacy can be introduced if the preceding discourse context specifies a suitable situation (e.g., a romantic story whose protagonist is a peanut). Here predicates that would normally conflict with the noun because they require animacy (the peanut was in love) were actually more easily predictable than canonical predicates (the peanut was salted), as revealed by an enhanced N 400 for canonical predicates as compared to animacy-violating predicates.

To investigate the contrast between a Semantic Similarity account of contextual influence and a Free Pragmatic account that allows for free pragmatic enrichment in sentence meaning composition, we will look into the way subjects make probabilistic predictions on the completion of
a sentence given a preceding discourse. Quantitatively, the semantic similarity can be determined by Latent Semantic Analysis (Landauer \& Dumais, 1997), whereas we will use the framework of Bayesian Pragmatics (Frank \& Goodman, 2012) to calculate the pragmatic influence - in particular, concerning the rationality of the speaker's intentions in a narrative. As a model of lexical structure we apply the Generative Lexicon approach (Pustejovsky, 1995). In our experimental design we will use the established observation that the conditional probability of a word given a preceding context is negatively correlated with the amplitude of its N400 component measured in EEG.

## Background

The general idea of Bayesian Pragmatics is to account for the rational cooperation between speaker and hearer in an act of communication by modelling the hearer's probabilistic expectations about the speaker's communicative intentions by Bayes's Theorem. Bayesian pragmatics has been successfully used e.g. to explain results in a number of behavioral experiments (e.g., Frank \& Goodman, 2012). It has so far not been validated in EEG studies.

Bayesian pragmatics offers itself as a model also in what one might call the Predictive Completion Task (PCT) of communication. Predictive coding is widely acknowledged in cognitive science as a general mechanism by which the subject at every point in time generates the most probable prediction of the next event on the basis of ongoing perceptual input and learned statistical regularities (Hohwy, 2013). In a PCT the hearer at every moment in a communicative situation has to generate a probabilistic prediction about how a sentence/discourse being uttered by the speaker will be continued. To get a quantitative grasp of this task, we define $P_{T}(a \mid c)$ as the conditional probability of a sentence/discourse being continued with the word $a$ given that the word is preceded by a context $c$ under the assumption that the complete sentence/discourse is true. We will call $P_{T}$ the truth-guided predictive probability function of the hearer. The problem of the hearer is to estimate the truth-guided predictive probability.

The Semantic Similarity and the Free Pragmatic views provide competing theories of how the hearer accomplishes the Predictive Completion Task. To be able to discern between the two theories and given that the overall frequency of the word $a$ in language use and the syntactic congruency of the word $a$ relative to the preceding context
is known to have a major influence on $P_{T}(a \mid c)$, we will in the course of this paper (and in the experiment) presuppose that the frequency of $a$ is held invariant and that the syntactic congruency between $a$ and its context is granted.

According to the first view, $P_{T}(a \mid c)$ should be estimated solely on the basis of the semantic similarities between the lexical meaning of the word $a$ and the semantic properties of the preceding context $c$. The semantic similarity can be quantified by Latent Semantic Analysis, LSA (Landauer \& Dumais, 1997).

The Free Pragmatic View in contrast maintains that pragmatic aspects of the discourse directly interact with meaning components retrieved from the lexicon as well as with any further node in the sentence meaning composition tree. It thus challenges a rigorous notion of compositionality, according to which the meaning of a complex expression is determined by the meanings of its syntactic parts and the way the parts are combined (Werning, 2004, 2005a, 2005b, 2012). Pragmatic enrichment is supposed to be "free" because not only lateral modulations of a word or phrase are allowed, e.g. when the meaning of a word is modulated by the meaning of its argument - cut the cake (vertical cutting) vs. cut the grass (horizontal cutting) - but any, however remote information can in principle modulate the meaning of a linguistic expression at any stage in semantic composition. For example, cut the grass, given a lawn-seller situation, might be interpreted as vertical cutting. Accordingly, a situation introduced in a discourse preceding the sentence may result in the modulation of the meanings of words or phrases in the sentence and of the sentence itself (Cosentino, Adornetti, \& Ferretti, 2013). These modulations will then influence the intuitive truth-conditions of the sentence. This view, as developed for example by Recanati (2012) amounts to a weakening of the rigorous notion of compositionality by introducing context-dependent semantic flexibility by means of modulation. In the Predictive Completion task Bayesian Pragmatics can be used to quantitatively model the Free Pragmatic account (see Predictions).

## Design

The contrasting quantitative predictions of the Semantic Similarity and the Free Pragmatic views can be applied to a previous EEG experiment of ours (Cosentino, Baggio, Kontinen, Garwels, \& Werning, 2014; Cosentino, Baggio, Kontinen, \& Werning, 2017). To design the experiment we combined a particular idea of Pustejovsky's (1995) Generative Lexicon approach with Gibson's (1979) notion of affordances. According to the Generative Lexicon approach, the lexical entry of concrete nouns (e.g. banana) contain a "Qualia Structure" which, among others, specifies a so-called Telic component (e.g. eat) that is retrieved in sentence meaning composition. This retrieval is typically triggered by verbs like use and enjoy that take the respective noun as argument. This explains why sentences such as (a) and (c) are typically understood as having the meaning of (b) and, respectively, (d):
(a) The child enjoyed the banana.
(b) The child enjoyed eating the banana.
(c) The man used his jackknife for the cake.
(d) The man used his jackknife for cutting the cake.

In turn, Gibson proposed that many objects come with subject- and situation-dependent affordances. These are dispositional properties (e.g., sit-ability) that relate to actions to be potentially performed on that object (Werning, 2010). We distinguish between ad-hoc affordances and generic affordances. Generic affordances are affordances of a class of objects that are represented as part of the mental concept of the class (e.g., chair - sit). Ad-hoc affordances are affordances that a particular object has for a particular agent in a particular situation (e.g., this chair - hide under, for a child in a peekaboo game). In line with Pustejovsky, generic affordances are often stored as telic components in the lexicon of nouns and thus in semantic long-term memory.

| Ctx |  |  |

Table 1. Sample stimuli for EEG experiment on context effects on Telic lexical component. The table illustrates a $2 \times 2$ design, in which two categories of noun-verb combinations, +TLex and -TLex, are combined with two categories of discourse contexts, Telic Standard Context (TStdCtx) and Telic New Context (TNewCtx). The cue verb is underlined while the corresponding noun preceding the cue verb is in bold. The original stimuli were Italian and here are translated to English.

In our $2 \times 2$ experimental design (see Tab. 1) the first variable - TelicLexicalMatch - refers back to Pustejovsky's notion of a Telic component. The Telic component of the lexical entry specifies the function or the purpose of an object. With regard to the variable TelicLexicalMatch the two conditions, +TLex vs. -TLex varied in whether the cue verb (e.g., pour or, respectively, hang) expresses the telic component in the lexical entry of a given noun $n$ (e.g., funnel). With regard to the second variable - TContext - we varied the discourse context such that in the first condition TStdCtx a standard context preceded the target sentence, whereas in the second condition TNewCtx the preceding discourse context introduced a new telic role as an ad-hoc affordance for the object denoted by the noun, facilitating an action expressible by the -TLex verb (hang).

## Predictions

Semantic Similarity View: With word frequency held constant and syntactic congruency granted, the Semantic Similarity view now entails that the only predictor for a verb given its preceding context is the semantic similarity of the former to the latter. Given that we leave the corresponding noun $n$ (funnel), which precedes the cue verb $v_{i}$ (pour/hang), the same in all four conditions, the semantic similarity is a cumulative (i.e. in both arguments strictly monotonously increasing) function $f^{+}$of the semantic similarity $S\left(v_{i}, n\right)$ between the verb and the noun and the semantic similarity $S\left(v_{i}, c_{j}\right)$ between the verb and the preceding context $c_{j}$ excluding the noun. According to this view the truth-guided predictive probability $P_{T, n}\left(v_{i} \mid c_{j}\right)$ of the verb $v_{i}$ following the noun $n$ given the context $c_{j}$ should hence be estimated by the hearer as follows (see Eqn. (4) in Table 2).

Semantic Similarity view:

$$
P_{T, n}\left(v_{i} \mid c_{j}\right)=f^{+}\left(S\left(v_{i}, n\right), S\left(v_{i}, c_{j}\right)\right)
$$

The experimental settings were chosen such that the semantic similarity - determined by LSA -between the cue verb and the context excluding the noun was invariant across all four conditions (see Eqn. (6) in Table 2). Therefore, $P_{T, n}\left(v_{i} \mid c_{j}\right)$ should depend solely on whether the verb expresses the telic lexical component of the noun, i.e. belongs to +TLex, and correspondingly has a high semantic similarity to the noun - determined again by LSA - as opposed to a verb belonging to -TLex with a low semantic similarity to the noun (see (5)). We can now immediately mathematically derive the four comparative predictions regarding $\quad P_{T, n}\left(v_{i} \mid c_{j}\right)$ for $i \in\{+$ TLex, - TLex $\} \quad$ and $j \in\{$ TStdCtx, TNewCtx $\}$. These predictions are captured by the formulae (11), (15), (16) and (17) shown in Table 2 together with their derivations.

Bayesian Pragmatics: If the Free Pragmatic as opposed to the Similarity View is true the hearer will use a different strategy to estimate $P_{T}(a \mid c)$. From a pragmatic point of view, narratives are goal-directed discourses. In our examples the speaker has the goal to attribute an action to the narrative's protagonist which $\mathrm{s} /$ he performs on a given object: In the above examples, performing the action of pouring or, respectively, hanging on the funnel. In the narrative, the speaker embeds this action in a situation which he may introduce by a discourse context that precedes the description of the action. The speaker in other words has to choose a preceding context to let this action appear rational. To describe this choice situation quantitatively we can define the rationality-guided conditional probability $P_{R, n}\left(c_{j} \mid v_{i}\right)$ as the probability of the speaker to choose under the assumption of narrative rationality - a context $c_{j}$ given that he aims at attributing to the protagonist the action denoted by $v_{i}$ to be performed on the object denoted by $n$. Using Bayes's Theorem $P_{R, n}\left(c_{j} \mid v_{i}\right)$ can be transformed to allow the hearer, in the PCT, to estimate the truth-guided
predictive probability by equating it to the rationality-guided probability of the speaker (see Eqns. (1) and (3) in Table 2):

Free Pragmatic view:
$P_{T, n}\left(v_{i} \mid c_{j}\right)=P_{R, n}\left(v_{i} \mid c_{j}\right)$,
where, according to Bayes's Theorem,
$P_{R, n}\left(v_{i} \mid c_{j}\right)=K\left(c_{j}\right) \cdot P_{R, n}\left(c_{j} \mid v_{i}\right) P_{R, n}\left(v_{i}\right)$.
Here $\quad K\left(c_{j}\right)=\left(\sum_{v \in V} P_{R, n}\left(c_{j} \mid v\right) P_{R, n}(v)\right)^{-1} \quad$ is $\quad$ a normalizing factor and $V$ is the set all (syntactically congruent) verbs. We may assume that the rationalityguided prior probability $P_{R, n}\left(v_{i}\right)$ of an action expressed by the verb $v_{i}$ being performed on the object denoted by the noun $n$ is fully determined by the semantic similarity between the verb and the noun as computed by LSA (see Eqn. (2)):

$$
P_{R, n}\left(v_{i}\right)=S\left(v_{i}, n\right)
$$

For, the lexical entry of a concrete noun can be assumed to reflect the semantic memory of the learned statistical regularities between objects denoted by the noun and actions rationally performed on them. This assumption is part and parcel also of the idea that concrete nouns have telic lexical components in the sense of Pustejovsky's (Pustejovsky, 1995) Generative Lexicon. If the verb corresponds to the telic lexical entry of the nouns, the semantic similarity between them should hence be high. In the experimental settings we can implement a comparative variation of the rationality-guided probability $P_{R, n}\left(c_{j} \mid v_{i}\right)$ of the speaker to choose a context $c_{j}$ given that he aims at attributing to the protagonist the action denoted by $v_{i}$ to be performed on the object denoted by $n$ as captured by the inequalities (7)-(10) in Table 2. This immediately allows us to generate comparative predictions about the conditional predictive probability of the hearer as a consequence of the Bayesian interpretation of the Free Pragmatic view. Making the idealizing assumption that the normalizing factor, which is unknown not only to us, but also to the hearer, is the same for all contexts and in particular, $K\left(c_{1}\right)=K\left(c_{2}\right)=K$, we can generate predictions not only for comparisons within the same context, but also across contexts. The so attained predictions of the Free Pragmatic view are captured in formulae (11), (12), (13) and (14) in Table 2, shown together with their mathematical derivation history.

Correlation with N400 amplitude: To test the predictions, we exploited an empirically already well established relationship between the probability of a word given a preceding context and the amplitude of the N400 component of the event-related potential measured on the onset of the word in EEG. Granted that the cue word is syntactically congruent with its context (i.e., no syntactic violation) and that the frequency as well as length of the word are invariant, the truth-guided predictive probability $P_{T}(a \mid c)$ of the word $a$ given the preceding context $c$ is negatively correlated with the amplitude of the word's N400. Support for the negative correlation between the truth-guided predictive probability of a word given a
preceding context and the word's N 400 comes from multiple sources of evidence. Most importantly, Cloze probability is a strong predictor of the amplitude of the N400 component. Cloze probability values are obtained by asking participants in a Cloze task to complete an incomplete sentence with the word they consider to be the most likely completion. Kutas \& Hillyard (1984) found that the amplitude of the N400 component measured on the target word has a nearly inverse linear relationship with its Cloze probability, that is, relative to more expected words, the N400 amplitude increases as the expectancy of a word in context decreases. DeLong, Urbach, \& Kutas, 2005 confirmed that the preceding words in a sentence are used by readers to estimate relative likelihoods for upcoming words and the differences in the likelihood of the target word are reflected in differences regarding the N400 component. This effect has been observed not only in single sentences (Van Petten, Coulson, Rubin, Plante, \& Parks, 1999), but also for short texts (Otten \& Van Berkum, 2007; Van Berkum, Brown, Zwitserlood, Kooijman, \& Hagoort, 2005). Even more subtle differences in the semantic relatedness between the words in a sentence are found to influence the conditional probability of an upcoming word and affect the amplitude of the N400 measured on that word. For instance, in the sentence The girl was writing letters when her friend spilled coffee on the tablecloth/paper" the semantically unrelated word tablecloth elicits a larger N400 than the semantically related word paper (Baggio, van Lambalgen, \& Hagoort, 2008). The integration of world knowledge during the interpretation of sentences such as The Dutch trains are yellow/white/sour and very crowded (the target words are underlined) also modulates the amplitude of the N400 component. This reflects the role of the (Dutch) subjects' knowledge that Dutch trains are typically yellow for establishing the conditional probability of the target word (Hagoort, Hald, Bastiaansen, \& Petersson, 2004). This stresses the point that the predictive conditional probability, in fact, is guided by expectations regarding the truth of the continuing sentence. Additional evidence of a negative correlation between the predictive conditional probability of a word and the amplitude of its N 400 component is provided by a study previously conducted in our laboratory. In a sentence-picture verification study on scalar implicatures, logical and pragmatic responders provide different truth-value judgements to under-informative sentences (e.g., Some As are B, when it is known that all As are B). Whereas logical responders evaluate these sentences as true, pragmatic responders reject them as false. These divergent responses correlate with significant differences regarding the N400 and can be explained on the basis of expected probabilities of words relative to truth presumed by the subject (Spychalska, Kontinen, \& Werning, 2016). Similar findings have been reported in a study about bare numerals (Spychalska, Kontinen, Noveck, Roesch, \& Werning, 2015).

## Experiment

Method: Twenty-two right-handed native speakers of Italian ( 13 males; mean age $=29.2$ years) were presented with a total of 160 stories in a $2 \times 2$ design (see Table 1). The ERPs recording was time-locked to the onset of the cue words, which were always verbs occurring in the midst of the sentence and matched on word length, number of syllables and mean word frequency. The preceding contexts were pair-wise matched for number of words. The experimental stimuli were translated into English and underwent Latent Semantic Analysis to check for the semantic similarity values between the cue verbs and the preceding nouns or, respectively, between the cue verbs and the preceding contexts. Whereas the difference between $S(+$ TLex, $n)$ and $S(-$ TLex, $n)$ was significant $(\mathrm{t}(39)=5,449, \mathrm{p}<.001)$, there was no significant difference between the cue verbs and the preceding contexts across all experimental conditions. Using average amplitude per condition across all EEG electrodes, a 2(Context: TStdCtx vs. TNewCtx) $\times 2$ (TelicLexicalMatch: +TLex vs. - TLex) repeated measures analysis of variance (ANOVA) was performed in the time window between 400 and 500 ms after critical word onset. A follow-up ANOVA was performed which involved specifically a predetermined region over centro-parietal sites at which the N400 is maximal. In this case, a 2(Context: TStdCtx vs. TNewCtx) $\times 2$ (TelicLexicalMatch: +TLex vs. - TLex $) \times 7$ (Electrodes: $\mathrm{CP} 1, \mathrm{CP} 2, \mathrm{CPz}, \mathrm{Pz}, \mathrm{P} 1, \mathrm{P} 2, \mathrm{POz}$ ) ANOVA was conducted. Bonferroni-adjusted planned comparisons were performed to decompose the effect of trial type in this region.

Figure 1. Crossing over regarding the N400 component. Bars show the average amplitude of the N 400 for the four conditions. The numbers in brackets correspond to the inequalities as predicted by the Free Pragmatic View (see Table 2, (11), (12) and (13)). Note that the fact that the difference between the +TLex and the -TLex verb in TNewCtx is not significant is also consistent with Free Pragmatic View (14).

Results: Given the standard context TStdCtx, the N400 for -TLex $(\mathrm{M}(\mathrm{TStdCtx},-\mathrm{TLex})=-1.67 \mu \mathrm{~V})$ is significantly enhanced compared to +TLex $(\mathrm{M}(\mathrm{TStdCtx},+$ TLex $)=-.64$ $\mu \mathrm{V}, \mathrm{t}(20)=3.069, \mathrm{p}=.006$, CI $1.03 \pm .70)$. Relative to the standard context TStdCtx, the TNewCtx significantly enhances the N400 component for +TLex (M(TStdCtx, + TLex $=-1.15 \mu \mathrm{~V}, \mathrm{t}(20)=2.276, \mathrm{p}=.034$, CI $.51 \pm .47)$, whereas it significantly reduces the N 400 component for TLex $(\mathrm{M}(\mathrm{TStdCtx},-\mathrm{TLex})=-.88 \mu \mathrm{~V}, \mathrm{t}(20)=-2.745$,
$\mathrm{p}=.012$, CI $-.79 \pm .60$. Finally, given a preceding context TNewCtx, the mean amplitude of the N400 component measured on +TLex was not significantly different compared to that measured on $-\mathrm{TLex}(\mathrm{t}(20)=.964, \mathrm{p}=.34)$ See Fig. 1. The follow-up ANOVA of the predetermined N400 region showed a significant Contextx TelicLexicalMatch interaction, $\mathrm{F}(1,20)=11.267, \mathrm{p}<.005$. There was no interaction with electrodes in this region.

## Discussion

In order to test the predictions made by the Free Pragmatic View and the Semantic Similarity View, we rely on the empirically well-founded observation that the truthguided conditional probability $P_{T}(a \mid c)$ of the word $a$ given the preceding context $c$ (granted that no syntactic violation is involved and that features such as the frequency and length of the word are constant) is negatively correlated with the amplitude of the N400 component measured on that word succeeding the context.

In our experimental settings, we determined the semantic similarity $S_{n}\left(v_{i}\right)$ between the meaning of the verb $v_{i}$ and the preceding noun $n$ using LSA. This value gives us the prior probability of $P_{R, n}(+$ TLex $)$ and, respectively, $P_{R, n}(-T L e x)$ with the former (pour corresponds to the telic lexical component of funnel) being higher than the latter (hang does not correspond to the lexical component of funnel), as reported in equation (5). We also determined the semantic similarity values between the verb $v_{i}$ and the discourse context $c_{j}$ excluding the noun and kept these values constant across all experimental conditions (see (6)). With regard to what is relevant for the Semantic Similarity View, the experimental conditions differ only in the semantic similarity values between the verb $v_{i}$ and the preceding noun $n$. The Semantic Similarity view entails that these values are the only predictor of differences in the truth-guided conditional probability of the verb given the preceding context and the noun (see (11), (15), (16) and (17)) and, hence, they are the only predictor of differences regarding the amplitude of the N 400 component.

The Free Pragmatic view focuses instead on the differences in the rationality-guided probability of the speaker choosing a certain context given that he attributes to the narrative subject the aim of performing a certain action with an object. In the Free Pragmatic framework, the rationality-guided probability that the speaker chooses a standard context TStdCtx (e.g., funnel in a chemistry experiment) given that he attributes to the narrative subject the aim of performing the action denoted by the +TLex verb (pour) with the object denoted by the noun $n$ (funnel) is higher than that of choosing this context given the attributed aim of performing with that object the action denoted by the -TLex verb (hang) (see inequality (7)). Furthermore, it is more rational for the speaker to choose a context TNewCtx, which introduces a new ad-hoc affordance for the object (funnel glued to the wall), compared to choose the standard context TStdCtx, given that he attributes to the narrative subject the aim of performing the action denoted by the -

TLex verb (hang) with the object denoted by $n$ (see (8)). As captured by inequality (9), the rationality-guided probability of the speaker choosing the standard context TStdCtx compared to TNewCtx is higher given that he attributes to the narrative subject the aim of performing the action denoted by the +TLex verb with the object denoted by $n$. Finally, as expressed by (10), the rationality-guided probability that the speaker chooses TNewCtx given that he attributes to the narrative subject the aim of performing the action denoted by the -TLex verb with the object denoted by $n$ is higher than the rationality-guided probability of choosing this context given the attribution to the narrative subject of the aim of performing the action denoted by the + TLex verb with the object denoted by $n$.

Given that the Free Pragmatic view estimates the truthguided predictive probability of a word by equating it with its rationality-guided probability (see (1)), the Free Pragmatic view not only predicts (11), in line with the Semantic Similarity View, but, in contrast to the Semantic Similarity View, predicts a crossing-over regarding the N400 component, as expressed by the inequalities (12), (13). With regard to the comparison expressed in (14) the Free Pragmatic View does not make an unambiguous prediction. For, a greater/smaller comparison of the values of the product $P_{R, n}\left(v_{i} \mid c_{j}\right)=K\left(c_{j}\right) \cdot P_{R, n}\left(c_{j} \mid v_{i}\right) P_{R, n}\left(v_{i}\right)$ depends not only on the numerical value of the prior probability $P_{R, n}\left(v_{i}\right)$, which is given through the equation $P_{R, n}\left(v_{i}\right)=S\left(v_{i}, n\right)$, but also on the unknown numerical value of and not just the inequalities between the likelihoods $P_{R, n}\left(c_{j} \mid v_{i}\right)$.

Given the negative correlation between the truth-guided conditional probability of a word given a preceding context and the amplitude of its N400 component, the results of our EEG study can be used to directly evaluate the different predictions of the two views. In our experiment, we found that, if preceded by a standard discourse context TStdCtx, a -TLex verb incongruent with the noun's telic component (funnel-hang) elicited an enhanced N 400 compared to a + TLex verb congruent with the telic component (funnelpour) (confirming (11)). However, given a discourse context TNewCtx, in which a new function for the object is introduced as an ad-hoc affordance, we observed a crossingover regarding the direction of the N400 effect: Comparing TNewCtx with TStdCtx, first, the N400 for the -TLex verb was significantly smaller in TNewCtx than in TStdCtx (disconfirming (15) and confirming (12)). Second, the N400 for the +TLex verb was significantly greater in TNewCtx than in TStdCtx (disconfirming (16) and confirming (13)). Finally, given a preceding context TNewCtx , the N 400 measured on the +TLex verb was not significantly different compared to that measured on the -TLex verb (see Fig. 1). This result is not decisive between the two views (neither confirming nor disconfirming (17) and being consistent with (14)).

The reported differences regarding the N400 component are best explained by the assumption that hearer accomplishes the Predictive Completion Task as envisaged
by the Free Pragmatic View, namely by estimating $P_{T, n}\left(v_{i} \mid c_{j}\right)$ through equating it with $P_{R, n}\left(v_{i} \mid c_{j}\right)$ and applying Bayes's Theorem to it. Indeed, the crossing-over regarding the N400 cannot be explained solely in terms of

|  | Free Pragmatic View | Semantic Similarity View |

# The Neural Mechanisms of Relational Reasoning: Dissociating Representational Types 

Julia Wertheim (wertheim@tf.uni-freiburg.de)<br>Cognitive Computation Lab, University of Freiburg, Georges-Köhler-Allee 74, 79110 Freiburg, Germany<br>Marco Ragni (ragni@informatik.uni-freiburg.de)<br>Cognitive Computation Lab, University of Freiburg, Georges-Köhler-Allee 5279110 Freiburg, Germany

#### Abstract

The ability to reason about information is an essential human capability. It is less understood from the perspective of neurocognitive processes which can serve to constrain cognitive theories by implications from neuroscientific data. Despite some progress in the last decades, some disagreement about the experimental results and the cognitive processes of reasoning with abstract relations versus visuospatial relations persist. We conducted a cross-study meta-analysis of neuroimaging studies to determine the neural correlates of visuospatial and abstract relational reasoning. We analyzed 884 stereotactic data points from 38 studies and 692 subjects. We found that relational reasoning is mediated by the frontoparietal network, especially the right precuneus and the left pars triangularis. Problems with abstract relations are processed by enhanced activation in the inferior parietal lobe, whereas visuospatial reasoning is promoted by prefrontal domains. Our results disentangle the neurocognitive mechanisms of different representational types of relational reasoning across study designs.

Keywords: meta-analysis; fMRI; reasoning; relational reasoning; analogical reasoning; mental representation, precuneus, pars triangularis

## Introduction

Relational reasoning expedites human everyday life to a great extent. Using relational expressions can decrease the number of statements we would need otherwise to describe the situation. If we want to 'decompress' this information, we draw inferences from the given information to extract what is implicitly present. For example, suppose you are visiting London for the first time and you want to visit London Eye. You take the underground, arrive at Waterloo Station and ask a fellow passenger for the directions. She tells you that the London Eye is behind Jubilee Gardens which are, from your perspective, in front of Waterloo Station. Due to this description, you can easily find your goal destination. But how would you find your way from the station to London Eye without having any explicit information about the spatial orientation? You do need to reason, that means, you need to extract the information from the two statements by inferring that the London Eye is located behind the train station.

Reasoning has been subject to neurocognitive research for the past thirty years. With the advent of neuroimaging methods such as positron emission tomography (PET) and
functional magnetic resonance imaging (fMRI) in the late 1990 s and early 2000 s, seminal work has been accomplished by investigating the neural correlates of reasoning (Prado, Chadha \& Booth, 2011). The potential for research in relational reasoning is manifold. For instance, Knauff and Johnson-Laird (2002) proposed to differentiate deductive relational reasoning tasks based on the kind of mental representation necessary to represent relations. They established the categories of visual, spatial and visuospatial mental representation of the relations which differs from the mental representation of objects they relate. For our study, we decided to reevaluate the differentiations and employed new definitions for the types of mental representation. A relation helps to structure human experiences about one or many objects in everyday life and they can be of different types. A spatial relation reflects implicitly or explicitly an order of objects (e.g., the apple is to the left of the pear). Such a relation can be perceived by the visual system and additionally by other sensory systems that allow to perceive order such as 'touch' for instance. A pure visual relation in turn is only perceivable by the visual system and by no other perception system (e.g., the grass is greener than the tree). Visuospatial relations are perceivable by both, the visual and other systems, such as 'laying on top of something' - this is an ordered relation and at the same time the relation 'top' presupposes a surface perceived visually. Abstract relations are inconceivable by any sensory systems, such as mental attributions (e.g., smarter than) or abstract mathematical operations (e.g., ' $=$ ').

To the best of our knowledge, there is currently no study investigating such aspects of relational reasoning that directly relate to different degrees of imaginability of relations. To collect a sufficient number of data by often diverse study designs, we decided to use a broader, more inclusive relaxation on the data aggregation. Such a relaxation on the rather strict definitions is necessary since methods such as activation likelihood estimation (ALE) are more accurate for larger datasets (Eickhoff et al., 2016).

On the basis of this experimental background, we decided to investigate relational reasoning in general as well as two of its variants, visuospatial and abstract relational reasoning. Our hypotheses are: (1) For the abstract condition, we expect enhanced activation in the posterior parietal cortex (PPC) (Hobeika, Diard-Detoeuf, Garcin, Levy \& Volle,

2016; Maier, Ragni, Wenczel \& Franzmeier, 2014; Wendelken 2015) and the rostrolateral prefrontal cortex (RLPFC) which are regions known to be involved in the processing of abstract information (Christoff, Ream, Geddes \& Gabrieli, 2003). (2) We expect activation in the right superior parietal lobule (SPL) for the visuospatial condition. This is because it is hypothesized that visuospatial mental representations in reasoning are constructed and maintained by the help of these regions (Maier et al., 2014; Ragni, Franzmeier, Maier \& Knauff, 2016).

To study the neural correlates of relational reasoning we considered 38 experiments with a total of 692 participants and 884 foci to find the neural sites which are most likely to be active during relational reasoning in general and in visuospatial and abstract relational reasoning. The results are interpreted in the light of prior neurocognitive research.

## Methods

We apply the ALE method (Eickhoff, Bzdok, Laird, Kurth \& Fox, 2012) which has become a standard to conduct meta-analyses to investigate neural correlates (e.g., Hobeika et al., 2016). We include as neuroimaging methods functional magnet resonance imaging (fMRI) and positron emission tomography (PET) data.

## Paper Acquisition and Selection

For acquiring neuroimaging data, we conducted several online search queries via the online platforms PubMed, ScienceDirect and Google Scholar to find peer-reviewed fMRI and PET studies (see Table 1) between 1998 and 2017. We used the search terms 'fMRI OR PET OR Neuroimaging', 'relational OR transitive reasoning' and 'visual reasoning OR spatial reasoning OR visuospatial reasoning' in all queries and additionally for the query in Science direct 'healthy', and for Google Scholar 'MNI OR Talairach'. Additional articles were found via the reference lists of similar papers, the meta-analysis conducted by Prado, Chadha and Booth (2011) and the reviews by Knauff (2006) and Maier et al. (2014). Due to a review of the metaanalysis conducted by Prado, Chadha and Booth (2011), 'reasoning vs. baseline' conditions (such as fixation cross or maintenance tasks, see e.g., Wendelken, Nakhabenko, Donohue, Carter \& Bunge, 2008 and Ruff, Knauff, Fangmeier \& Spreer, 2003, respectively) as well as 'highvs. low-level reasoning' conditions were included since they
represent an aspect of reasoning. Additionally, experimental data were only included when they were reported in MNI or Talairach space and yielded from whole brain analyses.

## Paper Categorization

We decided to categorize the data along different axes: by the type of mental representation of the relation (abstract, spatial, visual, visuospatial, none), by the stimulus (letters, sentences, shapes, words, numbers) and the type of stimulus presentation (visual or auditory) (see Tables 1 and 2). We acknowledge that these differences may reflect differences in neural activation as well but chose to only consider the types of mental representation and subtraction for the sake of including more studies in each group and yielding more robust results.

When reviewing the articles, we realized that our definitions for the mental representations of relations did not fit to what can be found in actual studies. Because of that, we decided to lower our criteria so that we merged the groups 'visual', 'spatial' and 'visuospatial' to the group 'visuospatial' (see Table 2). Also, we redefined the criteria so that visuospatial relations are relations that are easy to mentally envision in a spatial and/or visual manner in the aforementioned sense. For abstract tasks, we included all tasks that are impossible to potentially perceive by senses, such as mathematical tasks and operators (e.g., ' $=$ ', '<', ' $>$ ').

## Activation Likelihood Estimation

ALE is an established method for conducting meta-analyses of neuroimaging data (Eickhoff et al., 2012). It is implemented in the statistical tool GingerALE ${ }^{1}$ (we used version 2.3.6) to determine the likelihood of individual brain regions activating for a specific task. GingerALE features the conduction of either single dataset analyses or conjunction and contrast analyses between datasets.

The ALE algorithm maps the stereotactic data of each experiment on a template brain to generate Modeled Activation (MA) maps. Since the reported data are as points, it reconstructs the scanning data by assigning each data point the center of a Gaussian distribution. The points are blurred by the full width at half maximum (FWHM) which is determined by the subject size of the respective dataset (Eickhoff et al., 2012). The MA maps are merged to render the final ALE file. For each voxel, the likelihood confidence of finding each value is calculated by neglecting spatial information from the dataset and analyzing the probabilities of values being part of an MA map. The information from the two files is combined and a threshold is applied to constitute the final ALE map (Eickhoff et al., 2012). In our analysis, we chose a standard setting of 1000 permutations, the cluster-level family-wise error (FWE) method with a $p$-value of 0.01 and an uncorrected $p$ of 0.001 (Eickhoff et al., 2016). The cluster-level FWE method generates a random dataset tantamount to the set at hand (regarding subject size, number of foci and number of

[^540]studies) which is compared to the actual data set. Foci originally represented in MNI (Montreal Neurological Institute) space were converted to Talairach space. In conjunction and contrast analyses, the ALE maps of two sets are examined in activation likelihood for their overlap and distinctness respectively.

Table 2: Details of the paper categorizations with regard to the quantitative parameters of the groups.

| Representation | Studies | Subjects | Foci |
| :--- | :--- | :--- | :--- |
| all | 38 | 692 | 884 |
| abstract | 10 | 179 | 394 |
| spatial | 2 | 16 | 23 |
| visual | 8 | 161 | 47 |
| visuospatial | 28 | 521 | 445 |
| none | 2 | 26 | 23 |

## Results

## Relational Reasoning

For the relational reasoning condition, activation was most likely found in the right precuneus (BA 7) and the left middle occipital gyrus (BA 31). Concerning the frontal lobe, the left inferior frontal gyrus (pars triangularis), left posterior-medial frontal, left and right middle frontal gyrus (BA 6) and the left middle orbital gyrus (BA 46) were found. Additionally, activation was found in the right basal ganglia (Tables 3 and 4).

Table 3: Overview of brain activation

|  | Frontal |  |  |  | Parietal |  | S | O |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  | 46 | 6 | 44 | 45 | 7 | 40 | 13 | 31 |

| Visuospatial |  | 0 | 1 | - | 0 |  |  |  |
| Abstract |  |  |  |  | - | 1 |  |  |

Note. Semicircles indicate significant clusters in the respective hemisphere. Filled halves indicate that the respective side's cluster was larger in this half. Abbreviations: S: Sub-Lobar, O: Occipital.

## Reasoning with Visuospatial Relations

In the visuospatial condition, activation was most likely in the left inferior frontal gyrus (triangularis, BA 44), posterior-medial frontal (BA 6), right and left middle frontal gyrus (BA 6) and the left inferior parietal lobule (hIP3, BA 7) and right superior parietal lobule (BA 7A).

## Reasoning with Abstract Relations

Activation in reasoning about abstract relations was found in the right angular gyrus and left superior parietal lobule (hIP $1 / 3$ respectively, both BA 7) and the left and right inferior frontal gyrus (triangularis, BA 45) and precentral gyrus (BA 45).

Table 4: ALE Results. Only significant clusters and a differentiated anatomical localization is reported.

## Discussion

## Relational Reasoning involves the fronto-parietal network and occipital lobe

For reasoning about relations, we found activation likelihood in the fronto-parietal network (right pars triangularis, posterior-medial frontal lobe, middle frontal gyrus, precuneus, left dorsolateral prefrontal cortex (DLPFC) and pars triangularis). These results are in accordance with the activation detected in the studies by Hobeika et al. (2016) and Prado, Chadha and Booth (2011). The largest cluster was found in the right precuneus (16800 $\mathrm{mm}^{3}$ ). The weighted center of this cluster is located in the frontal precuneus which is assumed to be involved in mental imagery (Cavanna \& Trimble, 2006). The second largest cluster ( $6256 \mathrm{~mm}^{3}$ ) was found in the left pars triangularis, also known as DLPFC. It is known to be involved in working memory and relational integration (Waltz et al., 1999), as well as speech and language production (Foundas, Eure, Luevano \& Weinberger, 1998)

Furthermore, activation was found in the right basal ganglia (BA 13), which are involved in reasoning and rule application (Melrose, Poulin \& Stern, 2007), a demand inductive reasoning tasks pose. Additionally, activation was found in the occipital lobe (left middle occipital gyrus). Prado, Chadha and Booth (2011) did not find such activation for relational reasoning, though they only considered deductive reasoning tasks. This reliable activation pattern might be due to the portion of tasks with visual contents which are not considered classical deduction tasks. In contrast to Prado, Chadha and Booth (2011), Hobeika et al. (2016) and Wendelken et al. (2008), we did not find any activation of the RLPFC. A rather surprising result when considering the consistent reports thereof in the literature.

## Visuospatial relational processing is executed by prefrontal activation

In visuospatial relational reasoning, the fronto-parietal network exhibited activation as well. Activation was mainly found in the left pars triangularis (BA 44) and posterior medial frontal (BA 9) and the inferior parietal lobule (hIP3) and right middle frontal gyrus (BA 45). This suggests that visuospatial relational reasoning is rather mediated by prefrontal activation, considering the multitude of clusters across the PFC. Also, parietal activation in the inferior parietal lobule (IPL) was found, suggesting that visuospatial processing does more heavily rely on context related processes than on mental imagery.

## Abstract relational reasoning relies on the intraparietal sulcus

In the abstract reasoning condition, we found activation in the right intraparietal sulcus (IPS) and left IPL. Since the analysis consisted of 10 studies only, the results are sparse. Nonetheless, they indicate that the IPL is essential for
abstract relational reasoning. Since the IPL is known to be involved in abstraction (Wurm \& Lingnau, 2015), this might imply the IPL's crucial role in the abstraction of contents from relational information.

## Conclusion

The meta-analysis unraveled some crucial details about the neural mechanisms of relational reasoning. Our results suggest that relational reasoning heavily relies on mental imagery and representation as well as a multitude of regions in the prefrontal cortex such as the DLPFC for relational integration and pars triangularis for language processing. No significant activation in the RLPFC was found, opposed to predictions by previous studies. We found striking differences between the type of representation of relations, so that visuospatial relations seem to rather rely on context, opposed to abstract relations which rely on abstraction of relation and mental imagery. Since the inclusion criteria concerning stimulus presentation and task requirements were relaxed, we assume that these areas mediate the general process of relational reasoning.

# How the truth can make a great lie: An empirical investigation of the folk concept of lying by falsely implicating 

Alex Wiegmann (Alex.Wiegmann@psych.uni-goettingen.de) ${ }^{1 *}$<br>Pascale Willemsen (Pascale.Willemsen@rub.de) ${ }^{2 *}$<br>${ }^{1}$ University of Göttingen, Department of Cognitive Science, Gosslerstr. 14, 37170 Göttingen<br>${ }^{2}$ Institute for Philosophy II, Ruhr-University Bochum, Universitätsstraße 150, 44801 Bochum<br>* both authors contributed equally to this research

#### Abstract

Is it possible to lie despite not saying anyhing false? While the spontaneous answer seems to be 'no', there is some evidence from ordinary language that a lie does not require what is said to be believed-false. In this paper, we will argue for a pragmatic extension of the standard definition of lying. More specifically, we will present three experiments which show that people's concept of lying is not about what is said, but about what is implied by saying it that way. We test three Gricean conversational maxims. For each one of them we demonstrate that if a speaker implies something misleading, even by saying something semantically true, it is still considered lying.

Keywords: lying; concept of lying, deceiving; Grice; conversational implicature

## Introduction

According to the standard philosophical definition of lying, an agent lies if she makes "a believed-false statement to another person with the intention that that other person believes that statement to be true" (Mahon, 2008). Such a definition of lying entails four necessary conditions, namely the Statement Condition, the Untruhfulness Condition, the Addressee Condition, and the Intention-to-Deceive Condition. According to Intention-to-Deceive Condition, a lying agent aim to deceive. In order to deceive, however, the lie needs to be directed at someone capable of forming false beliefs (Addressee Condition; for a critical perspective see Rutschmann \& Wiegmann, 2017). The means to deceive the addressee is said to be a linguistic statement. The Statement Condition is not limited to verbal or written statements but further includes other linguistic symbols. Finally, this statement need to be uttered untruthfully. Untruthfulness does not require the uttered statement to be objectively false but that the speaker believes his statement to be false. As a consequence, an agent might be lying even if what she believes to be false turns out true. In an empirical study, Wiegmann, Samland, and Waldmann (2016) demonstrated that lay people's intuitions about lying are in line with the Untruthfulness Condition

However, there seem to be cases in which lies do not even require that the agent believes what is said to be false. Benjamin Franklin famously said that "Half a truth is often a great lie". So-called lies of omission seem quite frequent in ordinary conversations. The American elections 2016 provide many interesting examples in which both presidential candidates were criticized for lying, even though what they said was not, strictly speaking, false. Those cases include oversimplifications, using outdated or misleading statistics
(for instance on the murder rate, African American unemployment, or tax deficits), and suspiciously loose speech.

In this paper, we will empirically test the possibility that lying is not tied to semantic falsity but rather about false implicatures. We hypothesise that at the core of people's concept of lying is the discrepancy between what the speaker believes to be true and the belief she believes to create in the addressee by what she says or by what she implies by saying it.

## Conversational Implicatures

Many philosophers and linguists believe that what is relevant for a conversation is not only what we say but also what we imply by saying it. According to Grice (1975), every conversational context rests on the assumption that both speakers share a conversational goal, for instance making a decision on where to travel, or discussing various political opinions. Conversational goals can be introduced in various ways, most easily by direct questions, such as "Where shall we go for the summer holidays next year?". In light of this shared goal, both speakers can expect the other to be cooperative, that is to make their "conversational contribution such as is required, at the stage at which it occurs, by the accepted purpose or direction of the talk exchange in which [they] are engaged." (Grice, 1975, p. 46) In order to make pursuing this joint conversation goal as efficient as possible, four Maxims should be obeyed:

1. Quantity

- Make your contribution as informative as required (for the current purpose of the exchange)
- Do not make your contribution more informative than is required

2. Quality

- Do not say what you believe to be false
- Do not say that for which you lack adequate evidence

3. Relation (Be relevant!)
4. Manner

- Avoid obscurity of expression
- Avoid ambiguity
- Be brief (avoid unnecessary prolixity)
- Be orderly

Violations of these maxims at the level of what is said are very typical in ordinary language-so typical that we are seldom surprised when people do it. Non-literal speech such as irony ("If you want to have a heavenly summer experience,

I recommend London! Warm and sunny all day!"), metaphors ("You're a peach!"), or hyperbole ("This is the best cake I have ever eaten in my entire life.") provide the most obvious examples in which people immediately infer what is meant beyond what is said (cf. Viebahn, in press). Such an inference is possible because we expect our conversational partner to be cooperative, and therefore interpret even violations of the conversational maxims as furthering the joint communicative goal (cf. Dinges, 2015).

## Lying and Falsely Implicating

If there is such a thing as lying by falsely implicating, it might work very similarly. A speaker utters something that violates a conversational maxim. The addressee immediately tries to infer what this utterance might contribute to the joint conversational goal. However, most crucially, in addition to violating a maxim, the speaker also violates the Cooperative Principle. For the addressee, there is yet no indication that the Cooperative Principle has been violated.
We suggest that lying is not only a matter of what is said but also of what is implied (cf. Meibauer, 2005). If a person intentionally violates a maxim in order to create a belief in the addressee which the speaker believes to be false, this violation is considered a case of lying, irrespective of what is said is true at a semantic level. If this hypothesis is correct, then the Untruhfulness Condition under its semantic reading is too limited to adequately capture the folk concept of lying. Rather, central to the folk concept of lying is a discrepancy between what the speaker believes to be true and what he believes to make the listener believe. Whether this belief is generated by what is said or what is implied by so saying seems to be secondary.

## Experiment 1: Violating the Maxim of Quantity

According to Grice, the Cooperative Principle requires the agent to make their contribution as informative as required, and to not omit relevant information. In our first experiment, we test whether violations of the Maxim of Quantity are considered lies. Our hypothesis presupposes that deceiving by violating conversational maxims is only possible of the addressee believes the speaker to be cooperative, that is to share with her a conversational goal. Consequently, we created vignettes in which to agents conversationally interact and agent A asks a question. Agent B, however, intentionally omits information which he believes to be relevant to agent $A$ but which might also get $B$ into trouble.

In the literature on lies of omission, two variants are discussed. On the one hand, a speaker might completely refrain from making a declarative statement. In our experiment, the speaker suggests changing the topic and asks a question in return. On the other hand, lies of omissions might also be told by using half-truths (Vincent and Castelfranchi, 1981). In the experimental condition Half-Truth, the speaker provides an answer to the question, and, thus, makes a statement. However, he omits the relevant, yet potentially troublesome piece of information. Again, the speaker is not untruthful as he believes his statement to be true. We predict
that participants will consider both scenarios instances of lying.

## Methods

The experiment was run online in the U.K (same in all following experiments) using Prolific Academics. 474 participants started the experiment, 451 were included in the analysis (we excluded participants who did not finish the survey, went through it in less than 40 seconds, or failed an attention check - we used the same criteria in all following experiments). $50 \%$ identified as male, $50 \%$ as female. Mean age was 32 years and participants earned $£ 0.20$ for their participation (same amount in all experiments).

Participants first read general instructions (same procedure in all following experiments). They were then randomly assigned to one of four conditions in a 2 (vignette: Couple vs. Car) * 2 (deception: ChangeTopic vs. Half-Truth) betweensubjects design. They were presented with one of two vignettes, namely either Couple or Car. The Couple vignette reads as follows.

Couple: Peter and Jane have been a couple for a year now. They are very happy and just moved in together. Peter trusts Jane, but he knows about her ex- fiancé Steven who still tries to win Jane back. Thus, Peter is very jealous and does not like Jane meeting Steven. Jane is sometimes thinking about getting back together with Steven. As they work in the same company, they have coffee from time to time to talk about their joint projects. Today, Jane and Steven have coffee after lunch to finalize a cost calculation they are supposed to send to their client the next morning. After a few minutes, Steven asks Jane if they could talk about each other and getting back together. Jane tells Steven that they don't have much time and need to focus on the project.

In the evening, Peter and Jane have dinner. Peter asks Jane "What did you do during your lunch break?"
In the ChangeTopic Condition, the story continued as follows:

To avoid mentioning that she saw Steven during lunch, Jane quickly changes the subject and says:
"Let's talk about something other than work. How was the football training?"

Just as Jane intended, Peter never asks about her lunch break and does not believe Jane met with Steven."

In the Half-Truth Condition, the ending was changed to:
"To avoid mentioning that she saw Steven during lunch, Jane tells Peter only half the truth, omitting her meeting with Steven:
"I had lunch at the cafeteria. Then I had a coffee and went back to the office. It was such a busy day."

Just as Jane intended, Peter never asks about her lunch break and does not believe Jane met with Steven.

After reading the vignettes, participants were asked: "Do you rather agree or disagree with the following statement:

Jane lied to Peter"; and they could choose between "I (rather) agree" and "I (rather) disagree" (same test question and response options in all following experiments except of Experiment 3c).

## Results and Discussion

The results of the experiment are summarized in Figure 1. In the Couple condition, only $30 \%$ ( 34 out of 113) consider Jane's behaviour as a case of lying in ChangeTopic. However, $65 \%$ (74 out of 113) did so in Half-Truth. The difference between ChangeTopic and Half-Truth in the Couple vignette is statistically significant, $\chi^{2}(\mathrm{df}=1, \mathrm{~N}=226)=28.37, \mathrm{p}<$ 0.001 . Moreover, agreement in ChangeTopic is significantly below chance ( $50 \%$ ) level (binomial test, 34 out of 113, test value $=.5, \mathrm{p}<.0 .0001$ ), whereas agreement in Half-Truth is significantly above chance level, (binomial test, 74 out of 113, test value $=.5, \mathrm{p}<.0 .01$ ).
In the Car condition, $56 \%$ ( 60 out of 107) agreed that Nick lied to Kathy when Nick changed the topic. In contrast, $69 \%$ ( 81 out of 118) did so in Half-Truth. The difference between ChangeTopic and Half-Truth in Car is marginally significant $\chi^{2}(\mathrm{df}=1, \mathrm{~N}=225)=3.79, \mathrm{p}=0.0516$. ChangeTopic is not significantly different from chance (binomial test, 60 out of 107, test value $=.5, p=.2459$ ), but Half-Truth is above chance level (binomial test, 81 out of 118, test value $=.5, \mathrm{p}<$ .0.0001). Comparing Car and Couple showed a significant difference for ChangeTopic, $\chi^{2}(\mathrm{df}=1, \mathrm{~N}=220)=15.17$, $\mathrm{p}<0.001$, but no difference for Half-Truth, $\chi^{2} \quad(\mathrm{df}=1$, $\mathrm{N}=231)=0.26, \mathrm{p}=0.61$.
The results of our first experiments allow for a more nuanced view on whether we can lie by omission. If an agent deceives by answering to a question but omits facts which are relevant to the question, the agent is judged to have lied. However, changing the topic and omitting an answer altogether is not considered a case of lying.

Figure 1: Proportions of lie judgments as a function of vignette and kind of deception in Experiment 1

## Experiment 2: Violating the Maxim of Relation

The Maxim of Relation requires a speaker to only provide relevant information. In this experiment, we altered the vignettes used in experiment 1 such that the speaker provides information which is completely irrelevant to the actual question, but which seems relevant. All information that is given is true, and, thus, the Untruthfulness Condition of the standard definition of lying is not met.

## Methods

220 participants started the experiment, 208 were included in the analysis ( $44 \%$ identified as male, $56 \%$ as female). Mean age was 34 years. Participants were randomly assigned to one
of two conditions (vignette: Couple vs. Car) in a betweensubjects design. Here is the vignette for Couple.

Couple: Peter and Jane have been a couple for a year now. They are very happy and just moved in together. Peter trusts Jane, but he knows about her ex-fiancé Steven who still tries to win Jane back. Thus, Peter is very jealous and does not like Jane meeting Steven. Jane is sometimes thinking about getting back together with Steven. As they work in the same company, they have coffee from time to time to talk about their joint projects.
Today, Jane and Steven have coffee after lunch to finalize a cost calculation they are supposed to send to their client the next morning. After a few minutes, Steven asks Jane if they could talk about each other and getting back together. Jane tells Steven that they don't have much time and need to focus on the project. Steven has been sick the whole week, but he has nevertheless been at work.
In the evening, Peter and Jane have dinner. Peter asks Jane:
"You told me about this project with your ex-fiancé. Did you see him today?"
To avoid confirming that she saw Steven during lunch, Jane says:
"Steven has been sick the whole week."
Just as Jane intended, Peter does not believe Jane met with Steven.

## Results and Discussion

The results of the experiment are summarized in Figure 2. Let us start with the Couple vignette. The clear majority of participants, $81 \%$ ( 84 out of 104 ) considered Jane's behaviour a case of lying. This proportion is significantly different from chance $(50 \%)$ level (binomial test, 84 out of 104, test value $=.5, \mathrm{p}<.0 .0001$ ). For the Car vignette, we obtained similar results. $76 \%$ (79 out of 104) considered Nick's behaviour a case of lying. This proportion is significantly different from chance ( $50 \%$ ) level (binomial test, 79 out of 104, test value $=.5, \mathrm{p}<.0 .0001$ ). Comparing Car and Couple showed no significant difference, $\chi^{2}(\mathrm{df}=1, \mathrm{~N}=208)=0.71$, $\mathrm{p}=0.40$. Again, even though the agent was being truthful under a said-based definition of lying, people consider the agents' responses as lies.

Figure 2: Proportions of lie judgments as a function of vignette in Experiment 2

## Experiment 3: Violating the Maxim of Manner

The Maxim of Manner is not so much concerned with what is said, but how it is said. In this experiment, we empirically test whether the violation of its sub-maxims lead to an answer being considered a lie. Experiment 3 is therefore divided into sub-chapters, with section a) investigating Ambiguity and

Context-Sensitivity, section b) Obscurity, and section c) the maxim of Order. In all conditions, what the speakers says is true under a semantic reading, and the speaker is being truthful. However, the speaker deceives the addressee by using ambiguous terms, or terms whose reference is highly context-dependent, or by presenting information in an order that does not reflect the temporal order of events.

In Experiment 3 c , we also address a potential objection to our experiments. It might be argued that the results we have gotten so far are a mere artefact of our experimental design. The argument might go like this: Lying is typically considered a case of deceiving or misleading. In all experiments presented so far, we only asked people whether they agreed or disagreed that the agent lied, and we did not give any alternative options. However, it is well-known that deceiving others for one's own benefit is morally condemned. Thus, participants might have agreed to lie statement only to express their disapproval, while not in fact believing that the agent lied. If we had also asked participants whether the agent deceived, agreement with the lie statement might decline. We believe that this point is well taken. In Experiment 3, we therefore added a new independent variable, namely the number of questions asked after the scenarios.

## Exp. 3a) Ambiguity

Methods 204 participants started the experiment, 197 were included in the analysis. $42 \%$ identified as male, $58 \%$ as female. Mean age was 34 years. Participants were randomly assigned to one of two conditions (vignette: Couple vs. Car) in a between-subjects design.
Car: Nick is a car salesman. He is currently trying to sell a small car. Nick's wife is the boss of the company. They have been a couple since high school. She drives the same model as the one Nick is trying to sell. She is satisfied with her car and the thinks that the boot is spacious enough.

Kathy is interested in buying the car. However, she needs the car for grocery shopping, and to take her two kids to their rugby matches. Thus, she needs a spacious boot. Kathy wonders if the car's boot is big enough for her daily needs. She asks:
"I always need to move a lot of stuff in the boot. This one looks rather small to me. Do you believe that the boot is big enough?"
Nick realizes that Kathy might not buy the car if he can't convince her that the boot is big enough for her daily needs. To avoid mentioning that he only knows one person who drives the car and who is very happy with the boot's size, Nick says:
"My wife has the same car and shared your worries, but then she was surprised how spacious the boot is. Also my boss has never had any problems with the boot. And even my first love in high school with her three kids says that the boot is big enough.".

Just as Nick intended, Kathy believes that Nick knows three different people who are satisfied with the size of the boot. She does not believe that the three people are in fact one and the same person.

## Results and Discussion

The results of the experiment are summarized in Figure 3. For the Couple vignette, the clear majority of participants, $83 \%$ (80 out of 96 ) considered Jane's behavior a case of lying. This proportion is significantly different from chance ( $50 \%$ ) level, (binomial test, 80 out of 96 , test value $=.5, \mathrm{p}<.0 .0001$ ). For the Car vignette, we obtained similar results. $80 \%$ ( 81 out of 101) considered Nick's behaviour a lie. This proportion is significantly different from chance ( $50 \%$ ) level (binomial test, 81 out of 101, test value $=.5, \mathrm{p}<.0 .0001$ ). Comparing Car and Couple revealed no significant difference, $\chi^{2} \quad(\mathrm{df}=1$, $\mathrm{N}=197$ ) $=0.32, \mathrm{p}=0.57$.

In both conditions, participants believed that the speaker told a lie, even though what the speaker said was true and believed to be true. The results put additional pressure on advocates of a semantically grounded understanding of the Untruthfulness condition and the Statement Condition.

Figure 3: Proportions of lie judgments as a function of vignette in Experiment 3a

## Exp. 3b) Obscurity

Methods 210 participants started the experiment, 206 were included in the analysis. $45 \%$ identified as male, $55 \%$ as female. Mean age was 34 years. Participants were randomly assigned to one of two conditions (vignette: Couple vs. Car) in a between-subjects design. They were presented with one of the following stories.

Car: Nick is a car salesman. He is currently trying to sell his brother's car which has 55,000 miles on it. Nick's brother needs to get as much money for the car as possible. For this reason, he set the milometer back to 25,000 miles before asking Nick to sell it. As a consequence of the manipulation, the milometer shows 30,000 miles less than actually driven. Nick has decided to ask for 5000 GBP. Nick knows that if a client learned about the manipulated milometer, Nick won't be able to sell the car for 5000 GBP.

Kathy is interested in buying the car. Kathy is surprised that a 10-year old car has only 25,000 miles on it. She says to Nick:
"Is this milometer accurate?"
To avoid mentioning that the milometer does not show the correct distance driven with this car (55,000 miles), Nick mentions that the milometer measures distances perfectly accurate, in the sense that if you drive one mile the tolerance is less than $0.1 \%$ (i.e., the milometer measures something between 1,758 and 1,762 yards):
"The milometer is super accurate and only allows for a $0.1 \%$ tolerance".

Just as Nick intended, Kathy believes that the milometer shows the correct distance driven with the car, and she does not believe that the milometer was set back.

Results and Discussion The results of the experiment are summarized in Figure 4. The clear majority of participants, $90 \%$ ( 93 out of 103) considered Jane's behavior a case of lying. This proportion is significantly different from chance ( $50 \%$ ) level (binomial test, 93 out of 103 , test value $=.5$, $\mathrm{p}<.0 .0001$ ).
For the Car vignette, the results are similar. 78\% (80 out of 103) agreed that Nick lied to Kathy. This proportion is significantly different from chance ( $50 \%$ ) level, (binomial test, 80 out of 103 , test value $=.5, \mathrm{p}<.0 .0001$ ).

Comparing Car and Couple showed a significant difference, $\chi^{2}(\mathrm{df}=1, \mathrm{~N}=206)=6.10, \mathrm{p}<0.05$, with higher lying rates for the Couple vignette.

Figure 4: Proportions of lie judgments as a function of vignette in Experiment 3b

## Exp. 3c) Order

Methods 407 participants started the experiment, 386 were included in the analysis. $46 \%$ identified as male, $54 \%$ as female. Mean age was 35 years.
Participants were randomly assigned to one of four conditions in a 2 (vignette: Couple vs. Car) x 2 (number of questions: OneQuestion vs. FiveQuestion) in a betweensubjects design.
Couple: Peter and Jane have been a couple for a year now. They are very happy and just moved in together. Peter trusts Jane, but he knows about her ex-fiancé Steven who still tries to win Jane back and works in the same company as Jane. Thus, Peter is very jealous and does not like Jane meeting Steven. Jane is sometimes thinking about getting back together with Steven.

Today, the traffic on Jane's way to work was very busy. At work, Jane always do the things that feels most important for her first and the things she does not consider important last. Peter knows about this habit. He also knows that today Jane is supposed to meet to talk about a joint project but also that the project is not very important. Today, Jane first wants to see Steven. This is not because she thinks that the project is the most important thing to do today but rather because she aches for Steven. So she visits him for a few minutes and discusses a few questions about a joint project. She then works on a big project of a client. Afterwards, she writes a couple of emails to clients and before she drives home she started writing an application for a higher position in her company.
In the evening, Peter and Jane have dinner. Peter wants to know about Jane's day:
"When did you meet Steven?"
To avoid mentioning that seeing Steven was the first thing she did, she does mention this event last:
"The traffic on my way to the company was really busy. I worked on this big project I told you about recently. I wrote a couple of emails to clients and started writing my application for the higher position in our company. I shortly visited Steven, discussed a few question about our joint project and drove home."

Just as Jane intended, Peter thinks that meeting Steven was the last thing she did at work.

In the OneQuestion Condition, participants were asked: "Do you rather agree or disagree with the following statement: Jane lied to Peter". Participants could choose between "I (rather) agree" and "I (rather) disagree". In FiveQuestions, participants were asked: "Do you rather agree or disagree with the following statement:

## Jane deceived Peter.

Jane's behaviour was morally bad.
Jane did not want to hurt Peter's feelings.
Jane's behaviour is blameworthy.
Jane lied to Peter.
And could choose for each statement between "I (rather) agree" and "I (rather) disagree".

Results and Discussion The results of the experiment are summarized in Figure 5. Let us start with the standard (One Question) Couple vignette. The clear majority of participants, ( $74 \%, 68$ out of 92 ) agreed that Jane lied to Peter. This proportion is significantly different from chance ( $50 \%$ ) level (binomial test, 68 out of 92 , test value $=.5, \mathrm{p}<.0 .0001$ ). In the 5Question variant of the Couple vignette, we found a similar pattern. The clear majority of participants ( $75 \%, 74$ out of 99) considered Jane's behaviour a case of lying. This proportion is significantly different from chance (50\%) level, (binomial test, 74 out of 99 , test value $=.5, \mathrm{p}<.0 .0001$ ). There was no significant difference between the OneQuestion and the FiveQuestion variant of the Couple vignette, $\chi^{2}(\mathrm{df}=1$, $\mathrm{N}=191$ ) $=0.02, \mathrm{p}=0.90$.

In the standard (OneQuestion) Car condition, the clear majority of participants ( $86 \%, 83$ out of 96) considered Nicks's behaviour a case of lying. This proportion is significantly different from chance ( $50 \%$ ) level (binomial test, 83 out of 96 , test value $=.5, \mathrm{p}<.0 .0001)$.

This pattern was similar for the 5Question variant of the Car vignette. The clear majority of participants $(79 \%, 78$ out of 99) considered Nick's behaviour a case of lying. This proportion is significantly different from chance (50\%) level (binomial test, 78 out of 99 , test value $=.5, p<.0 .0001$ ). There was no significant difference between the OneQuestion and the FiveQuestion variant of the Couple vignette, $\chi^{2}(\mathrm{df}=1$, $\mathrm{N}=195)=1.992, \mathrm{p}=0.16$.

Deceiving by mentioning the relevant facts in reversed order was considered lying. Furthermore, providing participants with the opportunity to express their moral evaluation of the agent and allowing them to indicate that the agent did only deceive another person (in contrast to: lied to) did not affect lie judgments.

Figure 5: Proportions of lie judgments as a function of vignette and number of questions in Experiment 3c

## General Discussion

Do people consider utterances that are not semantically wrong but pragmatically misleading lies? In this paper, we showed that for something to be a lie, subjective falsity at the semantic level is not necessary. A speaker might say something which is both true and which he believes to be true. What seems to be at the heart of people's concept of lying is that the speaker believes to create a belief in the addressee which he himself believes to be false. Whether this false belief is the result of a wrong statement or a false implicature seems to be secondary. In three experiments, we tested whether the violation of three Conversational Maxims would lead to something semantically true being considered a lie. For all the Maxims (Quantity, Relation, and Manner) this effect showed.

When the speaker violates the Maxim of Quantity by omitting relevant information (Exp. 1), participants considered such a statement to be a lie. These results support those philosophers and linguists who have argued for lies of omissions to be actual lies. However, those results put pressure on a semantically grounded understanding of the standard definition of lying and on authors who have denied that lies of omissions can be actual lies (Mahon 2003; Dynel 2011). Furthermore, Experiments 2 and 3 also indicate that said-based definitions cannot account for people's concept of lying. Our results rather indicate that lying occurs at the level of pragmatics, by deceiving others through falsely implicating.
There are two argumentative lines one might want to argue for in line of our results. The most radical way to deal with our results is to reject the standard definition of lying and to search for a radically new definition that focuses on pragmatics alone. We believe such a dismissal of the standard definition to be too rash. The standard definition seems to adequately capture the folk's intuitions in most cases of lying. However, things get messier around the edges. Alternatively, we suggest a reinterpretation that allows us to adequately map folk intuitions by making as few changes as possible. First, the Untruthfulness Condition seems more appropriately understood at the level of pragmatics. In line with previous research, we suggest maintaining a subjective understanding of untruthfulness, but to decouple it from what is said in the semantic sense. Accordingly, an agent is being untruthful if there is a discrepancy between what the agent believes to be
true and what he believes to communicate by saying something. Second, such an adaption allows for untruthfulness to be demonstrated without making a statement. If our account is appropriate, we believe that an agent may lie by falsely implicating by answering with a question in return ("Did you see your ex-fiancé today?""Are going to ask me this question every day now? What is wrong with you?), by requesting ("Don't you ever ask me this again!"), etc. Additional research is required on the extent to which we should re-interpret the Statement Condition in a more pragmatic fashion.

## Acknowledgments

This project was supported by the Leibniz Association through funding for the Leibniz ScienceCampus Primate Cognition at Georg-August University Goettingen., the Konrad-Adenauer Foundation, and the Research School at Ruhr-University Bochum.

We would like to thank Emanuel Viebahn for challenging discussions and his comments on a previous version of this paper.

# Eliciting Middle School Students’ Ideas About Graphs Supports Their Learning from a Computer Model 

Eliane Stampfer Wiese (eliane.wiese@berkeley.edu)<br>Graduate School of Education, 4407 Tolman Hall, Berkeley, CA 94720 USA<br>Anna N. Rafferty (arafferty@carleton.edu)<br>Computer Science Department, One North College Street, Northfield, MN 55057 USA<br>Marcia C. Linn (mclinn@berkeley.edu)<br>Graduate School of Education, 4611 Tolman Hall, Berkeley, CA 94720 USA

#### Abstract

When middle school students learn science content with graphs, the graphing and science knowledge may be mutually reinforcing: understanding the science content may help students interpret a related graph, and information from a graph may illustrate a scientific concept. We examine this relationship between graphing and science by studying how students learn from interactive computer models with accompanying data graphs. The computer models provide an animated simulation that illustrates an unobservable phenomenon, while the data graph tracks one or more quantities over time. This ordering study, on middle school students learning about photosynthesis, indicates that engaging with novel graph concepts helped students interpret their data as they experimented with the computer model. The study also provided some support for the opposite direction: experimenting with the model first helped students make sense of the graphs.

Keywords: Graphing; Photosynthesis; Knowledge Integration

## Learning From Graphs in Science

Graphs are important in science and improving students' integration of graph and science concepts is often neglected, especially at the middle school level (Lai et al. 2016). Graphs can help students test hypotheses to make sense of new science concepts (e.g., Vitale, Madhok, \& Linn, 2016). When linked to an animated simulation, time-series graphs can record and summarize information that points to key relationships. Identifying the main points of a computer simulation is not trivial for students: animations can be deceptively clear, giving a false sense of understanding (Chiu, Chen, \& Linn, 2013), and students may focus on discrete events instead of looking for an underlying pattern (Vitale et al., 2016). While animations provide visualizations of mechanisms and processes, graphs provide visualizations of relationships between variables. Thus, graphs may help students focus on the underlying quantitative relationships in the animations.

While graphs have the potential to be extremely useful for learning science content, middle school students often have difficulty interpreting them (Lai et al., 2016). Graphs are generally taught in math classes, and students may not spontaneously transfer their knowledge to science contexts (Grant, 2013). Prior work notes common student problems in graph interpretation, many stemming from misunderstanding what the graph axes represent (e.g., Clement, 1985). This type of confusion may result from shallow reasoning based on superficial similarity (e.g., Janvier, 1981) or the ease of extracting
irrelevant data from the graph (e.g., Clement, 1985, McDermott, Rosenquist, Popp, \& van Zee, 1983). Therefore, while graphs can be powerful tools, novices need support to work with them. Misinterpretations of graphs could lead students to misunderstand the science being conveyed. On the other hand, if students have a firm grasp of the science content, that knowledge may help them interpret the graph by constraining potential interpretations to ones that are consistent with their science knowledge (Ainsworth, 2006). It is therefore plausible that graph and science knowledge could be mutually reinforcing. To examine if this reinforcement is uni- or bidirectional, we assigned students to see graph-focused steps either before or after an animated computer model of plant growth. Graph First students learned more science from the simulation, with some advantage for Model First students in interpreting a specific graph feature.

## Photosynthesis in the WISE Platform

The ordering experiment on graphing was implemented via a seventh-grade unit on photosynthesis, which was designed with the Knowledge Integration (KI) framework (Linn, Lee, Tinker, Husic, \& Chiu, 2006), using the Web-Based Inquiry Science Environment (WISE: http://www.wise.berkeley.edu). The unit focuses on processes of energy transformation and aligns with the Next Generation Science Standards (NGSS Lead States, 2013). In photosynthesis, glucose is created and stores energy. The energy is released during cellular respiration. A key difference between photosynthesis (making glucose) and cellular respiration (using glucose) is that plants can only make glucose when there is light, but they must use glucose all the time to perform basic cellular functions. This concept is targeted in the plant growth activities (Figure 1.

The plant growth activities begin with predicting when the plant will make and use glucose (multiple-choice text selection). Next, students interact with the animation from the plant growth model, which shows the plant's glucose stores growing when the light is on and shrinking when the light is off. Students then draw a graph to show their predictions for the cumulative glucose that will be made, used, and stored with the light on for a few weeks and then off, and also select which graph shapes match their predictions (multiple choice: all lines increase with light. In the dark, one is horizontal, one decreases, one increases at the same rate, and one in-

Figure 1: Sequence of activities in Studies 1 and 2.
creases more sharply). Finally, students see the experimental steps: interacting with the full plant growth model (with the graph) and graph interpretation. The two experimental steps, described below, are ordered randomly. Test questions assessed how students connect ideas. As shown in Figure 3a, one prompt presented a graph of glucose stored and asked students to explain how turning the light off affected the shape of the graph (Glucose Stored). Another prompt gave an incorrect prediction: that glucose stored would not change when the light was off (Marcia's Prediction). Students explained if the prediction was correct and matched it to a graph (Figure 3b). These questions were intended to measure how well students can connect a graph's shape to its meaning.

## Exploring the Plant Growth Model

The plant growth model allows students to turn a light on or off, while the accompanying time-series graph shows the cumulative amounts of glucose made, used, and stored (Figure 2F). In this model, glucose is made at a constant rate when the light is on, and glucose is used at a constant rate all the time. Students were again asked when the plant makes and uses glucose. The cumulative graph shows these relationships directly: the running total for glucose made only increases while the light is on, but the running total for glucose used increases until the plant dies.

Students were also asked to run a specific trial with the model: leave the light on for 4 weeks in a row, and then turn it off. This trial shows that plants draw on stored glucose to survive in the dark. To structure students' thinking about this trial, students were asked when the plant died, and what best explained why the plant died (Figure 2k). Correctly answering both questions requires reading the graph.

## Ordering Study: Graph First vs. Model First

The graph that accompanies the photosynthesis model is complex: it is cumulative rather than instantaneous and it presents three quantities changing over time. Science knowledge may help students avoid the error of reading the graph as instantaneous (e.g., the line for glucose made is not zero in the dark). While science knowledge could help students interpret the graph, the graph may also help students learn science by illustrating a relationship between quantities of glucose made, used, and stored that explains how plants survive periods of darkness. The KI framework proposes that eliciting students' ideas is crucial for learning because ideas
cannot be leveraged or inspected if they are not first brought to the student's attention. We designed a graph interpretation step to elicit students' ideas about graphs and to prompt them to connect their ideas about a graph's shape to its meaning. Questions asked if an interpretation of a given graph was correct (e.g., the plant is making glucose when the glucose made line is flat). The graph interpretation step was more extensive in Study 1, and is described in more detail for each study.

To examine the effects of graph and science knowledge on each other, we sequenced the graph interpretation step either directly before or after the computer model. Two seventh grade teachers at Bay Area public schools used this WISE unit to teach photosynthesis, and their students were randomly assigned to either the Graph First or Model First sequence. Students did pre- and post-tests individually, and did the unit individually or in teacher-assigned pairs ${ }^{1}$

## Study 1: Extensive Elicitation of Graph Ideas

We ran the first iteration of the study in six 7th grade classes, all taught by Mrs. R ${ }^{2}$ Students completed a pretest, but it is not included in the analyses because it was not matched to the post-test. Since the pre-test and the unit took longer than Mrs. R. expected, she requested a revised and shortened post-test.

Materials. The post-tes ${ }^{3}$ included the questions Glucose Stored and Marcia's Prediction (Figure 3). Students could access the plant growth model on both the pre- and post-test. The experimental step to elicit students' graph ideas asked students to interpret four cumulative graphs, all showing glucose made, used, and stored when the light was shining (three also showed darkness). Two graphs were consistent with the model and two were incorrect. For each graph, students were given one or two interpretations and asked if those interpretations were correct. In total, the elicitation step included five true/false items (one shown in Figure 2 a ) and three openended prompts for students to explain their reasoning.

[^541]

Figure 2: Screenshots. (a) A true/false graph interpretation item in Study 1. (b) The graph interpretation item in Study 2. (c) The plant growth model, with an animation on the left and graphed the output on the right. Correct answers in bold.

Method and Participants. The pretest was administered over 1-2 class days before students began the unit. Students then worked on the unit for seven class days. Most students worked in teacher-assigned pairs, and they were randomly assigned to the Graph First or Model First conditions (withinclass). Most students completed the model-related steps over two class periods. The posttest was administered two school days after the unit, and took one class period.

177 students across Mrs. R's six classes worked on the WISE unit, with 24 to 35 students per class. Five students worked individually, with the rest in pairs. The 89 groups (176 students; 43 Graph First and 46 Model First) who did the experimental activities are included in the analyses of embedded items. Of those, 173 did the posttest and are included in the post-test analyses.

Results: Embedded Assessments. 96\% of groups correctly selected that the plant would make glucose only when the light was on (Graph First: 98\%, Model First: 93\%). 71\% of groups correctly selected that the plant would use glucose all the time (Graph First: 72\%, Model First: 70\%). Students selected which of four shapes (or none) best matched their ideas for glucose made, used, and stored (all lines increase when the light is on. When the light is off, one increases at the same rate, one increases more sharply, one decreases, and one is horizontal.). Most students selected the correct shapes for glucose made and stored, but only $43 \%$ did so for glucose used. The most common incorrect shape was flat after the light was turned off ( $22 \%$ ). Of students who predicted, in text, that plants would use glucose all the time, only $55 \%$ selected the correct graph. Thus either students hold multiple conflicting ideas about when plants use glucose or are unable to connect their science ideas to the graph shape.

Students were engaged with the model; $93 \%$ of groups ran at least one trial where the plant died. However, students' choice to run the suggested trial (light on for four weeks, then off) differed by condition: $88.4 \%$ of Graph First groups vs. $71.7 \%$ of Model First groups. 70\% of Graph First groups and $45 \%$ of Model First groups chose the correct explana-
tion for why the plant died. A logistic regression on answer correctness (with factors for conditions in this study and the unrelated study) confirmed that there was a main effect of condition on whether they responded correctly $(t(86)=2.27$, $p=.023$ ). A logistic regression on whether students ran the suggested trial found a marginally significant effect of condition $(t(86)=1.92, p=.055)$. To determine if running the trial mediated the effect of condition, we re-ran the previous logistic regression on students' answers with running the trial as an additional factor. Running the trial was the only significant factor $(t(85)=3.20, p=.0014 ; 67.6 \%$ correct if trial was run vs. $16.7 \%$ correct without this trial), indicating that running the trial mediated the effect of condition. Thus, structuring exploration with a specific trial is more effective for learning than non-structured exploration, even when both uncover the key information (i.e. the plant dying).

To determine if lack of engagement in general led students to ignore the directions, we coded all five open-response items within the activity (but before the experimental steps) as on-task (answering the question, correctly or not) or offtask (blank, I don't know, or nonsense answers). 20 responses were coded by two authors with $100 \%$ agreement; remaining responses were coded by one of the authors. Both conditions showed high engagement, with means of $98 \%$ on-task responses (means were 4.91/5 for Graph First, 4.89/5 for Model First, $t(87)=.16, p=.87$ ). We repeated the logistic regression on students' answers with all covariates above and engagement as an additional covariate $(t(84)=0.68, p=.50)$ and found that only running the suggested trial was significant $(t(84)=3.39, p=.0007)$. Repeating the logistic regression on whether students ran the suggested trial with factors for conditions and engagement also showed the same effect: ordering condition was marginally significant $(t(85)=1.90$, $p=.058$ ), and engagement was not $(t(85)=0.54, p=.58)$.

Performance on the graph items did not show differences across conditions, suggesting that interacting with the model first did improve graph interpretation in general. Two questions focused on interpretation of a flat line in a cumulative

2: Vague, incorrect, or not focused on stored glucose. (1) When the light was turned off less glucose was used. (2) no because, if you leave the light off it will die
3: Partially correct or simple. (1) The total glucose stored was steadily going up then when the light turned off it went down. (2) Marcia's prediction is not correct. Even though the plant will not make glucose or use anymore, the amount of glucose stored would go down and so will the glucose made.
4S: Plants survive in the dark by using stored glucose. (1) when the light turned off the plant did not make glucose but only used the glucose that the plant stored. (2) No, a plant to use glucose needs glucose. And plant don't get the needed sunlight when the light is off so has to eat into the glucose stored.
4G: Explanation of graph shapes. (1) Turning the light off in addition to causing the glucose stored to go down, it would also cause the glucose made to stop increasing and just stay the same. Turning the light off would not, however, effect the total glucose used, which would keep going up. (2) Marcia's prediction is incorrect because the glucose stored line in the graph goes down and doesn't stay level.

5: Relating the graph's shape to the plant's use of stored glucose. (1) It affected the shape of the graph because the plant cannot make glucose, so the plant has to use the stored glucose. This makes the stored glucose go down in quantity. (2) No, because if the plant doesn't make any at night and still uses it where is it coming from. It must be the storage and that must make it go down.

Table 1: Rubric for scoring (1) Glucose Stored and (2) Marcia's Prediction (0 is blank, 1 is off-topic or "don't know").
graph. Groups in the Graph First condition had lower average scores on these items than groups in the Model First condition (average score $55 \%$ vs. $80 \%$; ANOVA with factors for conditions in both studies found a main effect of ordering condition: $F(1,88)=13.23, p<.001)$. Both conditions scored near chance for the other items, $46 \%-63 \%$.

Results: Post-Test. The test items Glucose Stored and Marcia's Prediction each have one question with an objectively correct answer (when is the light turned off and which graph matches Marcia's prediction) and one open-response that encourages connections between graph and science ideas. The objective questions were scored as correct or not. For the open-ended questions, we developed KI rubrics that required linking the graph shape to processes of plant growth to get the highest score (a 5). Full explanations of either the graph or the science concepts were scored a 4, and were coded for graph or science ideas (see Table 1 ). Two of the authors coded an initial set of responses for each question, reconciling differences and revising the rubric. The same two authors coded a second test set for each question ( 39 answers for Glucose Stored, with $85 \%$ agreement and Cohen's kappa of $.79 ; 31$ answers for Marcia's Prediction, with $90 \%$ agreement and Cohen's kappa of .85). For both questions, the second test sets included responses from both studies.

For Glucose Stored, most students correctly identified that the light was turned off in week 6 (Graph First: 88\%, Model First: $90 \%$ ). Mean scores for their explanations of how turning the light off affected the shape of the graph were 2.9 overall ( 2.94 for Graph First and 2.85 for Model First). All students scored a 2 or higher, indicating engagement with the task ( 0 s are blank and 1 s are off task). $24 \%$ of the Graph First and $21 \%$ of the Model First condition scored a 4 or 5 .

For Marcia's Prediction, students were below ceiling but above chance for selecting the graph that matched her incorrect prediction (Graph First: 62\% correct; Model First: 57\% correct). Mean scores for their explanations of why the prediction was correct or not were 3.4 overall ( 3.5 for Graph First and 3.2 for Model First). $98 \%$ of students gave on-task answers. $60 \%$ of the Graph First and $50 \%$ of the Model First
condition scored a 4 or 5. A MANOVA on the two explanation items with conditions in both studies as factors showed no significant difference by condition for either study (ordering condition: $F(2,168)=1.2, p=.3)$.

## Study 2: Targeted Elicitation of Graph Ideas

Materials. Since Mrs. R's students took longer than we anticipated to complete the experiment, we shortened the materials before repeating the study with Mr. W's classes. The first questions on the pre- and post-test were the same as on the post-test in Study 1, with additional questions afterward. In the unit, on steps that all students saw in the same order, we removed open-response explanation prompts or replaced them with multiple-choice questions. Since Mrs. R's students were confused about the flat segment of the glucose made line, we added a cumulative graph activity. Students were given a table of glucose made each week and filled in a column with the running total. This running total was then shown as a graph, and students were asked to interpret the flat segment. In Study 1, students drew prediction graphs and then characterized the shapes afterward. In Study 2, we reversed this sequence to help students plan their predictions. We also shortened the steps in the ordering experiment. Instead of eliciting ideas about several graphs, we asked students to interpret the flat segment of the glucose made graph with a multiple choice question and an open-response explanation (see Figure 2b). In the modeling activity we removed all open-ended prompts, and replaced them with one prompt that asked students if their initial predictions on when the plant would make and use glucose had been correct. We retained all multiple choice questions.

Method and Participants. As in Study 1, the pre- and posttest were done individually, each on a single class day, with the pretest two days before students started the unit and the posttest right after. Students did the unit in groups of 1-2 over five class days, with a one-week gap between the first three days and the final two days. As in Study 1, most students took 1-2 class days for the experimental steps.

79 students across Mr. W's 7th grade classes used the

(b) Marcia made this prediction: (1) When the light is off: the amount of glucose stored will not change, the plant will not make more glucose, and the plant will still use glucose. (2) When the light is on, the plant will make, use, and store glucose.

Figure 3: (a) Glucose Stored requires graph interpretation and science knowledge of when a plant makes and uses glucose. (b) Marcia's Prediction requires finding a graph shape to show an idea, and critiquing that idea with science knowledge.

WISE unit, with 23-29 students per class. As in Study 1, groups were assigned randomly to conditions (within-class). 24 groups did not reach the experimental steps and are not included in the analysis. The 10 Graph First groups and 18 Model First groups are included in the analysis below (43 students total. 11 did the unit individually, the rest in pairs). Of those students, 39 did both the pre- and post-test and are included in those analyses (13 Graph First and 26 Model First).

Results: Embedded Assessments. 79\% of groups correctly predicted when the plant would make glucose (Graph First: $90 \%$, Model First: $72 \%$ ) and $29 \%$ correctly predicted when the plant would use glucose (Graph First: 30\%, Model First: $27 \%$ ). Students were not above chance ( $11-25 \%$ ) in selecting which graph shapes matched glucose made, used, and stored. In the most common shape for total glucose made ( $35 \%$ ), the line decreased in the dark, a nonsensical answer for cumulative glucose made. Students with the correct text predictions were somewhat more likely to select the correct graphs, but still performed poorly ( $14 \%$ correct for glucose made and $25 \%$ for stored). These predictions suggest that students struggled both with the science content and the graphs.

Only $75 \%$ of groups interacted with the model. To measured engagement, we coded for on-task responses on earlier step. On the two earlier steps, overall $75 \%$ of responses were on-task (means were 1.6/2 for Graph First, 1.4/2 for model first, $t(26)=.56, p=.57$ ). Despite lower engagement, we ran the same analyses as in Study 1. Graph First groups ran the suggested trial more frequently than Model First (50\% vs. $27.8 \%$ ), but were not more correct in explaining why the plant died ( $10 \%$ vs. $11 \%$ ). These trends were not significant for condition (all analyses here are logistic regressions with factors for conditions in both studies; ordering condition $t(25)=1.17, p=.24$ for suggested trial and $t(25)=0.0$, $p=1.0$ for answering correctly). Of the 10 groups who ran the trial, 3 answered correctly, compared with none of the 18 groups who did not run the trial, but this trend was not significant $(t(24)=.0003, p=.99)$. We repeated the logistic regression on running the trial with engagement as an additional covariate, which was not significant $(t(23)=0.96$, $p=.33)$. The replication of trends but not reliable effects may be due to small sample sizes, lack of engagement, or lack of prior knowledge, leading to very low performance on many items. Performance on the graph interpretation item
was above chance but below ceiling; 54\% of groups correctly said that the plant was not making glucose when the line was flat. There was no significant difference by condition.

Results: Pre- and Post-tests. On Glucose Stored, identification of when the light was turned off rose from pre- to posttest (from 4/13 to 9/13 for Graph First, and from 12/26 to 16/26 for Model First; McNemar test from pre- to posttest, $p=.02$ ). A logistic regression on posttest scores with pretest score and study conditions as covariates was not significant for ordering condition. Mean explanation scores also rose from preto post-test (Graph First: 1.2 to 2.3, Model First: 1.4 to 1.9). For selecting which graph matched Marcia's Prediction, students were below chance at pretest ( $2 / 13$ correct for Graph First, $5 / 26$ for Model First) and just above chance at post-test (Graph First: 4/13 correct, Model First: 7/26). Explanation scores rose from pre- to post-test for the Graph First group (. 6 to 1.6) but not for Model First (. 8 to .7). $82 \%$ of responses at pre-test were blank or off task, with the remaining students answering with incorrect or overly simple ideas. At post-test, 1 Model First and 3 Graph First students had a complex idea about the graph or the science.

A full factorial repeated measures ANOVA with test time, question, and conditions in both studies indicates improvement from pre- to posttest on the explanation items, with significant factors for test time $(F(1,36)=10.3, p=.003)$, question $(F(1,36)=36.7, p<.001)$, and a time by ordering condition interaction $(F(1,36)=4.8, p=.035)$. While estimated marginal means for Graph First were lower than Model First at pretest (.9 vs. 1.1) and higher at posttest (1.9 vs. 1.3), ordering condition was not significant in a MANCOVA on the two post-test explanation scores (with pretest scores as covariates and condition in the unrelated study as a factor).

## Discussion

This study provided support for graph understanding helping students to interpret a science model and some support for science understanding helping students interpret specific graph features. While students had difficulty interpreting cumulative graphs, eliciting students' ideas about those graphs helped them make sense of glucose production, use, and storage in the photosynthesis model.

Graph First students were more likely to figure out that the plant dies when it runs out of stored glucose. Interestingly,
this effect was strongly mediated by whether students ran the suggested trial leading to plant death (significant in Study 1, with the same pattern in Study 2). The finding that elicitation of graph ideas, without feedback, improved learning from the model is consistent with other research on knowledge integration (Linn et al., 2006). The cumulative graph in the model was more familiar to Graph First students since they had just been examining cumulative graphs. To run the suggested trial, students needed to read the graph to turn the light off at the right week, and Graph First students may have extracted this information better than Model First students. Furthermore, students in both conditions were equally engaged on prior steps and engagement was not predictive of following the directions to run the suggested trial. We note that condition differences were significant in Mrs. R's classes, and the pattern was similar in Mr. W's classes.

In both studies, performance was not mediated by running any trial where the plant died, only the suggested trial, which was followed by questions to structure students' thinking. This result is consistent with prior work showing that without structure, students may uncover the necessary information but miss key patterns (Reiser, 2004, Vitale et al., 2016).

Study 1 provides some evidence that exploring the model helped students interpret flat lines in cumulative graphs, as Model First groups performed better than Graph First groups on those questions. Science knowledge may have helped constrain students' interpretations of those graphs. However, there were no condition differences when considering all of the graph interpretation questions together; exploring the model may help only with particular graph features.

This research only varied the order of activities. All students were prompted to think about cumulative graphs before the experimental steps (Figure 1). The treatment elicited students' ideas about relevant graphs by suggesting interpretations that connected graph shapes to their meanings. This treatment may have prepared students to distinguish among alternative interpretations while exploring the model.

Further, this study captures difficulties that students have with cumulative graphs in science. In the graph prediction step, many students chose graph shapes that did not match their text predictions, and in the graph interpretation step, many students agreed with interpretations that did not follow from the given graph. Of the $71 \%$ of Mrs. R's groups who said that plants use glucose all the time, only $55 \%$ of them selected a graph shape that matched this prediction. The most common incorrect answer suggested that students were interpreting the graph as instantaneous instead of cumulative. Mr. W's students also seemed to demonstrate this error: the most common graph selected for glucose made decreased when the light was off. This would have been a more reasonable choice if the graphs were instantaneous instead of cumulative, as it would have been the only shape consistent with the plant making less glucose in the dark. While these examples show difficulties going from meaning to graph, students also had difficulty with the reverse in the graph interpretation
steps. Students in Study 1 were near chance for those steps, and almost half of the groups in Study 2 did not recognize that no glucose is made when that line is flat. Graph misconceptions documented in prior work have focused on instantaneous graphs. Our results show that the type of misinterpretations noted in prior work also affect cumulative graphs (specifically, interpreting the graph as if the axes were different, i.e., instantaneous vs. cumulative). Though students exhibited difficulties, Study 2 shows pre- to post-test improvement on graph interpretation and on explanations.

Conclusion. When learning science from computer models with complex graph output, students may benefit from interpreting graphs before interacting with the model. This study demonstrates the power of eliciting student ideas, a component of the knowledge integration framework that is intended to prepare students to distinguish among alternatives in the experiment (Linn et al., 2006). While graphs are currently under-utilized in middle school science, this study shows how graphs can be leveraged to help students connect graph and science ideas.

# Counterfactual Conditionals and Normative Rules 

Meredith R Wilkinson (mwilkinson@dmu.ac.uk)<br>School of Allied Health Sciences, De Montfort University, The Gateway, Leicester, UK, LE1 9BH<br>Shira Elqayam (selqayam@dmu.ac.uk)<br>Division of Psychology, De Montfort University, The Gateway, Leicester, UK, LE1 9BH<br>Valerie Thompson (valerie.thompson@usask.ca)<br>Department of Psychology, University of Saskatchewan, 9 Campus Drive, Saskatoon, Canada, S7N 5A5<br>David E Over (david.over@durham.ac.uk)<br>Department of Psychology, Durham University Science Site, South Road, Durham, UK, DH1 3LE

#### Abstract

Counterfactual thinking is the consideration of how things could have turned out differently, usually taking the form of counterfactual conditionals. This experiment examined the psychological mechanisms that transform counterfactuals into deontic guidance rules for the future. We examined how counterfactual thinking translates into deontic guidance rules by asking participants to infer these deontic conclusions from the counterfactual premises. Participants were presented with a vignette and a counterfactual conditional, and assigned to either a control condition or a suppression condition in which they were additionally presented with conflicting normative rules. The presence of conflicting norms reduced the likelihood of positive deontic conclusions being endorsed and increased the likelihood of negative deontic conclusions being endorsed. Future intentionality and regret intensity ratings were reduced in the suppression condition. The same conditions that affect normative inference also affect regret and future planning, suggesting similar cognitive mechanisms underlie these processes.

Keywords: conflicting norms; counterfactual thinking; deontic introduction; new paradigm; regret

## Introduction

All of us have to make many deontic judgments about what we 'should' and 'ought' to do. As Elqayam, Thompson, Wilkinson, Evans and Over (2015) note, when we learn about poverty in Somalia, we naturally infer that we ought to donate to famine relief. Such inferences are made on a daily basis, often about such everyday matters as the type of coffee we 'must' or 'should' buy, or the types of food we 'must not' or 'should not' eat. People readily infer these deontic statements from premises that contain no deontic content. However, very little is known about the psychological processes underlying the inferences.

Recently reasoning research has undergone a shift towards the 'new paradigm' of reasoning (Elqayam \& Over, 2013 and see other contributions in this special issue; Evans, 2012). The 'new paradigm' of reasoning rejects binary logic, regards reasoning as strongly related to judgement and decision making, focuses on probabilities and emphasizes pragmatic factors. Such an approach
demonstrates how reasoning can be applied to our everyday judgement and decision making. If this is the case, then it is persuasive that reasoning, judgement and decision making may adopt similar psychological processes.

This paper expands upon our previous work within this area (Elqayam et al., 2015), where we examined how we make such deontic judgements from non-deontic content, a process termed deontic introduction. The next section presents an overview of our previous research on this area with the use of conflicting norms. Our aim for this paper is to see if we can extend Elqayam et al.'s (2015) findings with counterfactual conditionals and this is why the section after examines previous work on counterfactual thinking to set the scene for our own research. Within this section we refer to literature on the functional basis of counterfactual thinking (e.g., Epstude \& Roese, 2008) which provides a rationale for us extending our work on deontic introduction into this domain. The final section before the method section provides an overview of the hypotheses for our current experiment.

## Previous Work on Deontic Introduction

Elqayam et al. (2015) examined the process of deontic introduction which entails making deontic inferences from content that contains no deontic material and which is pragmatic or informal type of inference (e.g., Hahn \& Oaksford, 2007). Deontic introduction is an inference which is socially contextualised, based on previous beliefs and desires and is probabilistic and defeasible (e.g., Oaksford \& Chater, 2007). By defeasible we mean an inference can be withdrawn or suppressed in light of additional information (Elio \& Pelletier, 1997).

Elqayam et al. (2015) propose that deontic introduction depends on a chain of inferences which are largely implicit. We begin with a conditional that bears utility (utility conditional) (e.g., If you pull the dog's tail, then it will bite you). When presented with this statement we make a goal valence inference in that a valenced outcome (positive negative or neutral) is implicitly inferred from the description of the outcome (e.g., being bitten is bad). We
then make a causal inference which infers a causal link between the action and outcome (e.g., pulling the dog's tail makes the dog bite). Given we now have the information that being bitten is bad and that pulling to dog's tail makes the dog bite psychological value passes via the causal link from the inferred goal to the action (e.g., pulling the dog's tail is costly) this is known as valence transference. This then feeds into deontic bridging: the valence can bridge into a novel norm expressed by a deontic operator (e.g., you should not pull the dog's tail).

Elqayam et al. (2015) conducted a series of experiments to test various features of the model. They adopted the same core design throughout their studies: they presented a vignette describing a protagonist and a situation with a utility conditional presented underneath. Then participants had to rate the degree to which it follows that the protagonist must, should and may (positive deontic operator) and must not, should not and need not (negative deontic operator) and going to and not going to (inductive conclusion) take the action to bring around the outcome. This experiment examines Elqayam et al.'s defeasibility hypothesis, and so the inference suppression paradigm was adopted (e.g., Stevenson \& Over, 1995) in which an additional premise is presented to weaken the strength of the initial argument. Our particular focus is on conflicting norms. Say we are informed that going to a particular holiday region will lead us to having a good holiday. Since this is something we wish to do it is likely that we would choose to go to that location. If we are later informed that the particular holiday region has hunts for endangered species, and we are against such hunting, this causes a conflict between the norm generated by deontic introduction and the pre-existing norm presented separately. This blocks deontic bridging by priming a normative conclusion that is opposite to the one generated by deontic bridging. The result is that participants are less likely to infer positive deontic operators when a conflicting norm is presented compared to when it is not, and more likely to endorse negative deontic operators when a conflicting norm is present compared to when it is not, as found by Elqayam et al. (2015). We wish to examine whether this effect occurs for counterfactual conditionals.

## Previous Work on Counterfactual Thinking

Counterfactual thinking can be defined in more than one way, but in the context of this paper, we take it to be considering how things could have turned out differently, for better or worse (see Byrne, 2016 for a review). A student who does not study hard for an exam and then subsequently fails that exam may imagine a world in which they did study and they received a good mark. This process may in turn then lead them to the decision that in future they will study for exams. Whilst such a process of counterfactual thinking elicits emotions such as regret (e.g., Wilkinson, Ball, \& Alford, 2015; Zeelenberg, 1999) it is said to have functional properties in that it can help people
prepare for similar situations in the future (e.g., Epstude \& Roese, 2008).

Research on counterfactual thinking has often employed vignette-based paradigms, where participants are presented with a scenario about a protagonist and are required to make a judgement. This research has yielded some consistent results. One is the temporal order effect, in which actions are regretted more in the short term, and inactions more in the long term (e.g., Gilovich \& Medvec, 1994). Much related research has been done on counterfactual conditionals. These conditionals, of the form if $p$ had been $q$ would have been, presuppose that $p$ and $q$ are false. In the example of us going on holiday to a particular region, it could be asserted, "If I had gone on holiday to that particular region, then I would have enjoyed my holiday better".

When we are faced with a conflicting norm and the outcome turns out negatively we could argue that the outcome was out of our control since taking the action would mean that we behave in a manner which conflicts with our norms in life. In this instance participants may report that the protagonist may feel less regret when a conflicting norm is present relative to when it is not. Previous work has demonstrated that people are more likely to mutate controllable rather than uncontrollable features in the wake of a negative event (e.g., Girotto, Legrenzi \& Rizzo, 1991). If people are more likely to mutate controllable aspects of events, then it may follow that when an outcome is in a protagonist's control participants predict they will feel greater regret in the wake of a negative outcome relative to when it is not as much in their control.

Counterfactual thinking arises from comparing what actually happened to what might have happened. Such comparison, made 'upwards' (it could have been better), or 'downwards' (it could have been worse), help us plan for the future (e.g., Roese, 1994; Epstude \& Roese, 2008). We propose that these future plans are mediated by normative rule generation. For example, faced with a disappointing exam result, a student might think she could have done better had she not been hung over. This in turn leads to the creation of a normative rule, 'I should not drink on an exam's eve'. In the psychology of reasoning, this process is called 'deontic introduction' (Elqayam et al., 2015). Our goal is to study the psychological mechanisms governing this transition from counterfactual thinking to deontic rule, and its effect on future planning

## Hypotheses

This experiment aimed to extend that of Elqayam et al. (2015) by adopting counterfactual conditionals, rather than indicative conditionals, to examine the effect of conflicting norms. Indicative conditionals are of the form 'If $p$ than $q$ ', linking an antecedent $p$ to a consequent $q$. Please see below an example of a set of stimuli for one of the scenarios that participants had to reason about. The predictions were presented with reference to the stimuli.

Martin has a new girlfriend, Gabrielle. He is keen to impress her by cooking a meal and is at the supermarket looking at different oils since he is making an Italian dish. Martin can buy a special olive oil produced in Fontignani. He opts for the cheaper oil and goes home. After he has cooked the meal and serves up he finds that the pasta is a bit greasy. He says to his girlfriend:

If I had opted for the Fontignani olive oil, then our pasta dish would have tasted better. (control condition)

However, the Fontignani olive oil is produced using intensive farming practices. If Martin uses the Fontignani oil, then he will be contributing to environmental degradation of the area (additional information for suppression condition)

There are a number of predictions we have: (1) that conflicting norms will suppress deontic introduction for counterfactual conditionals in the same manner that they do for indicative conditionals. With a conflicting norm present, conclusions with positive deontic operators will be less likely to be rated and conclusions with negative deontic operators more likely to be rated relative to no conflicting norm being present. In the example above, (2) Martin will be viewed as less inclined to use Fontignani oil if there is a conflicting norm present, e.g. a wish to avoid environmental degradation. When participants are asked how likely the protagonist is to take the action in the future, they will rate it as less likely than when a conflicting norm is absent, and (3) the participants will predict the protagonist will feel less regret intensity in the conflicting norm condition relative to the control condition. The reason for this is that they would have needed to take an action that conflicted with a norm (e.g., contribute to environmental degradation) to bring around the desirable outcome.

Both the first and second hypotheses derive out of the work of Elqayam et al. who found that conflicting norms defeated deontic introduction and the third hypothesis relating to regret emerges from the previous literature on counterfactual thinking which indicates that participants are more likely to mutate controllable relative to uncontrollable aspects that led to an unfortunate outcome (e.g., Girotto et al., 1991). It therefore follows that if participants are more likely to mutate controllable aspects then these controllable aspects may in turn lead to the inference that the protagonist will feel greater regret when the situation was in their control and no conflicting norm was present then when the conflicting norm may have taken the outcome somewhat out of their control.

## Method

## Participants

Seventy-eight participants completed the experiment and were recruited via Crowdflower a crowd sourcing platform enabling members of the public to participate in research for a small financial reimbursement. There were 40 females
and 37 males with 1 participant not disclosing gender. Participants age range was 21-75 years. Twenty participants stated Canada was their country of residence, 27 UK, 29 USA and 1 Australia. One participant did not disclose a country of residence. If participants reported a diagnosis of dyslexia, if English was not their first language or they failed to answer the attention checking question correctly their data were excluded from analysis. This left us with 62 participants.

## Experimental Design, Materials and Procedure

A mixed design was adopted. Participants were either randomly assigned to the control condition, in which they were just presented with the vignette and conditional statement or the suppression condition, in which participants were additionally presented with a conflicting norm. Participants had to then complete three tasks which are explained below: (1) a deontic rating task, (2) an intentionality question and (3) a regret intensity question. The independent variables were whether participants were in the condition to which participants were assigned (control or suppression) and the deontic operators (must, should, may and must not, should not and need not). The dependent variables were conclusion rating of the deontic operators from $1=$ definitely does not follow to $7=$ definitely follows, future intentionality rating from $1=$ not at all likely to $7=$ highly likely and regret intensity rating from $1=$ low regret to $7=$ high regret. Each task was presented on a separate page. There was a practice item at the top of each page to get participants used to each task. Participants reasoned about five vignettes. Materials were modified from Elqayam et al. (2015) Experiment 3.

The deontic rating task asked participants to rate the degree to which it followed that the protagonist must, must not, should, may and need not take the action in the vignette. Participants were required to state for each deontic operator whether they thought it definitely does not follow, follows very weakly, follows weakly, follows to some degree, follows strongly or follows very strongly. Participants completed a regret rating task. They had to rate the degree of regret they thought the protagonist would feel on a 7 -point scale from $1=$ low regret to $7=$ a high regret. The future intentionality task asked participants to state the degree to which they thought that the protagonist would be likely to take the action in the future. Again, participants rated this on a 7 -point scale from $1=$ not at all likely to $7=$ highly likely.

## Results

## Deontic Introduction

As can be seen in Table 1, all positive deontic operators receive higher ratings in the control condition relative to the suppression condition and all negative operators receive higher ratings in the suppression condition relative to the control condition. A 2 (condition: suppression or control) x 6 (operator: must, must-not, should, should-not, may and need-not) ANOVA was conducted and found an operator $x$
condition interaction $F(5,255)=12.63, M S E=2.65, p<$ .01, $\eta_{\mathrm{p}}{ }^{2}=.20$. A significant main effect of operator was observed using a Greenhouse-Geisser correction $F(2.73$, $139.25)=45.50, M S E=2.65, p<.05, \eta_{\mathrm{p}}^{2}=.47$ but no main effect of condition $F(1,51)=1.04, M S E=2.56 p=.31$, $\eta_{\mathrm{p}}^{2}=.02$.

Table 1: Mean (and standard deviation) ratings for each deontic operator as a function of condition

| Operator | Control | Suppression |
| :--- | :--- | :--- |
| Must | $4.31(1.62)$ | $2.96(1.15)$ |
| Should | $5.55(0.92)$ | $3.80(0.93)$ |
| May | $5.37(1.21)$ | $4.93(1.19)$ |
| Must not | $1.96(1.28)$ | $2.76(1.38)$ |
| Should not | $2.06(1.35)$ | $3.09(1.24)$ |
| Need not | $2.93(1.24)$ | $3.54(1.62)$ |

In order to unpack the operator x condition interaction, we conducted six independent samples t-tests for each operator separately. This was found to be significant for the operators must, should and should not with a $p<.008$ with the adoption of a Bonferroni correction but not for the must not $p=.03$, may $p=.19$ and need-not $p=.13$. These fit with our first hypothesis that conflicting norms will lead to lower ratings for positive deontic operators compared to the control condition with the reverse the case for negative deontic operators.

## Future Intentionality and Regret Ratings

We then examined the future intentionality ratings comparing the control condition to the suppression condition. We compared mean likelihood ratings across the scenarios for the control and suppression conditions and found future intention ratings were higher in the control condition $(M=5.95, \mathrm{SD}=0.49)$ compared to the suppression condition $(M=4.48, S D=0.96)$ a finding which reached significance when conducting an independent samples t-test $t(51)=6.80 p<.01$. This supports our hypothesis that future intentionality will be weakened in the suppression condition.

Our final analysis considered the reported regret intensity that participants thought the protagonist would feel. It was found that participants thought the protagonists in the control condition would experience greater regret intensity $(\mathrm{M}=5.61, \mathrm{SD}=0.66)$ comparative to the suppression condition $(\mathrm{M}=4.44, \mathrm{SD}=1.09)$ a finding which was significant when undertaking an independent samples t-test $t(51)=4.58, p<.01$. This supports our hypothesis that the level of regret intensity the participant thinks the protagonist will feel is less in the suppression condition compared to the control condition.

## General Discussion

The aim of this experiment was to examine the process of deontic introduction for counterfactual conditionals rather than indicative conditionals. We examined the defeasibility
hypothesis adopting conflicting norms to block the deontic bridging stage of deontic introduction. We proposed three hypotheses at the start of our paper (1) that conflicting norms will suppress deontic introduction in the context of counterfactual conditionals, as they do with indicative conditionals, (2) when a conflicting norm is present participants will rate the protagonist's intention to take the action in the future as lower than when no conflicting norm is present and (3) when a conflicting norm is present regret intensity for the outcome will be rated as lower compared to when no conflicting norm is present.

Support was found for the first hypothesis with positive deontic operators rated as lower in the conflicting norms condition relative to the control condition with the reverse pattern occurring for negative deontic operators. This finding supports the defeasibility hypothesis of Elqayam et al. (2015) and extends to findings of Elqayam et al. to counterfactual conditionals. We propose the same explanation for these findings that Elqayam et al. offer in their paper. Deontic bridging is not able to occur due to a conflict between the pre-existing norm and the invited normative conclusion (generated by deontic introduction).

When it came to our item analysis for each of the operators we observed significant effects for must, should and should not. Taking into consideration the marginal significant effect of must not we note that the significant differences lie in those operators that express obligations and forbidding but not permissions. This finding suggests that perhaps the role of counterfactual thinking is to direct future action, making it functional (e.g., Epstude \& Roese, 2008). In this respect, obligations and forbidding are more powerful than permissions, and this could provide an explanation for the pattern of results we observed.

Our second hypothesis was that, for future intentionality ratings, participants would predict the protagonist would be less likely to take the action when a conflicting norm was present compared to when it was not. This is what we found. We propose that this result occurs because a conflicting norm prevents deontic bridging. Such a finding supports our prediction that deontic introduction can be used to direct future actions as a result of the presence of counterfactuals. This is in line with the notion of counterfactual thinking is functional (e.g., Epstude \& Roese, 2008).

Our third hypothesis was participants would report the protagonist feeling less regret when a conflicting norm was present compared to when it was not. This hypothesis was supported. We propose that this finding may occur for one of two reasons. The first is that the conflicting norm serves to distance the protagonist from the regretted incident by providing a justification or rationale for them not taking the action. In the case of Martin and the Fontignani olive oil, that justification would be the conflict between having the better meal and the fact that he does not want to contribute to environmental degradation. If this process is occurring, the decision could be seen as self-enhancing allowing one to distance oneself from the regretted outcome (e.g., Feeney,

Gardiner, Johnston, Jones \& McEvoy, 2005). A second reason this effect may occur could be linked to the controllability of the outcome. If we take away the conflicting norm in the case of Martin and the Fontignani olive oil the outcome is entirely within Martin's hands: he did not select the correct olive oil for the dish resulting in the dish not being as nice. However, when we add a conflicting norm, that outcome becomes less controllable, since he does not want to behave in a manner that conflicts with his normative framework. We propose that perhaps less regret is predicted in the suppression condition because participants view the outcome as less in control of the protagonist. Girotto et al. (1991) found that participants prefer to mutate controllable relative to uncontrollable events that lead to a negative outcome. We propose that, when a conflicting norm is presented, this makes taking the action to bring about the desired outcome less "controllable" in a normative sense: it becomes less permissible or even forbidden. Since people are more likely to mutate controllable than uncontrollable events that led to a negative outcome, it seems intuitive that greater regret intensity will be predicted for the control condition, where the outcome is within the protagonist's control, than in the suppression condition, in which the conflicting norm serves to block the action, making it uncontrollable in the normative sense. Both hypotheses are possible but the controllability one may be stronger since when it comes to distancing oneself from the outcome controllability may act as a moderator. A future avenue of research could use a controllability manipulation (controllable versus uncontrollable outcome) to examine what effect this direct manipulation has on deontic introduction.

A final suggestion for the result lies in the fact that participants have to make a comparison when presented with a conflicting norm. For Martin it is the choice between using the other oil and the meal not being as tasty to using the Fontignani oil and contributing to environmental degradation. It is possible that in these cases preference construction occurs on the spot.

The fact that conflicting norms demonstrate such consistent results when also accounting for Elqayam et al.'s (2015) findings strongly indicates that people are unwilling to go against their normative framework. Although we did not test it directly in our study one proposal is that whilst people will generally not go against their normative framework for small instances (e.g., having a nice meal) they may do so when the outcome generates sufficient benefit. For example, we may be told as children that it is wrong to lie, and we must tell the truth, and we may hold that norm. However, if we are placed in a situation in which lying could garner a benefit and especially a moral benefit (e.g., saving a life) then it may be the case that we act against our normative framework in this instance.

These findings have extended those of Elqayam et al. (2015) through demonstrating that their proposed model for deontic introduction can be applied to counterfactual conditionals. This is an important theoretical development
since it indicates that similar cognitive processes are at work when reasoning about counterfactual to indicative conditionals. We propose that an avenue for future research could be to test different components of the model of Elqayam et al. to see whether they are applicable for counterfactual counterfactuals in the same manner as they are for indicative conditionals. Elqayam et al.'s work has demonstrated that factors such as utility and probability, which are deeply rooted in the new paradigm, have an impact on deontic introduction for indicative conditionals. We propose that such effects may also occur when counterfactual conditionals are used.

Research on deontic introduction has begun by adopting a vignette-based paradigm like many areas of reasoning research. One challenge of that paradigm though is seeing the degree to which the model can apply to everyday life. We propose an interesting extension would entail asking participants to recall an instance of real life regret, to consider a counterfactual conditional, and then to complete the deontic rating task. Through adopting this approach, we hope to learn how deontic introduction can be applied to real life regrets, and whether the same experimental manipulations, such as conflicting norms, demonstrate the same suppression effects as they do in a vignette-based paradigm, where the participant is reasoning about an unknown protagonist.

From a methodological perspective we believe it would be interesting to examine the cognitive processes participants adopt directly via the adoption of think-aloud protocols. This is a process-tracing technique that requires participants to think aloud whilst working through a problem in order for the researcher to gain insight into participants’ thought processes (see Ericsson \& Simon, 1993). Wilkinson, Ball and Cooper (2010) have utilised think aloud protocols using counterfactual vignettes about mental states to good effect. Stenning and van Lambalgen (2008) show that experimental data can be enriched by the use of think aloud protocols, revealing how participants understand the task, and the trajectory of their reasoning processes. By adopting think aloud protocols whilst asking participants to complete the deontic rating task, future intentionality and regret questions could provide insights into their cognitive processes and potentially add further weight to the model of Elqayam et al. (2015). It would enable participants to state how they deal with the presence of a conflicting norm within their reasoning. This would enable the test of some of the predictions for the findings made within this section.

This experiment has extended one of the findings of Elqayam et al. (2015), demonstrating that deontic introduction in the context of conflicting norms is not only affected by indicative conditionals but also by counterfactual conditionals. This is an important finding for the new paradigm of reasoning (e.g., Evans, 2012; Manktelow, Over, \& Elqayam, 2011; Over, 2009) with subjective degrees of belief at its heart and social pragmatics and subjective psychological value having a significant role
to play (Elqayam \& Over, 2013). We believe that our research adds to this field by showing how counterfactual conditionals can give rise to new deontic norms. It supports the conclusion that, whilst our counterfactual thinking may cause us pain, it is truly functional (e.g., Epstude \& Roese, 2008). As Elqayam et al. (2015) noted, humans are quite ready to infer an 'ought' from an 'is' (see also Hume, 2000/1739-1740). Our findings indicate that humans are also often keen to infer an 'ought' from a 'would have been'.

# Modality Differences in Timing: Testing the Pacemaker Speed Explanation 

Emily A. Williams (Emily.A.Williams@Manchester.ac.uk)<br>Andrew J. Stewart (Andrew.J.Stewart @Manchester.ac.uk)<br>Luke A. Jones (Luke.Jones@Manchester.ac.uk)<br>Division of Neuroscience and Experimental Psychology, The University of Manchester, UK

#### Abstract

A classic effect in the timing field is that "sounds are judged longer than lights" (Goldstone, Boardman \& Lhamon, 1959). Recently, judgements for tactile durations have been found to fall between the two (Jones, Poliakoff \& Wells, 2009). These modality differences are commonly interpreted within scalar timing theory as the work of a central pacemaker which runs faster for sounds, then vibrations, and slowest for lights (Wearden, Edwards, Fakhri \& Percival, 1998). We investigated whether verbal estimates and temporal difference thresholds are correlated within each modality, but found this not to be the case. This suggests that differences in pacemaker speed may not be the main driver for modality differences in thresholds. In addition, we investigated sensory bias as an alternative to the pacemaker explanation, but this was found not to correlate with modality differences in timing.

Keywords: Time perception; interval timing; sensory modalities; pacemaker-accumulator; sensory bias.

## Introduction

The timing of stimulus duration by humans has historically been under-researched compared to other perceptual domains. One reason is that although humans possess a very sensitive discrimination for duration (with difference thresholds as low as 10 ms ), there is no sensory organ for time. This forces explanations to draw on hidden processes more heavily than for other sensory systems, such as vision and hearing. To date the most successful models of human timing have centred on the idea that humans possess an internal clock of a pacemaker-accumulator type, such as in scalar timing theory (SET: Gibbon, 1977; Gibbon, Church \& Meck, 1984). The pacemaker generates internal events ('pulses' or 'ticks') which are connected to an accumulator via a switch. The accumulator contents increase linearly with the duration being estimated and forms the basis for timing judgments (further memory and decision modules are also typically added to this clock model - see Gibbon et al., 1984).

Support for the idea of a pacemaker-accumulator internal clock comes from several sources. People (and animals) can stop and start timing like a stopwatch, even managing to 'pause' timing and continue after a short gap (Buhusi \& Meck, 2009). In addition, people can perform ordinality judgements, express one duration as a proportion of another, and average durations together, again suggesting a linear relationship between perceived time and real time (Wearden \& Jones, 2007).

Furthermore, it appears the speed of the internal clock can be altered. A key signature of a change in pacemaker speed
is the 'slope effect'. In verbal estimation ${ }^{1}$ tasks, when the stimulus durations are plotted against estimates of those durations, the difference between the experimental condition and control manifests itself as a difference in slope. This is consistent with a multiplicative increase in pacemaker speed, rather than a simple bias (which manifests as a difference in intercept). Such slope effects have been found for certain drugs (Meck, 1984), body temperature changes (for review see Wearden \& Penton-Voak, 1995), repetitive stimulation (Penton-Voak, Edwards, Percival \& Wearden, 1996), and filled versus unfilled durations (Wearden, Norton, Martin \& Montford-Bebb, 2007).

It is known that durations of sounds are judged longer than lights (Goldstone et al., 1959). This effect manifests as a difference in slope (Wearden et al., 1998), where the auditory slope is steeper than the visual slope. It has been argued that the pacemaker runs at a faster speed for auditory than visual stimuli (Wearden et al., 1998; Penney, Gibbon \& Meck, 2000). This has sparked a debate about whether there is a central pacemaker that runs at different speeds for different modalities, or separate pacemakers for each modality (See Grondin, 2010). These auditory-visual differences have been found to occur on a range of timing tasks, from temporal generalization (Wearden et al., 1998), to temporal bisection (Penney et al., 2000), to temporal difference thresholds (Jones et al., 2009), suggesting the effect is not task-dependent.

Recently, the temporal judgement of tactile stimuli has been investigated. Jones et al. (2009) found that verbal estimation slopes and temporal difference thresholds for tactile stimuli fall between those for auditory and visual stimuli. Additionally, the two tasks share an inverted pattern, where estimation slopes are highest (most accurate) and thresholds are lowest (most sensitive) for auditory stimuli, for example. It has been suggested that a faster pacemaker is a more accurate pacemaker (Troche \& Rammsayer, 2011), which appears to be the case, but this assertion has yet to be empirically investigated. Therefore, the present series of studies will begin with a replication of Jones et al. (2009), but analysis will also examine whether estimation slopes and difference thresholds correlate with each other for auditory, visual, and tactile stimuli.

In contrast to the pacemaker speed explanation, it has been suggested that modality differences could be due to

[^542]intrinsic differences between the different sensory systems (Yuasa \& Yotsumoto, 2015), e.g. some combination of differences in transduction rates (Zampini, Shore \& Spence, 2003) and attentional biases (Spence, Shore \& Klein, 2001). Therefore, we will investigate whether these aspects of sensory bias or salience correlate with differences between auditory, visual and tactile stimuli. The present study will operationalise sensory bias as the 'point of subjective simultaneity' on a temporal order judgement task, i.e. the duration that one modality has to precede another by, in order for the two modalities to be judged as simultaneous.

In summary, the aim of the current work is to investigate whether verbal estimates and temporal difference thresholds correlate within each modality, and whether modality differences can be alternatively explained by a measure of sensory bias.

## Experiment 1a: Verbal Estimation

## Method

Participants 52 right-handed participants (staff and students of the University of Manchester and some members of the general population) completed all three tasks in a counterbalanced order and received $£ 10$ for their time.

Apparatus and Materials Participants were seated at a table in a dark room, with their chin on a chin rest. A PC presented the experiments, written in E-Prime (Psychology Software Tools, Pittsburgh, PA). A 17" Samsung Syncmaster monitor stood at a distance of 60 cm . Participants' eyes were level with the top of the monitor and the fixation cue and questions were displayed $20^{\circ}$ below eye level. A black foam grip ( $5.5 \times 9.5 \times 4.5 \mathrm{~cm}$ ) was secured to the table 30 cm in front of participants in the centreline. Behind the grip was a Sony speaker, which presented the auditory stimuli ( 500 Hz sine wave tones), and to the left of the grip was a numerical keypad ( $8.5 \times 12 \mathrm{~cm}$ ) for use with the left hand.

The grip housed an Oticon-A (100 Ohm) bone conductor with vibrating surface $1.6 \mathrm{~cm} \times 2.4 \mathrm{~cm}$. The bone conductor was inset into the foam in the index finger position when gripped with the right hand, and driven by a 500 Hz sine wave signal through a TactAmp 4.2 amplifier (Dancer Design). Visual stimuli were presented via a 6 mm green LED light ( $87 \mathrm{~cd} / \mathrm{m}^{2}$ ), embedded in a black plastic casing ( 4 x $4 \times 1.75 \mathrm{~cm}$ ) and attached on top of the foam block. The LED was $16^{\circ}$ below the fixation cue ( $36^{\circ}$ below eye level) and 32 cm in front of participants.

Participants wore 3 M Peltor ear protectors with inset earphones, which played white noise ( 56 dB ) during the tasks to mask the sound of the vibrations.

Procedure On each trial participants estimated the duration of a stimulus. The task contained 150 trials, where ten stimulus durations (77, 203, 348, 461, 582, 767, 834, 958, 1065 , and 1183 ms ) were presented in each modality
(auditory, visual, and tactile) five times. Trials were grouped into three counterbalanced blocks by modality.

Each trial began with the presentation of a fixation cross for $500-1000 \mathrm{~ms}$, which was followed by the stimulus. Participants were prompted on-screen to type in their estimate in milliseconds and were reminded that 1 second $=$ 1000 ms . The task lasted approximately 17 minutes.

## Results

Outliers were defined as estimation functions that were invariant to stimulus duration (identified as linear regressions not significantly different to 0 ), which suggested an inability to perform the task. This led to the exclusion of one individual, leaving a sample of 51 participants. See Figure 1 for the mean verbal estimates for each modality.

The hypothesis that verbal estimates would be highest for auditory stimuli and lowest for visual stimuli was examined using a factorial ANOVA with two repeated measures factors: modality (auditory, visual and tactile) and stimulus duration.

Figure 1: Mean verbal estimates for each modality against stimulus durations.

The ANOVA found a main effect of stimulus duration, $F_{(2.60,130.17)}=750.70, p<.001, \eta_{\mathrm{p}}^{2}=.938$. Post hoc analyses revealed that each of the 10 stimulus durations were estimated as significantly differently from each other ( $p$ < . 001 for all comparisons).
There was also a main effect of modality, $F_{(2,100)}=7.50, p$ $=.001, \mathrm{\eta}_{\mathrm{p}}^{2}=.131$. Post hoc analyses revealed that participants estimated auditory stimuli to be significantly longer than visual $(\mathrm{p}=.006)$ and tactile $(\mathrm{p}=.012)$ stimuli. However, estimates for visual and tactile stimuli did not significantly differ ( $\mathrm{p}=.909$ ) .

The interaction between stimulus duration and modality was also significant, $F_{(8.39,419.32)}=4.914, p<.001, \eta_{\mathrm{p}}{ }^{2}$ $=.089$. In order to investigate this interaction, linear regressions were conducted to extract the slope and intercept values of each participant's verbal estimation function for each modality. See Figure 2 for mean slope values.

Figure 2: Mean slope values for auditory, visual and tactile stimuli. Error bars denote standard error.

A repeated measures one-way ANOVA comparing the slopes across modalities found a significant difference between them, $F_{(2,100)}=12.76, p<.001, \mathrm{n}_{\mathrm{p}}^{2}=.203$. Post hoc analyses confirmed that auditory slopes were significantly higher than visual slopes ( $p<.001$ ), but not significantly different to tactile slopes ( $p=1.00$ ). In addition, the tactile slopes were significantly higher than visual slopes ( $p=$ .001).

## Discussion

Verbal estimation slopes for auditory stimuli were significantly and multiplicatively higher than those for visual stimuli, with tactile slopes falling between the two. As perfect estimates would have a slope of 1 , this suggests that people are more accurate when estimating durations of sounds and vibrations than lights, but tend to underestimate all three modalities. This is the same pattern of results found as in Jones et al. (2009).

Auditory and tactile estimates differed significantly in the first ANOVA, but further analysis on slopes (as pacemaker speed differences are said to manifest as slope effects) found the slopes not to differ. The significant difference between the two in the first ANOVA was perhaps due to a difference in intercept.

## Experiment 1b: Temporal Difference Thresholds

## Method

Participants The same participants completed this experiment as in Experiment 1a.

Apparatus and Materials The same apparatus and materials were used as in Experiment 1a.

Procedure Participants completed a 50-trial threshold task in each of the three modalities in a counterbalanced order. The test stimuli were the same as in Experiment 1a.

Each trial began with the presentation of a fixation cross for $500-1000 \mathrm{~ms}$, which was followed by the stimuli. The first stimulus (the standard) was always 700 ms , while the second stimulus (the comparator) began at 1000 ms in duration. A 500-1000 ms delay occurred between the two stimuli, and a $125-250 \mathrm{~ms}$ delay followed the second stimulus. The order of the standard and the comparator was counterbalanced between trials. Participants pressed ' 1 ' or ' 2 ' on the keypad depending on whether they thought the first or the second stimulus was longer.

This task used a weighted 3-up 1-down staircase method (Kaernbach, 1991), which allowed for the calculation of the difference in stimulus durations that participants can discriminate $75 \%$ of the time. The step size was 15 ms for the first 30 trials, then 10 ms for the last 20 trials. Thresholds were calculated as the mean difference between the standard and comparator durations across the last 20 trials. The task took approximately 18 minutes to complete.

## Results

Outliers were defined as thresholds greater than 600 ms (twice the starting difference) which suggested an inability to perform the task. However, no participant had thresholds above this value, giving a full sample of 52 participants.

Figure 3 shows the mean difference between the standard and comparator durations across the 50 trials for the three modalities. The resulting temporal difference thresholds can be seen in Figure 4.

Figure 3: Mean difference between the standard and comparator across the 50 trials for each modality. The vertical dashed line separates the last 20 trials over which the temporal difference thresholds were calculated.

The hypothesis that thresholds would differ according to the modality of the stimuli was examined using a one-way repeated measures ANOVA. This test found a significant difference between thresholds for the different modalities, $F_{(2,102)}=30.89, p<.001, \mathrm{\eta}_{\mathrm{p}}^{2}=.377$. Post hoc analyses
confirmed that thresholds for auditory stimuli and tactile stimuli were significantly lower than thresholds for visual stimuli ( $p<.001$ for each comparison). However, thresholds for auditory and tactile stimuli did not significantly differ ( $p$ $=.079$ ).

Figure 4: Mean temporal difference thresholds for each modality. Error bars denote standard error.

## Discussion

Thresholds for visual stimuli were significantly higher than both auditory and tactile stimuli, while auditory and tactile thresholds did not significantly differ. This suggests that people have greater sensitivity to the durations of sounds and vibrations than lights. This pattern of thresholds was reported previously by Jones et al. (2009).

## Research Question 1: Do Estimates and Thresholds Correlate within Each Modality?

## Results

The same outlier criteria were applied as in the previous sections, with the addition of values 2.5 SDs from the mean. Following removal, this left 51, 49 and 51 participants for auditory, visual and tactile correlations respectively.

Three Pearson's product-moment correlation coefficients found no correlations between estimation slopes and thresholds within each modality (See Table 1).

Table 1: Correlations between verbal estimation slopes and temporal difference thresholds within each modality.

| Modality | $d f$ | $r$ | $p$ |
| :--- | :---: | :---: | :---: |
| Auditory | 49 | -.099 | .490 |
| Visual | 47 | -.123 | .398 |
| Tactile | 49 | -.130 | .362 |

## Discussion

It had been argued that the differences between modalities in these two tasks were due to the pacemaker running at a faster rate for auditory stimuli and a slower rate for visual
stimuli (Wearden et al., 1998; Jones et al., 2009) and that a faster pacemaker leads to greater accuracy and sensitivity (Troche \& Rammsayer, 2011). However, accuracy in estimates (slopes) and sensitivity to duration (thresholds) did not correlate for within any modality. This poses a problem for applying the pacemaker explanation to both of these tasks. It could be argued that estimates (magnitude judgements) and thresholds (discrimination judgements) rely on different mechanisms and are of different levels of abstraction, but we expected small correlations despite the transformative nature of estimations.

## Experiment 2: Sensory Bias, measured by PSS

This experiment will calculate sensory bias, as measured by the point of subjective simultaneity (PSS) on a temporal order judgement task. The PSS measures the duration that one modality has to precede another by, in order for the two modalities to be judged as simultaneous. This can be seen as a measure of relative salience between the different senses and is affected by the intrinsic properties of each sensory system, e.g. transduction rates (Zampini et al., 2003) and attentional biases (Spence et al., 2001).

Previous research has found sensory biases (measured by PSS) in favour of auditory stimuli when compared with visual (Zampini et al., 2003) and tactile stimuli (Zampini, Shore \& Spence, 2005) and in favour of tactile stimuli when compared with visual stimuli (Spence et al., 2001). Therefore, PSSs appear to follow the same modality pattern as estimates and thresholds.

This measure of sensory bias will be investigated as an alternative explanation for the differences between auditory, visual and tactile performance on estimation and threshold tasks in the next section.

## Methods

Participants The same participants completed this experiment as in Experiment 1a and 1b.

Apparatus and Materials The same apparatus and materials were used as in Experiment 1a and 1b.

Procedure Participants were presented with two crossmodal stimuli ( 15 ms each) in quick succession and were asked which occurred first. The task contained 300 trials, where participants were presented with three modality pairs (Aud-Vis, Aud-Tac, Vis-Tac), at 10 different stimulus onset asynchronies (SOAs, -400, -200, -90, -55, -20, +20, +55, $+90,+200$, and +400 ms ), each repeated 10 times. Negative SOAs mean that the first-named stimulus in the pairing came first (e.g. auditory in the Aud-Vis stimulus pair), whereas positive SOAs indicate that the second-named modality came first. Trials were separated into three counterbalanced blocks by modality pair.

On each trial a fixation cross appeared on the screen after a 500 ms delay, where it remained for the rest of the trial. The first stimulus was presented following a random
duration between 500-1000 ms. After the randomly selected SOA, the second stimulus was presented. For example, if the Aud-Vis modality pair was presented with the -400 ms SOA, participants heard a 15 ms tone, followed by a delay of 385 ms , and then saw the green LED illuminate for 15 ms . After a $125-250 \mathrm{~ms}$ delay, participants were then prompted to answer "Which stimulus came first?" and participants pressed ' 1 ' or ' 2 ' on the keypad. The task took approximately 15 minutes to complete.

## Results

Cumulative Gaussian psychometric functions were fitted to participants' individual data, coded according to 'proportion auditory-first', for example. The PSS and just noticeable difference (JND) were extracted for each individual for each modality pair.

Participants' PSSs were inspected for outliers, identified as those with related JNDs greater than 400 ms (Zampini et al., 2003), which suggested an inability to complete the task. This resulted in the exclusion of eight individuals, leaving a sample of 44 participants. See Figure 5 for PSSs for each cross-modal comparison.

Figure 5: Mean Point of Subjective Simultaneity for auditory-visual, visual-tactile and tactile-auditory comparisons. Error bars denote standard error.

No significant sensory bias was found between auditory and visual stimuli, indicated by the PSS not departing from zero $\left(t_{(43)}=.94, p=.354\right)$. However, the PSS for visualtactile comparisons was significantly above zero, $t_{(43)}=$ $3.24, p=.002$. Participants were biased in favour of tactile stimuli in this comparison, and required visual stimuli to be presented 37 ms before tactile stimuli, for the pair to be judged as simultaneous. In addition, the PSS for auditorytactile comparisons was also significantly above zero $\left(t_{(43)}=\right.$ 3.21, $p=.003$ ). Participants were biased in favour of auditory stimuli in this comparison, and required tactile stimuli to be presented 22 ms before auditory stimuli for subjective simultaneity.

## Discussion

Significant sensory biases were found in favour of auditory stimuli when compared with tactile stimuli, and in favour of tactile stimuli when compared with visual stimuli, which concurs with previous research (Spence et al., 2001; Zampini et al., 2005). However, no significant sensory biases were found between auditory and visual stimuli. This was unexpected and is contrary to both previous research (Zampini et al., 2003), and our hypothesis that the large differences between auditory and visual estimates and thresholds may be due to large sensory biases.

Nevertheless, the next section will investigate whether these sensory biases correlate with the differences between modalities in estimates and thresholds.

## Research Question 2: Do cross-modal PSSs correlate with the differences between modalities in estimates and thresholds?

## Results

The same outlier criteria were applied as in the previous sections, leaving a sample 44 participants.

Six Pearson's product-moment correlation coefficients found no correlations between PSSs and estimation slopes or thresholds for any cross-modal pair (See Table 2).

Table 2: Correlations between cross-modal PSSs and slope and threshold differences for each cross-modal pair.

| Variable 1 | Variable 2 | $r$ | $p$ |
| :---: | :--- | :---: | :---: |
| Aud-Vis PSS | Aud - Vis Slope | .004 | 1.00 |
|  | Aud - Vis Threshold | .061 | 1.00 |
| Aud-Tac PSS | Aud - Tac Slope | -.217 | .314 |
|  | Aud - Tac Threshold | .288 | .116 |
| Tac-Vis PSS | Tac - Vis Slope | .323 | .066 |
|  | Tac - Vis Threshold | -.333 | .054 |

## Discussion

Cross-modal sensory biases, as measured by PSSs, were found not to correlate with the differences in estimates and thresholds between each modality pair. This suggests that the differences in auditory, visual and tactile estimates and thresholds cannot be explained by the intrinsic sensory biases of the three different systems.

## General Discussion

We aimed to investigate the pacemaker explanation for differences between auditory, visual and tactile estimates and thresholds, and discovered three main findings. Firstly, the pattern of differences between the modalities appears to be robust as we replicated these in Experiments 1a and 1b (with minor differences in magnitude). Secondly, estimates and thresholds do not correlate within each modality. This poses a problem for the idea that both the slopes in verbal
estimation and the order of thresholds are mostly determined by pacemaker rate. Finally, the modality differences in estimates and thresholds did not correlate with sensory biases, potentially ruling out this alternative explanation. These findings generate several possible conclusions:

1. Pacemaker rate does not determine estimation slopes or threshold values
2. Pacemaker rate determines estimation slopes but not threshold values (or vice-versa)
3. Pacemaker rate contributes to both slopes and thresholds, but this contribution is washed out by other cognitive processes
Despite these theoretical uncertainties, the present research can state that the assertion that faster pacemakers give rise to smaller thresholds (Troche \& Rammsayer, 2011) is flawed, if one assumes that the pacemaker underlies both estimation and threshold tasks.

At present, there is no published model of how the scalar timing theory system operates in threshold tasks, unlike for temporal generalization (Droit-Volet, Clément \& Wearden, 2001), temporal bisection (Wearden, 1991) and verbal estimation (Wearden, 2015). Additionally, the mathematical consequences of increasing pacemaker speed on timing performance (and the assumptions this is based on) in tasks are not explored or predicted in any great detail in the literature. Therefore, our future work will examine the role of the pacemaker in a model of threshold behavior and model mathematical implications of altering pacemaker rate.

Overall, the simple pacemaker speed explanation appears to fail and a more nuanced explanation is required.

Without the knowledge of human cognitive processes, instructional design is blind. (Sweller, Ayres, \& Kalyuga, 2011)

#### Abstract

Based on the established framework of Cognitive Load Theory, the presented research focuses on the inspection of cognitive load factors in an interrupted learning task. The task itself is inspired from basic cognitive research and demands participants to learn abstract symbol combinations of varying complexity. In addition, they have to deal with interruptions while performing the task. Experimental results indicate the influence of task complexity on how interruptions effect learning performance. However, questions on underlying learner cognition persist, rising the need for a more in-depth way of examination. For this purpose, a cognitive model within the cognitive architecture ACT-R is developed to clarify cognitive processes and mechanisms within different conditions of the task. Preliminary results from a first model for the easy task condition already indicate some fit between human and model data. Modeling work continues with adjusting the current model and implementing a model for the difficult task condition.

Keywords: Cognitive Load; Interruptions; Learning; ACT-R

## Introduction

Learning constitutes an omnipresent requirement throughout the entire life, whether practicing to bring out the first words as a toddler, preparing for an exam within a course of study or gaining knowledge in a foreign language in mature age. When approaching learning from a psychological perspective, a variety of cognitive processes related to information capture, storage and retrieval come to the fore. They share the commonality to pose load on learners' limited mental resources, raising the need of welldesigned instructional material. Such should support learners' efforts in acquiring the desired knowledge, skills and abilities without overloading their mental capacities.

## Theoretical background

A prominent and often quoted theory in the field of instructional design is the Cognitive Load Theory (Sweller, 1988; Sweller, Ayres, \& Kalyuga, 2011). It deals with the question how certain aspects of a learning scenario demand
learners' cognitive resources. The theory postulates a practically unlimited storage capacity of long-term memory, the mental representation and organization of knowledge via schemata, and a limitation of working memory in terms of duration and capacity. In addition, mental resource demands in learning situations arise from different sources: Schema acquisition and automation build the core focus of each learning process and characterize the facet of germane load. Task complexity in relation to learners' previous knowledge constitutes intrinsic load and is traditionally defined in terms of related information that has to be processed simultaneously, referred to as element interactivity (Sweller, 2010). Extraneous load is increased by inappropriate instructional presentation and situational constraints. The latter comprise, for instance, aspects like performing the learning task in a distracting context with competing goals being present. The activation of such task-irrelevant information detracts cognitive resources needed for the learning task (Gerjets, Scheiter, \& Schorr, 2003). In consequence, learners are prone to switch to simpler tasksolving strategies that are less demanding, but at the same time less effective.

Cognitive Load Theory assumes that learning performance would be impaired if the sum of load imposed by the outlined factors exceeds the provided capacity of human working memory. However, the assumption of pure additivity has been questioned in more recent research (Park, 2010; Kalyuga, 2011; Wirzberger, Beege, Schneider, Nebel, \& Rey, 2016), supporting the need for a theoretical reformulation. A possible time-related extension assumes that intrinsic and extraneous aspects affect performance on a structural and short-term level, while the germane aspect has to be considered on processual and long-term accounts (Wirzberger et al., 2016). In consequence, load induced due to schema acquisition should change over time, while structural load facets should pose a constant level of load. A further essential pre-assumption within the postulated framework comprises the fact that spare cognitive capacity is primarily devoted to foster schema acquisition.

## Research focus

The overall project goal comprises to addresses cognitive processes behind the outlined facets of cognitive load. Within the subsection of research introduced in this paper, the particular influence of structural load components over various stages of the task is queried. In more detail, demands posed by increased task complexity and embedded interruptions are assumed to impair performance to different extents, depending on the achieved progress in the process of schema acquisition.

## Experimental setting

A basic learning task was used to approach the research focus, facilitating the concise definition and control of experimental factors. Since it required no previous knowledge, potential confounding effects of this relevant predictor could be ruled out.

## Methods

The experimental setting comprised 116 student participants ( $M_{\text {age }}=23.25$ years, $S D_{\text {age }}=4.34$, range: 18-44 years, $80 \%$ female) from different courses of study. They were required to figure out and memorize four combinations of arbitrary geometric symbols within 64 trials while being interrupted five times over the task. Interruptions occurred at the same predefined points in time (i.e., after trials 8,24 , 32, 40 and 56) for reasons of comparability across participants. Symbol combinations were either easy (two symbols) or difficult (three symbols) and split up in input (one or two symbols) and response (always one symbol). Participants were randomly assigned to one of the two combination conditions, resulting in a between-subjects manipulation of task complexity.

Figure 1: Schematic structure of a learning trial followed by an interruption in the easy task condition.

As depicted in Figure 1, in the learning part, symbols were presented one after another at the outset of each trial and participants had to indicate which symbol completed the combination. Responses were provided by selecting the correct symbol from an offered choice on the screen via mouse click. For instance, a square being displayed should result in choosing a star. After indicating their response, participants received feedback, as well as the correct solution in the case of an incorrect response. The target combinations represented the knowledge schemata that should be obtained over the task.

Within the interrupting secondary task, participants had to search, count and indicate two out of four types of geometric symbols from a visual search picture. Inspired by evidence from the subitizing task (Jensen, Reese, \& Reese, 1950), seven to nine instances per symbol were displayed, to ensure that equal cognitive mechanisms were used across participants. Performance was recorded continuously during both subtasks via correctness and duration of responses.

Regarding the experimental design, performance efficiency computed as quotient from correct responses and reaction times in seconds (Hoffman \& Schraw, 2010), represented the dependent variable. It reflected the amount of mental resources invested to acquire the task-related schema, characterizing the germane load component. Both structural load components were considered as independent variables: The number of symbols that defined a combination determined the intrinsic load component. Such a priori estimation of task complexity by the number of interacting elements followed Beckmann (2010) and Wirzberger et al. (2016). The interrupting secondary task represented the extraneous load component that was addressed in terms of inappropriate situational constraints.

## Results

The influence of interruptions on task performance in both conditions was inspected by analyses of variance (ANOVAs) based on linear mixed models with Type III sums of squares and Satterthwaite approximation for degrees of freedom of fixed effects.

Results showed significant main effects of pre- vs. postinterruption performance, $F(1,118.12)=16.71, p<.001$, and time of interruption occurrence over the task, $F(4,152.12)=11.72, p<.001$. Moreover, significant interactions between condition and pre- vs. post-interruption performance, $F(1,118.12)=16.86, p<.001$, and the condition and interruption occurrence, $F(4,152.12)=11.75$, $p<.001$, were observed. Post-hoc pairwise comparisons with Tukey's HSD supported the pattern depicted in Figure 2. They indicated a loss in performance efficiency after facing an interruption, but only in the easy task condition. The entire model achieved a conditional pseudo- $\mathrm{R}^{2}$ of .44 , indicating about $44 \%$ of explained variance.

Figure 2: Changes in efficiency due to interruptions. Error bars indicate $95 \%$ confidence intervals.

In terms of interruption performance, a significant main effect showed up for interruption occurrence over the task, $F(4,464.77)=12.53, p<.001$, while no significant difference between conditions was observable. Such pattern also receives visual support from Figure 3. The entire model obtained a conditional pseudo- $\mathrm{R}^{2}$ of .36 , indicating about $36 \%$ of explained variance.

Figure 3: Changes in interruption performance over the task. Error bars indicate $95 \%$ confidence intervals.

By contrast, when comparing the amount of totally recalled and correctly recalled symbol combinations in both conditions, participant achieved nearly equal scores that did not differ significantly.

## Discussion

Taken together, experimental results support influences of both structural load features on the observed task performance. However, the demand to inspect differences between conditions in more detail on a cognitive level arises. Although experimentally manipulated performance measurement provides a controlled way of assessment, it merely operates on indirect means and therefore lacks accessibility. On that point, the method of cognitive
modeling becomes of value, since it offers the opportunity to clarify cognitive processes and mechanisms that underlie observable performance.

## Cognitive modeling approach

Implementing a cognitive model structure raises the need to clearly think about each step within a given task and to ensure compatibility with founded psychological theories on human information processing. The cognitive architecture ACT-R (Anderson \& Lebiere, 1998; Anderson, 2007) provides an elaborated cognitive modeling approach to establish a relationship between underlying biological structures and emerging patterns of behavior. It operates on a set of modules mapping the structure of the brain, illustrated in Figure 4. While the peripheral modules are responsible for handling visual and auditory inputs and motor and vocal outputs, the central modules focus on goal planning, declarative memory, intermediate problem states and action coordination (Anderson, 2007). The predicted BOLD responses in the corresponding brain regions, for instance the basal ganglia in terms of the procedural module, have already been validated by fMRI data (Borst \& Anderson, 2015). Although processes in different modules can be executed in parallel, a limitation in capacity to one element at the same time exists, representing known bottlenecks in information processing resources (Borst, Taatgen, \& van Rijn, 2010; Nijboer, Borst, van Rijn, \& Taatgen, 2016).

Figure 4: Overview of ACT-R core modules. Adapted from Borst \& Anderson (2015) and Anderson (2007).

In contrast to other cognitive modeling approaches, ACTR is characterized by applying both symbolic and subsymbolic features (Anderson, 2007). Amongst the symbolic aspects, information is stored and processed by chunks. Interaction between modules happens by selection of production rules in the procedural module that scans the content of the buffers and, based on the resulting pattern,
chooses a suitable production rule that triggers the related action. If more than one production rule fits, the subsymbolic cost-benefit mechanism of utility decides, which production rule is selected. The level of activation, another important subsymbolic feature, reflects the availability of information in declarative memory and is determined by the context and history of use.

## Model concept

A draft of the steps to be performed during the interrupting task and the learning trials are sketched in Figure 5 and Figure 6. If an intended action cannot be finished within the given timeframe, the model can switch to the next logical step instead.

Figure 5: Outline of steps to perform in each learning trial of the task.

The concept of the cognitive model for the actual task setting is inspired by several sources of research. At first, Whelan (2007) framed a potential fMRI based measurement approach of the outlined cognitive load facets. In line with existing evidence from neuroimaging literature, he states that extraneous load triggers activity in particular in brain regions corresponding with sensory processing. Such aligns well to the extraneous load induction by a visual search task and is incorporated in the model due to the broad occupation of visual resources. The intrinsic load component is proposed to be associated with activity in brain regions responsible for maintaining and manipulating the attentional focus. In more complex tasks, entailing more interrelated elements, higher demands are posed on the corresponding goal and problem state resources. In addition, this provides a toe-hold for subsymbolic mechanisms like spreading activation, directly mapping the concept of activation distribution between related nodes of information.

Regarding the germane load facet, Whelan (2007) postulates a correspondence in particular with brain activation patterns representing motivation. This is plausible, since learners need to be motivated to dedicate available cognitive resources exclusively to schema acquisition. Based on that, in the difficult condition, a strategy shift towards a more heuristic encoding approach with increasing task progress is assumed. In detail, participants more and more tend towards retrieving the potential solution right with encoding the first symbol, which compensates for interruption costs and enables faster responses. Due to the resulting reduction in reaction time, they can achieve a better performance efficiency. The model incorporates such behavior by applying the subsymbolic mechanism of utility learning, which rewards each successful strategy adjustment.

Figure 6: Outline of steps to perform in each occurrence of the interrupting task.

Beyond that, the model bases upon existing modeling work regarding interruption and resumption during task
processing (Trafton, Altmann, Brock, \& Minz, 2003; Wirzberger \& Russwinkel, 2015). In brief, this tradition of research explains the loss in task performance after facing an interruption due to a decay in activation of the task representation. The resulting failure in accessibility of information can be adjusted within the model via subsymbolic chunk-related parameters like retrieval threshold, base-level decay or retrieval latency. On the perceptual level, the cognitive switch between both tasks is triggered bottom-up, at which the change in instruction color represents the salient screen change (Wirzberger \& Russwinkel, 2015). On the processing level, due to this salience, the interrupting task receives immediate attention, represented by a high utility of the task switch. In addition, during both stages of the task, more specific actions are regarded as more useful, for instance attending and encoding available stimuli instead of just searching around. Thus, the related productions receive slightly higher utility and can be performed as soon as they match.

Related to the concept of memory activation is the important question, which components constitute working memory in ACT-R models. The current model follows a recently introduced approach by Nijboer et al. (2016), who discuss a multi-component working memory system that can explain memory interference in dual tasking. It involves the problem state as limited short-term resource to hold and manipulate information, the activated content of the declarative memory as well as the mechanism of subvocalized rehearsal as additional support to prevent activation decay. In particular processes of rehearsal are occupied to a greater extent in the difficult condition, potentially explaining the diverging patterns between conditions.

## Preliminary results ${ }^{1}$

The currently available preliminary model is able to complete the easy task condition, highly demands visual perception, and already employs some subsymbolic parameters. Besides of an enabled base-level learning parameter, defaulting to the well-established value of 0.5 , it operates on increased visual-number finsts, aligning to the available button selection on the screen. Moreover, it induces some instantaneous noise in retrieval-related activation to better account for human variability in memory performance.

Approaching the comparison between human and model data, aside from a graphical inspection, Schunn and Wallach (2005) recommend a combination of numerical goodness-of-fit measures on relative trend magnitude and those assessing deviation from the exact location. In particular, they approve $\mathrm{R}^{2}$ as a measure of relative magnitude, for it relates directly to the accounted proportion of variance and better evaluates models with strong correlations to human data. In order to assess deviation from the exact location, the RMSSD (root mean squared scaled deviation) constitutes

[^543]the measure of choice. It scales the deviation between each mean of human and model data by the corresponding standard error of the human data mean. In this vein, the RMSSD provides a scale invariant opportunity to assess model fit in units of the standard error.

Figure 7: Comparison of performance in trials before and after an interruption.

At first glance, Figure 7 indicates a reasonable fit in terms of impaired task performance due the induced interruptions. This impression receives support by the quite well RMSSD of 3.73 and an explained proportion of variance of $32 \%$ ( $\mathrm{R}=.32$ ) for the selected pre-post interruption trials. When examining task performance in more detail, although the model can relatively map the given amount of correct responses during the learning trials, it shows a decreased match in terms of reaction time. The model constantly reacts much faster than human participants, which degrades the overall fit in performance efficiency. In addition, the model needs to better map interruption performance, indicated by Figure 8 as well as the rather high RMSSD of 7.84 and smaller proportion of explained variance of $29 \%\left(\mathrm{R}^{2}=.29\right)$.

Figure 8: Comparison of performance in interruption task
As a potential solution, the model has to speed up counting during the visual search task, since mostly it is not
able to successfully finish the second counting run or even end counting earlier.

## Further steps

Pending steps within the ongoing modeling project involve the adjustment of outlined weaknesses in model performance. Moreover, due to the theoretical match with the concept of element interactivity, spreading activation has to be included as well. A second stream of work concerns the implementation of the difficult task condition. This involves the inclusion of productions that represent the aforementioned alternating task processing strategies.

## Conclusion

Overall, this project constitutes an elaborated contribution to understanding cognitive processes that underlie knowledge acquisition from given instructional content. In doing so, it provides relevant insights into a so far rather vague defined theoretical framework, and additionally contributes to interconnect methodological approaches from different fields of research.

# Does Associative Memory Play a Role in Solving Physics Problems? 

K. Wood, R.P. McLaren \& I.P.L. McLaren (i.p.1.mclaren@exeter.ac.uk)

School of Psychology, University of Exeter, UK

#### Abstract

Previous research has found that people frequently provide incorrect predictions about the path of moving objects when given an idealised physics problem to solve. The aim of this research was to explore whether these incorrect predictions are due to the application of an incorrect naïve physics theory, whether incorrect perceptions generated from past experiences lead to misconceptions of how moving objects behave, or whether it is a combination of both. Thirty-one participants volunteered to take part in the experiment which followed a two (experience congruent/incongruent with naïve physics theory) by two (carried versus free-moving object) within-subject design. The dependent variable was participant response (straight down or curved forwards). Results of the study revealed that participants provided answers both consistent and inconsistent with the naïve physics theory. This suggests that responses were primarily elicited through the retrieval of associatively-mediated memories of similar scenarios - some of which contain perceptual illusions. Possible methodological limitations and alternative theoretical explanations are discussed, along with practical and theoretical implications for education and learning.

## Introduction

Objects are constantly moving all around us. Therefore, it seems realistic that an individual should be able to correctly predict the path of a moving object (Zago \& Lacquaniti, 2005). However, research has found that people are frequently incorrect in their predictions when given an idealised problem to solve (McCloskey, Caramazza \& Green, 1980; McCloskey, Washburn \& Felch, 1983; McLaren, Wood \& McLaren, 2013). The aim of this study is to investigate whether conscious reasoning leads people to apply an incorrect theory to basic physics problems (a propositional account, cf. Mitchell, De Houwer and Lovibond, 2009) or whether automatic associative memories (McLaren, 2011) generate misperceptions of how moving objects behave (the associative account), or even if a combination of both is needed to explain these predictions (a dual-process account (McLaren et al., 2014)). We first introduce the on-going debate as to whether human mental life is best explained in propositional terms, associative terms or both, before going on to consider other related examples of problem solving in humans (and other animals) which may cast light on this research question.

Both the propositional (see also Shanks, 2007) and dualprocess (McLaren et al., 2014) approaches agree that human learning incorporates a conscious, calculating component, and that past experiences play a crucial role. However, disagreement exists on whether human learning can be explained by one unitary set of processes or requires multiple processes for its full characterisation. The dualprocess approach refers to two modes of processing which are fundamentally distinct: associative processes which create links between representations without conscious knowledge and regardless of the individual's intentions, and cognitive processes which consciously employ rules and reasoning (McLaren, Green \& Mackintosh, 1994). It is
argued that whilst both human and non-human species are capable of associative learning, humans alone possess rulebased processes which allow logical reasoning (Povinelli, 2004). However, Mitchell, De Houwer and Lovibond (2009) argue that evidence for these two distinct learning processes is ambiguous. They state that rule-based learning and associative learning are part of a combined system where associative learning relies on conscious, effortful and calculated processes, rather than implicit, automatic processes.

The present study explores all three of the theoretical approaches discussed above, in relation to how people solve physics problems. However, the working hypothesis is that associative processes, in the form of associative memory, primarily drive responses to physics problems in most people. Mental rotation tasks share similarities to the basic physics problems used in this current study, in requiring a simulation of the physical world (Neiworth \& Rilling, 1987). Therefore, they provide a solid starting point for exploring whether associative memory plays a primary role in responding to these types of problems. During a discrimination task involving shape rotations, Shepard and Metzler (1971) found an increased reaction time for larger rotations. This linear relationship led Shepard and Metzler to conclude that people have a general purpose rotation ability. They suggested that participants created mental representations of the first image and then, when shown the second image, mentally rotated it to match the first. However, something resembling mental rotation has also been demonstrated in pigeons (Neiworth \& Rilling, 1987). If humans alone possess rule-based processes which allow logical reasoning (Povinelli, 2004), then mental rotation in pigeons might suggest a role for associative processes in these tasks. Pigeons were trained to respond to images of clocks with rotating hands and were then tested in a discrimination task. Neiworth and Rilling found the pigeons not only performed above chance when discriminating rotations they had been trained on, but also in trials involving rotations they had not been trained on. The pigeons appeared to know where the clock hand should reappear given the time that had gone by, and were able to indicate whether it was right or wrong when the clock hand reappeared. These findings provide support for the primary role of associative memory because the pigeons had considerable experience of successive events during training, and, as a result, were later able to extrapolate novel rotations similar to the rotations they had previously experienced. It can, therefore, be argued that it is also extrapolation based on experience that enables humans to solve similar problems. Rather than utilising a generalpurpose rotation ability, people's ability to apparently mentally rotate objects might instead come from their vast experience of objects in different orientations in the environment (Edelman \& Bülthoff, 1992). A corollary of this position is that if people's responses are driven by associative memory and experience, then changing
contextual variables (i.e. the surface features of the task) should potentially change people's answers. We make use of this logic in the study reported here.

Previous research on naïve physics problems has helped inform the current research. According to McCloskey, Caramazza and Green (1980), when presented with problems involving a ball bearing entering a horizontally positioned curved tube, people tend to utilise the belief that the ball will exit the tube with a "curvy impetus". The majority of participants verbally indicated in a later interview that they believed the ball would acquire a force or momentum in the tube that would cause it to continue to travel in a curved motion upon its exit, gradually losing momentum until the trajectory became straight. This led McCloskey et al. (1980) to conclude that participants were using a naïve theory of motion. McCloskey, Washburn and Felch (1983) later provided evidence for a naïve physics theory in problems involving falling objects. Participants appeared to apply the incorrect non-Newtonian theory that, whilst free-moving objects will fall in a curved motion, carried objects will fall straight down. McCloskey et al. (1983) suggest that a perceptual illusion occurs when people observe a carried object falling. For instance, when an individual drops something whilst cycling, the object ends up behind them due to the cyclist maintaining a constant speed before noticing the object has fallen. Whilst the cyclist continues at a constant speed, the object gradually loses speed as soon as it starts to fall. Although the object falls forward in a curved motion, the observer is likely to believe that the object fell straight down (or backwards) because it is behind the cyclist in their frame of reference.

Whilst it appears that participants are consistently getting basic physics problems wrong due to explicitly applying an incorrect non-Newtonian theory, there is the alternative possibility that these responses are primarily elicited through the retrieval of associatively-mediated memories of similar scenarios - some of which contain perceptual illusions (Zago \& Lacquaniti, 2005). Participants may later offer an explanation congruent with a naïve physics theory to justify their reasoning, in an attempt to rationalise their responses in a scientific way. In order to provide evidence for the use of associatively-mediated memories in these problems, it needs to be demonstrated that individuals can produce systematically different answers to essentially the same problem (Sloman, 1996) when the contextual cues accompanying it are varied. If participants cannot explain their answers using a consistent rule, then this indicates automatic associative processing followed by conscious reasoning to justify their initial automatic responses.

A study by McLaren, Wood and McLaren (2013) explored whether experience is primary in explaining why people incorrectly predict the directions of moving objects. Participants were required to complete a questionnaire containing eight physics problems, each concerning falling objects, and were asked to indicate which path they thought each falling object would take. They found that participants gave responses that were both consistent and inconsistent with the naïve physics theory, depending on the context of the problem. In a series of structurally identical but contextually varied scenarios, around half of the carried objects were predicted (on the basis of extrapolation from experience) to fall in a curved forwards motion whilst the
others were predicted to fall straight down. Equally, around half of the free-moving objects were predicted to fall straight down whilst the others were predicted to fall in a curved forwards motion. A naïve physics view would predict that all the carried objects fall straight down, and all the free-moving objects follow a curved forwards path. McLaren et al. (2013) argued that if participants' responses were produced by applying a naïve physics theory, the theory would have to be consistently applied across all scenarios. In fact, the variation in contextual cues led to responses that were consistent with their predictions rather than the naïve physics view. Therefore, a more feasible explanation for the responses is that participants were primarily responding to these problems using their own experiences of events similar in structure or context to predict the paths of the falling objects.

The present research was predicated on the existence of both propositional and associative processes in humans. Whilst it might appear that people apply an incorrect naïve physics theory when solving basic physics problems (McCloskey et al., 1980; McCloskey et al., 1983) the presence of the inconsistent responses seen in McLaren et al.'s (2013) study suggests that associative memory plays a significant role in generating these incorrect predictions. Thus, it is possible that participants' responses are based on associative memory rather than propositional inference or reasoning and that naïve physics accounts are later presented as a reason for these responses (i.e. an epiphenomenon). This study aims to extend McLaren et al.'s (2013) work in order to determine whether results in support of the associative account can be replicated under more controlled conditions. In order to do this, a number of possible weaknesses and limitations that were identified in McLaren et al.'s (2013) study were eliminated. Firstly, the number of possible paths of falling objects that participants could pick from was reduced from five to two in order to simplify the analysis of participants' responses. Secondly, the number of problems was increased from eight to twelve to improve reliability. Thirdly, each image was carefully refined to avoid any confounding characteristics such as motion lines and object position - these are now equated across problems. Fourthly, each participant was tested on a computer individually and then interviewed afterwards rather than given a questionnaire to complete in class. This was to strengthen validity of the experiment by avoiding confounding variables such as responses of classmates at the same table and noisy distractions. The interview was done to ensure enough information was provided to generate reliable qualitative data. If these findings show responses that are both consistent and inconsistent with the naïve physics theory, depending on the context in which they are presented, this will support the theory that people are making use of associative memories when responding to these problems.

## Experiment

## Method

## Participants

Thirty-one participants volunteered to take part in the experiment. Participants consisted of 17 females and 14 males ( $\mathrm{M}=26.45$ years, $\mathrm{SD}=8.37$ ) living in Exeter and the surrounding areas ( 15 undergraduate students, 5 college
students, 10 professionals and 1 postgraduate student). All participants had a GCSE in Physics and one had an A Level in Physics. Final year psychology students with prior knowledge of the theories explored in this study were excluded from participation.

## Materials and Design

The experiment followed a 2 (experience congruent/ incongruent with naïve physics theory) by 2 (carried/freemoving object) within-subject design. The dependent variable was participant response (straight down/curved forwards). Each participant was presented with the same 12 basic physics problems, constructed using Microsoft Word and Microsoft PowerPoint and programmed using SuperLab software on a Macintosh computer. The experiment contained what was essentially the same physics problem presented in 12 different ways, using different contextual features. All of the problems were framed around falling objects travelling at the same speed. Six problems involved carried objects and the other six problems involved freemoving objects. These two types of problems were divided into subcategories, based on whether the predicted answer was congruent or incongruent with the naïve physics theory. Therefore, the four categories of problems were: Carried Congruent (e.g. Figure 1), Carried - Incongruent (e.g. Figure 2), Free-moving - Congruent (e.g. Figure 3) and Free-Moving - Incongruent (e.g. Figure 4).

There were three problems in each of the four categories. Carried - Congruent: a seagull in flight dropping an icecream, a plane dropping a crate and a running student dropping a book; Carried - Incongruent: a swinging monkey dropping a banana, a plane dropping a bouncing bomb and a running cricketer dropping a ball; Free-Moving Congruent: a cannonball fired off a cliff, a skier approaching a crevasse and a toy car falling off a table; Free-Moving Incongruent: a river flowing off a cliff, a skater dropping into a half-pipe and a toy train falling off a broken track. The congruent problems were based on problems used in previous research that resulted in responses congruent with the naïve physics theory (i.e. straight down for carried objects and curved forwards for free-moving objects). The incongruent problems, which were designed to elicit responses incongruent with the naive physics theory (i.e. curved forwards for carried objects and straight down for free-moving objects), were selected based on the research team's own visualisations of how the objects would appear to behave from associated experiences (e.g. a skater can be associated with dropping straight down into a half-pipe).

## Procedure

Firstly, participants were given a consent form to sign, which briefed them on the procedure of the experiment and their right to withdraw at any time. They then read the onscreen instructions as follows: "You are about to view a series of scenarios in which objects are seen falling to the ground. Firstly, look at the scenario and decide which path you think the object will take on its journey, and then, from the two choices offered, select which path you think most resembles the one you thought of. Indicate your choice by pressing the corresponding number on the keyboard. For example, if you think Path 1 is most similar to the path you thought of, press the key ' 1 '. When making your choice,
please ignore the effects of air/wind resistance and friction. All objects are travelling at the same speed (Speed V). When you have made your choice, let the experimenter know. You will then be asked a couple of brief questions before moving on to the next scenario. Please give as full an answer as possible. If you are happy to continue, press the space bar to begin the experiment."

Figure 4. Free-Moving - Incongruent Problem

The experiment began with one of the 12 scenarios appearing on the screen. Participants were provided with
information about the scenario (see Figures 1-4) and were then asked to press the space bar to see the possible paths of the falling object (see Figure 5). These were shown side by side, with the object falling straight down or curved forwards. Participants were asked to select the path they thought was most likely. They were then asked to let the experimenter know that they had made their decision. The experimenter responded by asking a set list of questions about the scenario: "What was happening in the scenario?", "Which answer did you select?" and "Why did you select that answer?" The 12 scenarios were presented in random order to prevent bias.

Figure 5. Example of choices provided.
At the end of the experiment, participants were asked if they followed any specific rules to help them complete the experiment and if they had any general comments about the experiment. Participants 13 to 31 were also asked if they felt their approach changed at all during the experiment. This was because it became apparent during the experiment that some participants felt they were trying to apply a rule at first and then they later noticed their responses were inconsistent with the rule they had said they were applying. The experimenter then verbally debriefed participants about the nature of the study. The duration of the experiment was approximately 15 minutes for each participant.

## Results

As a first step, the data was analysed using a 4 (condition) x 2 (response) contingency chi-square test to see if the condition (carried-congruent, carried-incongruent, freecongruent or free-incongruent) had a significant effect on the responses given (straight down or curved forwards). A contingency chi-square test was chosen because it investigates whether there is a significant relationship between two variables. A significance level of $p=.05$ was used for all statistical tests. The results of the analysis, $\chi^{2}(3)=66.94, p<.001$ suggest that there was a highly significant effect. In other words, the responses given were not independent of the condition. As the condition did appear to have an effect on the responses given (see Table 1), a number of $2 \times 2$ contingency chi-square analyses were carried out to determine the nature of this effect. Collapsing over carried/free-moving, $\chi^{2}(1)=2.43, p=.119$ (ns) indicates that congruency had no main effect. A similar analysis for carried/free-moving after collapsing over congruency gave a $\chi^{2}(1)=3.89, p=.049$, which suggests there was a marginally significant relationship between this factor and response. Straight down was the most common response for carried problems and curved forwards was the
most popular response for free-moving problems. This finding is consistent with a naïve physics effect.

Table 1
Participants' Responses Categorised by Problem's Condition

| Condition | Response |  |
| :--- | :---: | :---: |
|  | Straight Down | Curved Forwards |
| Carried - Congruent | 64 | 29 |
| Carried - Incongruent | 34 | 59 |
| Free-Moving - Congruent | 17 | 76 |
| Free-Moving - Incongruent | 62 | 31 |

However, a naïve physics theory predicts a preference for straight down responses for carried objects and curved forwards responses for free-moving objects, regardless of congruency classification. These results were further broken down to investigate whether carried versus free-moving had an effect on response when looking at congruent and incongruent problems independently. The $\chi^{2}(1)=48.31, p$ $<.001$ for congruent problems and the $\chi^{2}(1)=16.89, p<$ .001 for incongruent problems suggest that carried versus free-moving had a highly significant but quite opposing effect on responses for both congruent and incongruent problems (see Figure 6). It can clearly be seen from Figure 6 that, whilst it is possible to get a pattern of results consistent with a naïve physics theory (congruent problem data shown in blue), it is also possible to construct similar problems that elicit the reverse pattern of results. In the congruent problems, carried objects tended to produce a straight down response and free-moving objects tended to produce a curved forwards response. Conversely, the incongruent problems, revealed the opposite pattern of responses, directly contradicting the naïve physics theory.

Figure 6. This graph represents the response difference score (No. curved forwards - No. straight down) for each of the four conditions, where a positive score denotes a bias for the curved forwards response over the straight down response.

## Discussion

The aim of this study was to determine whether experiences are primary in predicting the answer of basic physics problems. In order to do this, an extension of McLaren et al.'s (2013) study was developed. Specifically, the interest was whether participants responded both consistently and inconsistently with the naïve physics theory
depending on the context in which the problems were presented. The hypothesis was that associative processes in the form of associative memory primarily drive responses to physics problems in relatively naïve participants. Therefore, it was predicted that participants would provide answers both consistent and inconsistent with the naïve physics theory based on congruency categorisation. The results of the study revealed that they did.

## Evidence for Associative and Cognitive Processes?

Whilst we have strong evidence that contextual variables can influence the responses to essentially the same physics problem, a result which strengthens the case for associative memory influencing these responses, we also have a main effect of carried/free-moving that is consistent with a naïve physics view. Admittedly this effect could be due to the fact that memories of carried objects have a general tendency to elicit a straight down response (and more than a curved forwards response) because of an incorrect perception generated from past experience (McLaren et al., 2013). If the carrier of the object is still moving at a constant speed when the object falls then it will appear that the object has fallen straight down. Nevertheless, this is a post-hoc explanation of this finding, which would have undoubtedly been predicted by a naïve physics account. Thus, we must acknowledge the possibility of a more cognitive component to the responses made to our problems.

When exploring the qualitative data, it becomes clear that many participants do offer something reminiscent of a naïve physics theory when asked to explain their responses. However, the theory provided is inconsistently applied, as congruent questions are predominately explained using a naïve physics theory, whereas incongruent problems are predominately explained by an appeal to experience. If participants were consciously applying different rules in different situations, then they should be able to explain these diverse rules afterwards. However, this was not the case. For instance, in the seagull problem, the majority of participants' explanations were of the form: "I thought it was most likely to fall straight down or backwards because the bird is in motion but the ice cream is not". This sounds like a naïve physics theory, but on the other hand, in the skateboarder problem, the majority of participants' explanations did not refer to theory but to experience: "If you see skaters on a ramp they usually go straight down". Other incongruent problems are explained using an alternative theory. For instance, some participants failed to apply the straight down belief to carried objects but instead attempted to apply the rules of Newtonian physics by simply mentioning gravity: "gravity will pull it straight down". These inconsistent explanations for responses suggest that participants are automatically responding to problems and later coming up with rules when asked to explain why they selected their responses. At the end of the experiment, many participants indicated they had later become aware that the rule they provided as an explanation directly contradicted some of their responses. $74.4 \%$ of participants said that they felt their approach to the task changed as the experiment progressed. When asked if they had any further comments about the experiment, $71.0 \%$ said "no". However, the remaining $29.0 \%$ asked if all the problems had the same answer. This shows that whilst some of the participants suspected that the answers may all be the same due to the
similar structure, perceptions based on their own experiences were so powerful that they overrode these suspicions. The fact that the problems used in this experiment were essentially the same basic problem with different surface features shows how vulnerable associatively-mediated retrieval is to a change in the surface features of a problem.

## Implications

The findings in this study suggest that when participants are presented with problems, such as the ones in this study, memories are elicited first and rules are inferred later. These findings may have significant implications for education. If experiences are primary to predicting the answer of basic physics problems, this needs to be factored into the teaching methods applied to physics. For instance, children who are studying GCSE Physics are likely to have already formed many memories about the behaviour of moving objects, and because they are likely to believe things that they see with their own eyes rather more than what they are told (Wallach, 1987) this will need to be taken into account. Just telling them the correct theory may not be enough; some explicit acknowledgement of their own experience and why it might be misleading in terms of the physics of the situation may be required.

## Strengths and Limitations

This study has successfully replicated McLaren et al.'s (2013) findings using an improved methodology, whereby participants underwent the study in a controlled environment and were able to provide both quantitative data and qualitative data. The results of this study provide strong evidence for the case that associative memory plays an important role in problem solving and learning. However, one limitation of this study is the method of obtaining incongruent problems. The problems which were designed to elicit responses incongruent with the naive physics theory (i.e. curved forwards responses for carried objects and straight down responses for free-moving objects) were selected based solely on the research team's own experience of how the objects appear to behave. It would be useful for future research to find a more independent method of selecting incongruent problems. Another limitation of the study could be that it lacks ecological validity due to the use of images of two-dimensional objects on a computer monitor rather than real-life objects.

It is possible that some propositional theorists may argue that this study does not provide evidence for the primary role of associative memory in problem solving. Mitchell et al. (2009) allow that associative memory may have a role in learning. However, they believe it is propositional reasoning that elicits memories based on previous experience and extracts a rule from them. Therefore, it could be argued that, although the responses appear to be based on the participants' past experiences, it is conscious, propositional reasoning that enables the participants to apply these past experiences to the problems presented in the study. Although this alternative explanation covers most of the facts, it cannot easily explain the pattern of qualitative results found in this study. Participants' inconsistent explanations for their responses suggest that they responded to each problem automatically and later came up with a post-hoc justification to fit the response they had given,
even if their justification directly contradicted an explanation they had given for a previous problem. At the end of the experiment, many participants indicated that they had later become aware that their explanations directly contradicted some of their responses. This shows that perceptions based on their own experiences were so powerful that they overrode any logic.

## Directions for Future Research

As pointed out earlier, the experiment involves people predicting the path of objects drawn in two-dimensional images on a computer monitor. Although the results of this experiment are highly significant, it is important to find out whether the findings can be generalised to other more practical contexts. A possible extension of this study involves participants predicting the path of falling objects in real-life situations. For instance, a student running with a book along a corridor marked with a tape measure. The student could initially run without dropping the book to give participants a real-life illustration. The experimenter would then explain to the participant that the student will drop the book at a specified point the next time he runs along the corridor and ask them to indicate where they expect the book will fall. This may result in more accurate responses due to greater ecological validity. Alternatively, the scenarios could be presented using a video recording.
This study could be extended by running the experiment with a number of samples of participants from different age groups, academic disciplines, professions, or demographics, in order to determine whether the results can be generalised to different groups of participants. It would also be interesting to run the experiment with children in different developmental stages. Although younger children will have less experience with falling objects, they are likely to rely more on automatic associative memory because, according to Piaget (1972), they will not yet have developed the ability to apply a theory when solving problems. However, interestingly, some research has found evidence for children as young as 5 years old applying what appears to be a naïve physics theory to basic physics problems (Blown \& Bryce, 2013; Kaiser, Proffitt \& McCloskey, 1985; Vosniadou, 2002). It would be interesting to explore this further.

Another possible direction for future research is to study the transition from associatively-based to rule-based performance when solving basic physics problems. This could be achieved by firstly running the initial experiment with a group of participants to get a set of responses based on associative memory, and then training the same group of participants on Newtonian mechanics before running the experiment (using different problem variants) with them again. In the second trial, the participants would presumably respond correctly to the problems because they would be able to apply a rule they had recently learnt. This may sound straightforward, but note that most of the participants in this study had some knowledge of physics, and still made systematic errors.

## Conclusion

In conclusion, this study has provided strong evidence for the primary role of associative memory in human learning and problem solving. The highly reliable results show that people are frequently incorrect in their predictions of the
paths of moving objects, highlighting the importance of studying associative processes in humans and their interaction with more cognitive (propositional) processing. We suspect that our results will have practical implications for education, especially instruction in physics and applied mathematics.

# Sensorimotor Learning Modulates Automatic Imitation in Visual Speech 

Yuchunzi Wu<br>Department of Speech, Hearing and Phonetic Sciences, University College London, Chandler House, 2 Wakefield Street, London WC1N 1PF, UK<br>Bronwen Evans<br>Department of Speech, Hearing and Phonetic Sciences, University College London, Chandler House, 2<br>Wakefield Street, London WC1N 1PF, UK<br>Patti Adank<br>Department of Speech, Hearing and Phonetic Sciences, University College London, Chandler House, 2<br>Wakefield Street, London WC1N 1PF, UK

#### Abstract

People automatically imitate observed actions, including speech. Automatic Imitation (AI) is linked to observationexecution associations in the mirror neuron system (MNS). AI is measured using interference tasks, in which prompts (say "ba" or "da") are paired with congruent or incongruent distracters (video of someone saying "ba" or "da"). Faster responses for congruent than for incongruent prompt-distracter pairings signal AI. Observation-execution associations for speech actions are thought to be inflexible, unlike associations for manual actions, which have been shown to be flexible. We trained participants to reinforce or abolish their AI response by providing them with compatible (say "ba" for a video of someone saying "ba") or incompatible training (say "ba" for a video of "da"). After training, the AI response was reduced for participants who received incompatible training, thus showing that the MNS for speech actions is also flexible and subject to experience, like the MNS for manual actions.

# Whoa! Aww ... Ohh ... Hee! and Mmm: Infants' nuanced distinctions about the probable causes of emotional expressions 

Yang Wu

MIT
Paul Muentener
Tufts University

## Laura Schulz

MIT

#### Abstract

Can infants map diverse positive emotional expressions to their probable causes? Across two studies (including one pre-registered experiment), we used a preferential-looking task to find that infants as young as 12-17 months (mean: 14.8 months) successfully matched non-verbal vocalizations elicited by funny, exciting, adorable, sympathetic, and delicious images to their probable causes (Experiments 1 and 2). Do infants also posit unobserved causes of emotional expressions? In both exploratory and pre-registered experiments, an adult peeked into a box and made one of two distinct positive emotional vocalizations (Experiment 3: "Aww!" or "Mmm!"; Experiment 4: "Aww!" or "Whoa!"). Infants reaching into the box retrieved either a probable or improbable cause of the reaction. Infants were more likely to search again on incongruent trials. These results suggest that infants make nuanced distinctions among emotions, and infer probable causes of emotional reactions.

# Visual and Audio Aware Bi-Modal Video Emotion Recognition

#### Abstract

With rapid increase in the size of videos online, analysis and prediction of affective impact that video content will have on viewers has attracted much attention in the community. To solve this challenge several different kinds of information about video clips are exploited. Traditional methods normally focused on single modality, either audio or visual. Later on some researchers tried to establish multi-modal schemes and spend a lot of time choosing and extracting features by different fusion strategy. In this research, we proposed an end-toend model which can automatically extract features and target an emotional classification task by integrating audio and visual features together and also adding the temporal characteristics of the video. The experimental study on commonly used MediaEval 2015 Affective Impact of Movies has shown this method's potential and it is expected that this work could provide some insight for future video emotion recognition from feature fusion perspective.

Keywords: videos; multi-modal scheme; modal fusion; end-to-end; temporal characteristics

## Introduction

To better understand and analyse people's emotion response during watching videos, it is essential to study the cognitive determinants beneath the video presentation. Currently, content based approaches are the main trend for video emotion analysis, and a lot of models have been proposed to help identify the emotions evoked by videos (Hanjalic, 2006), among which affective analysis based on video visual contents have been studied for several years. Several approaches which employed different machine learning models such as Bayesian network (Soleymani, Kierkels, Chanel, \& Pun, 2009), Hidden Markov Models (Kang, 2003) have been proposed and proven applicable to tackle with this challenge.

Though visual content based video emotion analysis has proven applicable in real applications, there still exists challenges since even the same scene could cause different emotions (Choe, Chun, Noh, Lee, \& Zhang, 2013). Recently audio related features have also proven its effectiveness in emotion analysis (Cui, Jin, Zhang, Luo, \& Tian, 2010). For example, Xu et al. tried to use audio emotional events (AEE) such as laughing, horror sounds and other features to detect horror and comedy movies (Xu, Chia, \& Jin, 2005).

While previous studies focused on video or audio features alone in detecting video emotion have proven their ease in implementation, to further improve the classification performance, some researchers indicate the possibility by combining visual features with audio features to form a hybrid fea-
ture that can carry information from two different modalities (domains) at the same time. Such methods can be roughly divided into two categories in terms of the way the features are combined, i.e., later fusion of classifiers (Yi, Wang, Zhang, \& Yu, 2015), and early fusion scheme, in which features are concatenated into a final classifier (Dai et al., 2015; P., Hayrapetyan, Tapaswi, \& Stiefelhagen, 2015).

In this research, we employed the idea of modal fusion and then proposed an end-to-end framework to integrate the visual and audio features for video emotion analysis. Recently with the development of deep learning techniques, a lot of advanced methods have been proposed for feature extraction. In this research, we used convolutional neural network (CNN) to extract video emotion related features as CNN has proven its success in learning intermediate representations from lowlevel features (Acar, Hopfgartner, \& Albayrak, 2014). Afterwards, taking into account the temporal characteristics of video, we further use Long Short Term Memory (LSTM) model (Hochreiter \& Schmidhuber, 1997) to integrate the extracted temporal features since it performs well on tasks that require integration of state information over time. Finally a multi-layer perceptron (MLP) is employed to classify the final video emotions.

To confirm the validity of the proposed method, we implement it in the Affective Impact of Movies Task 3 in the MediaEval challenge 2015 (Sjöberg et al., 2015). The task has now become a state-of-the-art benchmark which attracted a large number of research teams to test their models on this data set. The experimental study result against different bench experiments on this dataset shows the proposed method's potential in detecting video's emotion.

## Related Work

In the content-based video research, many researchers have used a lot of models to identify the emotions triggered by the video. Hanjalic argued the possibility to classify films according to their emotions and proposed the concept of "expectation of emotion", which is defined as one or a group of emotions that a filmmaker wishes to use to communicate with a certain culture or a particular audience through the film (Hanjalic, 2006). Through this concept, he proposed the video content information and its underlying characteristics to predict emotion. Later on, Soleymani et al. proposed a Bayesian framework to detect scene affect and the arousal

Figure 1: Visual and Audio Aware Video Emotion Analysis Framework
and valence values with content features were used to classify video emotions into 3 classes, i.e., calm, excited positive and excited negative (Soleymani et al., 2009). Similarly Arifin and Cheung established a framework based on the hierarchical coupling of dynamic Bayesian networks to establish the dependencies of the pleasure-activity-dominance emotion model (Arifin \& Cheung, 2008).

There are also various studies on video affective characterization using audio features, e.g., rhythm, tempo, melfrequency cepstral coefficients (MFCC), pitch, zero crossing rate. For example, three feature sets, i.e., intensity, timbre and rhythm were extracted from audio to classify video emotion using Gaussian mixture models (Lu, Liu, \& Zhang, 2006). Similarly, Xu et al. tried to use audio emotional events (AEE), including laughing, horror sounds and other features to detect horror and comedy movies (Xu et al., 2005).

In fact, there is a complex interaction between the audio and visual contents to determine the perceived mood. As such the video emotion analysis has begun to use feature fusion method to classify emotion into different classes (Yi et al., 2015). Similarly, Trigeorgis et al. selected the low level descriptors with the traditional adaboost as a classifier (Trigeorgis et al., 2015). Wang and Cheong derived the characteristics of multimodality by probabilistic inference based on two SVM models (Wang \& Cheong, 2006), where one SVM model is designed to process audio data and extracts the corresponding advanced audio information, while another SVM model is used to classify the captured video segments.

However, since these framework extracts basic features, they lack the ability to use raw inputs to automatically learn mid-level representations. With the development of deep learning techniques, some deep learning based approaches are also proposed in the literature. For example, Kahou et al. used a deep convolution neural network to analyse facial expressions within a frame and used a deep belief net to capture audio feature (Kahou et al., 2016). Levi and Hassner also
used convolution neural network to capture visual features to classify video into seven emotions (Levi \& Hassner, 2015).

## Proposed Approach

The overall pipeline of the proposed visual and audio aware emotion analysis framework is depicted as Fig. 1, where the whole process is divided into three steps: 1) video segment and low level feature extraction; 2) bi-modal visual and audio feature fusion; and 3) temporal feature integration and emotion classification.

## Video segment and low level feature extraction

To analyze video emotion, it is necessary to firstly divide a video into short videos with a length of $t$ seconds. In this study we set $t=1$ so that a video of length $T$ will have $T$ slices. This segmentation has two benefits. First, since the length of each video is different, this segmentation gives us better access to the visual and audio features. Second, Because of the temporal characteristics of the video, cutting the video into the same segments can be used for subsequent recurrent neural networks.

For each segment, we need to extract its visual and audio features separately. As to the visual features, we extract the $k$ key frames for each segment. Due to the strong correlation among frames within a second, we select $k=1$. The key frame is defined as the frame with the closest RGB histogram to the mean RGB histogram of the whole video clip using the Manhattan distance (Zhu, Jiang, Peng, \& Zhong, 2016). Assume that a video clip $V$ contains $n$ frames, the RGB histogram of $i$-th frame is defined as $h(i)$. The Manhattan distance $D$ between two frames $i$ and $j$ is calculated as follows:

$$
\begin{equation*}
D(i, j)=|h(i)-h(j)| \tag{1}
\end{equation*}
$$

and the key frame will be:

$$
\begin{equation*}
\underset{i}{\arg \min } D\left(i, \frac{1}{n} \sum_{j=1}^{n} h(j)\right) \tag{2}
\end{equation*}
$$

After getting the key frame, it will be resized to $256 * 256$ pixel, as suggested in (Krizhevsky, Sutskever, \& Hinton, 2012) as input for fine-tuning. The concept of fine-tuning is to use a model pre-trained on a large dataset, replacing its last layers, and fine-tune the weights on new task using backpropagation. In this study, AlexNet (Krizhevsky et al., 2012) is employed. AlexNet consists of five convolution layers and three fully connected layers. Here we select the fc7 layer of AlexNet which has 4096 neurons as our visual features.

As to the audio features, the traditional methods for audio emotion analysis need to select proper audio features, e.g., MFCC, energies, flatness, and etc. But they often have to conduct a lot of repeat tests to choose the best features. In order to take full advantage of the depth convolution neural network model in extracting data features, the original features of the data should be kept as much as possible in order to avoid losing information. In this research, we process the audio to spectrogram (Barker \& Virtanen, 2016), which is a visual representation of the spectrum of frequencies in a sound. We set the window function to 40 ms and the hop size to 20 ms to generate a spectrogram every second using short-time Fourier transform with a Hamming window (Allen, 1977). The resulting image is resized to $256 * 256$ pixels, here we also use the method of AlexNet finetune to extract the fc7 layer as a feature of the spectrogram.

## Bi-modal visual and audio feature fusion

From the last step we obtained visual and audio features for video emotion analysis. However, the length of features of both visual and audio is long and there maybe many redundancy in the features. It will be helpful if we can combine the two types of features and then reduce the overall dimension.

Let $x_{a} \in R^{D}$ denotes audio features and $x_{v} \in R^{D}$ denotes visual features, where $D \in R$ is the dimension of audio and visual features, the joint representation of features by fusion modal can be written as:

$$
\begin{equation*}
x_{f}=\alpha_{a} g\left(x_{a} ; w_{a}\right)+\alpha_{v} g\left(x_{v} ; w_{v}\right) \tag{3}
\end{equation*}
$$

where $g($.$) denotes the hidden layer of both audio and visual$ channel. $\alpha_{a}$ defines the weights of audio features and $\alpha_{v}$ defines the weights of visual features at the same time. The hidden layer of audio features is:

$$
\begin{equation*}
g\left(x_{a} ; w_{a}\right)=\theta\left(\left(w_{a}, x_{a}\right)+b_{a}\right) \tag{4}
\end{equation*}
$$

where $\theta$ denotes the activation function (rectified linear units (Zeiler et al., 2013), sigmoid etc.) of the audio hidden layer. Similarly the hidden layer of visual feature is:

$$
\begin{equation*}
g\left(x_{v} ; w_{v}\right)=\theta\left(\left(w_{v}, x_{v}\right)+b_{v}\right) \tag{5}
\end{equation*}
$$

## Temporal feature integration and emotion analysis

Though previous steps we have obtained fused features from visual and audio perspective, there is still a challenge about how to predict corresponding emotion status. Furthermore, in previous step the features are about a single frame, taking into account the temporal characteristics of video, it is necessary to study how these features can be used over time. In this research we will use the LSTM model to fuse sequence features together.

Recurrent Neural Networks (RNNs) are powerful networks and it can model input sequences of different lengths, because the parameters of the network can be shared over different parts (Mikolov, Karafiát, Burget, Cernocký, \& Khudanpur, 2010). RNNs are often trained by Back-Propagation Through Time (BPTT) algorithm, but the main problem with the BPTT is that the gradients tend to vanish or explode which was resulted by propagating the gradients down through layers. Therefore it is difficult to learn efficient long-term dependencies. To overcome this limitation, the Long-Short-Term-Memory (LSTM) (Hochreiter \& Schmidhuber, 1997) units have been created to capture long-term dependencies. LSTMs have the ability to remove or add information to the cell state through a well-designed structure called a "gate". It is believed that the LSTMs can model the temporal aspect of induced emotions in our task. Various units have been proposed in the community to constitute a LSTM. In this research, we employed the LSTM units described in (Zaremba \& Sutskever, 2014). The LSTM unit of time step $t$ consists of three sigmoidal gates, i.e., input gate $i_{t}$, output gate $o_{t}$, forgetting gate $f_{t}$. The most important part of the LSTM unit is a linear self-loop state cell $c_{t}$. The memory cell unit $c_{t}$ is a sum of two terms: the previous memory cell unit $c_{t-1}$ which is modulated by $f_{t}$, and $g_{t}$, a function of the current input and previous hidden state, modulated by the input gate it. $h_{t}$ denotes the hidden layer's output at step $t$. We can update our hidden layer for time step $t$ as follows:

$$
\begin{gather*}
i_{t}=\sigma\left(W_{x i} x_{t}+W_{h i} h_{t-1}+b_{i}\right)  \tag{6}\\
f_{t}=\sigma\left(W_{x f} x_{t}+W_{h f} h_{t-1}+b_{f}\right)  \tag{7}\\
o_{t}=\sigma\left(W_{x o} x_{t}+W_{h o} h_{t-1}+b_{o}\right)  \tag{8}\\
g_{t}=\tanh \left(W_{x c} x_{t}+W_{h c} h_{t-1}+b_{c}\right)  \tag{9}\\
c_{t}=f_{t} \odot c_{t-1}+i_{t} \odot g_{t}  \tag{10}\\
h_{t}=o_{t} \odot \tanh \left(c_{t}\right) \tag{11}
\end{gather*}
$$

where $x_{t}$ is the current fusion feature, $h_{t-1}$ is the previous hidden layer vector. $x \odot y$ denotes the element-wise product of vectors $x$ and $y$. In addition, $W_{x i}, W_{x f}, W_{x o}, W_{x c}, W_{h i}, W_{h f}$, $W_{h o}, W_{h c}$ are weights for the gates, and $b_{i}, b_{f}, b_{o}, b_{c}$ are biases for the gates. $\sigma$ is the nonlinear methods (e.g., sigmoid or tanh).

The output of the last time step of LSTM unit will be the input of the fully connected neural network, also known as multi-layer perception (MLP).The hidden layers and parameters of MLP will discuss in experiment. The prediction layer
will have 3 units $y_{l}(l=0,1,2)$ and the class probability is calculated by taking the softmax as below:

$$
\begin{equation*}
y_{l}: p\left(y_{l}=c\right)=\frac{\exp \left(y_{l}, c\right)}{\sum_{c^{\prime} \in C} \exp \left(y_{l}, c^{\prime}\right)} \tag{12}
\end{equation*}
$$

where $C$ denotes the three emotion states. Finally the label with the max probability will be the expected label.

## Experimental Study

## Dataset

In order to fairly verify the performance of our proposed method, we implement it on the dataset provided by MediaEval 2015 Afective Impact of Movies task (Sjöberg et al., 2015), which consists of 10,900 short video clips extracted from 199 Creative Commons-licensed movies of various genres. It is an extension of the LIRIS-ACCEDE dataset (Baveye, Dellandréa, Chamaret, \& Chen, 2015), which originally contains 9,800 excerpts extracted from 160 movies. The MediaEval 2015 task added 1,100 video clips additionally from 39 movies. The dataset is divided into training set and test set. The training set consists of 6,144 videos extracted from 100 movies while the test set includes 4,756 videos extracted from the remaining 99 movies. These videos last from 8 to 12 seconds and start and end with a cut or fade. The ground truth for each of 10,900 video clips consists of discrete labels for arousal (calm-neutral-active) and valence (negative-neutral-positive).

## Evaluation Metrics \& Baseline

In order to evaluate the affective detection task, the official and complete method is global precision (Sjöberg et al., 2015), which is the proportion of the number of correctly assigned videos in the total video samples and is defined as:

$$
\begin{equation*}
\text { Precision }=N_{c} / N_{t} \tag{13}
\end{equation*}
$$

where $N_{c}$ is the number of videos which are assigned to the correct class, and $N_{t}$ is the total number of test videos. In this research, we only compare the results obtained for the arousal classification. This is because compared to arousal, valence is not sensitive in the dataset. As such comparing the results of the arousal classification is a commonly adopted choice (Sjöberg et al., 2015).

To evaluate applicability of the model fusion approach, in this research we compared it against the proposed approach in predicting arousal values using only the image features or audio features. Furthermore, we also compared the proposed approach against early fusion and later fusion methods, respectively. In the early fusion model we simply concatenate the audio and video features together, while in later fusion schema, we firstly trained two MLP classifiers to represent the two modalities separately. Their predictions are denoted as $p_{a}$ and $p_{t}$ and the overall output emotion class can be assigned by

$$
\begin{equation*}
p=\alpha p_{a}+(1-\alpha) p_{t} \tag{14}
\end{equation*}
$$

where $\alpha$ indicates the relevant importance between audio and visual features. In this research we set $\alpha=0.56$, as indicated in (Goyal, Kumar, Guha, \& Narayanan, 2016).

Afterwards we also compare our results against state-ofart systems in the MediaEval 2015 challenge. These systems include: later fusion models with manually selected features (Yi et al., 2015; Chakraborty et al., 2015), early fusion models with manually selected features (P. et al., 2015; Trigeorgis et al., 2015), later fusion models with automatically selected features (Tiwari et al., 2016), early fusion models with automatically selected features (Dai et al., 2015; Seddati et al., 2015).

## Experiment Settings

We tested the different feature dimensions and found that the final result did not change much in the range of 250 to 1000. We decided to use feature size of 512 for both visual pathway and audio pathway. Therefore the fusion feature as the final LSTM model input has 512 dimensions. LSTM model can handle different video length, the longest video is 18 seconds that is 18 time steps. The system is trained end-to-end to predict the videos emotion class at each time step. It is found that the most significant parameter is the number of LSTM hidden layers. We compared LSTM networks with 64, 128, 256, and 512 hidden units, separately. Finally, we found that 256 hidden units can be selected to achieve the best results, as shown in Fig. 2. Afterwards we selected MLP as our classifier in which rectified linear units were used as nonlinear functions and stochastic gradient descent with minibatches was used for parameter updates (Zeiler et al., 2013). Also we used categorical cross-entropy loss function to get the best results. The hidden layer uses dropout to prevent overfitting, and the factor is set 0.5 . The number of hidden layer of MLP and the units' number can also affect the model results, and ultimately we chose one hidden layer with 64 hidden units.

Figure 2: Arousal Accuracy with Different Number of Hidden Layer Units

## Result and Analysis

Table 1 presents the proposed method's performance using different feature space and fusion strategy. It is observed that the performance of all feature fusion strategies are better than using only single feature. It is because that video images are the main cause of people's emotions, but audio
can complement the lack of information in video images. It is further found that our proposed model fusion method is better than both the simple early fusion and late fusion, affirming the effectiveness of multi-modal emotion classification. This maybe because early fusion leads to the sparsity of input vectors and late fusion has little consideration for visual and audio's correlation (Williams et al., 2009).

Table 1: Comparison of accuracy by different fusion models

| Approaches | Arousal Accuracy(\%) |
| :---: | :---: |
| Visual features only | 55.51 |
| Audio featues only | 55.14 |
| Early fusion | 55.71 |
| Later fusion | 55.70 |
| Modal fusion | $\mathbf{5 5 . 8 9}$ |

Table 2 is the experimental result of the propose method against most recently revealed results. The result demonstrates the feasibility and superiority of end-to-end training for video emotion classification. It is found that one system's result (Yi et al., 2015) is slightly higher (less than $0.1 \%$ ) than the proposed one. However, its features are selected manually, which is time-consuming, not universal and not portable. What's worse, their feature dimension is also long. End-toend training has better transfer learning properties and the training process is convenient. Using a well-trained model for another similar problem only needs a simple refinement. It is also observed from the table that the method proposed in (Tiwari et al., 2016) has the similar feature size to ours, while the proposed model outperforms their final arousal accuracy. This may because their feature fusion approach is rough and does not consider the temporal characteristics. This demonstrates that temporal features could play a role in video emotion analysis to a certain extent. As for the other methods, our result can outweigh them which shows that modal fusion has a great advantage compared with simple early fusion and later fusion. Fusing visual and audio feature in a mid-level is a potential strategy since visual and audio information in video have a certain interaction. It can also inferred that CNN has good performance in visual and audio feature extraction.

## Conclusion and Future Work

Video emotion recognition is an important challenge as detecting affective attitudes is an important research field in cognitive science. It is argued that visual and audio information are both important in detecting video emotion. Therefore in this paper we used a deep learning architecture to fuse visual and audio modalities for video affective classification. This end-to-end framework has the advantages of simple training and convenient transplantation and demonstrates that modal fusion with small size of features can compare against most state-of-art results obtained by participants of the MediaEval 2015 Affective Impact of Movies task. Furthermore, it would be interesting to study if it is feasible to
include information from other domains/modalities, e.g., abstract words (Siakaluk, Knol, \& Pexman, 2014), which deserve future study in the future work.

# Teaching Versus Active Learning: A Computational Analysis of Conditions that Affect Learning 

Scott Cheng-Hsin Yang (scott.cheng.hsin.yang@gmail.com) \& Patrick Shafto (patrick.shafto@gmail.com)<br>Department of Mathematics \& Computer Science, Rutgers University-Newark

#### Abstract

Researchers have debated whether instructional-based teaching or exploration-based active learning is better for decades with unsatisfying results. A main obstacle is the difficulty in precisely controlling and characterizing the pedagogical methods used and the learning conditions in empirical studies. To address this, we leveraged existing computational models of teaching and active learning to formalize the methods and the learning process. We compared the two pedagogical methods in a concept-learning framework and investigated their effectiveness under various scenarios. Our results show that when the learner and teacher are conceptually aligned, teaching is at least as effective as, and often much more effective than active learning, but when the alignment is broken, active learning can yield moderate improvement over teaching. We conclude by discussing our results' implications for the debate and the prospects of bringing computational models to bear on complex real-world problems that are resistant to simple experimental investigation.

Keywords: pedagogical methods; direct instruction; self exploration; Bayesian teaching; active learning

For centuries, the predominant pedagogical method has been instructional-based teaching such as lecturing. Over the past several decades, constructivism has received increased attention, and educational practitioners have been incorporating constructivist pedagogical methods that emphasize active learning, exploration, and discovery by the learners themselves (Bruner, 1961; Vygotsky, 1978). These methods are typically described as being opposite: the instruction-based method is teacher-centred and passive, while the explorationbased method is learner-centred and active.

Researchers have taken up the debate between instructionbased teaching and active learning, with unsatisfying results. Early cognitive science extolled the virtues of active learning (Bruner, 1961). However, more recently researchers have alternately found evidence for both teaching (Mayer, 2004) and active learning (Sweller, 1988; Gureckis \& Markant, 2012). Researchers have also found instances of equivalence (Klahr \& Nigam, 2004) and nuanced interplay between teaching and active learning when in sequence (Bonawitz et al., 2011; DeCaro \& Rittle-Johnson, 2012). This has led researchers to propose new constructs, such as Guided Play (Weisberg, Hirsh-Pasek, \& Golinkoff, 2013), which have moved forward the debate. However, when and why teaching or active learning may yield better outcomes remain largely unresolved.

One of the greatest barriers to resolving this debate is the difficulty in fully characterizing the pedagogical methods used and precisely controlling the conditions under which they are used (Prince, 2004). We argue that by abstracting away from the particulars of specific learning material (e.g., biology or mathematics) and idealizing the learning process (to be rational and normative), we may use computational
models to formalize the methods and conditions and thus clarify when and why teaching may outperform active learning, and vice versa. Computational models of both teaching and active learning exist in the cognitive science and machine learning literature (e.g., Shafto \& Goodman, 2008; MacKay, 1992). These models have been shown to describe human behavior well in a variety of simple learning settings and higherlevel perceptions (Shafto, Goodman, \& Griffiths, 2014; Castro et al., 2009; Gureckis \& Markant, 2009; Yang, Lengyel, \& Wolpert, 2016). However, the two types of models have never been compared in the same framework.

We provide the first computational comparison between teaching and active learning. Following previous computational work, we use a concept learning task to assess the effectiveness of the two pedagogical methods. To approximate some of the complexity of real-world learning problems, we design the concept space to be hierarchical and introduce partial ambiguity between concepts by introducing overlap between the concepts. As an illustration, the categories "bird" and "sea animals" are partially ambiguous due to the existence of examples that are in both categories. Such ambiguity makes certain examples uninformative for grasping distinctions between the concepts, thus limiting the performance of active learning. In these cases the guidance of a knowledgeable and helpful teacher may be of great import, by avoiding such ambiguous examples. Using varying degrees of ambiguity, we will investigate under what scenario is the effectiveness of teaching more pronounced.

Given perfect knowledge and rational inference, we know that teaching is at least as effective as active learning. This assumes that the teacher is knowledgeable and helpful and that the learner and teacher use the same inference scheme. There is little reason to believe that these assumptions are met in everyday educational settings (Chi, Siler, \& Jeong, 2004). The effect of an unhelpful teacher is easy to imagine (random guidance), but the effects of a teacher with imperfect knowledge of a learner or a teacher operating with incorrect beliefs about the world is less apparent. To investigate this, we introduce a conceptually misaligned teaching model in which we vary the types and degrees of misalignment between the teacher's and learner's concept spaces. Using this, we explore scenarios under which exploration outperforms teaching.

## Framework

The most common and simplest concept learning tasks use concept spaces with a single-layer of Boolean concepts where the features can be discrete or continuous (e.g., Shafto \& Goodman, 2008; Castro et al., 2009; Gureckis \& Markant,
2009). While this is a sensible framework for certain questions, to accentuate differences between the models and ensure that we can model the kinds of challenging concept learning problems that appear in more realistic scenarios, we adopt a more complex concept space with two-layered Boolean concepts, where the features of the higher-level concepts are themselves concepts. In particular, a two-layered concept space allows us to introduce partial ambiguity between the concepts that only teaching, but not exploration, can resolve (explained later in more details with an example). Similarly, this allows us more interesting variations in the ways that teachers may be incorrect about learner's beliefs, or the true state of the world. Below we begin the description of the framework by describing the concept space and setting notations before presenting a detailed example, and the simulations results.

## Concept space

A concept space contains two concepts. A concept contains at least 1 and up to 6 distinct patterns. There are in total 6 types of patterns (Fig. 1 left), and they are all the Boolean concepts that have 4 features with balanced binary labels, that is, two features labeled 0 and two features labeled 1. Figure 1 provides two example concept spaces. Formally, we denote the concept space by $H$, the concepts by $h=\left\{h_{1}, h_{2}\right\}$, the $j^{\text {th }}$ pattern in a concept by $f_{j}$, the features by $x$, and the feature's binary label by $y=\{0,1\}$.

The prior probability on the concept space is hierarchically uniform. This means that $P\left(h_{1}\right)=P\left(h_{2}\right)=\frac{1}{2}$ and that $P\left(f_{j} \mid h_{k}\right)=\frac{1}{N_{k}}$ for all $j$, where $N_{k}$ is the number of patterns in $h_{k}$. We say that the concepts are ambiguous when two concepts have shared patterns, and the degree of ambiguity, $a$, is defined by the number of shared patterns (see Fig. 1 for example). Recall that ambiguous concepts allow a stronger distinction to be made between teaching and active learning.

For the discussion of concept misalignment-where the teacher may be incorrect about the learner's beliefs or the true state of the world-we denote the learner's concept space by $H_{L}$, the teacher's concept space by $H_{T}$, and the true world space by $H_{W}$. We quantify the degree of misalignment, $m$, between two concept spaces by the the minimum number of pattern "moves" within a concept space to make the two concept spaces equivalent. The move operation includes moving a pattern between two concepts, removing a pattern, or adding a pattern. Misalignment with $H_{W}$ is sometimes referred to as misconception. Later we will investigate how the effectiveness of teaching degrades when the learner has misconceptions ( $H_{W}=H_{T} \neq H_{L}$ ) and when the teacher has misconceptions $\left(H_{W}=H_{L} \neq H_{T}\right)$.

## An example trial

First, a concept in $H_{W}$ is chosen as the correct answer; then, a pattern within that concept is chosen as the underlying pattern. On the first trial, a pedagogical method of choice (optimal exploration or teaching) computes scores (according to Eq. 3 or Eq. 6, respectively) for all four potential features.

Figure 1: The six types of patterns, denoted $f$, are used to construct concepts. The positions-top left (TL), top right (TR), bottom left (BL), and bottom right (BR)-of the small squares with blue outline represent the four features. The colors-white or black-represents the binary feature labels which correspond to individual observations. For Concept space A, the prior for each pattern in Concepts 1 and 2 are $P\left(f \mid h_{1}\right) P\left(h_{1}\right)=\frac{1}{5} \times \frac{1}{2}$ and $P\left(f \mid h_{2}\right) P\left(h_{2}\right)=\frac{1}{3} \times \frac{1}{2}$, respectively. The degree of ambiguity, $a$, is 2 because $f_{3}$ and $f_{5}$ in $h_{1}$ are also in $h_{2}$. For Concept space B, $P\left(f \mid h_{1}\right) P\left(h_{1}\right)=\frac{1}{6} \times \frac{1}{2}$, $P\left(f \mid h_{2}\right) P\left(h_{2}\right)=1 \times \frac{1}{2}$, and $a=1$. The degree of misalignment between Concept spaces A and B is 2 : one has to make two "moves" in Concept space A (delete the last pattern in Concept 2 and move the second pattern from Concept 2 to Concept 1) in order to make it equivalent to Concept space B.

The learner queries the world the feature with the highest score, and the world labels the query according to the predetermined underlying pattern. With this observation, the chosen pedagogical method computes the scores for the remaining three features. Then, the learner queries; the world labels; and the process repeats until every feature is queried. Before the first query and after each query, the learner's posterior belief (via Eq. 2) about the correct concept is recorded.

We now give a concrete example that compares optimal exploration with optimal teaching. We first name the features as Top Left (TL), Top Right (TR), Bottom Left (BL), and Bottom Right (BR; see Fig. 1 caption). Figure 2A shows the concept space under consideration, the target concept, and the target underlying pattern. In this case, the teacher's concept space, the learner's concept space, and the world are all aligned ( $H_{W}=H_{T}=H_{L}$ ). Figure 2B shows the scores that exploration and teaching assign to each query. The reasoning behind the scoring is based on predicted outcomes. For example, if TL is queried and labeled black, then one can rule out all patterns in $h_{2}$ and be certain that $h_{1}$ is the answer. This is good. But if TR is queried and labeled black, one can only rule out $f_{2}$ in $h_{1}$ and $f_{1}$ in $h_{2}$, leaving the two concepts equally likely, which is not good. Following this reasoning, the active learner or teacher considers all the possible outcomes (if TL is white...; if TB is black...; if TB is white...; and so on) and chooses the one that best resolves the answer. In this case, before observing anything, both optimal exploration and optimal teaching scores TL or BR the highest. In this trial the learner chooses TL and observes white.

Given this data, $\mathcal{D}=\left\{x_{1}=T L, y_{1}=1\right\}$, the learner rules out $f_{1}$ and $f_{2}$ in $h_{1}$; thus, at this point, the learner believes that $P\left(h_{1} \mid \mathcal{D}\right)=\frac{1}{4}$ and that $P\left(h_{2} \mid \mathcal{D}\right)=\frac{3}{4}$. Optimal exploration chooses a query that reduces the expected uncertainty about arriving at an answer. Intuitively, uncertainty is highest when $h_{1}$ and $h_{2}$ are equally likely and lowest when one is definitely correct. Following the above reasoning, an ac-

Figure 2: An example trial. A. The concept space under consideration. The predetermined underlying pattern is $f_{3}$ in $h_{2}$ (red box), which happen to be equivalent to $f_{3}$ in $h_{1}$. B. Query scorings for optimal exploration according to Eq. 3 (left) and for optimal teaching according to Eqs. 6 (right). The "x" indicates that an observation has been made on that feature, so that feature is excluded from the set of potential queries. The chosen query in each step is highlighted yellow and outlined with a thick border. C-D. Performances of optimal exploration and teaching following the observation sequences given in B. Blue squares indicate that the feature value has not yet been observed.
tive learner computes the expected uncertainty in each predicted case. After summing over all the expected uncertainty weighted by the chance those case would occur, the optimal explorer can then assign a score to each query to indicate how much certainty was gained (or uncertainty is reduced). Here, the sum shows that BR leads to the highest information gain, mainly because it helps reach certainty with a $50 \%$ chance.

Optimal teaching chooses a query to maximize the learner's inference for a desired concept. As such, the query depends on the answers that the teacher has in mind. The reasoning behind optimal teaching is again based on predicted cases and goes as follows: If the real answer is $h_{1}, \mathrm{BR}$ will be white, and TR and BL will be black. Hence, when BR is revealed, the learner will infer that both concepts are equally likely, and when TR or BL is revealed, the learner will consider $h_{2}$ to be more likely. Thus, to help the learner infer the hypothetical answer of $h_{1}$, the teacher will guide the learner to query BR, even though it is, in some sense, ambiguous. Following the same kind of reasoning, the teacher concludes that, for $h_{2}$, TR or BL is the better choice. Now, because the learner knows that the teacher is helpful, the learner can actually infer the answer with certainty just by the teacher's guidance because the guidance is answer-dependent.

This line of reasoning shows that optimal teaching can be better than optimal exploration for two reasons. First, the teacher helps reduce irrelevant search by tailoring guidance based on the answer. This is consistent with theories that support instructional-based teaching (Kirschner, Sweller, \& Clark, 2006). Second, because the guidance depends on teacher's knowledge of the answer, the learner can leverage pedagogical reasoning-the fact that the teacher is knowledgeable and helpful-to make stronger inferences.

Figure 2C-D show the performance with optimal exploration and teaching, respectively. The performance is defined as the learner's posterior belief about the target concept after observing some data (Equation 2 is used for exploration, and Eq. 4 is used for teaching). The performance with optimal exploration eventually reaches chance level because the
underlying pattern, $f_{3}$ in $h_{2}$, is ambiguous in this case. The performance with teaching reaches 1 even for the ambiguous pattern because in optimal teaching the learner can use pedagogical reasoning to break this ambiguity. This type of performance difference via pedagogical reasoning is not possible with single-layered concept space.

## Inference

The learner's inference follows Bayes' rule. Given some data $\mathcal{D}=\left\{x_{i}, y_{i}\right\}_{i=1}^{N}$, the learner's joint posterior is

$$
\begin{align*}
P(h, f \mid \mathcal{D}) & =\frac{P(\mathcal{D} \mid h, f) P(h, f)}{\sum_{k, j} P\left(\mathcal{D} \mid h_{k}, f_{j}\right) P\left(h_{k}, f_{j}\right)}=\frac{1}{Z} P(\mathcal{D} \mid f) P(f \mid h) P(h) \\
& =\frac{1}{Z} \prod_{i} P\left(y_{i} \mid x_{i}, f\right) P(f \mid h) P(h) \tag{1}
\end{align*}
$$

In our framework, labelling is deterministic, so the likelihood $P\left(y_{i} \mid x_{i}, f_{j}\right)$ is either 0 or 1 . The normalizing constant, $Z$, can be computed exactly by enumeration in our simple setting.

The joint posterior of Eq. 1 can be used to obtain the concept posterior,

$$
\begin{equation*}
P(h \mid \mathcal{D})=\sum_{j} P\left(h, f_{j} \mid \mathcal{D}\right), \tag{2}
\end{equation*}
$$

by marginalizing out $f$. It can also be used to obtain the pattern posterior, $P(f \mid \mathcal{D})=\sum_{k} P\left(h_{k}, f \mid \mathcal{D}\right)$, by marginalizing out $h$. This is used for computing the predictive distribution.

## Optimal exploration

We model optimal exploration following a Bayesian active learning model that chooses query $x$ to myopically maximize the expected information gain (MacKay, 1992). The probability of choosing an $x$ is

$$
\begin{equation*}
P(x \mid \mathcal{D})=\lim _{\alpha \rightarrow \infty} \frac{1}{Z}\left[\langle\mathrm{H}[h \mid \mathcal{D}]-\mathrm{H}[h \mid \mathcal{D}, x, y]\rangle_{P(y \mid x, \mathcal{D})}\right]^{\alpha} \tag{3}
\end{equation*}
$$

Here, $Z=\sum_{x^{\prime}}\left[\left\langle\mathrm{H}[h \mid \mathcal{D}]-\mathrm{H}\left[h \mid \mathcal{D}, x^{\prime}, y\right]\right\rangle_{P\left(y \mid x^{\prime}, \mathcal{D}\right)}\right]^{\alpha}$ is the normalizer to produce a probability distribution over $x$, and
$\mathrm{H}[h \mid \cdot]=-\sum_{h} P(h \mid \cdot) \log P(h \mid \cdot)$ is the Shannon entropy. Because $\mathrm{H}[h \mid \cdot]$ is a measure of the uncertainty of the posterior, the difference in entropy before and after receiving a new observation pair $\{x, y\}$ in Eq. 3 quantifies the expected reduction in $h$ uncertainty, which is information gain. The expectation operator, $\langle\cdots\rangle_{P(y \mid x, \mathcal{D})}$, indicates that the learner does not know exactly whether the label for $x^{*}$ will be 0 or 1 but maintains a predictive distribution. The predictive distribution is given by $P(y \mid x, \mathcal{D})=\sum_{j} P\left(y \mid x, f_{j}\right) P\left(f_{j} \mid \mathcal{D}\right)$. The limit $\alpha \rightarrow \infty$ assigns probability uniformly over the $x$ 's that produce the highest argument value. It returns the set of values that have the highest probability when there is more than one; it is equivalent to $\arg \max$ when there is a single highest argument value.

## Optimal teaching

We define optimal teaching to satisfy three assumptions (Shafto \& Goodman, 2008; Shafto et al., 2014). First, the teacher knows the correct answer. Second, $H_{W}=H_{T}=H_{L}$, and the teacher and learner use exactly the same inference scheme. Third, the teacher and the learner are cooperative. From the learner's perspective, this means that the learner reasons about how the teacher, knowing the answer, chooses the most helpful guidance. From the teacher's perspective, this means that the teacher provides guidance while being aware of the learner's inference.

We begin the formulation with the learner's inference. Given the guidance, $x$, from the teacher and the corresponding new observation, $y$, the learner's inference follows

$$
\begin{equation*}
P_{L}(h, f \mid x, y, \mathcal{D})=\frac{P(y \mid x, f) P_{T}(x \mid h, \mathcal{D}) P_{L}(f, h \mid \mathcal{D})}{\sum_{j, k} P\left(y \mid x, f_{j}\right) P_{T}\left(x \mid h_{k}, \mathcal{D}\right) P_{L}\left(f_{j}, h_{k} \mid \mathcal{D}\right)} \tag{4}
\end{equation*}
$$

Note that the teacher's guidance carries information about the answer via the likelihood, $P_{T}(x \mid h, \mathcal{D})$. The cooperative inference mentioned above can be modeled by combining Eq. 4 with

$$
\begin{align*}
& P_{L}(h \mid x, \mathcal{D})=\frac{1}{Z}\left\langle\sum_{j} P_{L}\left(h, f_{j} \mid x, y, \mathcal{D}\right)\right\rangle_{P_{L}(y \mid x, h, \mathcal{D})}  \tag{5}\\
& P_{T}(x \mid h, \mathcal{D})=\lim _{\alpha \rightarrow \infty} \frac{\left[P_{L}(h \mid x, \mathcal{D}) P(x)\right]^{\alpha}}{\sum_{x^{\prime}}\left[P_{L}\left(h \mid x^{\prime}, \mathcal{D}\right) P\left(x^{\prime}\right)\right]^{\alpha}} \tag{6}
\end{align*}
$$

where $P_{L}(y \mid x, h, \mathcal{D})=\sum_{j} P\left(y \mid x, f_{j}\right) P_{L}\left(f_{j}, h \mid \mathcal{D}\right), Z$ is a normalizer, and $P(x)$ is a uniform distribution over $x$. This system of equations (4-6) is first iterated until convergence, then an $x$ is sampled from Eq. 6 conditioned on the teacher's knowledge of the true concept. A sensible initial condition is a uniform $P_{T}(x \mid h, \mathcal{D})$ in Eq. 4. Compared to Eq. 3, the extra $h$ in the expectation operator, $\langle\cdots\rangle_{P_{L}(y \mid x, h, \mathcal{D})}$, shows that teacher and learner reasons about one $h$ at a time. The subscript $L$ in $P_{L}(\cdot)$ emphasizes that the concept-pattern joint prior and posterior are based on the learner's reasoning; the subscript $T$ in $P_{T}(x \mid h, \mathcal{D})$ emphasizes that the $x$ is based on the teacher's reasoning; and the unsubscripted $P(y \mid x, f)$ indicates that the label likelihood is provided by the true world. ${ }^{1}$

[^544]
## Conceptually misaligned teaching

Optimal teaching is always at least as good as optimal exploration because the teacher's guidance offers extra information about the correct answer. But what happens when the assumptions of optimal teaching are violated? We consider two types of violation that breaks the second assumption of the learner and teacher sharing the same inference by introducing misconception in the learner (type 1: $H_{W}=H_{T} \neq H_{L}$ ) and misconception in the teacher (type 2: $H_{W}=H_{L} \neq H_{T}$ ). Note that the first and third assumptions of optimal teaching are still kept. The first assumption poses that regardless of whether the teacher has misconception, the teacher knows the correct concept label. The third assumptions poses that the teacher and learner still reason cooperatively. This leads us to introduce conceptually misaligned teaching, where the two agents, the learner and teacher, reason about each other while wrongly assuming the other agent's concept space. Computationally, the teacher provides $x$ by going through Eqs. 4-6 with $H_{T}$, thinking that the learner also operates with $H_{T}$. Having received $x$, the learner also goes through Eqs. 4-6, while assuming that the teacher also has $H_{L}$ in mind. The first type of violation (misconception in learner) is a common issue in education (Chi et al., 2004), and the second type (misconception in teacher but not in learner) is a natural counterpart simulation to do.

## Simulations: systematic comparison

In the Framework section, we gave a detailed example of how exploration compares to teaching given a particular underlying pattern and concept space. In this section, we compare the performance of the two pedagogical methods in a systematic manner over different classes of concept spaces. This will lead us to address more broadly the condition under which teaching is better than active learning and vice versa. To this end, we consider three scenarios.

For all three scenarios, a concept space with degree of ambiguity, $a$, contains $6+a$ patterns. All 6 patterns in Fig. 1 are used at least once, but no pattern is used more than twice. Figure 1 shows two example concept spaces that satisfy the above criteria. The first scenario assumes that $H_{W}=H_{L}=H_{T}$ and entertains concept spaces of varying degree of ambiguity from $a=0$ to 5 . For a given $a$, the simulation includes all combinations of assignments of $6+a$ patterns to two concepts, with isomorphic concept spaces counted only once. The second scenario assumes $H_{W}=H_{T} \neq H_{L}$ and a fixed $a=1$. We consider all pairings of $H_{T}$ and $H_{L}$ with $a=1$ up to concept-space pair isomorphism, and label each pair with their degree of misalignment, $m$, which can vary from 0 to 6 . The third scenario assumes $H_{W}=H_{L} \neq H_{T}$ and $a=1$. The

[^545]

Figure 3: A. Double-performance plot for the trial in Fig. 2. B. Double-performance plot averaged over concept spaces with differing degree of ambiguity. The numbers indicate the $a$ of the curve, ranging from 0 to 5 in increments of 1 from the rightmost curve to the leftmost curve. C. Double-performance plot for a learner with differing degree of misconception, $m$, as described in the Concept Space section under Framework. The numbers indicate the $m$ of the curves. All concept spaces have $a=1$, so the curve with $m=0$ matches the curve with $a=1$ in A. D. Double-performance plot for a teacher with differing degree of misconception. The numbers again indicate $m$ and increases from the top to bottom in order of the curves' end points.
pairing and labeling are done as in the second scenario.
To visualize the relative performances of exploration and teaching, we plot the two pedagogical methods against each other (Fig. 3A). On this double-performance plot, curves above the diagonal indicates that teaching is better than optimal exploration, and curves below indicates that teaching is worse. To reveal higher-order trends, we average single-trial performances firstly over the patterns in individual concept space, weighted by the patterns' prior probabilities, and secondly over concept spaces that have the same label; that is, the same $a$ or $m$, with each concept space contributing equal weight. Figure 3B, C, and D show the relative performances under the first, second, and third scenario, respectively.

Figure 3B shows that optimal teaching is better than optimal exploration when the concepts are partially ambiguous but no better or worse when the concept spaces are fully unambiguous. When the concept space is fully ambiguous, performances remain at chance level for both teaching and exploration. The advantage of of teaching in absolute performance, as judged by the end points on the double-performance plot, is most pronounced with a $30 \%$ improvement over exploration at a medium degree of ambiguity of $a=3$. Overall, teaching is better than exploration under partial ambiguity because of the reduction in irrelevant search and pedagogical reasoning described in the example task.

Figure 3C shows that on average, teaching and exploration perform similarly when the learner's concept space is wrong. On the one hand, this shows that teaching is robust against learner's misconceptions (in terms of hurting learning) even when the misconception is strong; on the other hand, it shows that the benefits of teaching (in terms of boosting learning) diminishes in the face of a little misconception. The trial-by-trial performances reveal extreme cases when teaching is much worse than exploration ( $0 \%$ vs. $>80 \%$ ). This happens when the learner's concept space looks like Concept space B in Fig. 1, where $h_{1}$ contains all the patterns and $h_{2}$ contains only one pattern which is also in $h_{1}$. This suggests that the learner's strong prior bias for an ambiguous pattern ( $f_{3}$ from $h_{1}$ or $f_{1}$ from $h_{2}$ ) being associated with a particular hypothesis
(i.e., with $h_{2}$ ) can distort the effect of pedagogical reasoning when there is conceptual misalignment.

Figure 3D shows that teaching with the wrong concept space leads to evidently poorer performance (roughly 10-20\% worse) during learning, but only somewhat poorer performance (up to about $10 \%$ worse) at the end of learning (after observing all feature values). The exceptions are when $0<m<3$; then teaching ends up very slightly ( $<5 \%$ ) better. Thus, while the advantage of teaching quickly diminishes with misalignment, the final performance of teaching is rather robust. Interestingly, the first and third scenarios combine to show that exploration before teaching is better than the other way around, as the advantage of teaching comes in after the first observation (Fig. 3C), but its disadvantage due to potential misalignment comes in at the first query (Fig. 3E). This is consistent with previous findings on the interplay between exploration and teaching in learning mathematical concepts (Schwartz \& Martin, 2004; DeCaro \& Rittle-Johnson, 2012).

In summary, our analysis shows that if one knows little about the structures of $H_{W}, H_{T}$, and $H_{L}$ and their alignments, teaching is the preferred pedagogical method because it can potentially be much better and will unlikely be much worse than exploration. If one knows that there is moderate amount of misalignment, exploration is the preferred method. If one knows the detailed structures of $H_{W}, H_{T}$, and $H_{L}$, the alignments among them, and a particular target concept, detailed analysis should be done to choose the better method.

Lastly, it is worth considering our results in the context of popular explanations in favor of active learning. These reasons, including attentional control, enhanced memory, stress relief, and etc. (Springer, Stanne, \& Donovan, 1999; Prince, 2004; Markant, Ruggeri, Gureckis, \& Xu, 2016), all suggest that a learner who explores actively maintains an $H_{L}$ more consistent with $H_{W}$ than a leaner who receives passive teaching guidance. A model that includes pedagogical-methoddependent effect on the concept space is an important direction for future work.

## Discussion

Researchers have debated whether teaching or active learning is better for decades without reaching a consensus. A main barrier is the difficulty in precisely controlling the pedagogical method and learning conditions for meaningful comparison of results that support generalization. We argue that by formalizing the learning conditions and the pedagogical methods, we may clarify when and why which pedagogical method is more effective. We adopt existing models for optimal exploration and optimal teaching and introduce a model for conceptually misaligned teaching. Our computational analysis showed that optimal teaching is much better than exploration when the concepts in play are partially ambiguous, but this effect diminishes very quickly with conceptual misalignment between the learner and teacher.

We expect this trend in our results to generalize to larger concept spaces with richer structures. Optimal teaching should be increasingly more effective than optimal exploration because a larger space allows for greater reduction in irrelevant search and a richer structure allows for finer pedagogical reasoning. However, when there is conceptual misalignment, we expect this advantage of teaching to diminish quickly because the ways of misinterpreting guidance and observation also increases with the complexity of the concept space. The exact scaling between the rate of diminishing benefit and the size and complexity of concept space and is an interesting question for future work.

We have focused on the pedagogical method that best leads the learner to a specific concept. This approach is common to concept learning experiments. However, in many realworld scenarios, we may also be interested in generalization: what does performance on one task predict about future performance on related tasks. To capture this, we would need to consider concept spaces with much richer structure that would support incremental building of compositional concepts and/or transfer learning. Although beyond the scope of the current research, even defining what such conceptual structures should look like in order to capture some of the richness of real-world concept learning problems is another interesting question for future work.

Debates about the relative efficacy of different pedagogical methods have plagued the literature. Because of the complexity of concepts and the variability in the application of the pedagogical methods themselves, empirical tests have been largely inconclusive. Our approach has been to abstract away from some of the details and ask the question in an idealized setting: under what circumstances would we expect teaching or active learning to perform better. Our results yielded the surprising conclusion that, even when the assumptions of teaching are not perfectly met, it is quite robust. While there is more work to be done to capture the richness of psychological theories of active learning, our approach provides a way forward where empirical research has not been as successful as initially hoped. Considerable work remains, but systematic computational analysis of theories themselves provides a po-
tentially promising complement to more traditional empirical methods for uncovering more optimal methods of delivering educational content.

#### Abstract

Visual aids have been found to provide an unusually efficient means of risk communication for diverse and vulnerable individuals facing high-stakes choices (e.g., health, finance, natural hazards). Research indicates the benefits of visual aids follow from scaffolding of cognitive and metacognitive processes that enable independent evaluation and understanding of risk-i.e., risk literacy (see Skilled Decision Theory; Cokely et al.,. 2012; in press). Here, we present a brief review and progress report on the development of an online adaptive graph literacy tutor developed as part of the RiskLiteracy.org decision education platform. We begin with a brief review of theoretical foundations of the current tutor based on graph comprehension theory. Next, we discuss key steps in developing and validating our pseudo-intelligent adaptive tutor with emphasis on cognitive and psychometric item analyses and transfer assessments (i.e., decision-making biases). Finally, we present recent changes in technical implementation of the RiskLiteracy.org platform (i.e., Python based with a NoSQL database) that are designed to facilitate interactive, yet brief ( 5 minute to 3 hour) and easier-to-develop training and risk communication tutors. Discussion focuses on emerging opportunities including cognitive oriented usability analyses that should help promote an effective, enjoyable, and inclusive user experience.

Keywords: Graph literacy, decision making, risk literacy, intelligent tutors, risk communication, brain training, numeracy

## Introduction

Well-informed, skilled decision making is associated with a wide-range of socially and economically valuable decision making outcomes (e.g., health, wealth, happiness; for a review see Skilled Decision Theory, Cokely et al., in press). In part, the benefits of general decision making skill, as measured by tests like the Berlin Numeracy Test, result because skilled decision makers tend to be better prepared to independently evaluate and understand risk as presented in common risk communications (e.g., information about health, finance, natural hazards; RiskLiteracy.org) (Cokely et al., 2012). Unfortunately, individuals with lower skill levels, including many at-risk individuals, are routinely biased by standard and well-intentioned risk communication practices, which can result in dangerous decision errors (e.g., ignoring a heart attack; Petrova et al., 2016).

To help address limitations of current risk communication practices, recent scientific efforts have endeavored to develop more inclusive decision education technologies and outreach platforms (e.g., adaptive decision support and training). For
example, simple, transparent visual aids have been found to dramatically enhance risk literacy and independent decision making, conferring major benefits to diverse decision makers who vary widely in ages, backgrounds, abilities, cultures, and values (Garcia-Retamero \& Cokely, 2013). Consider a recent systematic review by Garcia-Retamero and Cokely (2017) spanning dozens of experiments involving more than 25,000 participants from 60 countries. This work specifically mapped informed, skilled decision-making and how it interacts with graph literacy and visual aids, presenting insights on (a) visual aid effectiveness, (b) heuristics for construction and evaluation of user-friendly visual aids, and (c) the relatively large and robust benefits of visual aids for diverse individuals. While the review documented remarkably large benefits of visual aids for "real world" decision making in general, the review also identified some significant problems, namely: 1) Despite the successes of well-designed visual aids, some at-risk users lack basic graph evaluation and interpretation skills and are not graph literate enough to benefit from effective risk communications (Galesic \& Garcia-Retamero, 2011) and 2) Given conflicts of interests and other factors, it can be hard to get risk communicators to adhere to best design practices (e.g., distorted visual aids can shape attitudes and perceptions without violating truth in advertising regulations, etc.).

In what follows, we present an overview of details, successes, and obstacles in our ongoing efforts to develop a brief and adaptive computerized training programs using the RiskLiteracy.org platform. Focus will be on the development of our Graph Literacy Tutor (Cokely et al., in press; WollerCarter, 2015). A growing body of evidence has documented that substantial, decision-relevant benefits tend to emerge in a relatively short amount of time. Recent advances in the platform also enable more rapid and robust development of pseudo-intelligent (adaptive, but not fully intelligent) interfaces that reduce the costs and time required for development of brief interactive training and risk communication programs (Koedinger \& Corbett, 2006). Accordingly, we begin by reviewing our formal cognitive science based on graph comprehension research and Skilled Decision Theory. We then discuss the development and testing of specific graph literacy modules and assessments and we present results from a recent control trial study documenting near and (relatively) far transfer (i.e., graph literacy training improved graph literacy skills, but also improved text based decision skills including resistance to framing and reference class neglect). Next, we consider advances in platform design and implementation, including efforts to integrate psychometric approaches to circumvent the need for more extensive intelligent tutor engines. We close with brief discussion of future directions, limitations, and ongoing projects focusing on user experience optimization.

## Cognitive Processes in Graph Comprehension

Theoretically, the design of an efficient graph literacy training program will depend on the accuracy of our
understanding of the underlying essential (causal) cognitive processes. As such, we drew from the well-established body of empirical literature on graph comprehension to provide a foundation for our tutor development. Graph comprehension models generally indicate that when an individual views a graph they engage in three processes: 1) encoding of the visual pattern, 2) translation of the identified visual features into conceptual relations, and 3) the selection of referents for the identified concepts (Bertin, 1983; Carpenter \& Shah, 1998; Cleveland \& McGill, 1986; Kosslyn, 1989; Lohse, 1993; Okan, Galesic, \& Garcia-Retamero, 2016; Pinker, 1990; Simkin \& Hastie, 1987; Shah \& Carpenter, 1995). Together these processes allow for individuals to make a piece-wise interpretation of graphs before fully integrating the underlying mental model required for inductive and deductive inferences (e.g., reasoning that goes beyond givens). Theoretically, each step of this evaluation process involves essential processes and judgments that an individual must accurately make to correctly interpret the visualized data.

Broadly, it is often assumed that graph comprehension focuses on encoding the visual pattern, which requires the identification of key features of the graph (e.g., attending to many bars of varying height in a bar chart). Once key features are identified, a relative visual judgement is made to determine relative shape of the graph (e.g., positions of the graph elements within the axis, size, and length of the elements within the graph, the slope or angle of graph items).

Translating the identified visual features into conceptual relations then assigns relative quantitative meaning to the features of the graph. The comparison of size and spatial relations between graph features (e.g., a line graph with one positive and one negatively slopped line). For example, tall bars on a traditional bar graph would be interpreted as "more" compared to short bars. There is reason to believe that the spatial-to-conceptual mappings (e.g., "higher equals more," "steeper equals faster") found with graphs are analogous to ecological heuristics that persist within both adults and children with zero graphing experience (Gattis, 2002; Gattis \& Holyoak, 1996).

Theoretically, the final step in graph comprehension is determining the referents of the concepts identified. Here, one must accurately identify the associations of variables within the graph with numerical values. This is where the conventional features of the graph (title, axes labels, legends, and numerical values) are added into the mental representation of the whole graph. For instance, one must identify the context that the graph represents or the scale at which the y-axis is set before an inference can be made. This process seems to be closer to a skill that is not analogous to real-world conventions (Okan, Garcia-Retamero, Galesic, \& Cokely, 2012). This assumes that the skills needed to create proper schema for the conventional elements are trainable.

## Skilled Graph Comprehension

The idea that reading a graph is trainable is embodied in many theories. One holds that graph schema will be formed in
long-term memory (Maichle, 1994; Peebles \& Cheng, 2001; Pinker, 1990; Ratwani \& Trafton, 2008). Training graph literacy should then aim to increase the available schemas and enhance the already present ones, aiding in the identification of the conventional graph features and improving inferences made. Specifically, the training of skills would be aimed at the increasing of knowledge content, and thus can be relatively independent of limited working memory or visuospatial abilities (Hegarty \& Waller, 2005; Shah et al., 2005). Previous research has found that expertise in a specific domain can increase associations between visual patterns and concepts (Tabachneck-Schijf, Leonardo, \& Simon, 1997) and that inferences become easier to make (Roth \& Bown, 2003). One strategy to train is the use of online adaptive tutors (Anderson, Corbett, \& Koedinger, 1995; Koedinger \& Corbett, 2006; Lovett, Meyer, \& Thille, 2008).

The benefits of tutors are often attributed to factors such as: reduction of cognitive load during learning via worked examples, faster (ideally immediate) performance feedback, easier to understand instructions, frequent and more precise diagnostic tests of knowledge, consistent and direct modes of delivering material, and greater opportunities for detection and self-correction of errors during learning (Corbett \& Anderson, 1991; Koedinger \& Aleven, 2007; Mathan \& Koedinger, 2005; Roediger \& Karnicke, 2006; Sweller, Van Merrieoboer, \& Pass, 1998).

Validated adaptive tutors are currently available for many topics in math, statistics, reading, and physics. However, despite the ubiquitous nature of visual aids in risk communications, there are few validated computerized graph tutors available. However, the available graph tutors are generally designed for specialized, narrow audiences (e.g., geared toward younger high school students). Among the few graph literacy training programs that have been specifically designed for diverse adults, none have been subject to evidence-based validity studies providing estimates of: 1) the efficacy of graph literacy training for various users, 2) the magnitude of associated benefits for naturalistic decision making (e.g., interpreting real high-stakes risk communications about health and natural hazards), and 3) essential usability and user experience outcomes, strengths, and weaknesses.

## RiskLiteracy.org Graph Tutor Methods

Woller-Carter (2015) created an online graph tutor for RiskLiteracy.org that trained participants on the foundations of graph literacy and the application of graphs to everyday risky situations. The graph tutor was the prototype that which the new online graph tutor was created upon. The goal of the graph tutor is to briefly and efficiently train adult learners in essential selection, design, and display of graphs that are common in risk communications and related decision education programs. Broadly, the graph tutor contains two major components. The first consists of graph selection tasks where participants choose the correct graph that (by current standards) is best-suited for depicting specific types of data. The second major training component is the graph design
task, which requires participants to identify the necessary information from data to create a graph that accords with best practices by selecting from four candidate graphs.

Note that all graph selection tasks were chosen from an initial study where 217 participants completed multiple graph selection problems, the Berlin Numeracy Test, and the Graph Literacy Assessment (Cokely, Galesic, Schulz, \& GarciaRetaneri, 2012; Galesic \& Garcia-Retamero, 2011). An item analysis based on Classical Testing Theory was conducted to parse out item difficulty and discriminability, in accordance with Formal Item Response Theory approaches. The same procedure was followed for the graph design task. In total, 862 participants completed a random sample of 10-11 graph design problems (e.g., Approximately 100 participants/problems). Analyses provided a detailed account of the relevant psychometric properties of all task items, facilitating a theoretical optimization of problem type across the underlying skill dimensions (e.g., precisely selected items that were most representative and unbiased problems spanning the difficulty range; see Woller-Carter, 2015).

## Control Trial Results

Woller-Carter (2015) found large pre-test, post-test differences in graph literacy that remained significant even after controlling for initial levels of graph literacy $(t(89)=$ 5.23, $p \leq .001, d=1.10$ ) after participants completed the graph tutor. Interestingly, beyond general competency in graph literacy, compared to a control group that completed a STEM Foundations study skills training, graph literacy training also significantly improved some general decision making skills for decision tasks that did not otherwise include any visual aid or graphical content $(\mathrm{F}(3,87)=10.08, p \leq .001$, $\mathrm{R}^{2}=.033, d=1.30$ ). Findings are consistent with Skilled Decision Theory and theoretical accounts of risk literacy (Cokey et al., in press). Partial mediation between condition and decision task performance indicated that improvements in graph literacy directly mediated observed improvements in general decision making skills (e.g., learning how to represent data in a graph also helps people represent decisionrelevant data in useful ways).

## Additional Decision-Making Items

To further explore how risky decision-making interacts with graph literacy the creation of sensitive measurement tools is needed. The results of the 2015 tutor indicated what type of tools may be necessary. Training graph literacy aided in general decision-making skills that focused on "visualizable" risk situations (e.g., sunk cost). For instance, if someone is confronted with a risky decision and the aid of a graph would increase their ability to decide (e.g., icon arrays and safe sex practices), then graph literacy training will help (Cokely \& Garcia-Retamero, 2015). Our lab took the firsts steps by conducting a battery of previous, validated bias questions. Then we used Formal Item Response Theory to analyze the problems for difficulty and discriminability. The battery focused on three different biases: Sunk cost, reference class
neglect, and framing. Fifty-three University of Oklahoma students completed 90 ( 30 each bias) decision tasks taken from various sources.

The finished product are six psychometrically sensitive questions for each of the three types of bias. Results of the analysis are seen below in Figure 1.

## Sunk Cost

## Reference Class Neglect

## Framing

Figure 1. Visual representations of the Formal Item Response Theory analysis for the three biases in our pilot measurement study: Sunk cost (top), reference class neglect (middle), and framing (bottom).

## Construction of Python Graph Literacy Tutor

To better create a tutor development platform that meets the needs of brief risk interventions the decision was made to transfer the initial graph tutor from a Flash based platform built in Carnagie Mellon University's Cognitive Tutor Authoring Tools (CTAT) to an independent Python built, Flask tutor. For an example of the original graph tutor see figure 2. A large and growing body of research has made CTAT a quintessential and evolving intelligent tool for large scale tutors. Despite many advantages, there are many potentially valuable applications for (pseudo)intelligent and adaptive tutors which may be narrow. For example, many general-use decision support systems or decision aids made for risk communication may only require between 10 and 120
minutes to complete (e.g., mortgage or surgical risk disclosure; medical treatment risk information). There is currently no well-established solution, like CTAT, for the creation of small scale, brief, scientifically validated interventions. To fill this gap, following a survey of the available literature, we developed a "proof of concept" application in Python, following best practices based on CTAT and related efforts (Aleven, Mclaren, Sewall, \& Koedinger, 2009; Anderson, Corbett, Koedinger, \& Pelletier, 1995; Walker, Koedinger, Mclaren, \& Rummel, 2006). Specifically, we implemented the Risk Literacy Graph Tutor platform in Python, to assess viability and trade-offs, as compared to standard approaches implemented in Adobe Flash.

Figure 2. The original graph literacy tutor programmed in CTAT. The tutor was hosted on moodle.com, an open source Learning Management System.

The new graph tutor was built from the ground up with Flask, a micro web framework written in Python. Some notable advantages of Flask include:

- Flask is not tied to specific libraries or tools allowing flexible design of the graph tutor to better suit immediate needs (e.g., database connectivity, form validation, etc.).
- Flask is lightweight (no object-relational mapping, simple routing, and easy set-up) reducing the system requirements and development time.
- Flask is documented and community adopted, reducing the learning curve of implementing new solutions.

Beyond several notable benefits of re-development of the graph tutor, there are also some notable costs. First, the initial tutor programmed in Flash proved problematic with the number of online interfaces pivoting from the platform and potentially requiring extra authentication. These issues were persistent enough that, ultimately, an entirely new web template (e.g., User interface) had to be created. Second, the Learning Management System (LMS) platform (e.g., Moodle or Blackboard) had to be entirely abandoned to better accommodate easier implementation for experimentation, which could prove problematic whenever researchers want to track large numbers of specific users over extended periods
of time (e.g., months). Third, creating online tools that use the Intelligent Tutoring System (ITS) model.

Creating an authorizing adaptive tutor in Python also required development of additional infrastructure components. First, we developed APIs ("Application Programming Interfaces") for user profiles and tutor validation, database connectivity, and a user interface. More specifically, the previous graph tutor used a LMS to track students, which needed a student to enroll in the created class and be approved by the class admin. Now, users can create their own profile that is encrypted and inserted into a database. This design allows for the sharing of the tutor to participants for experimental purposes or for a casual user to independently take the tutor.

Backend and platform development also employed MongoDB, a NoSQL database, to power our tutor application. As a NoSQL database, MongoDB records are structured like that of Python dictionary objects. This feature was emphasized in our selection of a database management system (DBMS) as it relied on existing knowledge of Python, reducing the prerequisites to contribute new features for the graph tutor in the future. There are many technical differences between MongoDB and other DBMS; however, the nuances of SQL versus NoSQL, or variations of DBMS within the NoSQL categories generally seem practically irrelevant for (most) projects of similar size and scope. Finally, authorizing via Java Script allows for the immediate feedback essential to worked-example tutors, which proved essential given the theoretical and practical importance of immediate user feedback during training.

## Conclusions

Graphs are ubiquitous across modern media and risk communications. For many people, graphs simplify and clarify important information about risk, which is essential for informed decision making. In this paper we presented a brief overview of progress and ongoing efforts aimed at developing inclusive decision education programs designed to efficiently improve fundamental adult graph literacy and decision making skills. These efforts represent a significant extension to the RiskLiteracy.org platform, which has been accessed by more than 50,000 people from 166 countries since 2012. The mission of this multinational collaborative effort is to advance the science for informed decision making, with support of a network of scientists who provide validated educational resources such as research instruments (e.g., Berlin Numeracy Test) and inclusive decision education programs (e.g., the Graph Literacy Tutor). Beyond increasing the availability of skilled decision making resources, the current review also provides an overview of the first proof-of-concept for the Python-based (simplified) extension of the RiskLiteracy.org platform. Although this new approach may streamline development of related dynamic risk communications and training programs, several pressing issues remain. For example, we currently have a need for greater integration of iterative (life-cycle) approaches to user-experience and usability optimization.

There is also a need to further investigate the robustness of and longitudinal stability of training effects across diverse participants and naturalistic decision tasks.

In closing, it is useful to note that most consumers should not expect to gain any general cognitive benefit from commercially available products designed to train general cognitive capacities. While this may seem problematic for us given our stated goals, our approach is actually quite different. Our goal is not to train basic abilities or capacities. Instead, we are focused on complex types of cognitive skills that must be acquired through deliberate practice and training (Cokely et al., in press), with an emphasis on acquired skills that are known to be valuable for everyday and high-stakes naturalistic decision making (e.g., numeracy, risk literacy, graph literacy). Accordingly, it should not be surprising that our basic skill tutor results indicate near and far(ish) transfer to applications beyond the specific training context (e.g., learning how bar graphs can be used to deceive in general may help people navigate complicated graphs in political, financial, or health contexts). Just as skilled reading comprehension is a valuable component of many everyday activities, the ability to evaluate and understand risk is also widely-applicable. To the extent our control trial results generalize, we should expect that there are likely many currently under-appreciated opportunities to develop and apply pseudo-intelligent tutoring programs to great effect.

#### Abstract

Decades of research in decision making have established that there are some situations where human judgments cannot be modelled according to classical probability theory. Yet if we abandon classical (Bayesian) probability theory as an overarching framework for constructing cognitive models, what do we replace it with? In this contribution we outline a way to divide the space of possible computational level models of probabilistic judgment into a hierarchy of levels of increasing complexity, with classical Bayesian probability models occupying the lowest level. Each level has a unique experimental signature, and we examine which level is best able to describe human behavior in a particular probabilistic reasoning task.

Keywords: Probabilistic reasoning, disjunction fallacy, quantum theory.

## Introduction

2017 marks 35 years since the publication of the volume "Judgment under Uncertainty: Heuristics and Biases" edited by Kahneman, Slovic and Tversky (1982), which has since become a seminal text for those interested in violations of normative reasoning. The years since have seen a great deal of research aimed at better understanding the conditions under which human decision makers do or do not make 'normative' decisions, that is, decisions that can be thought of as being 'correct' by some measure. Note that in this contribution, in common with many other studies, we take the definition of 'normative' to be essentially equivalent to compatibility with classical/Bayesian probability theory. That is, behaving in a normative way is less about providing judgments that are 'accurate' in the sense of reflecting real likelihoods, and rather about self consistency (Oaksford \& Chater, 2009).

Despite the large amount of research that has been done to understand when and why these deviations from normative prescription occur, there are some notable gaps in our understanding of the structure of non-normative judgments. In part this has been caused by a tendency amongst researchers to define non-normative judgments by the properties they do not possess, ie a simple relation to an underlying probability distribution representing a belief state. This has led to a peculiar splintering of the study of decision making, most visible in the heuristics programme, where different decision making tasks are assumed to be executed with the aid of different heuristics (eg Gigerenzer et al, 2015). Few have considered the relationships between heuristics, or whether they reflect some deeper structure.

A different approach, advocated by some adherents of the Bayesian cognition program (see Jones \& Love, 2011), has been to deal with violations of normative (Bayesian) prescription by including extra variables and relations that, while they may be framed in a Bayesian way, conflict somewhat with the spirit of the Bayesian approach. An example is provided by Bayesian efforts to deal with order effects in probabilistic inference, where, for example, decision makers may judge $p(E \mid A, B) \neq p(E \mid B, A)$. One possible solution is to posit that decision makers are sensitive also to the order in which evidence is presented, and that the probabilities for judgments therefore should also be conditioned on the order of presentation. Formally this saves face for the Bayesian approach, but it is hard to see how this does anything other than redescribe the problem. A genuine solution to the problem of order effects would also need to explain why decision makers possess this sensitivity, and make testable predictions.

What we want to do in this contribution is approach the problem from a different angle. Suppose we assume that there is some sort of computational structure underlying nonnormative behaviour, presumably that can be understood as a generalisation of the Bayesian approach, and we ask whether we can constrain the structure of this theory in some way. Specifically, can we derive predictions that are sensitive only to some general fact about the structure of the theory and not to the precise details? If we can do this we can perhaps sketch out a space of acceptable computational level theories which can then be investigated in more detail by other means.

This approach is inspired in part by recent work in the field of quantum cognition (Pothos \& Buseyemer, 2013), which is the attempt to use the formal probability theory derived from quantum physics to describe human decision making. The advantage of such an approach, so proponents claim, is that quantum probability theory is a formal, all encompassing framework that is nevertheless able to account for deviations from classical, Bayesian, behaviour. However quantum probability theory has a very particular structure (see Busemeyer \& Bruza 2012), and it is not obvious that this is either necessary or sufficient to explain human behaviour. The study reported here can therefore be thought of as an attempt to test the sufficiency of the quantum approach for explaining certain types of non-normative behaviours. However it is also much more general, since we will see that quantum theory is just one example of a specific class of models sharing the
same structural properties. In order to avoid getting bogged down in arguments about the suitability of quantum theory to describe human decision making, we will avoid making reference to specific computational models beyond classical probability theory.

The rest of this contribution is structured as follows: In Section 2 we explain how we can situate different computational level models of decision making in a hierarchy, and we show that classical and quantum probability theories belong to two different levels, each with a unique experimental signature. In Section 3 we describe an experiment designed to test which level in the hierarchy is necessary and sufficient to explain human behaviour in a particular probabilistic reasoning task. In Section 4 we conclude and outline some future directions.

## A Hierarchy of Formal Theories

Given two disjoint events, $A$ and $B$, a key property of classical probability theory is that the probability of the disjunction, $A \cup B$ is equal to the sum of the probabilities of the individual events. This can be generalised for an arbitrary number of disjoint events as,

$$
\begin{equation*}
p\left(\cup_{i} A_{i}\right)=\sum_{i} p\left(A_{i}\right) \tag{1}
\end{equation*}
$$

This result expresses the property of classical probability known as linearity (more formally $\sigma$-additivity, Kolmogorov, 1933/1950). Classical probability models are therefore examples of linear models mapping events to probabilities.

In order to allow for the possibility of response errors it is useful to generalise this notion somewhat. Suppose we consider a more general class of models where, $p(A)=f(A)+\varepsilon$, where $\varepsilon$ is a constant. We will call these models linear if,

$$
\begin{equation*}
f\left(\cup_{i} A_{i}\right)=\sum_{i} f\left(A_{i}\right) \tag{2}
\end{equation*}
$$

Classical probability theory is obviously a special case of these linear models. These models can be used to capture the idea that judgments are noisy, so for example the probability assigned to the null event is not 0 . They can also capture simple types or response biases, for example an aversion to using the endpoints on a response scale.

It is important to note that general linear models can violate some properties of classical probability theory. For example for two disjoint events $A, B$ we have,
$p(A \cup B)=f(A \cup B)+\varepsilon=f(A)+f(B)+\varepsilon=p(A)+p(B)-\varepsilon$
Which is a violation of the classical law for disjoint events. However it is easy to see that any law of classical probability that is violated by a general linear model will be violated by some multiple of $\varepsilon$, and so these sorts of effects are easy to spot. In particular, consider the quantity,

$$
\begin{equation*}
\mathscr{I}_{2}(A, B)=p(A \cup B)-p(A)-p(B)=-\varepsilon \tag{4}
\end{equation*}
$$

We call expressions of this form 'interference' terms, because of the analogy with quantum models. In a simple classical probability theory model this quantity is 0 . In a general linear model this term is no longer zero, but it is instead equal to some constant which should be the same for all events $A, B$. The way to test the general class of linear models is therefore to examine different sets of events and test whether $\mathscr{I}_{2}(A, B)$ depends on the alternatives under consideration. This generalises the notion of the failure of a simple classical model.

The occurrence of widespread violations of classical probability rules in decision making experiments, including conjunction and disjunction fallacies (Tversky \& Kahneman, 1983), has lead many to reject linear models as accounts of the way human decision makers assign probabilities to events. However few have explored proposals for concrete models beyond linear ones.

A natural generalisation of linear models is to consider those which contain a bilinear term. The appropriate generalisation is to have,

$$
\begin{equation*}
p(A)=g(A, A)+f(A)+\varepsilon \tag{5}
\end{equation*}
$$

where $f(\cdot)$ is linear as above, and $g(\cdot, \cdot)$ is linear in both its arguments,

$$
\begin{equation*}
g\left(\cup_{i} A_{i}, B\right)=\sum_{i} g\left(A_{i}, B\right), \quad g\left(A, \cup_{i} B_{i}\right)=\sum_{i} g\left(A, B_{i}\right) \tag{6}
\end{equation*}
$$

If we now consider the probability assigned to the disjunction $A \cup B$ we see,

$$
\begin{align*}
p(A \cup B)= & g(A \cup B, A \cup B)+f(A \cup B)+\varepsilon \\
= & g(A, A)+g(B, B)+g(A, B)+g(B, A)  \tag{7}\\
& +f(A)+f(B)+\varepsilon \\
= & p(A)+p(B)+g(A, B)+g(B, A)-\varepsilon
\end{align*}
$$

Considering again the quantity $\mathscr{I}_{2}(A, B)$ we see,

$$
\begin{align*}
\mathscr{I}_{2}(A, B) & =p(A \cup B)-p(A)-p(B) \\
& =g(A, B)+g(B, A)-\varepsilon \tag{8}
\end{align*}
$$

which is generally non-zero, but also crucially will depend on $A$ and $B$, allowing us to distinguish bilinear models from linear ones.

Although we will not prove this here, the class of bilinear models includes quantum theory as a special case (Sorkin, 1994). However clearly this framework is more general than any specific model.

Once we have made the choice to step beyond linear models, a whole world of possibilities is opened up. Why stop at bilinear models? Why not consider a model containing a trilinear a function $h(A, B, C)$ ? The answer is that such models are possible, and in the same way that the quantity Eq.(8) provides us with a way to test between linear and bilinear models, a generalisation of this lets us distinguish between bilinear models and more complicated theories.

This rule comes from exploring what happens when we have three possible disjoint events $A, B, C$. Because $g(A, B)$ is bilinear it is straightforward, if tedious, to show,

$$
\begin{align*}
p(A \cup B \cup C)= & p(A \cup B)+p(B \cup C)+p(A \cup C)  \tag{9}\\
& -p(A)-p(B)-p(C)+\varepsilon
\end{align*}
$$

So if we define an analogue of $\mathscr{I}_{2}(A, B)$ for three events, $\mathscr{I}_{3}(A, B, C)$, then we have,

$$
\begin{align*}
\mathscr{I}_{3}(A, B, C)= & p(A \cup B \cup C)-p(A \cup B)-p(B \cup C)-p(A \cup C) \\
& +p(A)+p(B)+p(C) \\
& =\varepsilon \tag{10}
\end{align*}
$$

so this three way interference term is constant for all events $A, B, C$ if the underlying model is bilinear. This does not hold in higher order theories, such as ones based on a trilinear function (Sorkin, 1994). Therefore this provides a test of bilinear models versus more complex theories. Note also that this relation holds trivially for a linear model.

Although we will not show it here, it is straightforward to prove by induction that at every level in this hierarchy of possible model types there is a corresponding interference term $\mathscr{I}_{n}(A, B, C \ldots)$ which is constant for any model at that level or below (Sorkin, 1994). In other words we can make a very general statement; The experimental signature of a level $n$ model (ie a model based on a ' $n$-linear' function) is that a) The quantity $\mathscr{I}_{n}(A, B, C \ldots)$ depends on the events $A, B, \ldots$, but b) the quantity $\mathscr{I}_{n+1}(A, B, C \ldots)$ is constant.

We know from previous work that any theory that can capture human behavior, in particular disjunction fallacies, must be at least level two. The question is whether a level two theory is also sufficient, that is, whether there are particular effects in human decision making that arise when considering three alternatives. We will provide experimental evidence below that a level two theory is sufficient to explain behavior in a particular decision making task, however we can also motivate sufficiency on general grounds. Looking at the structure of $\mathrm{Eq}(8)$ for a bilinear theory, we see that the important terms involve the general function $g(\cdot, \cdot)$ evaluated on two different events, $A, B$. This framework is a computational level account, but presumably such a term must arise from a process level account wherein the two events $A, B$ are processed in parallel. In contrast a linear theory only ever involves functions with a single argument, and thus would not require a process level account with simultaneous consideration of multiple events. This strongly suggests that there is a specific sense in which a bilinear model requires a more complex underlying process to instantiate it. By analogy, the analagous term in a level $n$ model will involve a function of $n$ arguments, and, presumably, would require a process model in which $n$ events are considered in parallel.

If a higher order computational theory requires a more complex underlying process to produce it, then we can argue on general grounds that it is unlikely that human decision making is described by a theory of very high order. Of
course, this argument does not tell us whether to expect a bilinear, trilinear etc model, only that a lower level is likely to be preferred over a very high one. The question of exactly what level is needed is an empirical one, which we shall now examine.

## Experiment

We want to test the hypothesis that a bilinear model is necessary and sufficient to capture non-normative effects in human probabilistic reasoning. To do this we need to find sets of at least three disjoint alternatives such that are robust two way disjunction fallacies, in the sense that the interference term $\mathscr{I}_{2}(A, B)$ depends on the events $A, B$. Our approach will be to set up three scenarios, each with three disjoint events, and show that the term $\mathscr{I}_{2}(A, B)$ can be manipulated by introducing joint causes for some of the events. This will prove that a cognitive model capturing these judgments must be at least bilinear. We will then examine the higher order interference term $\mathscr{I}_{3}(A, B, C)$ in each scenario to check that a bilinear model is sufficient. The joint causes we will introduce will either cause the three events to be grouped into two natural sets, with one element shared between sets, or into one set with one singleton event. There are therefore two different ways of presenting each scenario, so we run each as a between participants condition.

## Methods

We recruited 300 participants, equally split into two between participants counterbalancing conditions. Recruitment was through Amazon Mechanical Turk, restricting geographical location to North America. Participants required approximately 20 minutes to complete the task and they were compensated $\$ 1$ for their time.

Both conditions consisted of three scenarios and each scenario described a hospital ward in a fictional town, specializing in a particular type of ailment. For example participants were told of a cancer ward, treating only patients of three types, those with lung cancer, stomach cancer, or throat cancer. For each scenario, participants were given some information creating a common cause between ailment pairs. For example, in one case participants were told that throat and lung cancers are caused by smoking, but throat and stomach cancers by alcoholism. Some rationale was provided to justify each association between ailments. All relations were constructed to look semi-plausible (the authors independently assessed this), but we did not aim for medical accuracy. The between participants condition implemented a counterbalancing manipulation, that presented the same scenarios but varied the common causes.

Participants went through each scenario in a blocked format presentation, so that, for example, no information about a subsequent scenario would be presented prior to finishing all questions relevant to the current scenario (scenario order was randomized). The block for each scenario had analogous format. Participants were first presented with the information about the hospital ward, the ailments treated there, and
the causal relations. Subsequently participants went through four or five multiple choice questions testing knowledge of the causal relations. The questions were meant to be straightforward and answerable on the basis of simple understanding of the presented information. Participants received corrective feedback, specifically if they responded incorrectly they were told so and asked to try again until they answered correctly (there were more than two alternatives for each question).

Once the training part was over, participants were told that they would be asked to make judgments about the proportion of various categories of patients at the fictional hospital. With each question, the text describing the hospital ward and the causal dependencies was included so that participants did not have to memorize anything, just understand the information provided. Each of the questions was prompted with the statement that each patient was brought to the hospital ward for only a single type of ailment (e.g., a single cancer type or a single fracture, depending on the scenario). Then, participants were asked to indicate on a 0 (None of them), to 100 (All of them) slider the proportion of patients likely to be admitted for ailment A in some questions, A or B in other questions, and A or B or C in another question; note, each combination of possibilities was shown only once. The triple disjunction was implemented as a catch question, since the total number of patients was fixed at 100. An additional three catch questions were included, where participants were just told to select a particular response, as a check that they were paying attention.

After participants finished responding to the questions for the three scenarios they were given a version of the the Cognitive Reflection Test (Frederick, 2005). The CRT is designed to discriminate between participants adopting either a more intuitive or a more deliberative thinking style (Toplak et al., 2011). The CRT has previously been shown to correlate well with measures of non-normativity in probabilistic judgments such as conjunction fallacies (Yearsley et al, 2016).
Aside on the physical analogue of this experiment It may be useful for those familiar with interference in physics to outline the analogy between this phenomena and 'interference' effects in human probabilistic decision making. This might help to motivate some of the experimental design, but this subsection can be safely skipped by any reader who wishes.

In the classic two slit interference experiment a particle can arrive at a given point via one of two paths. In quantum theory because of the wave-like nature of particles two things happen: 1) The particle in some sense (which we don't intend to make precise here) takes 'both' paths, and 2) The phase of the particle's wave-function depends on the details of the paths taken. By choosing the paths in a particular way we can cause the two paths to interfere in either a constructive way (so that the total probability of arriving at a point is greater than the sum of the probabilities to follow either path) or a destructive way (so that the total probability of arriving at a point is less than the sum of the probabilities to follow either
path.)
The analogy in decision making is that a disjunction $A \cup B$ of two disjoint events can happen in one of two ways. By manipulating the information we give about the events, for example by introducing a possible common cause, we can, empirically, cause the disjunction to be judged more likely than the sum of the probabilities for the individual events. This is the analogue of constructive interference in the physical set up. This helps us understand why the key experimental manipulation is essentially the stories we tell about the relationship between the different ailments. A pictorial representation is given in Fig 1.

Of course, this analogy is not meant to constitute a formal theory of quantum cognition, but such a theory can be formulated (Busemeyer \& Bruza, 2011; Yearsley \& Busemeyer, 2016).

Figure 1: Sketch of the analogy between the physical experiment and the decision making one. a) In a physical interference experiment, a quantum state can take one of three possible paths to a detector, and the different alternatives interfere. b) In our experiment, a patient ends up in a hospital ward due to one of three ailments. c) A pictorial representation of the different ailments for Condition 1. In Scenario 1 the three ailments were Lung, Throat and Stomach cancers. Lung and Throat cancers were linked (smoking), and Throat and Stomach cancers were linked (alcoholism). In Scenario 2 the three ailments were auto accidents, alcohol poisoning, and falls. Auto accidents and alcohol poisoning were linked (young people) and falls (old people) was a singleton. For Scenario 3 the ailments were fractures to wrists, ankles, or lower legs. Wrist and ankle fractures were given a common cause (everyday falls) and angle and lower leg fractures likewise (playing sports).

## Results

There are two critical tests to perform; firstly we must check that the two way interference terms $\mathscr{I}_{2}(A, B)$ vary depending on the events in each scenario and condition. Second, we must examine three way interference $\mathscr{I}_{3}(A, B, C)$ for each scenario and condition. In this contribution, we only report Bayesian statistical tests that were performed using JASP (JASP team, 2016). In particular we report Bayes factors for the alternative versus the null hypothesis, so that values $>1$
indicate evidence for the alternative hypothesis.
Recall that the two way interference term $\mathscr{I}_{2}(A, B)=$ $p(A \cup B)-p(A)-p(B)$. To check the behaviour of these terms we perform a Bayesian RM ANOVA, with scenario and event pair as the repeated measures, and the counterbalancing condition as a between subjects factor. We omit the CRT from this analysis to save space, but there are no interesting effects of CRT. The analysis of effects is shown in Table 1.

Table 1: Analysis of effects for Bayesian Repeated Measures ANOVA of two way interference terms

| Effect | $p($ incl $)$ | $p($ incl $\mid$ data $)$ | $\mathrm{BF}_{\text {Inclusion }}$ |
| :--- | :--- | :--- | :--- |
| Scenario | 0.737 | 1.000 | $2.44 \times 10^{4}$ |
| Condition | 0.737 | 0.999 | $2.49 \times 10^{2}$ |
| Pair | 0.737 | 1.000 | " $\infty$ |
| Scenario*Condition | 0.316 | 0.998 | $1.37 \times 10^{3}$ |
| Scenario*Pair | 0.316 | 1.000 | $2.11 \times 10^{4}$ |
| Condition*Pair | 0.316 | 0.998 | $1.35 \times 10^{3}$ |
| Scenario*Condition*Pair | 0.053 | 0.998 | $1.12 \times 10^{4}$ |

Recall that if the best description of this situation is via a linear model, ie if non-normative effects are either absent, or due only to response error, then we expect to see no effect of scenario, condition or pair. In contrast JASP actually returns a BF of inclusion for the pair variable of $\infty$, indicating an extremely large effect of pair. The other variables, and all the interaction terms, all have large Bayes factors. The large Bayes factors for the interaction terms are unsurprising given the experimental design - the difference between the same scenario in a different condition and a different scenario in the same condition is really a matter of convention.

This analysis shows that a model beyond a linear one is needed to explain these data. Now we perform the analogous test for $\mathscr{I}_{3}(A, B, C)$ to check if a bilinear model is sufficient.

Recall the three way interference term for each scenario is computed as $\mathscr{I}_{3}(A, B, C)=p(A \cup B \cup C)-p(A \cup B)-p(B \cup$ $C)-p(A \cup C)+p(A)+p(B)+p(C)$. To check the behaviour of these terms we perform a Bayesian RM ANOVA, with scenario as the repeated measure, and the counterbalancing condition and CRT as between subjects factors. The analysis of effects is shown in Table 2.

Table 2: Analysis of effects for Bayesian Repeated Measures ANOVA of three way interference terms

| Effect | $p($ incl $)$ | $p($ incl $\mid$ data $)$ | $\mathrm{BF}_{\text {Inclusion }}$ |
| :--- | :--- | :--- | :--- |
| Scenario | 0.737 | 0.313 | 0.163 |
| Condition | 0.737 | 0.407 | 0.245 |
| CRT | 0.737 | 0.141 | 0.059 |
| Scenario*Condition | 0.316 | 0.299 | 0.923 |
| Scenario*CRT | 0.316 | $2.92 \times 10^{-4}$ | $6.33 \times 10^{-4}$ |
| Condition*CRT | 0.316 | 0.003 | 0.006 |
| Scenario*Condition*CRT | 0.053 | $2.2 \times 10^{-7}$ | $3.97 \times 10^{-6}$ |

The results are striking; none of the Bayes factors for inclusion are greater than 1 , indicating that no model containing any combination of these effects is preferred over a null model. The conclusion then is that the terms $\mathscr{I}_{3}(A, B, C)$
are constant - they do not vary when we manipulate common causes implied for the events in the way that the terms $\mathscr{I}_{2}(A, B)$ do. This implies that a bilinear model is sufficient to explain these effects.

The lack of a significant effect of the CRT is actually reassuring; recall that the terms $\mathscr{I}_{3}(A, B, C)$ should be constant regardless of whether a decision maker is using a linear (classical) or bilinear (quantum) model. The CRT has previously been associated with the strength of various measures of nonnormativity (Yearsley et al, 2015) and the fact that it is not predictive here suggests that these effects behave very differently from other measures such as the size of conjunction fallacies.

## Conclusions and Future Directions

The empirical finding of so-called probabilistic fallacies in decision making has led to an intense debate over how much (if any) of human cognition should be understood in terms of the principles of classical, Bayesian, probability theory (Tversky \& Kahneman, 1983). Those who believe these findings cast doubt on the applicability of classical probability theory have tended to respond by abandoning all together the idea of a formal probabilistic framework for decision making. Recent advances in applying quantum probability theory to modelling human decision making (Pothos \& Busemeyer, 2013) raise the possibility that all (or most) of human cognition can be understood in formal probabilistic terms, but the appropriate approach is not classical probability theory but quantum probability.

However at least one objection to using quantum probability theory (there are many) is that it is unclear how exactly this expands the space of possible models. Most accounts of the relationship between quantum and classical models tend to focus on the issue of incompatibility, but this is notoriously hard to make precise. In addition, it is far from clear that quantum probability theory is the only way to generalise classical probability to include incompatible events.

What we have tried to do in this paper is to show how we may take a particular approach to divide up the space of possible computational level accounts of interference effects in decision making. The space of models is split into different levels, of increasing complexity in the sense of higher level interference effects. Classical probability theory, and its generalisations in the form of linear models, occupy the lowest level of this hierarchy, whereas bilinear models such as quantum theory sit at the next level up in complexity. Above these bilinear models are an infinite number of different levels, although we can argue on general grounds that we expect human behavior to be characterised by a relatively low level model.

Each level in the hierarchy has a unique experimental signature, and we used this to show that behavior in a particular probabilistic reasoning task is consistent with a bilinear theory. Of course, whether all current examples of nonnormative probabilistic reasoning are likewise consistent with a bilinear model is an open question. This level consists of
theories where interference between alternatives is computed pairwise. Quantum theory is situated at this level, however our approach is not able to distinguish between different models in a given level. Further work, for example looking at constraints obeyed by quantum theory but not other non-classical probability theories, could address this.

We finally want to outline some future directions for research. One important question is how well our findings generalise when we consider different kinds of relationships between events. In our scenarios different ailments were related, if at all, by common causes, for example smoking can cause both lung and throat cancer. This means that the associated interference terms $\mathscr{I}_{2}(A, B)=p(A \cup B)-p(A)-p(B)$, tend to be positive. It would be useful to show that we can generate negative interference terms by implying the appropriate relationships between conditions, and check that our conclusions still hold. Another future direction would be to extend this approach to other areas of cognition where quantum models have been proposed, for example perceptual decision making.

Another future direction is to try and extend this analysis to models which fall just outside our framework. One such example is the classical probability plus noise model due to Costello and Watts (2014). They propose a general linear model but with an error term which, rather than be a constant, depends on the type of event being considered, eg a single event, a conjunction or disjunction etc. The idea is that more complex events are associated with larger error terms, and they showed this can lead to conjunction fallacies in participants responses, even though the underlying belief states obey classical probability theory. This theory has a slightly different experimental signature from linear or bilinear models, but it can still be tested against them in a similar way. The results of this analysis will be presented elsewhere.

# Evidence for overt visual attention to hand gestures as a function of redundancy and speech disfluency 

Amelia Yeo (ayeo@wisc.edu)<br>Department of Psychology, 1202 W. Johnson Street<br>Madison, WI 53706 USA<br>Martha W. Alibali (martha.alibali@wisc.edu)<br>Department of Psychology, 1202 W. Johnson Street<br>Madison, WI 53706 USA

#### Abstract

We investigated the effect of gesture redundancy and speech disfluency on listeners' fixations to gestures. Participants watched a speaker producing a redundant or non-redundant gesture, while producing fluent or disfluent speech. Eye movements were recorded. Participants spent little time on a speaker's gestures regardless of condition. Gesture redundancy and speech disfluency did not affect listeners’ percentage dwell time to a speaker's gestures. However, listeners were more likely to fixate to a speaker's gestures when they expected the gesture to be non-redundant. Listeners were also more likely to fixate to a speaker's gestures when the speaker was disfluent. Thus, listeners allocate overt visual attention based on the expected usefulness of a speaker's gestures, although evidence does not suggest that they spend more time fixating on these gestures. Furthermore, listeners are sensitive to disfluency in a speaker's utterance and change how they attend to gestures based on qualities of the speech.

Keywords: gesture; eye tracking; communication; multimodal information processing; spatial features

## Introduction

Speakers usually move their hands when conveying a message. It seems intuitive to suggest that speakers gesture to communicate information to their audience. Indeed, at times speakers appear to produce gesture specifically for the purpose of communicating with the listener (Alibali, Heath \& Myers, 2011).

During the process of comprehension, listeners integrate speech and gesture (Willems, Özyürek, \& Hagoort, 2007). Since co-speech gestures can influence listeners’ comprehension of messages, how then do listeners allocate visual attention resources to speakers' gestures? Some researchers have argued that the content of gestures could be perceived peripherally (Gullberg \& Holmqvist, 1999). If true, this would negate the need for listeners to fixate to gestures during comprehension. However, gestures have also been shown to convey additional semantic content not found in speech (e.g., McNeill, 1992; Alibali, Evans, Hostetter, Ryan \& Mainela-Arnold, 2009; Hostetter, 2011). Fixating to these gestures could help comprehension. Communicating in everyday life is often a multimodal process that involves auditory input from speech and visual input from the speaker's face and body (i.e., MacDonald \&

McGurk, 1978; Ekman, 2004). Hence, understanding how listeners allocate visual attention during the process of face-to-face comprehension is important for understanding the mechanisms involved in the online process of interpersonal communication.

There is some evidence that listeners extend overt visual attention to a speaker's gestures (Nobe, Hayamizu, Hasegawa, \& Takahashi, 1997; 2000). In these studies, the authors presented participants with animations of a speaker uttering short phrases while making hand gestures, and recorded eye movements of the participants during the animations. Participants in the study were found to fixate to gestures consistently on most of the videos presented, preferring to fixate to gestures that occurred more slowly. In the follow-up study (Nobe et al., 2000), participants were found to be able to complete gesture reproduction and comprehension tasks without necessarily fixating to the specific gesture, suggesting that listeners indeed can encode aspects of speakers' gesture without gaze fixations. However, this raises the question of why listeners would consistently fixate to speakers' gestures if comprehension can occur without fixation.

In contrast, other studies of visual attention to gesture have found that listeners rarely fixated to a speaker's gestures, even when those gestures were essential for comprehension (i.e., listeners seldom fixated to gestures that offered information absent from, and thus, non-redundant, with speech). Listeners fixated overwhelmingly on the speaker's face (Gullberg \& Holmqvist, 1999, 2006; Gullberg \& Kita, 2009; Beattie, Webster, Ross, 2010), contrary to the findings by Nobe and colleagues (1997; 2000).

A possible explanation for the differences found in overt visual attention to gestures in these studies is that the speech content of the speakers in the previous experiments was vastly different. Some studies used stimuli that contained a narrative element, while other studies used shorter utterances without a story element, such as "let's count fingers". The difference in speech content could have caused listeners to attend more to the face of the speaker due to the expectation or existence of emotion cues in the speaker's face. Therefore, listeners might spend more time fixating to non-redundant gestures for speakers if the speech content does not contain a narrative element.

In cases where listeners were found to fixate to a speaker's gestures, numerous factors have been cited as potentially driving the fixations. These factors include whether the speaker fixated upon the gesture, the duration of the post-stroke hold (i.e., an aspect of the "form" of the gesture) and the location of the gesture in the speaker's gesture space (e.g., Gullberg \& Holmqvist, 2006; Gullberg \& Kita, 2009). The focus in the literature has thus been on particular physical features of gestures, with little research into the role of listener expectation on overt attention to gestures. Expectations, or predictions, that listeners hold about the usefulness of a speaker's gestures could influence how they attend to the speaker's gestures. In this study, we examine a higher-level feature of gesture, expected redundancy. Keeping all other physical features constant, we test whether the expected redundancy of a speaker's gestures will affect how listeners attend to those gestures. If listeners do allocate attention differently to gestures depending on whether they expect the gesture to be useful for comprehension, then we should see listeners spend more time fixating to gestures and also be more likely to fixate to a speaker's gesture when the gesture offers disambiguating information absent in speech.

As mentioned above, previous studies that examined visual attention to gestures have focused on how physical qualities of a gesture influenced listeners' fixations. In multimodal communication, however, elements of speech can also influence how listeners attend to a speaker's gestures based on existing expectations. To date, no study to our knowledge has examined the role of speech disfluencies on listeners' fixations to a speaker's gestures. Disfluencies such as filled pauses cause a break in speech content and can occur at several points in speech (Ferreira \& Bailey, 2004). A filled pause (i.e., um) that occurs in the middle of a clause has been linked to the need for the speaker to select an option for production from among several competing choices (Clark \& Fox Tree, 2002). Listeners were more likely to remember a word when it was preceded by a filled pause (Corley, MacGregor \& Donaldson, 2007), suggesting that a filled pause could give rise to expectation in listeners that what is to follow is important, signaling listeners to allocate more attentional resources to encode what follows from it. When listeners hear an "um" from a speaker, they might also be more likely to fixate to the speaker's gesture space when the disambiguating information might be produced in gesture as compared to a situation where there is no need for disambiguation.

In this study, we examine the effect of gesture redundancy (i.e., whether a gesture is useful for disambiguating between two options) and speech disfluency on listeners' visual attention to gesture. To do this, we conducted a 2 by 2 fully within-subjects experiment, manipulating gesture redundancy and speech disfluency. We recorded the gaze fixation data (i.e., how long each participant fixated and how many fixations) of each participant as they watched a video of a speaker on each trial. The speaker produced either redundant or non-redundant gestures for a following
task and spoke with either disfluency or without disfluency. We hypothesize that listeners will be more likely to fixate to gestures that are non-redundant with speech. Participants are predicted to fixate at least once to gestures more often for trials with non-redundant gestures than for trials with redundant gestures. Participants are also predicted to spend more time fixating on these gestures. In addition, we also hypothesize that listeners will be more likely to fixate to gestures that accompany disfluent speech than to gestures that accompany fluent speech. This experiment will also allow us to examine whether spatial speech free from narrative content provides a context in which listeners attend less to the speaker's face. However, if the narrative nature of the stimuli used in previous studies was not the reason for the little time listeners spent gazing at gestures, then we expect participants in this study will display similarly low durations of fixations to gesture.

## Method

## Participants

Participants were 30 undergraduate students, all of whom reported being native English speakers. They were recruited from an Introductory Psychology course in exchange for extra credit.

## Materials

There were two sets of stimuli: shape arrays and speaker videos. We created four pairs of shape arrangements using Microsoft PowerPoint, giving eight arrays in total. Each of these eight arrays was repeated twice in the experiment, once paired with a speech-fluent video and once paired with a speech-disfluent video. Thus, there were sixteen target trials in total.

Each pair of shape arrays was identical in every aspect except for a single shape. In the arrays used for the gesture redundant condition, only one triangle was present. In the arrays used for the gesture non-redundant condition, two triangles were present. Thus, to create the arrays for the gesture non-redundant condition, one of the non-triangle shapes in the arrays for the gesture redundant condition was replaced with a triangle (Fig. 1).

Figure 1. An example of a shape array in the gesture redundant condition (left) and in the gesture non-redundant condition (right).

Next, we created eight videos, four featuring fluent speech and four featuring disfluent speech. Each video lasted approximately six seconds and showed a speaker describing a triangle according to a script, while facing the camera (Fig. 2). In the videos with fluent speech, the speaker produced an utterance, such as "the triangle changed color and turned green". In videos with disfluent speech, the speaker produced an utterance with the "um"
disfluency, for example, "the, um, triangle changed color and turned green". In the other of these eight videos, the actor produced exactly the same utterance except with a different color (e.g., orange/red/yellow instead of green). We created the videos such that there were fluent and disfluent pairs containing the same utterance that differed only in the inclusion, or exclusion, of the disfluency "um". In addition, the speaker produced four types of gestures that were paired with corresponding shape arrays. These gestures referred to the triangle that was undergoing the color change. Thus, in the gesture non-redundant condition, the gesture functioned to disambiguate the target triangle from the other triangle in the array. In each video, the speaker's gesture depicted either the pointed tip of the triangle (pointing up or down), or the relative placement of the triangle in the shape array (located high in the array or located above a line). Each gesture was scripted such that the actor began forming the gesture just before the word "triangle" in the utterance and held the gesture for approximately 2 seconds before dropping her hands. In each video, the actor produced only one gesture and gazed at the camera for the duration of the video.

Figure 2. Screen capture of the speaker producing a gesture of an upward-pointing triangle.

We also created shape arrays and speaker videos for filler trials. The purpose of the filler trials was to present the participant with variation in the speaker videos so as to reduce the chances of the participant inferring the purpose of the study. These filler trials contained an assortment of videos where the speaker did not gesture, or gestured while producing a slightly different utterance, such as "the orange triangle changed color and turned green". There were ten filler trials in total. The eight target trials and the filler trials all contained the same actor wearing the same clothing.

## Procedure

Participants were tested individually. Each participant was seated in front of a computer screen and a desk-mounted Eyelink 1000 eye tracker camera. The eye tracker recorded real-time fixations of each participant throughout the entire experiment and was calibrated for each participant before the trials began.

Before the experiment, participants were told that the speaker would always describe a color change of a triangle in the array. Thus, participants began the experiment knowing that it would always be a triangle that changed color. They were not told that the speaker would gesture; participants were not informed in any way that the study
was about gesture or speech disfluency.
During the experiment, each participant viewed 26 trials presented in random order using Experiment Builder from SR Research (Canada). Each trial contained a shape array that was presented onscreen for 5 seconds, followed by a video of the speaker describing the color change occurring to a triangle in the array. The video was programmed to start automatically. After the video, participants were presented with four options of shape arrays and were instructed to say aloud the option that fit the description of the speaker in the video. For example, if a trial presented the array in the gesture non-redundant, speech fluent condition (e.g., the array on the right in Fig. 1) followed by a video of the speaker producing an upward-pointing gesture (Fig. 2) while saying, "the triangle changed color and turned green", the correct option (in Fig. 3) to select would be option C.

The trials in the gesture non-redundant, speech disfluent condition were identical except that the speaker produced a filled pause, for instance, "the um, triangle changed color and turned green". Thus, gesture redundancy was manipulated by having either one or two triangles in the shape array.

Figure 3. Example of four response options in the gesture non-redundant conditions.

An example of a trial in the gesture redundant, speech fluent condition would be the left array in Figure 1 followed by a video of the speaker producing an upward-pointing gesture (Fig. 2) while saying, "the triangle changed color and turned green". The four response options would then contain the same shapes as in the original array but with the single triangle colored in four different colors. The trials in the gesture redundant, speech disfluent condition were identical except that the speaker produced a filled pause, for instance, "the um, triangle changed color and turned green". Thus, gesture redundancy and speech disfluency were perfectly orthogonal.

Each participant's verbal response for each trial was recorded with a microphone that was clipped on to his or her clothing. The verbal responses were recorded to audio files in the computer. At the end of the experiment, participants were debriefed and asked if they could guess the purpose of the study. None of the participants correctly stated the hypothesis about gesture redundancy or speech disfluency on listeners' fixation to a speakers' gestures. Throughout the whole procedure, an experimenter sat in a corner in the room unobtrusively and had no interaction with the participant. The whole experiment lasted for about 20 minutes.

## Coding

Each video was divided into interest areas for eye tracking analysis. The speaker's face was a separate interest area from her gesture space. The fixations of interest for this study were those that occurred to the speaker's gestures from the start to the end of her utterance, since her gestures always occurred as she was speaking. Fixation data that included each dwell time on each area and number of fixations was then exported from Data Viewer (SR Research) for analysis. For each trial, we thus obtained data regarding how long a participant fixated to the speaker's face, how long a participant fixated to the speaker's gesture space, how many fixations a participant made to the speaker's face and how many fixations a participant made to the speaker's gesture space.

## Results

Averaging across all conditions, participants spent the majority of the time fixated on the speaker's face, spending only $9.3 \%$ of the time fixating on the speaker's gestures.

Table 1 displays the average percentage dwell time spent by participants on the listeners' gestures across conditions. We conducted two-way within-subjects analysis of variance on the average percentage dwell time spent fixating on the speaker's gestures as a function of gesture redundancy and speech disfluency. There was no significant main effect of gesture redundancy, $F(1,112)=1.34, p=0.25$, nor was there a significant main effect of speech disfluency, $F<1$, $p=.66$.

There was also no significant interaction between gesture redundancy and speech disfluency on participants' dwell time to speaker's gestures, $F(1,112)=2.30, p=.13$. Even though participants on average spent a higher percentage of dwell time on non-redundant gestures, this difference was not significant.

Table 1. Average dwell time $\%$ to the speaker's gestures as a function of gesture redundancy and speech disfluency.

|  | Gesture |  |
| :---: | :---: | :---: |
| Speech | Redundant | Non-redundant |
| Disfluent | 7.33 | 10.1 |
| Fluent | 9.02 | 10.8 |

Since participants overwhelmingly fixated to the speaker's face in this experiment, we wanted to examine whether gesture redundancy and speech disfluency affected the likelihood of participants fixating at least once to the speaker's gestures. To test whether participants were more likely to fixate to a speaker's gestures as a function of gesture redundancy or speech disfluency, we classified whether each participant fixated on the video speaker's gesture space at least once while the speaker was talking. Thus, the outcome variable for this analysis was dichotomous, i.e., whether or not the participant fixated at least once to the speaker's gesture in each trial.

We analyzed these data using a binomial multilevel model with gesture redundancy and speech disfluency as fixed effects and participant as a random effect. The dependent variable was whether the participant had fixated to the speaker's gesture space (yes/no). The mean proportion of trials on which participants fixated at least once to the speaker's gesture space is displayed as a function of gesture redundancy (Fig. 4) and speech disfluency (Fig. 5).

Figure 4. Proportion of trials on which participants had at least one fixation to the speaker's gesture space as a function of gesture redundancy. Error bars are $\pm$ SE.

Figure 5. Proportion of trials on which participants had at least one fixation to the speaker's gesture space as a function of speech disfluency. Error bars are $\pm$ SE.

Listeners were significantly more likely to fixate to the speaker's gesture in the gesture non-redundant condition than in the gesture redundant condition, Wald's $z=3.06, p<$ .01 , odds ratio $=2.41$. Additionally, listeners were significantly more likely to fixate to the speaker's gesture in the disfluent speech condition than in the fluent speech condition, Wald's $z=2.21, p=.027$, odds ratio $=1.88$. There was no significant interaction between gesture redundancy and speech disfluency on the likelihood of participants fixating to a speaker's gesture, Wald's $z=1.35$, $p=.18$. In sum, participants were more likely to fixate at least once to non-redundant gestures, and they were also more likely to fixate at least once to the speaker's gestures when the speaker was disfluent.

## Discussion

The finding that participants spend little time fixating to a speaker's gestures reflects the results from some past studies. For example, Gullberg and Kita (2009) reported that listeners fixated on gestures only $8 \%$ of the time, even
though these gestures were first fixated by the speaker, showing that gesture fixation duration was low even when there was social impetus (i.e., directed gaze) to fixate at a gesture. Our findings align with this value. Listeners fixated to gestures on average about only $10 \%$ of the time, even for gestures that contained information not present in the speaker's utterance. These findings do not support the hypothesis that the previously reported low fixation durations on gestures were due to the narrative element in speech. Instead, listeners fixate overwhelmingly on the speaker's face even when the narrative element in speech is absent or greatly reduced.

However, we do not yet know if listeners direct so little overt visual attention to gesture because of the communicative context. Past studies, including this one, have featured speakers passively describing objects or actions. Although strengths of this paradigm are its simplicity and ease of experimental control, a limitation is that it tells us little about how people attend to each other's gestures when they are engaging in dialogue. During dialogue, speakers gesture differently depending on the feedback they receive from the listener (Holler \& Wilkin, 2011). This finding reflects observations of research involving instructional gestures. In the classroom, teachers have been found to gesture more when students lack understanding of the lesson (Alibali et al., 2013). Further research could explore how listeners attend to gestures in an instructional setting or in dialogue, using a wearable eye tracker.

As predicted, participants were more likely to fixate to non-redundant gestures than to redundant gestures. This finding implies that listeners preferentially direct overt visual attention to gestures that they expect to be useful for comprehension. Listeners direct overt attention to a speaker's gestures more often when the gesture conveys relevant information not present in speech, implying that listeners generate expectations about the perceived importance of the speaker's gestures and direct attention accordingly. However, we did not find support for the hypothesis that listeners would spend more time fixating to a speaker's gestures. While listeners were more likely to gaze at least once to the speaker's non-redundant gestures, they did not spend more time dwelling on those gestures, implying that the additional fixations to non-redundant gestures occurred very quickly. A potential explanation for this behavior is that visual information from fixated gestures is gleaned very quickly, making it unsurprising that fixation durations across conditions did not differ significantly.

On the surface, it might be unsurprising that listeners are less likely to fixate to gestures that are redundant. This study demonstrates that listeners are less likely to fixate to gestures that are redundant even when those gestures are holds (i.e., the form of the gesture is held in a pause) and occur in the center of the speaker's body, qualities that were reported to best attract listeners' fixations (e.g., Gullberg \& Holmqvist, 1999; 2006) Since we controlled for these features across the gesture redundant and gesture non-
redundant conditions, our findings imply that top-down factors such a redundancy can influence listeners' visual attention to gestures beyond the physical characteristics of those gestures. Few studies to date have explored the role of higher-level cognitive factors, such as expectations, on how listeners process gestures. For example, individuals could hold expectations about the usefulness of gesture based on an individual's communicative fluency, or individual's communicative style. A further direction would be to examine how these factors influence how listeners attend to gestures.

In this study, we also found support for the hypothesis that speech disfluency causes listeners to be more likely to attend to gestures during communication. These findings support the idea that disfluencies in speech can function as a signal to listeners on how to direct their cognitive resources during comprehension. However, we did not find support for the hypothesis that listeners spent more time fixating to gestures that co-occurred with disfluent speech as compared to gestures that occurred with fluent speech. Once again, it is possible that listeners quickly obtained information from gestures. If filled pauses in speech do indeed work as a signal for cross-modal attention shifts, future work could examine if how other forms of speech disfluencies (e.g., false starts) influence visual attention to a speaker's gestures.

As with any investigation, there are some limitations to this experiment. Due to convenience sampling, our sample was comprised of college undergraduates. Undergraduates could offer little variation in terms of cognitive skills as compared to the population at large. While little published research to date exists examining the role of individual differences in cognitive skills on attention to gestures, there is evidence suggesting that people produce gestures differently due to individual differences in spatial abilities (Hostetter \& Alibali, 2007; 2011). It may be the case that listeners with vastly different spatial skills could process a speaker's gestures differently. One way to address this would be to administer measures of verbal and spatial skills to undergraduate participants in future studies. Another way to address this limitation would be to recruit participants outside of the undergraduate pool.

Our participants were English speakers in the Midwestern USA, thus the results might not generalize to speakers of a different language or culture. Past studies on visual attention to gestures have sampled from English-speaking students in the United Kingdom (Beattie, Webster \& Ross, 2010), Dutch-speaking students (Gullberg \& Kita, 2009) and native Swedish speakers (Gullberg \& Holmqvist, 2006). Consistently low fixation durations to gesture across these samples appears to suggest that the effect is generalizable. However, Nobe and colleagues (1997; 2000) sampled from Japanese speakers, raising the question of whether the difference in attention to gestures of a speaker is partly due to cultural norms.

For instance, Graham and Argyle (1975) found that Italian speakers were better able to decode shapes being
described by the speaker when gesture was produced, in contrast to English speakers. If speakers' gestures possess different utility value to listeners depending on the language, we might expect listeners to attend to gestures differently too. Further research should test the assumption that listeners' processing of speakers' gestures is universal. There are undoubtedly common processes involved in multimodal communication across humans, but cultural norms in communication or in the use of hand gestures could also influence how listeners process these gestures.

Another limitation of this study involves the nature of scripted disfluencies. When disfluencies are produced naturally, they could be accompanied by changes in speech rate, tone of voice, or changes in facial expression. Having an actor utter a statement with a scripted disfluency across multiple trials is unnatural. While this choice was made to reduce stimuli variability, further research could use videos of speakers conversing naturally and examine the gaze of listeners when disfluency occurs naturally.

In conclusion, these findings provide another perspective on the question of how listeners process gestures. We show that listeners are more likely to fixate to a speaker's gestures when those gestures are non-redundant, after controlling for physical properties of gesture that have been reported to capture the attention of listeners. We also demonstrate that speech disfluencies can act as signals for listeners to shift attention multimodally. These findings highlight the causal role of expectations in how listeners attend to speakers' gesture.

## Acknowledgments

We thank Maia Ledesma and Kayla Diffee for assistance with production of stimuli, Youn Ku Choi for assistance with data collection, and Mitchell Nathan and Virginia Clinton for assistance with the eye tracker. We also thank Marianne Gullberg for helpful comments during presentation of a version of this work at the conference of the International Society for Gesture Studies in Paris.

#### Abstract

In this paper, we present a new task that investigates how people interact with and make judgments about towers of blocks. In Experiment 1, participants in the lab solved a series of problems in which they had to re-configure three blocks from an initial to a final configuration. We recorded whether they used one hand or two hands to do so. In Experiment 2, we asked participants online to judge whether they think the person in the lab used one or two hands. The results revealed a close correspondence between participants' actions in the lab, and the mental simulations of participants online. To explain participants' actions and mental simulations, we develop a model that plans over a symbolic representation of the situation, executes the plan using a geometric solver, and checks the plan's feasibility by taking into account the physical constraints of the scene. Our model explains participants' actions and judgments to a high degree of quantitative accuracy.

Keywords: planning; problem solving; logic-geometric programming; intuitive physics; scene understanding

## Introduction

Physical problem solving - converting knowledge into behavior to achieve a goal that involves physical object manipulation - is a core component of human intelligence and ubiquitous in everyday cognition. From young children playing with stacking cups to an adult moving furniture to redesign a room or to load a truck, our intuitive understanding of how to manipulate the physical world in order to meet our goals is remarkable. For instance, when rearranging the furniture in a room, one needs to form and execute a plan which takes into account both spatial and physical constraints, such as how big are the objects, and which objects might be stacked on top of others.

Two independently developed lines of research provide insights and starting points into exploring these computations: reasoning based on mental models, and motor control based on forward models. Firstly, the theoretical and behavioral work on reasoning and problem solving in symbolic domains (e.g., logical reasoning, or visuo-spatial reasoning) emphasizes the importance of common-sense knowledge. For instance, early Artificial Intelligence (AI) systems that were built to reason like humans do, focused on building models that capture aspects of common-sense knowledge about the physical world in the form of knowledge representations and methods to efficiently manipulate them (e.g., Newell, Shaw, \& Simon, 1958). Similarly, in cognitive psychology, the idea that problem solving begins with the construction of a mental model of the situation was explored in more detail by mental model theory (Johnson-Laird, 2005). While still operating over logical representations, mental model theory makes additional assumptions about what aspects of a situation people naturally represent, and how these representa-
tions support reasoning (Johnson-Laird, Khemlani, \& Goodwin, 2015). However, the theoretical and behavioral work on human reasoning and problem solving has tended to focus on symbolic domains (e.g., logical, spatial, and visuo-spatial reasoning Newman, Carpenter, Varma, \& Just, 2003; Byrne \& Johnson-Laird, 1989), and has not yet looked into situations that require reasoning about physical objects, and forming plans about how to interact with them.

Secondly, research on computational motor control and object manipulation emphasizes the knowledge and transformations necessary for skillful manipulation of objects. For instance, work on sensorimotor control and object manipulation extensively studied internal models of the forward dynamics of the arm and the objects, as well as how to choose actions to efficiently achieve one's goals based on internal models (Nagengast, Braun, \& Wolpert, 2009; Franklin \& Wolpert, 2011). However, this line of work has tended to focus on relatively simple actions, instead of settings that involve planning longer sequences of moves.

In this paper, we aim to bring these two different research traditions together. To better understand physical problem solving, we introduce an intuitive, yet complex task in which participants are asked to manipulate a stack of blocks to generate a target configuration. Consider Problem 1 shown in Figure 1. The task is to manipulate the blocks so that the scene on the left is turned to the scene on the right. While participants have no trouble doing this task, and even young children naturally perform such tasks, modeling people's actions is far from trivial and robotic systems rarely implement this kind of flexible manipulation. The task requires representing the initial state, the final state, and making a plan for how to get from A to B . Finding good action sequences in this task not only requires a symbolic high-level plan (e.g., which sequence of actions to take) and visuo-spatial reasoning, it also requires intuitive physical reasoning about how objects support each other (i.e., their dynamics) and actual motor control required to execute the high-level abstract plan. Such combination of rich behavior is common in everyday cognition, but has rarely been studied in the lab. We used two different versions of the task. In one version, participants in the lab were asked to generate the different configurations. In another version of the task, we had online participants judge whether they think the person in the lab used one or two hands to get from A to B (cf. Figure 1E).

We develop a novel computational model of physical problem solving that goes all the way from formulating an abstract symbolic plan to executing the low-level motor commands that are required to realize the plan. The model is com-

Figure 1: Experimental setup. A: Example for an initial and final configuration of the three blocks. B: Illustration for what moves were legal (green border) or illegal (red border). C and D: Some example problems. E: Screenshot of the experimental interface for participants in Experiment 2.
posed of three components: (1) a symbolic representation of the scene, (2) a geometric solver for motion synthesis, and (3) a physics engine for physical reasoning. Planning in the model operates over the symbolic representation of the scene. Each plan is composed of subgoals and finds a sequence of moves that turn the initial into the final configuration (see, e.g., Figure 3C, left side). An optimization-based kinematics solver takes the symbolic plan as its input and generates a full motion plan which we implement in a simulated twoarmed robot (Figure 3C, right side). We use a physics engine to check whether the plan that the kinematic solver came up with is feasible. More specifically, we test at each point when a subgoal is reached, whether the configuration is physically stable. If the plan includes an unstable configuration, it is discarded (Figure 3D for a plan that includes an unstable state). The model's task is to get from the initial stack shown in A to the target stack. However, just taking the red block and moving it to the right so that it's correctly positioned relative to the yellow block, causes the blocks to fall over.

For each pair of initial and target stack, the model is able to generate plans using either only one arm, or both arms. We score each plan based on its efficiency which is a function of the number of the moves it takes to get from the initial to the target stack, as well as the effort that the plan takes. We evaluate the contributions of the three different components of our model through lesion studies (i.e. we remove parts of the model and see how well it does, in order to gauge what components are necessary to capture people's behavior).

The remainder of this paper is organized as follows: first, we describe a novel, physical problem-solving task and show how participants solve the task in the lab and online. Next, we describe our computational model and analyze how well it does in accounting for participants' behavior. We conclude by highlighting the key contributions of the paper, and by suggesting several lines of future research.

## Stack re-configuration problems

Most classical paradigms used to study problem solving, such as the Tower of Hanoi and its variants require visuospatial reasoning and planning for successful solutions. Here we present a novel problem which requires the problemsolver to also take into account physical constraints, such as considering whether a particular configuration of blocks will be stable.

The problems involve an initial stack of three physical blocks on a table paired with an image showing the desired target stack of the same three blocks (Figure 1A). The three wooden blocks had the same size and mass, and were colored in red, yellow, and blue. Given the pair of initial and target stacks, the problem is to re-configure the initial stack such that it will match the target stack in the image. While interacting with the blocks, participants aren't allowed to touch more than one block at a time. Example legal and illegal moves are shown in Fig 1B. To solve each stack re-configuration problem, participants have to plan and execute a set of moves (using one or both hands) that will generate the target stack from the initial stack.

## Experiment 1: Physical task

The goal of Experiment 1 was to assess how participants interact with the scene to get from the initial to the final configuration for each problem. In particular, we were interested in seeing whether they used one hand or two hands to get from A to B.

## Methods

Participants 10 participants $\quad\left(M_{\text {age }}=35, S D_{\text {age }}=\right.$ $16.4, N_{\text {female }}=6$ ) were recruited from MIT's subject pool. The study took about 15 minutes to complete, and all participants were compensated for their participation.
Stimuli The three physical blocks used in the experiment were of size $10 \mathrm{~cm}-5 \mathrm{~cm}-5 \mathrm{~cm}$ (height-width-depth) and

Figure 2: The probability that participants used one hand in the lab (Physical) together with the mean judgments provided by participants online (Mental) for 34 different problems. Note: Error bars indicate $95 \%$ bootstrapped confidence intervals.
weighed about 50 grams. We manually arranged these 3 blocks into 38 different configurations and took a picture of each configuration. The configurations were constrained such that all blocks remained within a spatial boundary on a table, and the block or blocks touching the table were centered at one of three designated spots. Figure 2 shows some examples of initial and final configurations. ${ }^{1}$

Procedure After providing written consent, participants were introduced to the task, including what moves were legal and which ones were illegal. Starting from the initial stack configuration of Problem 1, participants were asked to reconfigure the blocks to the target stack of Problem 1, which was presented on a computer screen in front of them. They clicked on the "Continue" button on the screen to indicate that they were done and the experiment moved on to the next problem.

The initial configuration of the next problem, Problem 2 (Figure 2C), was the target configuration from the previous problem, and so on. This sequence of problems continued for a total number of 37 problems. ${ }^{2}$ The presentation order was the same for all participants. All participant responses were video-recorded. For each problem, we coded whether participants used one or two hands to solve it.

## Results

Figure 2 shows the proportion of participants who used one hand for each trial. In some trials, most participants used only one hand (e.g., Problem 21, Figure 1D), and in others most participants used both hands (e.g., Problem 34, Fig 1D). Across all trials, participants used one or two hands about equally. Participants often solved the problem with one hand if it was possible to do so. Some participants only used their non-dominant hand if it was impossible to achieve the target configuration with one hand only.

[^546]
## Discussion

Overall, we found that participants had no trouble doing the task. There was considerable variance in how participants solved the different problems with some participants almost exclusively using one hand (if possible) and others being more likely to use two hands to get to the target configuration.

Experiment 1 serves as a baseline to see how participants actually interact with the physical scene. In Experiment 2, we were interested to see how people mentally simulate the way in which they would interact with the scene to get from the initial to the final stack. If participants are able to mentally do this task, we would expect a close correspondence between the judgments participants make based on their mental simulation, and the actual behavior of participants in the lab.

## Experiment 2: Mental task

The goal of this experiment was to test whether participants can simulate how another person would interact with a physical scene to get from A to B.

## Methods

Participants 40 participants $\quad\left(M_{\text {age }}=35, S D_{\text {age }}=\right.$ $14, N_{\text {female }}=22$ ) were recruited via Amazon's crowdsourcing service Mechanical Turk. The experiment took 8.7 minutes ( $S D=4.4$ ) to complete and participants were compensated at an hourly rate of $6.0 \$$.
Stimuli The same pairs of initial and target stacks as Experiment 1 were used, with the exception that both stacks were presented on the screen side by side.
Procedure Participants saw two images side by side with the left image showing the initial stack and the right image showing the target stack (example pairs in Figure 1 except panel B). They were instructed that "The image on the left shows you the initial configuration of the blocks. The image on the right shows you the configuration after the person interacted with the blocks." Their task was to judge whether the person had used one hand or two hands to re-configure the stack. They entered their response by adjusting a slider bar at the bottom of the screen (see Figure 1). Then they clicked on the "Continue" button to proceed to the next problem. The different problems were presented in randomized order.

## Results

Figure 2 shows participants' mean judgments for the different problems. To assess how well participants' mental simulations correspond with the actions that participants took in the experiment, we compared the mean responses in Experiment 2 with the proportion of participants who used one hand in Experiment 1.

Overall, we found that participants' judgments about how many hands the person used correlated well with participants' actual behavior in the lab, $r=.73, p<.05$. Whereas there were many trials for which the correspondence between judgments and actions was very high (e.g. Problems 1-6, or 2132), there were also situations in which actions and judgments came apart. For example, in Problem 34 almost all participants in the lab used two hands, whereas online participants believed that it was likely that a person would only use one hand to re-configure the scene.

## Model

The model consists of three components: (1) a set of abstract motion primitives that can be composed to symbolic plans for re-configuring an input stack to a target stack, (2) a hierarchical kinematics-based optimization algorithm to find manipulation trajectories conditioned on the symbolic plan, (3) and a physics engine to evaluate the stability of the intermediate stages produced by the execution of the manipulation trajectories. The first two components of our model are based on the logic-geometric programming framework (Toussaint, 2015).

## Logic-geometric programming framework

The logic-geometric programming framework presents a solution to problems of combined task and motion planning. Such tasks involve sequential manipulation of a scene based on a geometrically defined goal function. It utilizes symbolic task descriptions as (in-)equality constraints within a hierarchical geometric solver to find full manipulation and object trajectories starting from a coarse-level solution to eventually fine-grained full-paths. Below, we present our representations and an algorithm for symbolic planning as well as a general outline of the geometric solver.
Symbolic plans Symbolic plans are sequences of a set of abstract move types defined using actuators, movable objects and fixed objects in a simulated world. The moves change the state of the actuators and the movable objects. The world is described as a linked list of fixed and movable objects with relative world coordinates: the position and rotation of a child object is defined relative to its parent.

In order to model our stack re-configuration tasks, we populated the world with three movable objects (red block R, green block G , and blue block B), and a fixed object (table T ). The world also includes a robotic body with arms and pincer hands (actuators: handL and handR) overall consisting of 12 degrees of freedom (two at each shoulder, two at each wrist, and two at each hand).

There are three types of moves: Grasp (Obj, Act) speci-
fies a grasp action with an actuator on a movable object. For example, $\operatorname{Grasp}(R$, handR) specifies a right hand grasp of the red block. This move changes the position of the object to inside in the actuator while clearing its previous location for moving other objects. The symbolic planning stage doesn't take into account rotation of the objects or the actuators.

Place (Obj, Supp_Obj, Act) specifies any place action that is not final of a movable object on another object using an actuator. For example, Place (B, T, handL) specifies placing the blue block on the table using the left hand. This move changes the position of the object (e.g., the red block) to be on top of the support object (e.g., an empty location on top of the table) while clearing its previous location. The rotation again is not handled at the symbolic planning stage.

Fix(Obj, Supp_Obj, Act) specifies any place action that is final of a movable object on another object using an actuator. For example, Fix (G, R, handR) specifies final fixation of the green block on top of the red block using the right hand. This move changes the position of the object (e.g., the green block) to be on top of the support object (e.g., red block) while clearing its previous location. Fix action is always final - the object isn't moved after.

Given a pair of stack configurations as input, we wish to find sequences of moves (symbolic plans) that transform the initial stack to the target stack. We used Monte Carlo tree search (MCTS) to find satisfying sequences by branching the search tree using the three move types, the three objects, the four support objects, and the two actuators. Our pruning algorithm was efficient to a certain extent - for example, if an object is already grasped, we did not branch the grasp move on it again. We also imposed a condition to produce a specialized set of solutions which we labeled as the efficient set, leaving the label inefficient for the universal set of solutions. To produce the efficient set, we would only branch the search tree to a Place (Obj, ., .) if the Fix (Obj, ., .) was not currently available for the block. We increased the maximum length of move sequences until no new unique solutions could be found.

After a sequence was deemed satisfactory, we assigned integral timestamps to each of the abstract moves that it is composed of. These timestamps indicated the discrete-time values that an abstract move should be executed at. The assignment was done in a way to allow the execution of as many concurrent moves as possible. Of course, when a solution is one-handed, only one move can be executed at a time, thereby each abstract move must be assigned a separate timestamp. However, with two-handed solutions, different blocks can be concurrently actuated by different hands. Example symbolic plans for a pair of initial and target stack configurations are shown in Fig 3.

We assigned a complexity score to every symbolic solution generated, denoted $s_{i, j}$ where $i$ indexes problems and $j$ indexes its solutions. The score for a sequence is equal to the discrete-time that this sequence takes to terminate.

Figure 3: Illustration of how the model works. A: The model successfully went from the inital to the final configuration. B: The symbolic plan for going from Step 1 to Step 2 using two hands. C: A more involved plan that requires 8 moves. D: Example of a scene where a plan fails because it created an unstable configuration (as determined by the physics engine).

Geometric solver The geometric solver can be thought of as compiling a symbolic plan to manipulation trajectories of actuators and movable objects. It is based on a hierarchical optimization procedure for combined task and motion planning where the tasks come from the symbolic plan. Conditioned on the symbolic plan, the geometric solver generates a number of equality and inequality constraints that need to be met by the optimization procedure. These constraints are solved using an optimization package ( k -order motion optimization framework, KOMO Toussaint, 2014) that can handle long-distance dependencies such as the dependencies between actuator and object trajectories across time steps. Due to space limits, we cannot provide any further the details of KOMO and the logic-geometric programming framework (but see Toussaint, 2015, 2014). Snapshots of example manipulation trajectories generated by this optimization procedure for a pair of initial and target stack configurations are shown in Fig 3.

## Physical stability inference

Because the geometric solver only considers kinematics and not the physical dynamics of the scene, it can find solutions that have physically unstable intermediate steps. In-
spired by (Battaglia, Hamrick, \& Tenenbaum, 2013), we infer whether a given intermediate configuration is stable by physically instantiating it in a physics engine (PhysX) and measuring the total kinetic energy over a total simulation duration of 1 sec with a burn-in period of 100 msecs . We reject a solution if the total kinetic energy exceeds an empirically determined threshold of 0.1 joules.

Similar to the complexity score for the symbolic solutions, we assigned an approximately metabolic cost score to every full model solution found (that is, solutions after the physical stability inference step), denoted $f_{i, j}$ where $i$ indexes problems and $j$ indexes its solutions. This score captures the extent to which a particular plan requires effort to execute. The score starts with the symbolic complexity score, $s_{i, j}$, but adds two more quantities: (1) an extra cost of 0.5 for moves involving multiple blocks (e.g., actuating-i.e., grasping, placing or fixing- the red block while the blue block rests on top of it), and (2) an extra cost of 0.5 for moves that result in an intermediate physically unstable configuration from which the solver can recover to reach the correct stable configuration (e.g., moving the yellow block while the red block is leaning on it, and subsequently moving the red block).

Figure 4: Scatter plots showing the relationship between different versions of the model (columns) and participants' actions in the lab (top), or mental simulations online (bottom). Note: $1=$ definitely one hand, $0=$ definitely two hands.

## Simulations and results

In addition to our full model, we also considered a lesioned model which leaves out the physical inference component. We assume that people aim to reach their goal efficiently. Hence, we assume that sequences with higher complexity scores or metabolic costs are less likely to be chosen (in the lab) or simulated (online) than those with lower complexity scores or costs. For a given problem $i$, we obtain the probability of choosing one-hand based on the symbolic complexity scores in the following way $\frac{\sum_{j \in \text { one-hand solutions }} e^{-s_{i, j}}}{\sum_{j \in \text { all solutions }} e^{-s_{i, j}}}$. This means that the model is more likely to choose a one-hand solution the lower the cost of one-hand solutions are relative to all possible solutions.For the full model, the probability of choosing one-hand, $\operatorname{Pr}($ One-hand $)$, is calculated identically but using the full model scores, $f_{i, j}$.

Overall, we found that the model accounted well for the data (see Fig. 4). In particular, we found that both physical stability inferences and efficiency were necessary to account for participants' judgments in Experiment 2 ( $r=.74$, comparisons to symbolic-efficient, symbolic-inefficient and full-model-inefficient $p<.05$ using direct hypothesis testing with the bootstrap samples).

Similarly, in Experiment 1, we found that physical stability inferences were necessary to best explain participants' behavior (with $r=.68$ of the full model compared to $r=0.63$ of a model that doesn't take into account efficiency). But we did not find a statistical difference between using only the efficient solutions versus all solutions ( $p=.06$ ).

## General Discussion

We presented a novel paradigm - the stack re-configuration problems - and studied people's solving these problems in the laboratory (Experiment 1) and mentally simulating what they think a person would do (Experiment 2). We found that participants' judgments about whether they think a person used one or two hands to get from the initial to the target configuration correlated well with participants' actual behavior in the lab.

In order to explain participants' behavior, we developed a computational model that flexibly combines a symbolic, geometric, and physical representation of the scene. It effi-
ciently plans over this representation by first forming a symbolic plan, trying to execute the plan using a geometric solver, and then checking whether the plan was feasible by consulting a physics simulation engine to make sure that each move resulted in a physically stable configuration.

The full model accounts well for participants' actions as well as mental simulations. A model that does not take into account the efficiency of different plans fares worse (particularly when trying to explain mental simulations). Moreover, it is crucial to consider how much effort different plans would take into account well for participants' actions and judgments. Participants chose to use two hands only when a one-hand solution would have required considerably more effort.

A striking aspect of problem solving is that it demands flexible systems that can operate with very little training opportunity, leading many researchers to emphasize the role of common-sense reasoning and model-building as the building blocks of human problem solving (Johnson-Laird, 2005). We find such flexibility and data efficiency in stark contrast with some of the main approaches to artificial intelligence today, in particular to deep learning (Silver et al., 2016). These approaches require huge amounts of data, yet their generalization capacity is limited in contrast to human's flexibility. Turning these data-hungry approaches to flexible problem solvers is a substantial challenge. This paper makes a few (block) moves in this direction.

#### Abstract

To avoid interference among similar memory traces it is required to form complex memory structures that include multiple components of the event, which helps one to distinguish one event from another. In a laboratory setting, these complex binding structures have been studied through a paradigm where one has to form a memory structure that includes two items and the context together (i.e., three-way binding). However, despite the long history of the theoretical concept, its importance, and the existence of the laboratory paradigm, three-way binding structures have only been examined in recall paradigms. Moreover, not all memory models consider the ability to form three-way binding structures as a default. Therefore, the current study examined the use and formation of three-way binding structures in an associative recognition paradigm. Results provide evidence that three-way binding structures are used during recognition, which implies that it is critical for memory models to properly represent them.

Keywords: episodic memory; recognition; three-way binding

## Introduction

LeSean McCoy is a running back in the National Football League (NFL) who started his career with the Philadelphia Eagles. After receiving several awards, and leading the team to the conference finals two times, McCoy was traded with Kiko Alonso, who was Buffalo Bills' linebacker with an "NFL Defensive Rookie of the Year" title. Knowing this fact, how would one later recall which team McCoy was playing before the trade? Even after restricting that there was a trade between McCoy and Alonso, simply recalling which team McCoy played for does not solve the answer since McCoy played for both the Eagles, and the Bills. Additionally retrieving the team that existed in the pre-trade period also does not help since both team existed before and after the trade. The only way to correctly retrieve this information is forming a coherent memory structure of [McCoy]-[Eagles]-[pre-trade] together, and later using the two cues together at retrieval (i.e., [McCoy] and [pre-trade]) as a compound cue.

Memory researchers call this kind of memory structure a three-way binding structure (Humphreys, Bain, \& Pike, 1989), and controlled laboratory experiments using recall paradigms provide evidence that adults robustly form these memory structures (e.g., Postman, 1964). Binding structures in memory research have been mainly studied using a paired associate learning paradigm, where participants are
given (usually two) lists of paired words to study, and are later tested. Especially the three-way binding structure could be examined when the word pairs in one list are repaired in another list (i.e., ABABr condition; Porter \& Duncan, 1953). As in the notation, in an ABABr condition the words in one list (i.e., first two letters 'AB') are identical in the other list (i.e., second two letters 'AB') but paired differently (i.e., last letter ' $r$ ' representing that the words are re-paired). Therefore the structure creates a strong interference between the two lists when trying to retrieve a piece of memory as in the NFL trading example. To correctly retrieve which words were paired in which list, one needs to use a three-way binding structure that includes the context of a specific list, and the two words together (e.g., [list_1]-[word_1]-[word_2]).

Correctly retrieving information from an ABABr condition could be thought as an exclusive or (XOR) problem since the arrangement of the ABABr condition is similar to the XOR operation (Wiles \& Humphreys, 1993). In the XOR operation, which is expressed by using the symbol $\underline{\vee}$, when zero is operated with zero the answer is one (i.e., $0 \underline{\vee} 0=1$ ), and zero operated with one is zero (i.e., $0 \underline{\vee} 1=0$ ). When one is operated with zero the answer is zero (i.e., $1 \underline{\vee} 0=0$ ), and one operated with one is one (i.e., $1 \bigvee 1=1$ ). Considering the first two terms as the cues at test (i.e., first term as the context, and second term as the item cue), and considering the answer of the XOR operation as the to-be-retrieved target, the process of retrieving an answer from the ABABr condition becomes identical to the XOR problem. The solution of the XOR has been well known to be impossible within a two dimensional plane that has independent inputs (e.g., Minsky \& Papert, 1969), and could be solved by increasing the dimension of the inputs such as using multiplicative (configural) coding of the inputs (Sloman \& Rumelhart, 1992). Similarly, the ABABr condition could not be solved with a two-way binding structure, in fact not even with multiple two-way binding structures (e.g., Humphreys, Bain, \& Pike, 1989), and requires a higher dimensional representation such as three-way binding structure.

Empirical evidence for the ability to form and use threeway binding structures implies that our memory system should be able to store three-way binding structures, and use
compound cues when retrieving these structures. However, not all theoretical accounts of episodic memory, and their computational models consider three-way binding structures as a default.

For example, the Search of Associative Memory (SAM; Gillund \& Shiffrin, 1984; Raaijmakers \& Shiffrin, 1981) theory does not consider three-way binding structures as a memory representation. The model assumes that memories are stored as association strengths between two components such as item and context, or item and item. Because these associations contain only two components, it is not possible to represent three-way bindings. On the retrieval side, SAM is unable to use compound cues when multiple cues are provided during retrieval. Rather it treats each cue independently and then combines the retrieved information of each cue by seeking overlapping information that are retrieved by each cue.

The Temporal Context Model (TCM) and its variants also do not employ three-way binding structures (Howard \& Kahana, 2002; Lohnas, Polyn, \& Kahana, 2015; Polyn, Norman, \& Kahana, 2009; Sederberg, Howard, \& Kahana, 2008). TCM employs a two-way binding between an item and the current context representation, which are stored in a matrix of item-context bindings. In TCM, the context is defined as a weighted sum of all past items where more recent items have a stronger weight in representing the current context. These assumptions even hold when word pairs are studied in a paired associate learning paradigm (e.g., Howard et al., 2009). TCM resembles SAM in that the representational structure is fundamentally restricted to two-way associations, and therefore cannot represent three-way bindings without extensive modification.

On the other hand, models that are capable of explaining the use and formation of three-way binding structures have slightly different assumptions. MINERVA 2 (Hintzman, 1984) encodes events as separate traces, in which context and item representations are concatenated into a single vector. Thus, items $\mathrm{A}\left(I_{A}\right)$ and $\mathrm{B}\left(I_{B}\right)$ in context $1\left(C_{1}\right)$ could be represented as $C_{1} \oplus I_{A} \oplus I_{B}$. Recognition decisions in the model are made by matching the cue vector to each memory trace and summing the similarities to produce a single index of memory strength that is then compared to a decision criterion.

MINERVA 2 is sensitive to three-way associations by virtue of a non-linearity at retrieval, where the similarity between a cue and a stored trace vector is raised to the third power. This enables the model to be more sensitive to conjunctions among studied elements, rather than the individual elements themselves. Consider if pairs A, B and C, D were studied in context 1 and pairs $\mathrm{A}, \mathrm{C}$, and $\mathrm{B}, \mathrm{D}$ were studied in context 2. A foil such as $C_{2} \oplus I_{A} \oplus I_{B}$ contains studied elements, but these were not all studied together. After the cubing process (increasing the similarity to the third power), the target $C_{1} \oplus I_{A} \oplus I_{B}$ receives a stronger match than the sum of the partial matches to $C_{2} \oplus I_{A} \oplus I_{B}$. Models in the Retrieving Effectively from Memory (REM; Criss \& Shiffrin, 2005; Shiffrin \& Steyvers, 1997) framework employ a sim-
ilar idea, where instead of a cubing process at retrieval the likelihood of feature match is multiplied across each element in the vector to calculate a likelihood ratio that the trace was a studied item, producing stronger matches to conjunctions of studied elements than studied elements distributed across different memory traces.

The MATRIX model (Humphreys, Bain, \& Pike, 1989; Osth \& Dennis, 2015; Pike, 1984) has a slightly different assumption about its storage representation by using tensor representations. Items and contexts are represented as vectors and the vectors are bound together using outer products to form a third-order tensor (i.e., $C_{1} \otimes I_{A} \otimes I_{B}$ ). Rather than having individual traces for each event, the MATRIX model sums all representations for each event into a single composite tensor. The tensor representation naturally allows the use of compound cues during retrieval by forming a second-order tensor (i.e., an outer product of an item and a context) to represent the compound cue. At retrieval, the cues are combined into a tensor and matched against the memory tensor using the dot product operation which produces a measure of memory strength that reflects how similar the combined cues match the contents of memory.

Interestingly, evidence for the use of three-way binding structures have only been examined with cued recall tasks (e.g., Porter \& Duncan, 1953; Shimamura, Jurica, Mangels, Gershberg, \& Knight, 1995; Yim, Dennis, \& Sloutsky, 2013) where a context and an item is given at test as a cue to recall the paired item during study (e.g., what was the word paired with 'apple' in 'the first list'?). To our knowledge, no recognition paradigm examined the use of three-way binding structures. A number of studies have examined the role of inter-item bindings in recognition memory by using an associative recognition task, where participants study pairs of items such as A-B, C-D, and E-F in a single list. At test, participants have to make discriminations between intact pairs, which were studied on the list (e.g., A-B), and rearranged pairs, which are studied items but in a novel arrangement (e.g., C-F).

Moreover, associative recognition tasks with the ABABr condition have been used in other studies with different purposes (e.g., Aue, Criss, \& Fischetti, 2012; Criss \& Shiffrin, 2005; Postman \& Stark, 1969). However, the design and goal of the studies do not focus on the use of three-way binding structures, mostly by not testing the word pairs from both lists together. This is especially relevant because the role of context has been generally neglected in models of associative recognition. For instance, the TODAM2 model of Murdock (1997) did not bind context to inter-item bindings due to an assumption that context was not employed in associative recognition as it was not relevant to the goal of the task.

Therefore, the current study examined whether three-way binding structures are used during recognition using a associative recognition task with the ABABr condition. We constructed an $A B A B r$ condition by presenting pairs in different contexts, such as A-B and C-D in context 1 and A-D and C-B
in context 2. At test, participants are given a pair and a context cue and asked if the pair occurred in the particular context. Successful discrimination in ABABr conditions would suggest a memory structure that is capable of representing three-way bindings. Demonstration of such bindings in both recognition and recall tasks would provide further evidence that memory models need to consider such representations.

## Experiment

The experiment tested whether people use three-way binding structures in an associative recognition paradigm. In addition to the ABABr condition, which requires a three-way binding structure for a correct recognition, we used an ABAC, and $A B C D$ condition. In the $A B A C$ condition, as in the notation, one item from each pair in the first context (i.e., A in ' $A B$ ') overlap with an item from each pair in the second context (i.e., A in 'AC') which results in a moderate overlap between the two contexts compared to the ABABr condition. At the minimum, it is required to form two two-way binding structures (i.e., item-to-item, and context-to-item) for a correct retrieval (Humphreys, Bain, \& Pike, 1989). Using the same scheme, in the ABCD condition there are no overlapping items between the contexts which results in two contexts with unique items. Since there is no overlap between the two contexts, a correct retrieval only requires a single item-to-item binding at the minimum (i.e., item-item, or cue-target binding). Therefore the level of overlap increases from the ABCD condition to the ABABr condition. Moreover, a more complex binding structure is required for a correct retrieval at test as the level of interference increases. Previous studies using a recall paradigm showed a negative correlation with the level of interference and performance (e.g., Yim, Dennis, \& Sloutsky, 2013). Therefore, the additional two conditions will serve as a reference point for the performance on the ABABr condition.

As part of the design, we defined context as the identity of the speaker that presents the word pair instead of using the temporal order of the 'list' (i.e., first list, and second list) as in previous studies. Embedding the context in the trial enables us to intermix different context in the study phase, and prevents the participants from using the temporal cue. A weakness of previous ABABr designs which use two successive study lists as their contexts is that the first list is naturally expected to have weaker memory strength than the second list. This enables participants to infer that an item is from the first list due to its weaker memory strength even with a two-way binding structure (e.g., Lohnas, Polyn, \& Kahana, 2015). By eliminating the memory strength confound, our design ensures that participants require a three way binding structure to achieve above chance performance in the task.

## Methods

Participants Forty-three undergraduate students at The University of Newcastle participated for course credit (36 females, $M=25.12$ years, $S D=9.87$ ).

Materials The stimuli were video clips of a speaker saying a word. There were nine female and nine male speakers, and each speaker had its own unique background scene (see Figure 1 A ). All words were high frequency words consisting of 54 adjectives, and 63 nouns. Most of the words were selected from the MacArthur-Bates Communicative Development Inventory through the Wordbank repository (Frank, Braginsky, Yurovsky, \& Marchman, 2016).
Procedure Participants were tested individually in the laboratory. There were nine blocks where each block had a study phase followed by a retention interval and a test phase. In the study phase, participants were told that they will be seeing two speakers each presenting different word pairs one at a time. They were also told to exactly remember who said which words together since they will be tested later. Each trial started with a fixation cross for 500 msec followed by a blank screen of 500 msec and a video clip presenting a word pair, which lasted for approximately 3400 msec (see Figure 1B). In all blocks, one of the speakers was always a female, and the other a male. Also, the video clips were presented on one side of the screen throughout the experiment depending on the speaker's sex (e.g., female on the left side, male on the right side), but was randomized across participants. There were eight trials in each study phase consisting of the $A B C D$, ABAC , and ABABr structures (see Table 1 for an example). The first word was always an adjective and the second word was always a noun. The presentation order of the eight trials corresponding for each structure were randomized every block.

Table 1: An example of the eight trials in each study phase. Each triplet in the Trials column represents the speaker's sex (M: male, F: female), first word (adjective), and second word (noun) in order. There are four trials for the ABABr structure, two trials each for the $A B A C$ and $A B C D$ structures.

| Condition | Trials |  |
| :---: | :--- | :--- |
| ABABr | $[\mathrm{M}]-$ green - hand | $[\mathrm{F}]-$ green - toy |
|  | $[\mathrm{M}]-$ hot - toy | $[\mathrm{F}]-$ hot - hand |
|  | $[\mathrm{M}]-$ empty - cat | $[\mathrm{F}]-$ empty - shoe |
| ABCD | $[\mathrm{M}]-$ tall - rain | $[\mathrm{F}]-$ quiet - ball |

During the 60 second retention interval participants were presented with two groups of dots on each side of the screen, and were told to choose the side that had more dots. After a 500 msec fixation (+++) the two groups of dots were presented for 250 msec followed by a random color dot mask, which was presented until a response was made. The number of dots varied between 10 and 40 where the ratio of the two numbers were randomly chosen among the following range:

Figure 1: Design and stimuli used in the experiment. (A) an example of the videos used in the experiment, (B) an example of the study phase, (C) an example of the test phase.
1.0991-1.1915, 1.1915-1.2917, 1.3302-1.4421, and 2.29062.4833 (adapted from Halberda \& Feigenson, 2008).

In the test phase, participant were presented with a video clip as in the study phase and were asked whether it was an old video that they saw during the study phase (i.e., same speaker saying the exact same word pair), or a new one (see Figure 1C). Responses were collected using a computer mouse by clicking the corresponding image on the screen. There were 18 test trials consisting of eight old videos, eight new videos that had the speaker swapped (re-arranged pairs), and two new videos that had a new word pair spoken by the female speaker and the male speaker (lure pairs). The words in the lure pair did not appear in the study phase, and the trials were randomized every block.

Presentation of all stimuli was controlled using MATLAB with Psychtoolbox-3 (Kleiner, Brainard, \& Pelli, 2007) equipped with a 22 inch monitor, and an individual headphone. The combination of the word pairs, and speakers were randomized across participants.

## Results

We analyzed and compared each condition regarding hit rate (HR), false alarm rate (FAR), $d^{\prime}$, and correct reaction time (RT). As shown in Figure 2A, HR was the highest for the ABAC condition ( $M=.76, S D=.14$ ) followed by the ABCD condition ( $M=.71, S D=.15$ ) and ABABr condition $(M=.67$, $S D=.11$ ). A linear mixed-effects model ${ }^{1}$ with subject as a random factor (random intercept model) supported the effect of Condition ( $\chi^{2}(2)=16.70, p<.001$ ), while a Tukey post-

[^547]hoc test only provided evidence for the difference between the ABAC condition and the other two condition (ABAC ABABr: $p<.001$; ABAC - ABCD: $p=.057$; ABCD ABABr: $p<.001$ ). Similarly, the FAR measured by the re-arranged pairs was the highest for the ABABr condition $(M=.40, S D=.15)$ followed by the $\mathrm{ABCD}(M=.25, S D$ $=.16)$, $\operatorname{ABAC}(M=.23, S D=.15)$, and the lures $(M=.17$, $S D=.16$; see Figure 2B). A linear mixed-effects model with subject as a random factor supported the effect of Condition $\left(\chi^{2}(2)=94.62, p<.001\right)$, while a Tukey post-hoc test provided evidence for the difference between the ABABr condition and the other conditions ( $p<.001$ ), and between the lures and the $\operatorname{ABAC}(p=.046)$ and ABCD conditions $(p=$ .001). There was no evidence for a difference between the $A B C D$ and $A B A C$ conditions. Unlike previous studies using a recall paradigm, where the $A B C D$ condition shows a better performance than the ABAC condition, the current results show a higher HR and lower FAR for the ABAC condition than the ABCD condition.

We measured discrimination using $d^{\prime}$ by comparing old pairs against rearranged pairs $\left(d_{\text {rearranged }}^{\prime}\right)$. As shown in Figure 2 C the ABABr condition showed the lowest ( $M=.74$, $S D=.64$ ), followed by the ABCD condition ( $M=1.30, S D$ $=.71)$, and ABAC condition $(M=1.53, S D=.80)$. Also, all conditions showed an above chance performance ( $t \mathrm{~s}(42)$ $>7.60$, Bonferroni adjusted $p \mathrm{~s}<.001$, Cohen's $d>1.16$ ), as evidenced by $d^{\prime}$ scores above zero in each condition. A linear mixed-effects model with subject as a random factor supported the effect of Condition $\left(\chi^{2}(2)=59.12, p<.001\right)$, while a Tukey post-hoc test provided evidence for the difference between the ABABr condition and the other two conditions (ABAC: $p<.001$; ABCD: $p<.001$ ), and between the ABAC and the ABCD condition $(p=.028)$.

Figure 2: Results of the Experiment. (A) hit rate (HR), (B) false alarm rate (FAR), (C) $d^{\prime}$ of distinguishing the re-arranged pairs from studied (old) pairs ( $d_{\text {rearranged }}^{\prime}$ ), (D) $d^{\prime}$ of distinguishing the lures from non-lures ( $d_{\text {lure }}^{\prime}$ ), and (E) correct reaction time (RT). Error bars represent $\pm 1$ SEM.

Discriminability of lures (new pairs) from intact pairs ( $d_{\text {lure }}^{\prime}$ ) was also calculated (see Figure 2D). The ABABr condition showed the lowest $d_{\text {lure }}^{\prime}(M=1.49, S D=.73)$, followed by the ABAC condition ( $M=1.77, S D=.88$ ), and ABCD condition ( $M=1.60, S D=.79$ ), while all conditions showed an above chance performance $(t \mathrm{~s}(42)>13.18$, Bonferroni adjusted $p \mathrm{~s}<.001$, Cohen's $d>2.01$ ). A linear mixed-effects model with subject as a random factor showed supported the effect of Condition ( $\chi^{2}(2)=17.87, p<.001$ ), where evidence for difference was found between the ABAC condition and the other two conditions (Tukey post-hoc test, ABABr: $p$ $<.001$; ABCD: $p=.022$ ), but not between the ABABr and ABCD conditions ( $p=.198$ ).

RT was first pre-processed by taking the median value of each condition for each participant. RT was the slowest for the ABABr condition ( $M=988 \mathrm{msec}, S D=299 \mathrm{msec}$ ) followed by the ABAC condition ( $M=974 \mathrm{msec}, S D=344$ msec ), and ABCD condition ( $M=866 \mathrm{msec}, S D=267 \mathrm{msec}$; see Figure 2E). A linear mixed-effects model with subject as a random effect showed a statistically significant effect of Condition $\left(\chi^{2}(2)=9.11, p=.011\right)$, where a Tukey post-hoc test provided evidence for the difference between the ABCD condition and the other two conditions (ABAC: $p=.035$; ABABr: $p=.015$ ), but not between the ABAC and ABABr conditions ( $p>.25$ ).

## General Discussion

In the current study we examined whether three-way binding structures are formed and used in a recognition task. Even though three-way binding structures are crucial in everyday life since items could be easily re-paired in different contexts, previous studies have only examined the structure with recall paradigms. The results most importantly showed that participants reliably use three-way binding structures during an associative recognition task. Based on both $d_{\text {rearranged }}^{\prime}$, and $d_{\text {lure }}^{\prime}$ measures, participants showed robust above chance level performance in the ABABr condition, which indicates that three-way bindings were formed and used. The overall pattern was similar to previous findings using recall tasks (e.g., Yim, Dennis, \& Sloutsky, 2013) where the ABABr condition
showed above chance accuracy while less accurate than the other two conditions, and required more time to respond due to greater interference. Our results also extend on previous studies by using two contexts that are inter-mixed within a single list. Past studies which have employed two temporally separated study lists allow for the possibility that participants could infer list membership on the basis of a difference in memory strength between the two lists.

One interesting difference from previous results was the performance in the ABAC condition. Previous studies show a better performance in the ABCD structure compared to the ABAC condition since there are less interference in the $A B C D$ condition. However, the ABAC condition showed the best performance in the current results. One possible explanation could be a speed-accuracy trade off since it took longer to respond in the ABAC condition than in the ABCD condition while the accuracy was higher. However, it will be hard to disentangle the cause with only relying on the current data set.

The evidence of using three-way binding structures in both recall and recognition tasks implicate that models that do not represent three-way binding structures should be re-examined (e.g., Gillund \& Shiffrin, 1984; Howard \& Kahana, 2002; Lohnas, Polyn, \& Kahana, 2015). Our results also cast doubt on the proposal that the associative recognition task does not employ a context representation (Murdock, 1997). However, future work may be needed to discriminate between the existing classes of models that are capable of predicting above chance ABABr performance. For instance, our results do not discriminate between multiple trace models such as MINERVA 2 (Hintzman, 1984) and REM (Shiffrin \& Steyvers, 1997) which can predict above chance $A B A B r$ performance by virtue of their non-linear similarity metrics at retrieval, and the class of tensor models (Humphreys, Bain, \& Pike, 1989; Osth \& Dennis, 2015) which employ explicit three-way bindings as third-order tensors. Another interesting possibility for future work concerns the time course of when three way bindings are accessible. Although there are studies showing that associative information arrives after information (e.g., Gronlund \& Ratcliff, 1989), further research should examine these
possibilities with three-way bindings.

## Acknowledgments

This research was supported under Australian Research Council's Discovery Projects funding scheme to SJD (project number DP150100272). We thank Emma K. Lindsay and Emma Kronja for their help on collecting data.

# Emotional and Cognitive Interest: How Creating Situational Interest Affects Learning with Multimedia 

Angela Yoo (ahyoo79@gatech.edu)<br>Department of Psychology, 654 Cherry St<br>Atlanta, GA 30332 USA

#### Abstract

Situational interest is the positive affect and sustained attention triggered by particular contexts (Hidi \& Renninger, 2006). Some studies show interesting information enhances learning while others find it hinders learning, producing the seductive detail effect. Limited evidence suggests the seductive detail effect is weakened if emotionally interesting information is relevant to main ideas. The present research shows the seductive detail effect occurs only under certain conditions. Harp and Mayer (1997) proposed that generating cognitive, rather than emotional, interest is more effective for improving learning by cueing relationships among concepts for easier processing. Hidi and Renninger (2006) argue distinguishing between the emotional and cognitive might be artificial. Present research found benefits from cognitive interest but no support as to whether cognitive interest is necessarily a distinct type of interest from emotional interest. There were some challenges with operationalizing cognitive interest, as well as validating strategies utilized to manipulate cognitive interest levels.

Keywords: learning, instruction, situational interest, cognitive interest, seductive detail effect

## Introduction

The idea of creating an interesting experience to enhance learning is at the forefront of educational issues, particularly with science, technology, engineering, and math (STEM) education and massive open online courses (MOOCs) (National Governor's Association, 2011; Norman, 2013). However, ensuring that interesting features are not detracting from the primary instructional purpose is difficult. This challenge of mediating a desire for interest and engagement with the need to produce effective learning outcomes is mirrored in educational and cognitive psychology, with research finding contradictory or mixed results for increasing interest levels in students (Rey, 2012).

## Interest Learning Theory

Empirical support exists for interest learning theory - the idea that the more interesting learning material is the more likely a student is to learn and remember the information (Ainley, Hidi. \& Berndorff, 2002; Schiefele, 1991; Schraw, Bruning, \& Svoboda, 1995). This is especially true when measuring elaborative processing and comprehension, rather than simple recall or recognition (Schiefele, 1991). Statistically significant correlations have been found between interest and
text order choice, interest and positive affect regarding the text, affect and time spent reading, and ultimately between persistence and test scores (Ainley et al., 2002). This implies that students' interests and enjoyment lead to more time and effort spent on a text, enabling them to learn more effectively.

Interest is typically divided into three categories: individual, topic, and situational (Ainley, Hidi, \& Berndorff, 2002). Individual interest and topic interest, which both involve attributes of a person, are not considered here because the focus of the present research is to examine manipulations of learning material. Situational interest refers to environmental stimuli and the general structural features of a situation, such as organization of information, unexpectedness, text cohesion, use of concrete ideas, and intensity of triggered emotions (Ainley et al., 2002; Schraw et al., 1995). Situational interest is briefer in duration than the other forms of interest but is still characterized by positive affect and sustained attention toward the material.

## Seductive Details

Not all research supports interest-based learning. Garner, Alexander, Gillingham, Kulikowich, and Brown (1991) found that efforts to artificially induce interest, particularly with extraneous details, divert the learner's attention and reduce the ability to recall relevant information. They termed these interesting but distracting details "seductive." These seductive details were highly memorable to participants on tests of learning compared to details that were of high importance but lower interest and also could lead to poorer recall and transfer scores (Harp \& Mayer, 1991).

In a meta-analysis of findings on seductive details, nearly two-thirds of the studies included in the analysis supported fully or partially the detrimental effects of seductive details (Rey, 2012). The data in aggregate appear to demonstrate up to a small to medium effect size $(\mathrm{d}=0.3)$ for the reduction in recall and a medium effect size $(d=0.48)$ for transfer of knowledge tasks.

Still one-third of the experiments seductive details did not hurt and sometimes even improved learning (Rey, 2012). These studies show that particular types of interesting detail, the learning domain, time limits, and amount of cognitive load can temper the distracting effects of seductive details. One example of how mitigating factors result in mixed data comes from the study by Garner et al. (1991). Researchers
found that moderately relevant and moderately interesting details were recalled more frequently by participants. Although the most important details, which were rated uninteresting, were not remembered as well, the finding that some of the germane details could be recalled if considered interesting gives interest learning theory some merit.

Studies considering illustrations that accompany text indicate that relevance is the key difference in determining whether details enhance or reduce learning. In the case of reading text, purely decorative illustrations do not benefit the understanding of the content of the text, but illustrations that depict the information, help to organize or interpret information, or provide memory devices for learning can moderately benefit the retention of that information (Carney \& Levin, 2002). Any lack of enhanced learning with purely decorative images could possibly be moderated by other variables, such as the learner's prior knowledge (Magner, Schwonke, Aleven, Popescu, \& Renkl, 2014). While decorative illustrations that incite situational interest can distract learners with little prior knowledge, illustrations can enhance learning for students with more prior knowledge.

## Cognitive Interest

Instead of adding emotional interest with seductive details, Harp and Mayer (1997) suggest using cognitive interest as an alternative way to enhance learning. Harp and Mayer argue that emotionally interesting seductive details do little to help cognitively. To generate cognitive interest, instruction on a topic should signal the underlying structure of relationships of relevant concepts. Such strategies would include identifying main ideas, relating information to prior knowledge, and linking related topics. The idea is that, if topics are presented in a way that learners find easier to understand, the topics will seem more interesting. When comparing performance on both recall and problem-solving transfer, Harp and Mayer (1997) found that students scored higher marks if using text and illustrations that helped to organize and explain a topic (i.e. cognitively interesting details) than if the text and illustrations included extraneous, irrelevant content (i.e. seductive details).

A criticism of cognitive interest comes from a neuroscientific perspective (Hidi \& Renninger, 2006). Separating affective from cognitive processes and, therefore, emotional from cognitive interest is arguably an artificial distinction because of the function of the lateral hypothalamus. The lateral hypothalamus plays a major role in seeking behavior and is responsible for inducing feelings of interest and curiosity (Panksepp, 1998). Hidi and Renninger (2006) claim that, regardless of the stimulus that triggers interest or regardless of whether the person is cognitively processing or affectively responding to the stimulus, the lateral hypothalamus is activated in the brain.

## Current Investigation

The present study focused on multimedia, specifically educational videos. Video was selected as the educational medium because it would be more directly applicable and
relevant to the growing use of technology in the classroom with MOOCs and other online formats. Participants in all conditions watched a video on human digestion that varied by condition.

Relevance of Interesting Details The purpose of the main study was twofold: to explore the mitigation of the seductive detail effect through increased relevance of interesting details to main ideas and to examine the distinction between cognitive and emotional interest.

Many of the previous studies have measured learning by using free recall after learners had been exposed to the learning material (Garner et al, 1991; Harp \& Mayer, 1997; Harp \& Mayer, 1998; Schiefele, 1991; Schraw et al., 1995). Free recall might not account for prior knowledge sufficiently or for variables, such as writing abilities or motivation to write large amounts of text, that could affec performance (Schiefele, 1991). Due to this possibility that free recall alone could be an insufficient measure, a post-test score also measured learning. A pretest score was used to explore the possibility of prior knowledge as a covariate for the experimental groups. Both the pre- and post-test consisted of multiple choice, fill-in-the-blank, and short answer questions, but the questions were different for the two forms. Some of the questions asked students to identify a concept through recall or recognition while other questions measured required students to explain causal relationships and make inferences. The variety of questions was used to overcome any potential issues with using only free response or essay questions.

By creating situational interest with statements that were emotionally engaging but less similar to the main idea of the video, the study was expected to replicate the findings of seductive detail effect researchers (Garner et al., 1991; Harp \& Mayer, 1997; Mayer et al., 2008; Rey, 2012). However, performance was predicted to improve with emotionally interesting details if relevance to the content of the videos was controlled. When the interesting details did not contain less relevant additional information, but instead contained similar information as the main idea, the distracting effect seen with seductive details was not expected to be found.

Distinguishing Emotional and Cognitive Interests The second aim of this research was to examine whether emotional interest and cognitive interest are separate constructs. The distinction between cognitive and emotional aspects contradicts the definition of interest, which necessitates both affective and cognitive changes. Therefore, the phrase "cognitive interest" is used in the remainder of this document to refer to interest incited by strategies used by Harp and Mayer (1997) emphasizing the cognitive processes of interest. "Emotional interest" will refer to strategies emphasizing affective processes, as exemplified by most interest learning researchers, such as Schiefele (1991). The use of "cognitive interest" and "emotional interest" does not indicate necessarily a true differentiation between the cognitive and emotional processes of interest.

For the possibility to remain that emotional interest and cognitive interest are indeed the same phenomenon, as proposed by Hidi and Renninger (2006), there should not be any interactive effects with emotional interest conditions and cognitive interest conditions. Lack of interaction, however, would not necessarily indicate that cognitive and emotional interests are undeniably the same, but the hypothesis that they are the same would remain tenable. On the other hand, the presence of significant interactions possibly would suggest they are indeed different phenomena. Due to the evidence from Harp and Mayer (1997), learning outcomes were expected to demonstrate an interactive effect. Learning was predicted to improve with more cognitive interest compared to conditions with low interest material or material with seductive details by increasing the efficiency of processing the material. However, when there was emotionally interesting material that was also relevant to the learning material, adding cognitive interest should not produce any additional benefits relative to what was already provided by details that were emotionally interesting and relevant.

## Methods

Participants were 93 undergraduates in introductory psychology courses. The experiment was a $3 \times 2$ factorial design with six videos total - one for each condition. Students were randomly assigned to each of the six conditions (Table 1). One hour-long session was required per participant.

Table 1: Participants in each experimental condition.

|  | Emotional Interest |  |  |
| :--- | :---: | :---: | :---: |
|  | Low | Relevant | Irrelevant <br> (Seductive Details) |
| Low Cognitive <br> Interest | 16 | 16 | 16 |
| High Cognitive <br> Interest | 15 | 15 | 15 |

During the experimental session, students completed a preliminary questionnaire and an exit questionnaire. The first questionnaire given before the video viewing contained basic demographic questions including age, year in school, major, GPA, and SAT scores; Likert-type items regarding interest levels on science, biology, and anatomy; and a prior knowledge assessment. The exit questionnaire completed after viewing that video was divided into two sections. The first section repeated the same Likert-type items from the preliminary questionnaire and included a free response prompt. The final section contained items about the content of the learning material. One such item was: "True or false: Chemical digestion begins in the mouth." Thirteen of the post-test questions required students to recall or recognize information presented directly in the videos. Twelve of the items required students to make inferences based on the information presented in the videos. The tests were piloted to determine validity and appropriate levels of difficulty.

Videos ranging from 11.5 to 12 minutes in length and involving screen capture and narration were used in each of the six conditions. The types of illustrations that were used in the screen capture for all conditions were representational pictures. Representational pictures are those that simply depict the concepts being described in the audio but do not provide any type of organizational support for the concepts (Carney \& Levin, 2002). Three of the videos did not include any features that would add cognitive interest and manipulated only the amount and relevance of emotional interest. The first of these three videos for the low cognitive interest conditions contained only basic facts about human digestion and served as the control (Table 2). In the highly relevant emotional interest condition, the video narrative supplemented the information in the control video with facts that had been rated as more interesting and more relevant to the main ideas in a previous pilot study. The video for the irrelevant emotional interest condition - or the seductive detail condition - included anecdotes and facts that had been rated interesting but less relevant to the video's main idea.

Table 2: Sample texts from video scripts.

| Control | Relevant <br> Emotional <br> Interest | Irrelevant Emotional <br> Interest <br> (Seductive Details) |
| :--- | :--- | :--- |

| is a shortage of there <br> donors and a great <br> need for donated <br> organs, researchers <br> are experimenting <br> with 3D-printed <br> livers for use in <br> transplant patients. |  |  |

A second set of videos used the same scripts as the previous set emotional interest videos but also included explanative summaries to provide cognitive interest. Explanative summaries were used in the study by Harp and Mayer (1997) to create cognitive interest. These explanative summary paragraphs of 3-6 sentences highlighted major components of the human digestive system, important steps involving these components, and some of the causal processes that occur. Because all the information was presented aurally, the explanative summaries were also presented through narration at 6 different points within each video.

Learning was measured with a free recall exercise and a post-test. For the free recall assessment, participants were instructed to write everything they could remember from the video about the digestive process. Raters awarded a point for each complete and correct statement and 0.5 points for a partially correct or partially complete statement. The free recall assessments were scored by the researcher and a second rater. The interrater reliability for the scores was calculated to be $\alpha=0.96$. For the pre- and post-tests, raters deducted a point for incorrect answers. No partial points were deducted.

The raw score was then converted to a percentage score for the post-test. The free recall score was not converted to a percentage because it is scored on a basis of accumulating points, unlike post-tests scored on a point-deduction basis. Even if an attempt was made to convert recall scores to percentages, comparisons would have been difficult with mean recall scores around $12 \%$ and mean post-test scores of $57 \%$. Comparing patterns of results across the 2 dependent measures, rather than considering comparably scaled means, was more important to underscore the reasons for conflicting results in previous studies.

## Results and Discussion

For the free recall exercise, SAT math scores ( $F=5.92, p=$ 0.02 ), pre-test scores ( $F=8.54, p<0.01$ ), and biology interest levels ( $F=7.13, p=0.01$ ) were found to covary significantly with free recall scores. Pre-test scores ( $F=10.66, p<0.01$ ) and interest in biology ( $F=7.87, p=0.01$ ) also significantly covaried with the post-test scores. Once the indicated covariates were considered, MANCOVAs show main effects for both cognitive ( $F=9.32, p<0.01$ ) and emotional $(F=$ 4.65, $p=0.02$ ) interest for free recall. A significant main effect for only cognitive interest ( $F=4.44, p=0.04$ ) resulted
for the post-test scores. Interactions were not significant for either the free recall scores ( $F=0.65, p=0.53$ ) or post-test scores ( $F=0.30, p=0.74$ ).

The results replicate the findings on cognitive interest of Harp and Mayer's 1997 study (Figure1). Compared to the conditions without cognitive interest, participants learning from the high cognitive interest materials had higher free recall ( $M=8.52, S D=4.82$ ) and post-test scores ( $M=59.02$, $S D=16.95$ ) when compared to free recall scores $(M=6.84$, $S D=3.40)$ and post-test scores ( $M=55.83, S D=17.66$ ) of those in the control condition (Figures 2 and 3).

Such results support the idea that material that is easier to process for learning also provides some level of situational interest - cognitive interest being a form of situational interest - and contributes to improved learning. One possible problem with this interpretation, however, is that adding explanative summaries to create cognitive interest consequently added a second opportunity to hear information that was being presented in the videos. Repeated exposure to learning material can improve performance on immediate recall (Tulving, 1967). Further studies investigating whether the improvement in learning can be attributed to the frequency of exposure or to the cognitive interest that arises from the clarity of organization and concepts is necessary.

Figure 1: Effects of adding explanative summaries for cognitive interest on free recall scores and post-test scores.

Figure 2: Effects of relevance of interesting material on free recall scores and post-test scores.

The results for emotional interest and the relevance of emotionally interesting details were mixed. Pairwise comparisons with Sidak-adjusted p values were statistically significant when comparing free recall results between the control groups and the seductive detail group ( $t=2.80, p=$ 0.02 ) (Figure 2). The control group's scores ( $M=8.10, S D=$ 5.38) were greater on average than the scores for the seductive detail condition ( $M=7.00, S D=3.77$ ). This result lends additional support to the seductive detail findings of Garner et al. (1991), Harp and Mayer (2006), and Mayer et al. (2008). Details in learning material that are not relevant to the main learning object appear to be harmful for learning when learning is measured by the ability to recall information. However, there were no other significant differences $(t=2.00, p=0.15)$ between the control and the relevant interest groups ( $M=7.85, S D=3.24$ ) or between the seductive detail and relevant interest groups ( $t=2.00, p=$ 0.74 ). These results could suggest that, while relevant emotional interest can compensate for any distracting aspects of seductive details, the amount of interest generated in the relevant emotional interest condition is not enough to be advantageous compared to low-interest learning material. However, due to the null results for relevant interest, making any conclusive statements is difficult.

Perhaps any effects of including such emotionally interesting information would have impacted affective states more so than cognitive processes. Further work using a variety of strategies to measure affect and cognition is necessary to determine what effects these details have.

As predicted, the format of assessment appears to affect the measure of learning outcomes (Figure 2). Recall assessments consisting of writing paragraphs tend to be more difficult to write, require more information to be encoded, and produce worse scores compared to assessments that rely on recognition (Tversky, 1973). Because the post-test questions relied on a combination of both recall and recognition items requiring only short answers or marking answer selections, the detrimental effects of seductive details were no longer observed. No discernible effects ( $F=1.03, p=0.37$ ) were found for overall post-test scores across the control ( $M=$ 56.77, $S D=19.33$ ), relevant emotional interest ( $M=58.45$, $S D=14.78$ ), and seductive detail ( $M=56.90, S D=18.00$ ) conditions. The difference between the free recall results and the post-test questionnaire could imply that seductive details are more harmful when deeper encoding is required. In contrast, when less encoding is needed for recognition tasks, seductive details seem to have less of an impact.

Figure 3: Effects of relevance of interesting material on free recall and post-test scores with and without cognitive interest.

Because interactions between cognitive and emotional interest were not statistically significant (Figure 3), the current study was unable to provide any further support to the idea that the two phenomena are distinct constructs. Firstly, the F values $(F=0.65, p=0.53$ for free recall; $F=0.30, p=$ 0.74 for post-test scores) were less than one for the interactions, suggesting other variables at play that could cause the relationships to appear nonlinear and lead to F values smaller than 1. Secondly, Hidi and Renninger's (2006) proposal that emotional and cognitive interests are part of the same construct remains tenable, as does Harp's and Mayer's (1997) idea that a dichotomy exists. However, reassessing the premise of the Harp and Mayer study (1997) provides some indications as to why finding a distinction would be difficult
using their methods. While the positive results found by Harp and Mayer (1997) seemed promising for learning based on cognitive interest, the separation between cognitive and emotional interest is problematic. Interest is defined as having both affective and cognitive dimensions, according to Hidi and Renninger (2006). To distinguish the two components would suggest that either an entirely different construct is being studied or that an essential component was neglected when interpreting the results of the study.

The latter possibility could be the case for the Harp and Mayer study (1997). When participants were asked to rate how interesting the learning material was, the average rating for the passage containing cognitively interesting details was not significantly different from the passage with emotionally
interesting details, showing that both passages were enjoyed equally. The interest ratings in all the conditions were greater than 7 out of a possible 10 points. These results demonstrate that positive affect was experienced in the cognitive interest conditions equal to that in the emotional interest conditions. Even though the researchers conducted a subsequent experiment to have participants distinguish interest based on "entertainment" as an approximation of emotion and interest based on how much the text supported the learner's understanding, participants initially interpreted "interest" as encompassing both these dimensions. Due to the questionable premise of manipulating only cognitive components of interest, in addition to the previously discussed problems of repeated exposure with explanative summaries, finding nonsignificant results for the interaction between emotional interest and cognitive interest is unsurprising.

## Conclusion

Although positive results for relevant interesting details and negative results for seductive details were expected, statistically significant differences were found only for seductive details. The seductive detail effect, however, did not appear with the post-test and could indicate that irrelevant details are problematic only when recall tasks require more encoding.

The current study was unable to demonstrate a distinction between the constructs of emotional and cognitive interest. Therefore, the lack of significant results for any interactive effects should not be interpreted as indicating that the two constructs are the same or different.

The difficulty in developing appropriate manipulations and measures serve to emphasize the importance of careful planning in the design of instructional material. Generating interest and possibly the right type of interest to increase learning outcomes is a challenge. The results of this experiment and the both corroborating and conflicting results in the literature illustrate the need for intentionality in the development of learning content. Failure to make the appropriate considerations can lead to unintended results or no effects for the attempts made to improve instruction.

There remains a need for a more substantive basis for beliefs that interest is a necessary motivating factor for learning. Additional studies with improved materials are needed to further explore whether the relevance of highinterest materials can mitigate the detrimental effects of seductive details and support interest learning theory. Finding more empirical evidence would support popular recommendations for stimulating interest in improving educational outcomes, especially for STEM subjects (National Governors Association, 2011). There would even be value to adding to a possible foundation for creating guidelines on how to select interesting information that is appropriate for a learning purpose, particularly with multimedia. If learning improvements cannot be consistently found, then perhaps this can deter misguided efforts in encouraging instruction that is interesting but ineffective.

# "I won't lie, it wasn't amazing": Modeling polite indirect speech 

Erica J. Yoon, Michael Henry Tessler, Noah D. Goodman and Michael C. Frank<br>\{ejyoon, mtessler, ngoodman, mcfrank\} @stanford.edu<br>Department of Psychology, Stanford University

#### Abstract

Why are we polite when we talk to one another? One hypothesis is that people expect others to choose what to say based on their goals both to transfer information efficiently (an epistemic goal) and to make the listener feel good (a social goal). In our previous work, we found that when these two goals conflict, they sometimes produce white lies. In the current work, we expand on this theory to consider another prominent case of polite speech: indirect remarks using negation (e.g., "It wasn't amazing"). With minimal extensions from our previous framework, our formal model suggests that a pragmatic speaker will produce more indirect remarks when the speaker wants to be informative and seem considerate at the same time. These predictions were borne out in a language production experiment. These findings suggest that the conflict between social and epistemic goals can account for a broad range of politeness phenomena.

Keywords: Politeness; computational modeling; communicative goals; pragmatics

## Introduction

Language users hear and produce polite speech on a daily basis. Adults and even young children spontaneously produce requests in polite forms (Axia \& Baroni, 1985; Clark \& Schunk, 1980), and speakers use politeness strategies even while arguing, preventing unnecessary offense to their interactants (Holtgraves, 1997). But being polite conflicts with one important goal of cooperative communication: exchanging information efficiently and accurately (Grice, 1975). People tell white lies ("Your new dress is gorgeous!") and produce indirect speech that is longer and more nuanced than the simplest form of their intended message ("I don't think that dress looks phenomenal on you" as opposed to "It looks terrible") to make others feel good. Speakers risk potential loss of their intended message (indirect speech), intentionally convey wrong information (lies), and suffer inefficiencies - all in the service of being polite. If information transfer were the only currency in communication, politeness would be both infelicitous and undesirable.

A cooperative speaker, however, can be imagined as one with both an epistemic goal to improve the listener's knowledge as well as a social goal to minimize potential damage to the hearer's (and the speaker's own) self-image, called face (Brown \& Levinson, 1987). If the speaker's intended meaning contains no threat to the speaker or listener's face, then the speaker will choose to convey the meaning in an explicit and efficient manner (putting it "on the record"). As the degree of face-threat becomes more severe, however, a speaker will choose to be polite by producing more indirect utterances.

Inspired by this set of ideas, we have argued that listeners think about polite speech as reflecting a tradeoff between two goals: information transfer (which we called epistemic utility) and face-saving (social utility; Yoon, Tessler, Goodman,
\& Frank, 2016). A speaker with a high weight on social utility will try to save her listener's face: She hides or risks losing information in her intended message by making her utterance false to some degree. On the other hand, a speaker with a high weight on epistemic utility prioritizes truthfulness and informativity, and she may risk a loss of the listener's (or the speaker's own) face. These ideas were formalized in a model of pragmatic language understanding, building on the Rational Speech Act (RSA) theory (for a review, see Goodman \& Frank, 2016). We tested the polite RSA model (pRSA) by examining white lies. The model captured human participants' inferences about a speaker's goals given her utterance (e.g., saying a good talk was "amazing" implies that she is being nice) and about the true state of the world given a speaker's goal (e.g., saying "good" may mean the talk was only okay if the speaker wanted to be nice).

In the current work, we extend our framework to another polite speech act: indirect speech. White lies are produced when a speaker tries to save the listener's face by stretching the truth. But instead of lying, people sometimes try to be polite by being more indirect. Through indirect speech, a speaker can express meaning that is different from the literal meaning of the utterance (Searle, 1975). In this work, we focus on negation ("not"), which has the potential to be indirect. For instance, "Mark isn't the cleanest person I know" may suggest that the speaker thinks Mark is unclean (inferred meaning) rather than not being the person who has the greatest degree of cleanliness (literal meaning). Negation can be used as a hedging or mitigating device to address an undesirable state that is face-threatening to the addressee (Brown \& Levinson, 1987; Grice, 1975).

What may lead a speaker to produce indirect remarks? An indirect remark may be motivated by the speaker's goal to convey some face-threatening information, while being seen as a polite person who avoids threatening others' face. In our previous work, we described a pragmatic listener that jointly inferred the true state and the goals of the speaker. Building on this model, we describe here a speaker whose goal is to lead this pragmatic listener to infer the true state and attribute to the speaker certain goals (e.g., face-saving). For instance, "It wasn't amazing" does not preclude the possibility that the presentation was bad, and may in fact be pragmatically strengthened to mean that it was actually bad. Yet because the speaker does not choose the more direct "It was bad", the listener will infer a face-saving goal. Thus saying "It wasn't amazing" can accomplish the goal of conveying that the presentation was bad while the speaker is seen as not wanting to make the listener feel bad. On the other hand, if the speaker does not care about being seen as face-saving,
she will produce less indirect speech. Further, if the presentation was actually good, or even decent, the speaker will prefer to produce a directly positive remark ("It was good") in either case. Thus we predict more indirect speech when the true state is bad, and an interaction with the speaker's desire to both be informative and be seen as wanting to save face. In what follows, we derive our hypotheses using our formal model and present an empirical test of the hypotheses.

## Computational Model

In the current work, we introduce a minimal extension to our previous RSA model (pRSA; Yoon et al., 2016) to allow for speaker production of indirect remarks using negation.

## Polite RSA

RSA models assume speakers choose utterances approximately optimally given a utility function (Goodman \& Stuhlmuller, 2013). pRSA posited that the speaker's utility function can be decomposed into two components. First, epistemic utility $\left(U_{\text {epi }}\right)$ refers to the standard, informative utility in RSA: the amount of information a literal listener ( $L_{0}$ ) would still not know about world state $s$ after hearing a speaker's utterance $w$. Second, social utility $\left(U_{s o c}\right)$ is the expected subjective utility of the state inferred given the utterance $w$. The expected subjective utility is related to the intrinsic value of the state, and we use a value function $(V)$ to map states to subjective utility values. This captures the affective consequences for the listener of being in state $s$. Finally, some utterances might be costlier than others. The utility of an utterance subtracts the cost $c(w)$ from the weighted combination of the social and epistemic utilities.
$U(w ; s ; \hat{\beta})=\beta_{e p i} \cdot \ln \left(P_{L_{0}}(s \mid w)\right)+\beta_{s o c} \cdot \mathbb{E}_{P_{L_{0}}(s \mid w)}[V(s)]-C(w)$
The speaker $\left(S_{1}\right)$ in pRSA chooses utterances $w$ softmaxoptimally given the state $s$ and his goal weights $\hat{\beta}$. The pragmatic listener $\left(L_{1}\right)$ jointly infers the state $s$ and the utility weights of the speaker, $\beta_{e p i}$ and $\beta_{s o c}$ (Goodman \& Lassiter, 2015; Kao, Wu, Bergen, \& Goodman, 2014).

$$
\begin{align*}
P_{L_{1}}(s, \hat{\beta} \mid w) & \propto P_{S_{1}}(w \mid s, \hat{\beta}) \cdot P(s) \cdot P(\hat{\boldsymbol{\beta}})  \tag{1}\\
P_{S_{1}}(w \mid s, \hat{\beta}) & \propto \exp \left(\lambda_{1} \cdot \mathbb{E}[U(w ; s ; \hat{\beta})]\right)  \tag{2}\\
P_{L_{0}}(s \mid w) & \propto[[w](s) \cdot P(s) \tag{3}
\end{align*}
$$

Within our experimental domain, we assumed there were five possible states of the world corresponding to the value placed on a particular referent (e.g., rating deserved by the presentation the speaker is commenting on, akin to a Yelp rating): $S=\left\{s_{1}, \ldots, s_{5}\right\}$. We assume a uniform prior distribution over possible states of the world. The states have subjective numerical values $V\left(s_{i}\right)=\alpha \cdot i$, where $\alpha$ is a free parameter. $[[w]](s)$ corresponds to the lexical meaning of the utterance $w$ (e.g., "good") when applied to state $s$. We gather independent ratings for these literal meanings.

## Extensions to pRSA

We build on pRSA by adding negative utterances and modeling a more sophisticated speaker. First, we extend the utterance alternatives to include negation. Previously we considered five possible utterances: \{It was terrible, bad, okay, good, and amazing\}, all direct assertions of specific states (e.g., "It was amazing" would be true for the state of 5 but untrue for the states of 1 or 2 ). Now the speaker may say, \{It wasn't terrible, bad, okay, good, and amazing\}. These utterances indirectly address the referent by negating certain state. We assume that it is more costly to say utterances with negation, which makes the utterance morphemically longer and is harder to process (Clark \& Chase, 1972). In our full data analysis, we put a prior on this negation cost parameters and infer its likely values from the data.

Most importantly, we extended the recursive reasoning in the model. For our experiment, we consider the pragmatic speaker ( $S_{2}$ ) who chooses an utterance based on the pragmatic listener model (Eq. 1), thinking about the state as well as goal weights that the pragmatic listener will infer.

$$
P_{S_{2}}(w \mid s, \hat{\beta}) \propto \exp \left(\lambda_{2} \cdot \ln \left(P_{L_{1}}(s, \hat{\beta} \mid w)\right)-C(w)\right)
$$

This crucially captures the idea that the speaker both wants to convey the state $s$, and to be seen as someone with goals $\hat{\beta}$. We simplify from the Yoon et al. (2016) model by including only a single mixture parameter $\phi$ governing the extent to which the speaker is being informative vs. face saving: $\beta_{e p i}=\phi, \beta_{s o c}=1-\phi$.

We implemented this model using the probabilistic programming language WebPPL (Goodman \& Stuhlmuller, $2014 \sqrt{1}$ In the next section, we explore the model's predictions for speaker productions of indirect speech with negation vs. direct speech with no negation.

## Model predictions

Before describing our experimental data, we derive predictions from the pRSA model. In these initial simulations, we use fixed goal weights and parameters - in later fits, we will derive these parameters from the data using Bayesian data analysis. Since the model requires measurements of literal semantics (e.g., what "not good" means on a given dimension), we first describe these measurements and then give model predictions using them.

## Semantic measurement

We probed judgments of literal meanings of the target words assumed by our model and used in all our experiments.
Materials, methods, and results 25 participants with IP addresses in the United States were recruited on Amazon's Mechanical Turk. We used 13 different context items that were previously used in Yoon et al. (2016), in which someone

[^548]

Figure 1: Semantic measurement results. Proportion of acceptances of utterance types (colors) combined with target words (facets) given the true state represented on a scale of hearts. Error bars represent 95\% confidence intervals.

Figure 2: Schematic model predictions (left), experimental results (center) and fitted model predictions (right) for average proportion of negation produced among all utterances, given true states (x-axis) and goals (colors).
evaluated a performance of some kind. For example, in one of the contexts, Ann saw a presentation, and Ann's feelings toward the presentation (true state) were shown on a scale out of five hearts (e.g., two out of five hearts filled in red color). The question of interest was "Do you think Ann thought the presentation was / wasn't X?" and participants responded by choosing either "no" or "yes." The target could be one of five possible words: terrible, bad, okay, good, and amazing, giving rise to ten different possible utterances (with negation or no negation). Each participant read 50 scenarios, depicting every possible combination of states and utterances. The order of context items was randomized, and there were a maximum of four repeats of each context item per participant. For this and subsequent experiments, we analyzed the data by collapsing across context items.

For each utterance-state pair, we computed the posterior distribution over the semantic weight (i.e., how consistent X utterance is with Y state) assuming a uniform prior over the weight. Meanings of the words as judged by participants were as one would expect (see Figure 1). We used the fraction of participants that endorsed utterance $w$ for state $s$ to set informative priors to infer posterior credible values of the literal meanings from data in the speaker production experiment.

## Model parameters and predictions

The $S_{2}$ speaker in our model has the goal to convey the state and to be seen as having a particular set of goals. We explore predictions for 3 hypothetical speakers, corresponding to 3 different $\phi$ mixture parameter weights: (a) an informative speaker who wants to convey high epistemic utility (prioritizing information transfer; $\phi=0.9$ ) (b) a social speaker who wants to convey high social utility (making the listener feel good; $\phi=0.1$ ) (c) a both-goal speaker who wants to convey a balance between the two utilities $(\phi=0.5){ }^{2}$

Figure 2 (left) shows the speaker's production probabilities associated with producing an indirect speech act (i.e., an utterance with negation) for the three different speakers as the true state of the world is varied. We see, consistent with our intuition, that indirect speech was relatively more preferred in bad states than in good states. As well, we see higher probability of negation production for the speaker who wants to convey both goals (epistemic and social) relative to each goal

[^549]independently. Indirect speech does not convey that much information and so the informative speaker (a) would disprefer it. The social speaker (b) who wants to convey a face-saving goal would tend to signal a better-that-actual state through direct positive remarks. The both-goal speaker produces indirect remarks to avoid direct remarks that are either true but face-threatening, or face-saving but false.

## Speaker production experiment

To compare against our model predictions, we measured participants' predictions for the most likely utterance ( $w$ ) produced by the speaker, given a description of the true state. For example, given that Ann wanted to make Bob feel good but felt that his poem deserved 2 out of 5 hearts, what would she say? We hypothesized that when there was no tradeoff between informativity and face-threat avoidance (i.e., when the addressee's performance was great), speakers would use truthful and face-saving direct remarks ("[Your poem] was amazing") regardless of their described goals. However, when there was a conflict between the epistemic and social goals (i.e., when the addressee's performance was poor), a speaker who tried to convey both goals would use vague indirect remarks ("[Your poem] wasn't terrible") more often than direct face-threatening remarks ("[Your poem] was bad"; preferred by a speaker who only considered the epistemic goal) or direct face-saving remarks ("[Your poem] was good"; preferred by a speaker who wanted to convey only a social goal).

## Method

Participants 202 participants with IP addresses in the United States were recruited on Amazon's Mechanical Turk.
Stimuli and Procedure As in the semantics measurements above, we used scenarios in which a person (e.g., Bob) gave some performance and asked for another person (e.g., Ann)'s opinion on the performance. Additionally, we provided information on the speaker Ann's goal - to make Bob feel good, or to give as accurate and informative feedback as possible, or both - and the true state - how Ann actually felt about Bob's performance (e.g., 2 out of 5 hearts). Each participant read 15 scenarios, depicting every possible combination of goals and states. The order of context items was randomized, and there were a maximum of two repeats of each context item per participant.

Each scenario was followed by a question that read, "If Ann wanted to make Bob feel good but not necessarily give informative feedback (or to give accurate and informative feedback but not necessarily make Bob feel good, or BOTH make Bob feel good AND give accurate and informative feedback), what would Ann be most likely to say?" Participants indicated their answer by choosing one of the options on the two dropdown menus, side-by-side, one for choosing between was vs. wasn't and the other for choosing among terrible, bad, okay, good, and amazing (see Figure 3).
Imagine that Justine wrote a review for a book, but Justine didn't know how good it was. Justine approached Kelly, who knows a lot about writing reviews, and asked "How was my review?"
Here's how Kelly actually felt about Justine's review:

If Kelly wanted to make Justine feel good, but not necessarily give informative feedback,
What would Kelly be most likely to say?
What would Kelly be most likely to say?

## Behavioral results

Our hypotheses for utterance production by speakers with different goals were borne out (see full results in Figure 4).
For good states (4 and 5 hearts), positive direct remarks were judged to be the most likely utterances across all three goal conditions. For less-than-perfect, but still decent states, there was a greater degree of expectation of white lies (e.g., "It was amazing" for 4 hearts) given a social goal. For bad states ( 1 and 2 hearts), as predicted, there were more instances of expected indirect remarks overall across all goal conditions given bad states. Critically, speakers with both informative and social goals produced more indirect remarks than were observed in the other two goal conditions (Figure 2, center).

## Model results

Model fitting In this experiment, participants were told what speakers' intentions were (e.g., wanted to make Bob feel good). We assume that the intention descriptions conveyed the weight mixture $\phi$ that the speaker was using. We put uninformative priors on this mixture $(\phi \sim \operatorname{Uniform}(0,1))$ and inferred their credible values separately for each goal condition ("wanted to X") using Bayesian data analytic techniques (Lee \& Wagenmakers, 2014). We also used the fraction of participants that endorsed utterance $w$ for state $s$ to set informative priors to infer posterior credible values of the literal meanings from data.

There were four additional parameters of the model, on which we put uninformative priors: the speaker optimality parameter $\left(\lambda_{S_{1}} \sim \operatorname{Unif}(0,20)\right)$; the pragmatic speaker optimality parameter $\left(\lambda_{S_{2}} \sim \operatorname{Unif}(0,5)\right)$; the value scale parameter ( $\alpha \sim \operatorname{Unif}(0,5)$ ) in the utility function; and the cost parameter $(C(u) \sim \operatorname{Unif}(1,10))$. We inferred their posterior credible values from the data. We ran 4 MCMC chains for 80,000 iterations, discarding the first 40,000 for burnin. The Maximum A-Posteriori (MAP) estimate and $95 \%$ Highest Probability Density Interval (HDI) were: $\lambda_{S_{1}}: 2.16$ [2.02, 3.61]; $\lambda_{S_{2}}: 0.91$ [0.83, 1.75]; $\alpha: 2.71[0.98,4.59] ; C(w): 2.04$ [1.95, 2.25]. To generate utterance predictions, given our model and the inferred parameters, we evaluated the posterior predictive distribution, marginalizing out all parameters.

Figure 4: Experimental results (solid lines) and fitted model predictions (dashed lines) for speaker production. Proportion of utterances chosen (utterance type - direct vs. indirect - in different colors and words shown on x-axis) given the true states (columns) and speaker goals (rows). Error bars represent $95 \%$ confidence intervals for the data and $95 \%$ highest density intervals for the model.

Results The inferred weights for each goal condition were largely as expected: For the "wanted to give informative feedback" (informative) condition, the model put a relatively high weight on epistemic utility ( 0.81 ). For the "wanted to make [listener] feel good" (social) condition, the model inferred that the speaker was using a moderate weight on epistemic utility ( 0.51 ). For the "wanted BOTH to make [the listener] feel good and give informative feedback" (both) condition, the model assigned a weight on epistemic utility between the weights for the other two goal conditions (0.57). Overall, the weights tended to be more biased towards prioritizing the epistemic utility.

The predictions for the speaker's utterance were overall highly consistent with the experimental findings (Figure 4). The posterior predictive of the model explained almost all of the variance in the production data $r^{2}(150)=0.962$ (Figure 5). The model successfully predicted distinct patterns for each goal condition. The informative speaker produced direct remarks whose literal meanings mapped onto the true states (e.g., "It was terrible" given 1 heart). The social speaker produced remarks that were positively biased compared to the true states (e.g., "It was okay" given 2 hearts).

While the model in the both condition did produce indirect utterances (e.g., "It wasn't terrible" given 1 heart) it did so slightly less than the empirical data. For this reason, the
model did not yield the expected difference for negation production between both-goal and social conditions (Figure 2, right); though the trend was numerically correct, the effect was much smaller in the fit model than the schematic one. There are several possible explanations for this small deviation. In our experimental data, the social speaker placed a higher weight on epistemic utility than in our schematic predictions. Thus, the particular goal descriptions we used in the experiment may have suggested that the social speaker still wanted to be seen as informative, and have led to little differentiation between the social vs both-goal speaker. Another possible cause is that participants preferred a different kind of indirect speech than the model - in particular, the bothgoal speaker preferred to produce "It wasn't amazing" in the schematic model predictions, whereas participants in our experiment chose "It wasn't terrible." This discrepancy between the two remarks is interesting, because their implied meaning is similar. In a pilot experiment where participants were asked to infer the true state (number of hearts) from an utterance, "It wasn't amazing" and "It wasn't terrible" were very similar ( 2 hearts).

## Discussion

Why are we polite? Here we explored a formal instantiation of the hypothesis that two conflicting speaker goals - epis-

Figure 5: Full distribution of human responses vs. model predictions. Error bars represent $95 \%$ confidence intervals for the data (vertical) and $95 \%$ highest density intervals for the model (horizontal).
temic and social - can be used to explain a range of polite behavior, including white lies and indirect speech acts using negation. Our model predicted that speakers should produce more indirect remarks in cases of greater face threat (given the addressee's poorer performance) and in cases where speakers wanted to be both informative and nice. Our experimental data confirmed these predictions. The model's overall fit to the data was very strong, although it did not show the predicted dominance of indirect speech for the both-goal speaker at low states. Whether this discrepancy between the initial and data-fitted predictions was due to variation in goal weight based on experimental scenarios or a discrepancy in preferences for particular utterances is a question for future work.

An important contribution of this work is in showing the generalizability of our formal model (pRSA) to the case of indirect speech acts. The current work took a step in addressing speakers' self-presentation: Not only do speakers want to save the listener's face, but they also want to save their own face, by appearing informative and considerate to the listener. In future work we hope to explore this aspect more and test how our model's utilities can be extended to capture the speaker's desire to appear polite, genuine, and even modest. Using the model to explore other kinds of polite speech such as indirect requests ("Would you mind closing the window?"; Clark \& Schunk, 1980) and manifestations of polite speech in different cultures (e.g., Holtgraves \& Joong-nam, 1990) are also important future directions.

In sum, our formal model and experimental work represent an advance in polite speech understanding. With a minimal extension to our existing model, we were able to capture subtle patterns in people's inferences about indirect speech production. Our empirical findings suggest that neither epistemic nor social motives alone motivate indirect speech; instead,
the need for indirect speech results from the conflict between these two. These findings provide strong support for a utilitytheoretic framing of politeness, and suggest new directions in understanding of pragmatic language use in social contexts.

# The Structure of Young Children's Numerical and Spatial Abilities 

Christopher Young<br>University of Chicago, Chicago, Illinois, United States<br>Stephen Raudenbush<br>University of Chicago<br>Brittney Fraumeni<br>University of Chicago<br>Susan Levine<br>University of Chicago

#### Abstract

We conducted a study of 400 preschool children to determine whether spatial and numerical skills rely on common processes. Children completed a battery of mathematical tasks as part of an ongoing preschool formative assessment development project. We created theoretically meaningful skills from these tasks and carried out item response theoretic analyses on each skill. We extracted Rasch scores for each of the skills and carried out multiple factor analyses to determine whether one or more factors best characterized spatial and numerical skills. Finally, we regressed factor scores on demographic variables, including age, gender, socioeconomic status, and verbal ability. We discuss how our results add to our understanding of the connection between spatial and numerical processes and their implications for closing the achievement gap in early education.

# Alternation blindness in the perception of binary sequences

#### Abstract

Binary information is prevalent in the environment. In this study, we examined how people process repetition and alternation in binary sequences. Across four paradigms involving estimation, working memory, change detection, and visual search, we found that the number of alternations is under-estimated compared to repetitions (Experiment 1). Moreover, recall for binary sequences deteriorates as the sequence alternates more (Experiment 2). Changes in bits are also harder to detect as the sequence alternates more (Experiment 3). Finally, visual targets superimposed on bits of a binary sequence take longer to process as alternation increases (Experiment 4). Overall, our results indicate that compared to repetition, alternation in a binary sequence is less salient in the sense of requiring more attention for successful encoding. The current study thus reveals the cognitive constraints in the representation of alternation and provides a new explanation for the over-alternation bias in randomness perception.

Keywords: alternation bias, randomness perception, working memory, attention, numerosity perception

## Introduction

Perceptually, many events in the world can be interpreted as binary, from the outcomes of coin flips to the daily alternations between the sun and the moon. Past research that examines the perception of binary information has focused on the perception of randomness (Bar-Hillel \& Wagenaar, 1991; Nickerson, 2002) and regularities (Julesz, 1962; Lopes \& Oden, 1987). Although it is difficult to define randomness (Ayton et al., 1989; Beltrami, 1999; Chater \& Vitányi, 2003; Fitelson \& Osherson, 2012; Oskarsson et al., 2009), there are systematic biases in people's conception of randomness, such as the gambler's fallacy (Kahneman \& Tversky, 1972) and the hot hand fallacy (Gilovich et al., 1985). One particular bias that has received much attention in the past is the over-alternation bias: a binary sequence that alternates more than expected on the basis of random generation tends to be judged as random (Bar-Hillel \& Wagenaar, 1991; Falk \& Konold, 1997; Lopes \& Oden, 1987; Nickerson, 2002), and people tend to produce random sequences that contain too many alternations (Kahneman \& Tversky, 1972; Wagenaar, 1972). This bias is robust across different stimulus types, sensory modalities, or presentation modes (Yu et al., in press).

A number of accounts have been proposed to explain the over-alternation bias. One explanation focuses on the limits of working memory (Baddeley, 1966; Kareev, 1992). Since people can only hold a limited number of items in working memory at any given time, the amount of bits being processed is constrained, leading to a biased sample of randomness (Hahn \& Warren, 2009; Miller \& Sanjuro, 2015; Yu et al., in press). Another prominent account of the over-alternation bias is the idea of local representativeness, which suggests that people assume equal frequency of outcomes within a local sequence (Tversky \& Kahneman, 1971). A recent account is offered by Falk and Konold (1997) who proposed an encoding hypothesis that states that the probability that a bit sequence is labelled random varies directly with the time needed to correctly memorize or copy it. However, this account has been challenged by recent work showing a discrepancy between encoding difficulty of the binary sequence and labeling the sequence as random (Zhao et al., 2014). While these explanations have offered valuable insights, there remains a possibility that people have an accurate view of randomness, but the cognitive limitations contribute to a biased conception of randomness (Rapoport \& Budescu, 1992).

## The current study

We explore a new explanation focusing on a perceptual limitation in the ability to represent alternations vs. repetitions. If alternations are under-represented compared to repetitions, there needs to be more alternations in the sequence in order for people to perceive a $50 \%$ alternation rate that is typically assumed in a random sequence.
In order to generate a binary sequence that contains different levels of alternations while maintaining the equal probability of outcomes, we used an algorithm that deviates from stochastic independence by allowing previous bit to influence the next one. Specifically, for each $p$ in the unit interval (from 0 to 1 ), let $D(p)$ generate a sequence of bits consisting of zeros and ones as follows:

A fair coin toss determines the $1^{\text {st }}$ bit. Suppose that the $n^{\text {th }}$ bit (for $n \geqslant 1$ ) has been constructed. Then with probability $p$ the $n+1^{\text {st }}$ bit is set equal to the opposite of the $n^{\text {th }}$ bit; with probability $1-p$ the $n+1^{\text {st }}$ bit is set equal to the $n^{\text {th }}$ bit. Repeat this process to generate a sequence of any length.

This procedure was first introduced by Zhao, Hahn, and Osherson (2014). $D(.5)$ is a genuinely random device. For $p<.5, \mathrm{D}(p)$ tends to repeat itself, resulting in long streaks, whereas for $p>.5, D(p)$ tends to alternate. The expected proportion of each bit is $50 \%$ for all $p \in[0,1]$, although empirically, the output might deviate from $50 \%$; however such deviations should be small and random (Yu et al., in press). For any sequence produced by $D(p)$, the expected proportion of alternation, called the "switch rate" of the generating process, is $p$. The expected proportion of repetitions, called the generating "repeat rate", is $1-p$.

We conducted four experiments to examine how people represent alternations vs. repetitions. In Experiment 1, participants viewed a binary sequence and estimated the number of switches or repeats in the sequence. In Experiment 2, participants viewed a binary sequence and recalled the sequence. In Experiment 3, participants viewed two sequences and judged whether the sequences were the same or different. In Experiment 4, participants searched for a target embedded in a binary sequence.

## Experiment 1

This experiment examined if there are differences in the estimation of alternation vs. repetition in binary sequences.

## Participants

Forty-five undergraduate students ( 32 female, mean age $=19.9$ years, $\mathrm{SD}=2.3$ ) from the University of British Columbia (UBC) participated for course credit. Participants in all experiments provided informed consent. All experiments reported here have been approved by the UBC Behavioral Research Ethics Board. We conducted a power analysis using G*Power (Faul, Erdfelder, Lang, \& Buchner, 2007), which showed that given an effect size of 0.53 (based on our prior work, Zhao \& Yu, 2016), a minimum of 38 participants would be required to have $95 \%$ power to detect the effect in our design.

## Stimuli

In each trial, participants viewed a 30-bit sequence. Each sequence contained circles of two colors: green (RGB: 0 2550 ) and blue (RGB: 00255 ). Each circle subtended $0.9^{\circ}$ in diameter (Figure 1a). There were five levels of switch rates in $D(p)$ in generating the sequences, where $p=0.1$, $0.3,0.5,0.7$, and 0.9 . Correspondingly, there were five levels of repeat rates $(1-p)=0.9,0.7,0.5,0.3$, and 0.1 .

Temporal sequences. For half of the trials, participants viewed a temporal sequence where the 30 circles were presented one after another, making simple visual grouping impossible. Each circle was presented at the center of the screen for 100 ms , and the inter-stimulus interval (ISI) was 100 ms with a blank screen (Figure 1a).

Spatial sequences. For the other half of the trials, participants viewed a spatial sequence, where the 30 circles were presented on the screen simultaneously. The circles were presented left to right. The space between two adjacent
circles in the sequence subtended $0.1^{\circ}$. Each sequence was presented on the screen for 1000 ms (Figure 1a).

## Procedure

There were 200 trials in total for each participant. In each trial, participants viewed a sequence with one of the five generating switch rates $(0.1,0.3,0.5,0.7$, or 0.9$)$. Each level of switch rate contained 40 trials, among which 20 trials were temporal sequences and 20 trials were spatial sequences. After viewing the 30 -bit sequence, participants were asked to estimate either the number of the color switches ( 10 trials), or the number of color repeats (10 trials). Specifically, the instruction for estimating color switches was "How many times did a dot have a DIFFERENT color from the previous dot in the sequence?" and the instruction for estimating color repeats was "How many times did a dot have the SAME color as the previous dot in the sequence?". Participants were also told that the range of their estimate was from 0 to 29 (29 was the maximum possible number of switches or repeats in the sequence). Participants typed in their estimate after seeing each sequence. In sum, there were three within-subjects factors: the generating switch rate of the sequence (from 0.1 to 0.9 ), the presentation of the sequence (temporal vs. spatial), and the estimation type (switches vs. repeats). The order of the trials was randomized for each participant. There was no mention of randomness in all experiments.

## Results and Discussion

Estimated switch rate was the derived by dividing the estimated number of switches from the participants by 29 (the maximum possible switches in the sequence). Likewise, estimated repeat rate was calculated by dividing the estimated number of repeats from the participants by 29 (the maximum possible repeats in the sequence). Observed switch rate was the objective switch rate in the sequence presented to the participants in each trial. Likewise, observed repeat rate was the objective repeat rate in the sequence presented in each trial. The generating switch rate was the $p$ in $D(p)$ in the algorithm that generated the sequence. The generating repeat rate was $1-p$. To verify that the presented sequence actually exhibited the generating switch rate or repeat rate, we plotted the observed switch rate or repeat rate for each sequence (Figure 1 b to e), which mapped closely to the generating switch rate or repeat rate.

We computed the signed error (estimated - observed switch rate or repeat rate) at each of the five generating levels. For temporal trials (Figure 1 b and d), a 5 (generating rate: $0.1,0.3,0.5,0.7$, and 0.9 ) $\times 2$ (estimation type: switches vs. repeats) repeated-measures ANOVA revealed a main effect of generating rate $[F(4,176)=162.3, p<.001$, $\left.\eta_{p}{ }^{2}=0.79\right]$ and of estimation type $[F(1,44)=49.34, p<.001$, $\left.\eta_{p}{ }^{2}=0.53\right]$, and a reliable interaction $[F(4,176)=10.75$, $\left.p<.001, \eta_{p}{ }^{2}=0.20\right]$. Pair-wise comparisons at each generating rate showed that participants underestimated the number of switches more than repeats at each of the five generating rates $[p \prime s<.01]$. For spatial trials (Figure 1 c and e), the same

ANOVA revealed a main effect of generating rate $\left[F(4,176)=107.2, p<.001, \eta_{p}^{2}=0.71\right]$ and of estimation type $\left[F(1,44)=114.2, \quad p<.001, \quad \eta_{p}^{2}=0.72\right]$, but no interaction [ $\left.F(4,176)=0.07, \quad p=.99, \quad \eta_{p}{ }^{2}<0.01\right]$. Again, pair-wise comparisons at each generating rate showed that participants underestimated the number of switches more than repeats at each of the five generating rates [ $p$ 's<.001].

Figure 1. Experiment 1. (a) Participants ( $\mathrm{N}=45$ ) were presented with temporal or spatial sequences, and estimated either the number of circles that had a different color from the previous circle (switch) or the number of circles that had the same color as the previous one (repeat). (b) The estimated switch rate and the observed switch rate were plotted for temporal trials. (c) The estimated switch rate and the observed switch rate were plotted for spatial trials. (d) The estimated repeat rate and the observed repeat rate were plotted for temporal trials. (e) The estimated repeat rate and the observed repeat rate were plotted for spatial trials. (Error bars reflect $\pm 1$ SEM; $\left.{ }^{*} p<.05, * * p<.01, * * * p<.001\right)$

We further compared the estimated switch or repeat rate with the observed switch or repeat rate. For temporal trials (Figure 1b), participants over-estimated the switch rate at 0.1 and 0.3 , but under-estimated the switch rate at $0.5,0.7$, and 0.9 . They also over-estimated the repeat rate at 0.1 and 0.3 , but under-estimated the repeat rate at 0.7 and 0.9 (Figure 1d). For spatial trials (Figure 1c), participants overestimated the switch rate only at 0.1 , and under-estimated the switch rate at $0.3,0.5,0.7$, and 0.9 . They over-estimated the repeat rate at $0.1,0.3$, and 0.5 , but under-estimated the repeat rate at 0.7 and 0.9 (Figure 1e).

Interestingly, when estimating the number of repeats, participants were the most accurate around 0.5 where the sequences were truly random. For the same random sequence, participants were significantly under-estimating the number of switches. In fact, for people to perceive a 0.5 switch rate, the sequence must contain more than $50 \%$ switches, with a switch rate of around 0.7 (Figure 1 b and c ).

This perceptual insensitivity to switches may underlie the conceptual over-alternation bias of randomness. Taken together, these results suggest that alternations in a binary sequence were under-represented compared to repetitions.

## Experiment 2

One explanation for the under-estimation of switches could involve working memory. Specifically, people may have trouble representing switches accurately in memory, mistaking them for repeating bits, thus leading to underestimation. To examine this possibility, here participants were asked to recall each sequence.

## Participants

Forty-five students ( 30 female, mean age $=19.6$ years, $\mathrm{SD}=1.2$ ) from UBC participated for course credit.

## Stimuli and Procedure

The stimuli were the same as those in Experiment 1, except for these differences: there were 10 circles per sequence to circumvent a floor effect in the recall task; each circle was slightly larger, subtending $1.4^{\circ}$ in diameter, and the distance between each circle in spatial sequences was $0.2^{\circ}$; and each spatial sequence was presented for 500 ms (Figure 2a).

The procedure was identical to Experiment 1, except for one difference: after seeing each sequence, participants were asked to recall the sequence as accurately as they could, by pressing two keys to produce the green circle (the "G" key) or the blue circle (the "B" key). Participants were instructed to recall the dots in the same order as they appeared. After each key press, the corresponding circle was presented on the screen for 100 ms , and then disappeared. To recall the spatial sequence, participants pressed one key and the corresponding circle appeared from left to right on the screen, and remained on the screen.

## Results and Discussion

Since the observed switch rate of the sequences mapped closely onto the generating switch rates (Experiment 1), for all following experiments task performance was plotted against the five generating switch rates.

To assess the accuracy of participants' recalled sequences, we divided the exact matches between the presented sequence and the recalled sequence by 10 . The accuracy was plotted over the five levels of switch rates. For temporal trials (Figure 2b), a one way repeated-measures ANOVA revealed a significant difference in accuracy across the five switch rates $\left[F(4,176)=75.61, p<.001, \eta_{p}{ }^{2}=0.63\right]$. Post-hoc Tukey HSD analysis showed all pair-wise comparisons were significant except between 0.7 and 0.9 , and 0.5 and 0.9 . For spatial trials (Figure 2c), accuracy was different across the switch rates $\left[F(4,176)=111.5, p<.001, \eta_{p}{ }^{2}=0.72\right]$, and posthoc Tukey HSD analysis showed that all pair-wise comparisons were significant except between 0.7 and 0.9 . These results demonstrate that as the switch rate of the sequence increased, recall accuracy decreased.

To obtain a more fine-grained analysis, from the second bit on, we calculated the recall accuracy of each bit depending on whether the bit repeated or switched from the previous bit. We compared the recall accuracy of switching versus repeating bits. For temporal trials (Figure 2d), a 5 (generating rate: $0.1,0.3,0.5,0.7$, and 0.9 ) $\times 2$ (bit type: repeating vs. switching) repeated-measures ANOVA showed a main effect of generating rate $[F(4,176)=75.61$, $\left.p<.001, \eta_{p}{ }^{2}=0.63\right]$ and of bit type $[F(1,44)=206.7, p<.001$, $\left.\eta_{p}{ }^{2}=0.82\right]$, and a reliable interaction $[F(4,176)=37.4, p<.001$, $\left.\eta_{p}{ }^{2}=0.46\right]$. Pair-wise comparisons at each generating rate showed that the recall accuracy of repeating bits was consistently higher than that of switching bits [ $p$ 's $<.01$ ]. For spatial trials (Figure 2e), the same ANOVA showed a main effect of generating rate $[F(4,176)=111.5, p<.001$, $\left.\eta_{p}{ }^{2}=0.46\right]$ and of bit type $\left[F(1,44)=28.84, p<.001, \eta_{p}{ }^{2}=0.40\right]$, and a reliable interaction $\left[F(4,176)=7.18, p<.001, \eta_{p}{ }^{2}=0.14\right]$. Pair-wise comparisons at each generating rate showed that the recall accuracy of repeating bits was higher than that of switching bits [ $p$ 's $<.001$ ] at switch rates $0.1,0.3$, and 0.5 .

Figure 2. Experiment 2. (a) Participants $(\mathrm{N}=45)$ were presented with 10 -bit temporal or spatial sequences, and recalled the sequences. Accuracy was calculated as the proportion of exact matches between the presented sequence and the recalled sequence for temporal trials (b) and spatial trials (c). From the second bit on in each sequence, recall accuracy of each bit was calculated depending on whether the bit repeated the previous bit, or switched from the previous bit, for temporal sequences (d) and spatial sequences (e). We also calculated the switch rate of the recalled sequences, plotted with observed switch rate of the presented
sequences for temporal trials (f) and spatial trials (g). (Error bars reflect $\left.\pm 1 \mathrm{SEM} ;{ }^{*} p<.05,{ }^{* *} p<.01,{ }^{* * *} p<.001\right)$

One problem with the accuracy measure based on exact matches was that it penalizes cases where participants reversed or misplaced bits but were nonetheless accurate. To circumvent this problem, we conducted another analysis where we calculated the switch rate of the recalled sequence, and compared that to the observed switch rate of the presented sequence (Figure 2 f and g ).

We computed signed error (switch rate of the recalled sequences - observed switch rate) separately for temporal and spatial trials. For temporal trials (Figure 2f), a one way repeated-measures ANOVA revealed a significant difference in signed error across the five generating switch rates $\left[F(4,176)=140.7, p<.001, \eta_{p}{ }^{2}=0.76\right]$. Post-hoc Tukey HSD analysis showed all pair-wise comparisons were significant except between 0.1 and 0.3 , and 0.1 and 0.5 , suggesting that errors were greater at higher switch rates. For spatial trials (Figure 2g), the same ANOVA revealed a significant difference in signed error across the five switch rates $\left[F(4,176)=92.54, p<.001, \eta_{p}^{2}=0.68\right]$. Post-hoc Tukey HSD analysis showed all pair-wise comparisons were significant except between 0.1 and 0.3 , and 0.1 and 0.5 , suggesting errors were greater at higher switch rates.

These results showed that as the sequence alternated more, recall accuracy diminished. The greater recall error in switching bits compared to repeating bits suggests that people are more likely to encode switches as repeats, than to encode repeats as switches.

## Experiment 3

What explains the encoding difficulty of switching bits? One explanation is that switching bits may be less salient than repeating bits. To examine salience, Experiment 3 used a change detection task where participants detected changes in two sequences that were presented one after another.

## Participants

Forty-five students ( 24 female, mean age $=20.6$ years, $\mathrm{SD}=1.8$ ) from UBC participated for course credit.

## Stimuli and Procedure

There were 200 trials in total. In each trial, participants were presented with two back-to-back sequences of 15 green and blue circles (Figure 3a). The color and size of the circles were identical to those used in Experiment 2. The sequences were generated with one of the five switch rates $(0.1$ to 0.9$)$ as before. There were 40 trials per switch rate, 20 of which contained a change where the color of one randomly selected circle was different between the two sequences, and 20 of which contained no change where the two sequences were the same. In each trial, all circles in the first sequence were presented simultaneously at the center of the screen for 500 ms , with an ISI of 500 ms , followed by the second sequence also presented for 500 ms . Participants had to judge whether the two sequences were the same or different
by pressing the " Y " key or the " N " key, respectively. The trials were presented in a random order.

## Results and Discussion

To examine the performance of the change detection task, we calculated A' by dividing the average of correct rejection rate and correct hit rate by two, then adding 0.5 to the resultant number (Pollack \& Noman, 1964). A' was plotted across the five generating switch rates (Figure 3b). There was a reliable difference in A' across the five rates [ $\left.F(4,176)=24.64, p<.001, \eta_{p}{ }^{2}=0.38\right]$. Post-hoc Tukey HSD analysis showed all pair-wise comparisons were significant except for between $0.5,0.7$, or 0.9 .

Figure 3. Experiment 3. (a) Participants ( $\mathrm{N}=45$ ) viewed two back-to-back sequences, and judged if the two sequences were the same or different. (b) Performance was assessed using A'. (c) Trials with changes were categorized into three change groups: 1. repeats to switches, 2. switches to repeats, and 3. switches to switches. (Error bars reflect $\pm 1 \mathrm{SEM} ; * * * p<.001$ )

We also examined change detection accuracy depending on the local environment where the change occurred. For all change trials, we categorized them into three groups: repeats to switches (e.g., 000 to 001,010 , or 100), switches to repeats (e.g., 010,001 , or 100 to 000), and switches to switches (e.g., 001 to 011 or 101,010 to 110 or 011,100 to 101 or 110). Since we only considered trials where a change occurred, there was no false alarm. Therefore, we used accuracy as the measure here (Figure 3c). Among the three types changes, there was a reliable difference in accuracy $\left[F(2,88)=55.95, p<.001, \eta_{p}{ }^{2}=0.56\right]$. Post-hoc Tukey HSD analysis showed that accuracy in the repeats to switches group was reliably higher than that in the switches to repeats and switches to switches groups [ $p$ ' $\ll .001$ ].

These results showed that as the sequence became more alternating, a change in the sequence was harder to detect. This suggests that repetitions were more salient than alternations. Moreover, a change was more salient when a streak was interrupted, than when an alternating pattern became streaky or remained alternating. This differential performance suggests that people may have paid more attention to the streak presented in the first sequence, than to the switches presented in the first sequence.

## Experiment 4

To provide further support for the salience account, Experiment 4 used a visual search task to measure attention to switching vs. repeating sequences.

## Participants

Forty-five students ( 33 female, mean age=19.6 years, $\mathrm{SD}=2.1$ ) from UBC participated for course credit.

## Stimuli and Procedure

As in Experiment 3, there were 200 trials, and in each trial, a sequence containing 15 colored circles were presented simultaneously on the screen. As before, the sequences were generated with one of the five switch rates, and there were 40 trials per switch rate. For each trial, participants had to search for a target (a red arrow pointing left " $<$ " or right " $>$ ") in one of the randomly selected circles in the sequence. They were asked to identify the direction at which the arrow was pointing as fast and as accurately as they could (Figure 4a). Half of the trials contained an arrow pointing left, and the other half contained an arrow pointing right. Each sequence was presented for 1500 ms . The trials were presented in a random order.

Figure 4. Experiment 4. (a) Participants viewed 15 -bit spatial sequences. The target was a small red arrow, pointing to the left or right, in one of the circles. Participants reported the direction of the arrow as fast and as accurately as they could. (b) Response time of correct trials was plotted. (Error bars reflect $\pm 1$ SEM)

## Results and Discussion

The accuracy of the target search task was high (mean $=97.5 \%, \mathrm{SD}=2 \%$ ). Thus, we only examined the response times of correct trials as our measure of attention (Figure 4b). There was a reliable difference in response time across the five switch rates $[F(4,176)=2.55, p<.05$, $\left.\eta_{p}{ }^{2}=0.05\right]$. Post-hoc Tukey HSD analysis showed a reliable difference in response times only between switch rates 0.1 and 0.5 . This result showed that participants were faster to find the target in sequences with more repetitions than with more switches. One explanation is that repeating sequences may draw attention more strongly than switching sequences.

## General Discussion

The goal of the current study was to examine how people represent alternations vs. repetitions in a binary sequence. Across four experiments using estimation, working memory, change detection, and visual search tasks, we found that the number of alternations was under-estimated more strongly than the number of repetitions (Experiment 1). This under-estimation of switches could be explained by the fact that recall accuracy diminished as the sequence became more alternating (Experiment 2). The greater encoding difficulty of alternations could be explained by the finding that changes were harder to detect as the sequence became more alternating (Experiment 3). Finally, visual targets were slower to be found as the sequence became more alternating, suggesting that alternating sequences draw attention less strongly than repeating sequences (Experiment 4). Overall, these results converge to support the same finding that people are more blind or insensitive to alternations than to repetitions, which suggests that alternations are under-represented compared to repetitions.

The current findings support a new account on the overalternation bias. Specifically, there is a perceptual limitation in the ability to accurately represent alternations as opposed to repetitions in a binary sequence. This means that for people to perceive a 0.5 switch rate, the sequence must contain more than $50 \%$ alternations (in fact around $70 \%$ ).

Why are alternations under-represented compared to repetitions? We offer two explanations. First, two alternating bits (e.g., 10) may be perceptually more complex than two repeating bits (e.g., 11), and this higher complexity in an alternation could be more difficult to encode. Second, people may implicitly chunk an alternation into a unit (e.g., perceiving 101010 as three chunks of 10 , Zhao \& Yu, 2016), but rely on numerosity perception for repetitions (e.g., perceiving 111111 as 1 repeating five times).

The current study reveals a perceptual limitation in the representation of alternations. The study is important in several ways: first, it provides a new explanation of the over-alternation bias in randomness perception; second, it reveals new insights on the limits in the perception of binary information; and finally, the same finding was replicated in four different paradigms using different measures. The current findings shed light on how people process binary information, which is fundamental to understanding the limits of the cognitive system.

#### Abstract

Optimizing the study of vocabulary words for highstakes tests such as the SAT or GRE prep can be problematic, given that many words are semantically, orthographically, or phonologically confusable. Companies marketing test preparation programs make multiple recommendations, such as clustering words on some basis, but little research has been carried out to examine what that basis should be. Across two experiments, we compare the efficacy of different types of clustering-categorical, alphabetical, and confusable--for the learning of semantically related words (Experiment 1) and confusable words (Experiment 2). We demonstrate that, in contrast to most learners' intuitions, an alphabetical sequence yields superior learning.

Keywords: memory, vocabulary learning, optimal sequencing, semantic clustering, alphabetical clustering

## Introduction

Vocabulary learning is a crucial component of learning languages, not only because knowing some minimum number of words is needed for a basic level of communication in a new language, but also because increasing one's vocabulary in one's own language can be critical in the context of high-stakes testing of various types. Applicants to undergraduate or graduate programs, for example, often spend months preparing for standardized examinations, such as the ACT, SAT, or GRE, and memorization plays an essential role in such preparation. Such vocabulary learning can be especially daunting for international applicants from non-English speaking backgrounds. To meet this demand from anxious testtakers, a huge test-preparation industry has sprung up, with each different business promising a different set of "secrets" to crack the SAT and GRE codes for a price.

Many of these organizations make recommendations for how very large sets of new words may be learned, including (a) using mnemonics (e.g., word imagery), (b) grouping words by their category membership, and (c)
by Greek/Latin roots. Test preparation programs-and hence, their students-often strongly promote one over the other, yet there has been only minimal research testing the relative efficacy of such methods.
The best way(s) to learn new vocabulary, therefore, is still an open question, and what method yields the best learning outcomes may in part depend on the characteristics of the to-be-learned words. When it comes to learning new vocabulary, for example, in preparation for the GRE or SAT exams, there are two large sources of difficulty. First, these tests require individuals to learn and distinguish between many semantically related words (e.g., personality traits: mendacious-callow). Second, there is a need to distinguish between confusable but semantically distinct words, such as words that are similar-looking and/or similarsounding (e.g., decry-descry).
While little to no research has been conducted on optimal sequencing for the learning of confusable pairs, there has been some research on semantic clustering, but evidence in support of semantic clustering, however, has been mixed. In the present studies, we specifically examine two popular methods-clustering by semantic category or by confusability, and alphabetically-clustered-and compare them against a random sequence. We examine the alphabetically-clustered sequence for a practical reason: lists of words are often organized alphabetically, and for this reason, there are many who may attempt to learn words in that order, out of convenience. Indeed-at least anecdotally-studying words alphabetically appears to be common among Chinese students preparing for the SAT and GRE exams. This alphabetical organization is not necessarily a conscious, explicit strategy, but simply a byproduct of how reading typically proceeds (i.e., start on page 1 and work your way through to the end). Studying words alphabetically does offer some structure,
but unlike semantic clustering or clustering of confusable words, clustering by initial letter appears somewhat arbitrary. However, given that it is a strategy that is widely used, and little is known as to whether this strategy is truly beneficial for vocabulary learning, we examine it in the present studies.

## Semantic Clustering

"Semantic clustering" refers to the practice of grouping vocabulary words into different categories based on their meanings (Tinkham, 1993). Such clustering is believed to be effective for several reasons, including that presenting words in semantic clusters allows for intra-category and inter-relational reinforcement (e.g., Seal, 1991), makes the meanings of words clearer by enabling learners to notice fine-grained distinctions between words (e.g., Gairns \& Redman, 1986), better reflects semantic networks in the "mental lexicon" (e.g., Aitchison, 2002), and draws attention to the semantics which may lead to deeper levels of mental processing (Erten \& Tekin, 2008). On the other hand, Schneider, Healy, and Bourne (1998) found that while clustering words semantically aided initial learning, it appeared to hinder relearning a week later.
What constitutes a "semantic cluster" has, however, differed greatly across researchers. Possible constructs include, but are not limited to, near synonyms (e.g., man, fellow, and guy; (Hippner-Page, 2000), topic-related items (e.g., crime: smuggling, jury, and court; Papasanasiou, 2009), and exemplars that fall under a super-ordinate category (e.g., fruit: apple, pear, and peach) (Waring, 1997). There is some, albeit limited, evidence supporting the facilitating effects of semantic clustering (e.g., Finkbeiner \& Nicol, 2003), but these conclusions have largely been drawn from examination of acquisition during training, rather than on the basis of long-term memory tests. Considerable research, however, has demonstrated that the manipulations that boost performance during training do not always boost learning (see, e.g., Soderstrom \& Bjork, 2015). Furthermore, conclusions are hard to draw because the random and semantically clustered conditions compare learning of different sets of words, making it unclear whether it is the sequence that enhances learning or whether a semantically related set of words is simply easier to learn.

## The Present Studies

We conducted two studies to examine the optimal sequence of vocabulary learning. Although previous studies have used separate lists for different conditions (e.g., Tinkham, 1993, 1997), we created one single set of GRE words for each experiment, ensuring that only sequencing would differ across conditions. Moreover, to test long-term memory, rather than just performance during acquisition,
we employed final criterion tests that were delayed by at least 24 hours.
In Experiment 1, we examined the optimal sequencing for learning semantically related words by comparing the efficacy of alphabetical, categorical (i.e., semantic clusters), and random sequences.

In Experiment 2, we examined the optimal sequencing for learning confusable words by comparing the efficacy of alphabetical, paired (confusable clusters), and random sequences. Whether confusable clusters or random sequencing creates more difficulties is unclear. Because confusable pairs are similar-looking and/or similarsounding, similarities in orthography and/or phonology could well interfere with performance during training, but then might also enhance retention performance. Alternatively, an alphabetical sequence resembles a hybrid of random and paired schedules to some degree, and thus might incorporate the best (or worst) of both worlds.

## Experiment 1

The purpose of Experiment 1 is to address the first challenge of vocabulary learning-the need to distinguish between semantically related words.

## Participants and Design

Participants were 152 undergraduates from the University of California, Los Angeles (UCLA) who participated in the experiment in exchange for course credit. Eight-two of them were native English-speakers, and 70 spoke English as a Second Language (ESL; $M_{\text {length of speaking English }}=5.34$ years). ESL students were expected to be at a decent English level due to the University's requirements. Participants were randomly assigned to one of three sequencing conditions: categorical, alphabetical, and random.

## Materials

A pool of 36 GRE word-synonym pairs was selected from GREedge, a theme-based word list. This word list contained six words from each of six different categories: Communication, Crime \& Law, Nature, Personality, Thoughts \& Ideas, and Time. College-level participants were expected to know the meaning of each paired synonym. Table 1 shows an example of the "Communication" related words. Within each category, there was one word that began with one of six initial letters-a, $c, i, m, p$, and $s-$ which allowed us to construct the six sets of words for the alphabetical condition. Table 2 shows an example of the words that begin with the letter $a$.

Table 1
Example of one of the six-word categorical sets: words relating to "Communication"

| Category | Initial | GRE Word | Synonym |
| :--- | ---: | :--- | :--- |
| Communication | $a$ | acrimonious | bitter |
|  | $c$ | circumlocution | rambling |
|  | $i$ | importune | beg |
|  | $m$ | missive | letter |
|  | $p$ | prattle | babble |
|  | $s$ | sententious | pithy |

Table 2
Example of one of the six-word alphabetical sets: words beginning with the letter $a$

| Initial | Category | GRE Word | Synonym |
| :--- | :--- | :--- | :--- |
| a | Communication | acrimonious | bitter |
|  | Crime \& Law | abjure | withdraw |
|  | Nature | arroyo | environment |
|  | Personality | abstemious | restrained |
|  | Thoughts \& Ideas | apotheosis | exaltation |
|  | Time | antediluvian | ancient |

## Procedure

Participants were told that their task was to learn 36 GRE words. Participants were presented one GRE wordsynonym pair at a time, and, for each pair, they were first asked to generate the synonym ( 8 sec ) before they were shown the correct answer ( 3 sec ). Therefore, the study phase consisted of tests-with-feedback trials (for a discussion of the benefits of testing and feedback on long-term retention, see Roediger \& Karpicke, 2006). The six pairs of a given set (e.g., a random set, a category set, or an alphabetical set) were always presented consecutively. Each set were presented three times, with the order of pairs randomized each time (hence, the alphabetical sequence was not strictly alphabetical, but grouped words starting with the same initial letter). Thus, any given pair was presented on an average spacing interval of 5-5. Between individuals, the order of the six sets was randomized.
After they completed studying all 36 pairs ( 3 times each), participants were asked to predict how many of the 36 pairs they would be able to answer correctly on the test the next day. They were then informed of the three different study sequences that had been used for different participants and asked to judge which one they believed would be most effective for learning vocabulary.
Twenty-four hours later, participants were emailed a link to take the final test. The test phase consisted of two portions: First, they were asked to complete a cued-recall task in which they were presented with the GRE word and asked to generate the synonym. Second, they were given a multiple-choice in which they were given the synonym and four options. The options, illustrated in Figure 1, were constructed such that one was the correct answer, one was a wrong answer from the same category, one was a wrong
answer with the same initial letter, and one was a random lure selected from the other GRE words they had studied.
Finally, we collected information about participants' GRE preparation status and language fluency and number of languages spoken.

Figure 1: Example of a multiple-choice trial in Experiment 1. Participants were only shown contents inside the square. The rest is only for illustration purpose.

## Results and Discussion

Sixteen participants were removed from subsequent analysis for the following reasons: five looked up answers, seven reported serious technical issues with the experiment, and four people indicated both. Among the remaining 136 participants, 74 were native English-speakers and 62 were ESL students ( $M_{\text {length of speaking English }}=5.42$ years).

Acquisition The increase in acquisition from the to the third time a given pair was presented during the study phase is shown in the left panel of Figure 2. By the end of the final trial, there was a trend for a difference between the three conditions, $F(2,133)=.2 .24, M S E=.07, p=.11$. Post-hoc analyses revealed that the random condition ( $M=$ $.73, S D=.18$ ) was marginally worse than the alphabetical ( $M=.79, S D=.18, p=.06$ ) and categorical conditions ( $M=.79, S D=.18, p=.08$ ). No significant difference between the alphabetical and categorical conditions was obtained, $p=.96$.

Final test Performance on the final cued recall test, illustrated in the right panel of Figure 2, suggested some differences (although limited) between conditions, $F(2,133)$ $=3.105, M S E=.04, p=.048$, but the pattern was somewhat different from that of the acquisition pattern. Post-hoc pairwise comparisons revealed that participants in the alphabetical condition $(M=.50, S D=.03)$ performed significantly better than those in the random condition ( $M=.40, S E=.03$ ), $p=.02$ ), but neither was significantly different from the categorical condition ( $M=$ $.44, S D=.21$ ), $p \mathrm{~s}>.10$. No significant differences in performance on the multiple-choice test among conditions were observed, $F(2,133)=1.764, p=.18$.

Figure 2: Study phase acquisition curves and final cued recall test in Experiment 1. Error bars represent one standard error of the mean.

Metacognitive responses With respect to the question "What sequence do you think is best for learning?" asked of participants at the end of the acquisition phase, 94 (70\%) of the 134 participants responding reported believing that categorical clustering would lead to the best learning, 35 ( $26 \%$ ) reported believing that a random sequence would be best, and only 5 (4\%) reported believing that an alphabetical sequence would be best. These metacognitive responses did not differ by assigned condition, $\chi^{2}(4)=7.34, p=.12$.
Overall, while Experiment 1 neither show evidence in favor of nor against categorical sequencing, it surprisingly suggested some benefits associated with an alphabetical sequencing strategy. Participants' metacognitive beliefs, however, showed limited faith in this "new" strategy.

## Experiment 2

Experiment 2 aimed to address the second challenge in GRE word learning: students' ability to distinguish between similar-looking and/or similar-sounding words.

## Participants and Design

Participants were 112 undergraduates from UCLA who participated in the experiment in exchange for course credit. Sixty-five of those participants were native Englishspeakers, and 47 ESL students ( $M_{\text {length of speaking English }}=5.60$ years). Despite being non-native English-speakers, these ELS students were expected to be at a decent English level due to the University's requirements. Participants were randomly assigned to one of three sequencing conditions: paired, alphabetical, and random.

## Materials

As in Experiment 1, we selected 36 GRE word- synonym pairs from several sites (e.g., Magoosh). However, each GRE word was also matched with another GRE word that was highly confusable. That is, 36 GRE words were broken
down into 18 confusable pairs. The words in nine of these pairs shared the same initial letters (e.g., augur-bode and auger- drill) and the remaining nine of these pairs did not (e.g., astringent-bitter and stringent-strict). Across all the GRE words, any initial letter was also made to appear at least three times (e.g., three words that began with ' $a$ '). College-level participants were expected to know the meaning of each paired synonym.
In the random condition, one randomized sequence of the 36 words was created for each participant. In the paired condition, the confusable paired-GRE words were always presented consecutively (e.g., augur-bode followed by auger- drill, or vice versa), and the order of pairs was randomized for each participant. In the alphabetical condition, the GRE words were presented in alphabetical order. Table 3 shows an example of two confusable pairs in alphabetical order: One same-initial pair (veracious and voracious) and one different-initial pair (pabulum and vinculum). As demonstrated below, Same-initial pairs by definition would still appear close to each other in alphabetical order (not necessarily consecutively), but different-initial pairs would for sure be shuffled.

## Table 3

Example of two confusable pairs in alphabetical order: One same-initial pair and one different-initial pair.

| Initial | GRE Word | Synonym |
| :---: | :--- | :--- |
| p | pabulum | sustenance |
| $\ldots$ | $\ldots$ | $\ldots$ |
| v | veracious | honest |
|  | vinculum | bond |
|  | voracious | greedy |

## Procedure

The procedure of Experiment 2 was similar to that of Experiment 1 with three exceptions: (a) Instead of repeating in sets of six, all 36 pairs were presented before they were repeated, yielding an average spacing interval of 35-35; (b) the alphabetical order here was strictly alphabetical, so the order of words in each of the three cycles of 36 trials was the same; and (c) the multiplechoice test used the GRE word as the cue and presented four studied synonyms as the options (the correct answer, the synonym of the confusable GRE word, a synonym of a word sharing the same initial letter, and another random synonym).

## Results and Discussion

Sixteen participants were removed from subsequent analysis: five looked up answers, and 11 reported serious technical issues with the experiment. Among the remaining 96 participants, 57 were native English-speakers and 39 were ESL students ( $M_{\text {length of speaking English }}=5.76$ years).

Acquisition The increase in acquisition from the first to the third time a given pair was presented during the study phase is shown in the left panel of Figure 3. Participants in different conditions exhibited a similar amount of accuracy boost by the end of the study phase, and the proportions of synonyms correctly recalled were not different, although performance in the alphabetical condition ( $M=.43, S D=.20$ ) was numerically better than that in the random $(M=.39, S D=.18)$ and paired $(M=$ $.37, S D=.18$ ) conditions. Unlike in Experiment 1, the curves were nearly linear with no indication of deceleration in learning rates at the end of the $3^{\text {rd }}$ presentation. One interpretation of this finding was that intrinsic confusion in confusable words made them naturally more difficult to learn than regular ones (indeed, accuracy rates were lower). Thus, three learning trials still left space for learning to improve at an accelerating rate before starting to slow down.

Figure 3: Study phase acquisition curves and final cued recall test in Experiment 2. Error bars represent one standard error of the mean.

Final test Performance on the final cued recall test is illustrated in the right panel of Figure 3. A 3 (sequencing condition) x 2 (pair type) mixed effects ANOVA performed on the cued-recall test performance, revealed a main effect of condition, $F(2,93)=3.45, M S E=.10, p=$ .036. Additionally, post-hoc pairwise comparisons revealed that the alphabetical condition $(M=.53, S D=25)$ yielded significantly better learning than the paired condition ( $M=$ $.39, S D=.19, p=.01)$. The random condition $(M=.44$, $S D=.25$ ) was not significantly different from either the paired condition ( $p=.33$ ) or the alphabetical condition ( $p$ $=.12$ ).

A main effect of pair type was also observed, $F(1,93)=$ $50.55, M S E=.01, p<.001$, with the GRE words from the pairs having different initial letters $(M=.50, S D=.23)$ being learned significantly better than the words from pairs sharing the same initial letter $(M=.39, S D=.24)$. There
was no interaction between condition and pair type, $F(2,93)=1.12, M S E=.01, p=.33$.

Figure 4 shows multiple-choice test performance by condition and pair type. A 3 (sequencing condition) x 2 (pair type) mixed effects ANOVA performed on the multiple-choice test performance revealed similar patterns to that obtained for the cued-recall test performance. Again, there was a trend-level effect of condition, $F(2,93)=2.22$, $M S E=.10, p=.12$. Pairwise comparisons revealed a similar pattern as found with the cued-recall test: the alphabetical condition ( $M=.77, S D=.03$ ) was marginally better than the paired $(M=.70, S D=.03, p=.06)$ and the random $(M=.70, S D=.03, p=.08)$ conditions.

Again, a significant effect of pair type, $F(1,93)=53.03$, $M S E=.01, p<.001$, was observed, with the differentinitial letter pairs $(M=.77, S D=.18)$ learned better than the same-initial letter pairs $(M=.67, S D=.18)$. Finally, there was no condition $x$ pair type interaction, $F(2,93)=1.57, M S E=.01, p=.21$

Figure 4: Multiple-choice test performance on Experiment 2 by condition and pair type. Error bars represent one standard error of the mean.

Metacognitive Responses When asked what sequence they believed was best for learning, 42 (44\%) participants reported that they believed that pairing confusable words would lead to the best learning, 39 ( $41 \%$ ) a random sequence would be best, and 15 ( $16 \%$ ) believed that an alphabetical sequence would be best. These metacognitive responses did not differ by experienced condition, $\chi^{2}(4)=6.30, p=.18$.

Overall, the findings of Experiment 2 demonstrate that when trying to learn confusable words, contrary to many people's belief (a majority of $84 \%$ thought that either random or paired order would be the best), an alphabetical order led to the greatest learning.

## General Discussion

The current study is one of the very few instances where the alphabetical order has been studied. Experiments 1 and 2 revealed some preliminary evidence on the merits of an
alphabetical word learning sequence. There was some suggestion that this strategy can be equally, if not more effective than strategies that are traditionally considered good (e.g., categorical or paired clustering).
It is worth pointing that while both being referred to as an "alphabetical sequence," the structures of the alphabetical order in Experiments 1 and 2 were not identical. In Experiment 1, the structure was not strictly alphabetical, but rather grouped words beginning with the same initial letter together. Participants went through an alphabetical cluster three times, so they were only exposed to one initial letter at any given time. Thus, it was more of an "alphabet-informed grouping." We speculate that one possibility is that this grouping offers an optimal level of support and difficulty: The support from the small degree of structure (i.e., shared initial letters) may ease extraneous cognitive processing load from the difficult word learning task; the otherwise-random nature of the words maintains a sense of difficulty to promote deeper processing. An alternative explanation could simply be that clustering alphabets gives learners another, redundant, cue to aid learning. The initial letter is another cue to the context in which words were learned. For example, the initials may have already narrowed down the list from 36 to six words, which may well require less cognitive effort to identify the correct answer, given that words in the same initial cluster are not too similar orthographically/phonologically. Therefore, while shared categories may be a contextual cue in categorical clustering, list position could be a contextual cue in an alphabetical sequencing. Each clustering method has its own advantage and both lead to respectable results.
In Experiment 2, the alphabetical sequence was truly alphabetical, with half same-initial and half different-initial confusable pairs. The advantage of this strategy was primarily reported in learning different-initial than sameinitial pairs. Thus, the benefit of alphabetizing a confusable word-list was observed at a global (the entire list with multiple initials) rather than a local (same-initial pairs grouped to the same alphabetical cluster) level. Consequently, an alphabetical condition represents a hybrid of randomization of the easier pairs (i.e., different-initial pairs) and confusability- clustering of the more difficult pairs (i.e., same initial pairs), which may have incidentally created a degree of "desirable difficulty" (Bjork, 1994). Alternatively, because learners in Experiment 2 learned all 36 words before repeating, those in the alphabetical condition may have simply used list position as a contextual cue to aid learning. For example, they may have linked to-be-learned words to some known knowledge (i.e., an alphabetical list) to help memorize.
We have already demonstrated some caveats when alphabetizing to-be-learned words. As suggested above, there might be differences in the role of "alphabet-informed grouping vs. alphabetical order. It is therefore unclear how far the benefits of an alphabetical sequence would extend. In the present studies, we presented participants relatively difficult words in a language that they were familiar with

Hence, knowledge about word etymology (e.g., Latin roots) or even passing familiarity with the to-be-learned words themselves (note the large jump in performance between the first and second trial of the study phase) may have supported learning. It is unclear how the optimal sequence might change for foreign language learning, where learners do not have this type of background knowledge.

As part of a critical factor in high-stakes tests, GRE word learning is a major concern of many students. The present studies extend the literature by suggesting the powerful potential of learning words in alphabetical order, a widely used, yet under-investigated alternative to clustering or random sequencing. Whether, however, the benefits of an alphabetical sequencing might generalize to vocabulary words that are less difficult and abstract than GRE words remains to be seen. In the meantime, it appears that generations of Chinese students who have been learning English vocabulary words grouped alphabetically may not have been engaging in what may seem, by some arguments, to be a misguided practice.

# Domain-General Learning of Neural Network Models to Solve Analogy Tasks - A Large-Scale Simulation 

Arianna Yuan (xfyuan@stanford.edu)<br>Department of Psychology, Stanford University, Stanford, CA 94305 USA

#### Abstract

Several computational models have been proposed to explain the mental processes underlying analogical reasoning. However, previous models either lack a learning component or use limited, artificial data for simulations. To address these issues, we build a domain-general neural network model that learns to solve analogy tasks in different modalities, e.g., texts and images. Importantly, it uses word representations and image representations computed from large-scale naturalistic corpus. The model reproduces several key findings in the analogical reasoning literature, including relational shift and familiarity effect, and demonstrates domain-general learning capacity. Our model also makes interesting predictions on cross-modality transfer of analogical reasoning that could be empirically tested. Our model makes the first step towards a computational framework that is able to learn analogy tasks using naturalistic data and transfer to other modalities.

Keywords: analogical reasoning; learning; cross-modality transfer; neural network models.

## Introduction

Analogy is arguably one of the most important mechanisms through which people acquire new knowledge (Gentner, Holyoak, \& Kokinov, 2001). Verbal analogy task such as "PIG:BOAR::DOG:? a. WOLF b. CAT" and visual analogy task such as Raven's Progressive Matrices has been widely used in standardized test to assess students' intellectual ability (Buck et al., 1998). For a long time, there has been a heated debate over whether analogy-mapping is a domain-specific or domain-general process (Forbus, Gentner, Markman, \& Ferguson, 1998). Nowadays, it has been increasingly clear that there are both a domain-general component and a domain-specific component in learning analogical reasoning.

One phenomenon related to the domain-general component is the relational shift in child development, i.e., early in development children tend to choose the item that is more associated to the third item in the analogy question A:B::C:[D1|D2] (Sternberg \& Nigro, 1980), and only older kids are able to use relational matching rather than associations to perform the task. Some researchers have argued that the lack of inhibitory control, which requires a full-blown pre-frontal cortex is partially responsible for the associative response (Richland \& Burchinal, 2013). The ability to inhibit associative responding and maintain the relational constraints imposed by $\mathrm{A}: \mathrm{B}$ is domain-general, i.e., it is a universal prerequisite for analogy-making no matter which sensory modality or semantic domain the analogy task is built on. Hence, if one person is trained to perform analogy task in a particularly domain or modality, it is likely that the training will help them do better in other domain or modality,
due to enhanced ability to suppress associative responses and to maintain contexts.

The evidence for a domain-specific component comes from the finding that children's ability to perform analogy task depends on their familiarity with the test material. Goswami and Brown (1990a, 1990b) found that when familiar concepts were used in analogy tasks, performances were much better. These findings underscore the contribution of domain-specific knowledge in analogy-making, yet change in this aspect is unlikely to boost task performance in other domain or modality.

Several computational models have been proposed to account for how people solve analogy tasks. A useful classification scheme is to group them into three types of models (French, 2002; Gentner \& Forbus, 2010): symbolic models (Kuehne, Forbus, Gentner, \& Quinn, 2000; Falkenhainer, Forbus, \& Gentner, 1989), connectionist models (Holyoak \& Thagard, 1989; Hummel \& Holyoak, 1997; Kollias \& McClelland, 2013) and hybrid models (Mitchell, 1993; Kokinov \& Petrov, 2000). Most of symbolic models represent analogy questions using predicates and logical forms. When asked to solve an analogy task such as $\mathrm{A}: \mathrm{B}:: \mathrm{C}:$ ?, they use symbolic manipulations and search algorithms to find the correct answer. One of the most influential symbolic approach to analogy-mapping is the Structure Mapping Engine (SME) (Falkenhainer et al., 1989; Gentner, 1983). It represents the base and source using predicate-calculus and compares the two representations to see if there is any structural similarities between them. Once optimal matching structures are identified, the system then transfer structure in the source to the target. Later version of SME have relaxed matching criteria to allow similar, but not identical predicate to match (Brian, 1990), but whether two predicates are similar need to be explicitly computed.

Contrary to these symbolic approaches, connectionist models often use distributed representation for the items in an analogy task and encode their semantic and structural similarity in a more implicit and continuous way, e.g., Kollias and McClelland (2013). The connectionist models learn to make a correct response by adjusting connection weights so that the spreading activation within the neural networks could reveal the distributed representation of the target, thus leading to the correct answer.

Previous computational models of analogy-making have significantly deepened our understanding of the mental processes underling analogical reasoning. Many of such models claim that they provide a domain-general explanation of how people perform analogy tasks. For example, the

Structure Mapping Engine, which was originally introduced to solve analogy task in discrete semantic space, was later used to answer analogy questions in continuous visual domain (Lovett, Forbus, \& Usher, 2007). Most of the connectionist models are theoretically domain-general as well, since we can easily feed the distributed representation of stimuli from different domain/modality to the input placeholders of those models. It is important for these models to be domain-general, since humans are able to make within-modality generalization, such as recognizing examples that they have never encountered before (Lake, Salakhutdinov, \& Tenenbaum, 2015), or make cross-modality transfer (Hupp \& Sloutsky, 2011). Specifically, it has been shown that relational knowledge is critical to the development of analogical reasoning (Goswami, 1991). If one person has received sufficient training to solve verbal analogy tasks, they would gain some experience in relational knowledge. When later asked to solve a visual analogy-making task, they do not need to learn it from scratch (Figure 1).

Figure 1: Stimuli used in the current study. Left: Verbal analogy task. Right: Visual analogy task.

Despite the generalization ability that previous computational models may have claimed, they are often missing some critical components. Symbolic approaches, for example, rarely address how people learn to make an analogy. Since the knowledge representations and the search algorithms in those models are preprogrammed, it is not clear how experience of analogy-making in one domain could facilitate analogy-making in another unfamiliar domain.

As for the connectionist models, despite their theoretically domain-general nature, none of the previous studies has directly tested cross-modality transfer. Particularly, they only demonstrate within-modality generalization, i.e., the models are trained on some examples and tested on a different set of examples in the same modality. Also, the distributed representation of stimuli are either manually defined according to the semantic features of the items, or randomly assigned to some localist codes, which are not very naturalistic.

Finally, all the previous modeling works have used small datasets, containing hundreds of examples at most. We are wondering if we could build a model that scales up to handle a very large and naturalistic dataset. Particularly, we want to understand if we use a dataset that reflects the statistical distribution of stimuli in real life, can the model still learn analogical reasoning and even make cross-modality transfer? This idea is motivated by the statistical learning account of language acquisition (Frost, Armstrong, Siegelman,
\& Christiansen, 2015), which proposes that language acquisition relies partially on a domain-general mechanism, which is learning and processing sensory stimuli unfolding across time and space (Saffran, Aslin, \& Newport, 1996). Early since 1990s, researchers have found that if you train a recurrent neural network to predict the next word in a sentence, the word representation it learns reveals the syntactic and semantic role of the word (Elman, 1990). Inspired by these previous studies, we use distributed representations of words that reflect the statistics of word co-occurrence in everyday life, which are more naturalistic.

As for the representations of visual stimuli, we process the images (geometric figures) using a deep convolutional neural network that has been trained to perform object recognition task (Krizhevsky, Sutskever, \& Hinton, 2012), and use the activation of the 7th hidden layer as the representations of the visual stimuli. Previous studies have shown that deep convolutional networks share a lot of similarities with human visual system (Yamins, Hong, Cadieu, \& DiCarlo, 2013). After we obtain the representations (embeddings) of the words and the images, we build a simple, light-weighted neural network to learn the analogy tasks.

## Experiment

Data. We first describe the representation we use for the word. The distributed representation of words are computed using the continuous Skip-Gram model (Mikolov, Sutskever, Chen, Corrado, \& Dean, 2013). It takes the current word to predict the surrounding window of context words. Hence, the estimated word embeddings capture the semantic and syntactic role of the words (Mikolov, Yih, \& Zweig, 2013). We download the pre-trained word vectors from Google Word2 Vec ${ }^{1}$, which have 300 dimensions. For computational simplicity and efficiency, we reduce the dimensionality to 30 using principle component analysis (PCA) so that each word has a $30-\mathrm{d}$ vector representation.

We use the same verbal analogy dataset from Mikolov, Yih, and Zweig (2013) ${ }^{2}$, which contains 19529 examples in total with 907 unique words. We divide the dataset into three sets, a training set (percentage: $80 \%, 15634$ examples) ${ }^{3}$, a validation set ( $10 \%, 1955$ examples) and a test set $(10 \%$, 1955 examples). We use the accuracy on validation data to tune the hyper-parameters of the model and report accuracies on the test data. We run two types of tasks. The first one is $\mathrm{A}: \mathrm{B}:: \mathrm{C}:[\mathrm{D} 1|\mathrm{D} 2| \ldots \mid \mathrm{Dn}]$, in which the model is given some choices and has to select the correct one (Task 1). We simulate Task 1 with different number of choices ranging from 2 to 5 . The second type of task takes the form of $\mathrm{A}: \mathrm{B}:: \mathrm{C}: ?$, i.e., the model is required to find the correct D from all words in its vocabulary (Task 2).

To simulate associative responses children usually give

[^550]when first learning analogy tasks, we construct three datasets from the original analogy dataset. All of them are binary-choice questions, but the incorrect alternatives have different levels of associations with the third item C in the question. In the High Association Dataset, each questions has an incorrect response alternative (foil) that is strongly associated with the third word in the analogy question, whereas examples in the Low Association Dataset contain alternatives that is weakly associated with the third item. Finally, in the Random Association Dataset, the incorrect response alternatives are randomly selected from the vocabulary so that it does not necessarily has a strong or weak association with the third item C. We determine word associations by calculating the cosine distance between the word vectors of the two words. The smaller the distance, the stronger the association.

As for the visual stimuli, we use the Shape dataset from Reed, Zhang, Zhang, and Lee (2015). It is a dataset of 2-D colored shapes, with 8 colors, 4 shapes, 4 scales, 5 row and column positions, and 24 rotation angles. We only use one value for the rotation variable to avoid potential confusion (e.g., a square rotated $180^{\circ}$ would be the same figure as the original figure, but it has a different label in the dataset), and vary the other 5 variables to create a dataset. An example question is showed in Figure 1, right. We generate 19080 examples in total and randomly split them into a training set ( $80 \%$ ), a validation set ( $10 \%$ ) and a test set ( $10 \%$ ). Next, we use the AlexNet, a deep neural network trained to recognize objects (Krizhevsky et al., 2012), to process these images. We use the pre-trained connection weights from Caffe (Jia et al., 2014) to process each image in our dataset and use the hidden activation of the 7th layer as its embedding. We also reduce the dimensionality of the image embeddings to 30 using PCA.

Model. The model architecture is fairly simple (Figure 2). There are three layers, the input layer, the hidden layer and the output layer. The input layer contains three pools that encode the first three items (A, B and C in the analogy question). Each pool has 30 nodes, which corresponds to the dimensionality of the word/visual embeddings. The connection weights from the input pool encoding $A$ to the hidden layer $H$ and the ones from the pool encoding $C$ to $H$ are the same, denoted by $W_{1}$. The connection weights from the pool encoding $B$ to the hidden layer $H$ are denoted by $W_{2}$. The connection weights from the hidden layer $H$ to the output layer $O$ is the embedding matrix of either the choices in the current example (Task 1) or the whole vocabulary (Task 2). Mathematically, the model can be described by the following equations:

$$
\begin{align*}
H & =W_{1} v_{A}+W_{2} v_{B}+W_{1} v_{C}+b  \tag{1}\\
O & =\phi\left(W_{0} H\right)
\end{align*}
$$

where $v_{A}, v_{B}, v_{C} \in \mathbb{R}^{30}$ are the word/image embeddings for the stimuli, $W_{1}, W_{2} \in \mathbb{R}^{30 \times 30}$ are the connection weights from the input pools to the hidden layer, $b \in \mathbb{R}^{30}$ is the bias in the hidden layer, and $W_{0}=\left[V_{D_{1}} ; V_{D_{2}} ; \ldots ; V_{D_{n}}\right]^{T} \in \mathbb{R}^{30 \times 30}$ is a matrix composed of embeddings of all the choices. We use
the softmax function $\phi(\boldsymbol{x})_{i}=\frac{e^{x_{i}}}{\sum_{j=1}^{n} e^{x_{j}}}$ to normalize the input $\boldsymbol{x}$ to the final layer $O$, which amounts to $W_{0} H$. The $i$ th value of the output, $\phi(\boldsymbol{x})_{i}$, indicates the probability of the $i$ th choice being correct.

Figure 2: Model Architecture with an exemplar question "Boy:Girl::Brother:[Sister|Mom]"

Training. The model is trained by back-propagation using the TensorFlow framework (Abadi et al., 2015). We only update the weights $W_{1}, W_{2}$ and $b$. We train the neural networks with a batch size of 50 for each task. We find that the model cannot learn well in the Task 2 setting, where it needs to pick up the correct $D$ from all the possible words. Therefore, in the following section we only report our results for Task 1. We run 2 simulations. In the first simulation, we examine whether we could reproduce the relational shift phenomenon. To this end, we train the model on a verbal analogy dataset with random association. As the training proceeds, we test it periodically on verbal High Association test set and verbal Low Association test set (within-modality), as well as the visual High Association test set and visual Low Association test set (cross-modality). In the second simulation, we look at the influences of number of choices on within-modality generalization and cross-modality transfer. Particularly, we first train the model to perform verbal analogy tasks with different numbers of choices, then test it on visual analogy tasks. We also conduct another version of the experiment in which the visual analogy tasks are learned first. We run each of the simulations 10 times with different random initialization of parameters, and in each run the model is trained for 41 epochs.

## Results

Simulation 1. We first test if our model reproduces the relational shift observed during child development. Figure 3 shows the accuracy curves of four test sets: verbal High Association Dataset, verbal Low Association Dataset, visual High Association Dataset and visual Low Association Dataset.

First of all, we notice that our model clearly demonstrates the tendency of associative responding in the early stage of learning, since the accuracy on the High Association Dataset grows slowly (solid curves), compared with the accuracies
on the Low Association Dataset. As the training proceeds, the model gradually learns to inhibit associative responses for High Association Dataset (black solid curve).

Second, the test accuracies on verbal sets are consistently higher than those on the visual test sets, which is not surprising given that the model is only trained on verbal stimuli. However, we still find a decent amount of cross-modality transfer. For one thing, the tendency to give associative responses earlier in the training is carried over to the visual modality, even though no visual stimuli has been used to train the network. In addition, as the accuracy on verbal Datasets gradually increases, the model also becomes better at answering questions in visual Low Association Dataset (gray dash-dot curve). However, this improvement is not reliably transferred to the visual High Association Dataset, as the accuracy of this dataset remains near chance-level after prolonged training (gray solid curve).

Third, we find that when the accuracy on verbal Low Association test stops to grow after roughly 3 epochs, the accuracy on the corresponding visual dataset continues to improve until after 11 epochs, which then slowly decreases (gray dash-dot curve). This can be explained by the domain-general and the domain-specific component of analogical reasoning. The model first learns the domain-general component of analogical reasoning from the training in the verbal domain, but later the training becomes detrimental to cross-modality transfer since it continuously shapes the model to be specific to the verbal domain, thus reducing the accuracy in the corresponding visual domain.

Figure 3: The effect of association on accuracy and cross-modality transfer. The dotted line indicates the chance-level.

Simulation 2. To understand the effect of number of choices on accuracy for different data type (train/test) and modality (verbal/visual), we run two linear models. In the first linear model, we look at two sets of data, which are obtained from the experiment "learning verbal analogy first" and the one "learning visual analogy first". In the "learning verbal analogy first" experiment (Figure 4, left), we find that both training and same-modality test accuracy are almost perfect, whereas the cross-modality accuracy is not. The linear model shows that for all of these three conditions, the accuracy decreases as the number of choices increases (train: $\beta=-0.005, t(114)=-2.57, p=0.011$,
same-modality test: $\beta=-0.004, t(114)=-2.12, p=0.036$, different-modality test: $\beta=-0.1, t(114)=-54.63, p<$ .001). However, we also find an interaction between test conditions and choice numbers. Particularly, the influence of choice numbers on different-modality test is much larger than the one on same-modality test, $\beta=0.096, t(114)=37.13$, $p<.001$. In the "learning visual analogy first" experiment (Figure 4, right), we find a similar effect of choice numbers on the different-modality test condition, as well as a similar interaction between test conditions and choice numbers, $\beta=$ $0.071, t(114)=14.07, p<.001$.

Although both modalities demonstrate near perfect performance of within-modality generalization after sufficient training ( $\sim 40$ epochs), the performance of "learning verbal analogy first" is consistently better than the one of "learning visual analogy first" throughout the training. For instance, half way through the training, the same-modality test accuracy of "learning verbal analogy first" is higher than the one of "learning visual analogy first" (mean difference is $4.77 \%, t(234)=3.279, p=0.001$ ). This implies that the semantic space of word embeddings may have a stronger structural regularity, which makes it easier to discover relations between words than images.

Figure 4: The influence of number of choices on accuracy. Solid dots indicate chance-levels.

## Visualization of connection weights

To get a deeper understanding of what the model has learned, we visualize the weight matrix $W_{1}$ and $W_{2}$. We find that $W_{1}$ is very much like a identity matrix (Figure 5, left), whereas $W_{2}$ does not have a easily describable pattern (Figure 5, right).

We compare our model with the vector offset method, which was used by Mikolov, Yih, and Zweig (2013) to solve analogy tasks. Given the problem $\mathrm{A}: \mathrm{B}:: \mathrm{C}: ?$, they found the word $D$ such that its embedding vector had the greatest cosine similarity to $x_{B}-x_{A}+x_{C}$. Their method amounts to assigning an identity matrix $I$ to $W_{1},-I$ to $W_{2}$, and a zero vector to the bias $b$ in our model. The weights of our neural network show that our model is not doing exactly the same thing as the vector offset method does, since $B$ does not approximate the negative identity matrix. Hence, its weights are tuned to solve the current analogy task, and the same weights are also capable of solving analogy task in another modality.

Figure 5: (a): Connections from A to the hidden layer. (b): Connections from B to the hidden layer. Lighter areas represent larger weights.

## Discussion

In this article, we build the first neural network model that can learn to solve analogy tasks and make cross-modality transfer. It uses word representations and image representations estimated from large-scale naturalistic corpora. The model demonstrates both the domain-general and the domain-specific component of analogical reasoning.

Specifically, we see that the accuracy on the same-modality test set is consistently higher than the accuracy on the cross-modality test set. This is aligned with the empirical finding that domain-specific knowledge boosts performance in analogical reasoning (Goswami \& Brown, 1990b). On the other hand, the model demonstrates the domain-general property of analogy-making by showing cross-modality transfer. This is relevant to a broader topic in cognitive science, the zero-shot learning. Zero-shot learning refers to the ability to solve a task despite not having received any training examples of that task. As human beings, we do zero-shot learning all the time. Only recently did researchers begin to simulate zero-shot learning using neural network models. For instance, in Socher, Ganjoo, Manning, and Ng (2013), they showed that learning the distributions of words in texts as a semantic space helps the model understand the visual appearances of objects, and enables the model to recognize objects even if no training data is available for that category. Our model contribute to the zero-shot learning literature by showing that zero-learning is possible for analogy-making task as well. It also makes some interesting predictions that can be empirically tested. The success of our model suggests the possibility that there might be some similar structural regularities in the word embeddings extracted from naturalistic corpus and in the image embeddings extracted from object recognition models. This similarity explains why our model makes cross-modal transfer.

Our results are also relevant to another line of research, the one-shot learning. One-shot learning refers to the problem of learning from one or very few examples. Classic deep learning neural networks could not perform one-shot learning, which is a common criticism of neural networks being plausible cognitive models of human learning (Lake, Ullman, Tenenbaum, \& Gershman, 2016). However, recently Vinyals, Blundell, Lillicrap, Wierstra, et al. (2016) showed
that if you match the training task with the test task, neural networks are able to learn from few examples. In their paper, they trained a network to map a query example to one of the four candidates example so that both of them belong to the same category. The model learned the task very well. Our results lend further support to their approach. We find that our model only learns efficiently under the Task 1 setting, where it chooses among a few choices rather than the whole vocabulary. Our work extends Vinyals and colleagues' results by showing that our network model can make an inference not only on unseen stimuli, but also on unseen stimuli from a completely different modality.

There are some limitations of the current work. First, the model is a simplification of the actual mental processes underlying analogy-making. A lot of previous computational model have given very insightful explanations of those mental processes (Gentner, 1983; Morrison et al., 2004; Kollias \& McClelland, 2013; Gergel' \& Farkaš, 2015), and our goal is not to argue against those models or to provide a better model. Instead, our goal is to demonstrate the possibility that domain-general neural network models can learn from large-scale, realistic datasets to solve analogy tasks. Second, we have not directly compared our model performance with human performance. It would be interesting to see how human would respond to the analogy questions in the current study and whether our model predictions align with human data in the future.

## Acknowledgments

A.Y. is grateful to Jay McClelland for helpful discussions about this work, and the whole Parallel Distributed Processing Lab at Stanford for their useful comments.

#### Abstract

In this study, we tested the effectiveness of a computer-based persuasive dialogue system designed to promote a plant-based diet. The production and consumption of meat and dairy has been shown to be a major cause of climate change and a threat to public health, bio-diversity, animal rights and human rights. A system promoting plant-based diets was developed, comprising conversational, motivational and argumentational elements. 280 participants were randomly assigned to one of four conditions, each representing a particular combination of motivational and argumentational modules. Male participants showed higher intention scores in the motivational conditions compared to the argumentation-only or control condition. Female participants scored higher overall, unaffected by condition. These results suggest that men and women are differentially sensitive to persuasive strategies regarding the adoption of a plant-based diet. It seems to be particularly worthwhile to use motivational - as opposed to merely argumentational - elements in a persuasive conversation.

Keywords: human-machine interaction; dialogue system; persuasive communication; cognitive dissonance; motivational interviewing.

## Introduction

When individuals experience a mismatch between their beliefs and their actual behavior, the phenomenon of cognitive dissonance (Festinger, 1957) kicks in: "an aversive state which motivates cognitive or behavioural actions to lower itself" (Dijkstra, 2009, p.792). For instance, most people do have a desire to behave ethically, but this desire is often not reflected in their actual behavior. People are often 'wilfully ignorant' when it comes to their ethical beliefs, actively ignoring or discarding relevant information
about those beliefs (Zane, Irwin \& Reczek, 2013).There are two ways in which you can deal with and/or solve cognitive dissonance. The first one is to change your cognitions in line with your current behavior. For example, you could change your belief: "behaving ethically is not so important for me (anymore)." The second way is to change your behavior in line with their current beliefs: actually acting in an ethical manner (Dijkstra, 2009; Hewstone, Jonas \& Stroebe; 2012).

The latter way of solving cognitive dissonance is often an ultimate goal of - for instance - health and sustainability communication professionals: they want people to change their behaviour, like: exercise more often (Riet et al., 2010); quit smoking (Ballast \& Dijkstra, 2011); reduce fat-intake (Wright, Velicer \& Prochaska, 2008); behave environmentally friendly (Bolderdijk et al., 2012) etc. However, people often change their cognitions instead of their actual behavior. Therefore, persuaders often start by trying to change people's cognitions. In order to achieve this, one has to address the most focal cognitions that people hold about a particular behaviour (Fishbein \& Yzer, 2003).

One problem area that is often associated with cognitive dissonance, is the consumption of meat and other animal products. Meat eaters are assumed to experience cognitive dissonance resulting for instance from the perceived aversive consequences of their diet ("I eat meat but eating meat hurts animals") (Cooper \& Fazio, 1984); or because it threatens their self-integrity ("ethical people don't eat meat, but I do") (Aronson, 1968). Most people believe it is wrong to hurt animals, while at the same time around $95 \%$ of the consumers in the U.S. eat meat. Researchers have referred to this phenomenon as the 'meat-paradox', and claim that
cognitive dissonance lies at the heart of this phenomenon (Bastian, Loughnan, Haslam \& Radke 2012; Rothgerber, 2014).

Besides solving the unpleasant feeling of cognitive dissonance that consumers may experience due to eating meat, there are several other important reasons to address meat consumption. First, the livestock industry is one of the largest polluters worldwide. In order to meet stringent climate change targets, the consumption of animal products should be reduced at least by half (Donham et al., 2007; Hedenus, Wirsenius \& Johansson, 2014; Hertwich et. al., 2010; Steinfeld et al., 2006). Second, the production of animal products is threatening rights and wellbeing of both humans and animals due to poor working conditions for the first, and poor living conditions for the latter (Pew Commission, 2008). Third, individual and public health is negatively affected by meat and dairy consumption. For instance, the growing consumption animal products is associated with an increase of diseases like obesity, type II diabetes (Cooney, 2014; Montonen et al., 2013), heart and vascular diseases (Yokoyama et al., (2014) and a variety of cancers, like colorectal, lung and bladder cancer (Lippi, Mattiuzzi \& Cervellin, 2016). Thus, a successful promotion of plant-based diets - diets without meat, dairy and eggs could have a great many positive outcomes for animals, humans, and the environment.

It has been claimed that one of the most effective strategies to reach persuasion is through conversation and interaction (Helme et al., 2011; Noar, Carlyle \& Cole, 2006). However, even if that were the case, face-to-face conversations are obviously very time consuming and costly (Southwell \& Yzer, 2007). A fruitful solution for this could be the deployment of human-machine interaction systems. There is a huge benefit in using online dialogue systems as larger target groups can be reached at lower costs. In addition, automated dialogues can also easily be tailored, which lowers resistance to persuasion and makes messages individually more relevant (Dijkstra, 2008). An added benefit for experimental research is that manipulations can be held more constant, making it easier to measure the effect(s) of the strategy/strategies employed within the dialogue system separately - and/or combined.

## The Dialogue System

We devised and tested a persuasive online dialogue system that promotes plant-based diets. Our system incorporates persuasive strategies aimed at reducing the consumption of animal products. First, an 'argumentation' module was designed to target cognitive dissonance by addressing focal beliefs about meat consumption. This module provides individually tailored arguments that address the individual's so-called 'disengagement' beliefs: beliefs that may be true in themselves, but that are not valid arguments in the discussion at hand (e.g., "Our ancestors ate meat" is true, but it is not a valid reason why a present-day individual should still be eating meat).

In addition, a second module was designed to reduce the likelihood of experiencing negative affect and resistance to counter arguments and persuasion. In building this module, we borrowed heavily from the theoretical framework of Motivational Interviewing (MI). MI is "a collaborative conversation style for strengthening a person's own motivation and commitment to change" (Miller \& Rollnick, 2002). In this method, the receiver formulates its own goals, capacities and reasons regarding his/her behavior change towards the targeted behavior. Dialogue in MI is framed in such a way to emphasize one's autonomy and to avoid any direct confrontation with the target individual. Important elements of MI are: 1) an explicit consent question, asking whether an individual agrees with talking about a specific topic; 2) a 'motivation ruler', which consists of asking one to number or 'grade' their motivation to change and subsequent questioning and giving feedback on the number they choose (e.g., "You chose " 2 ", what would it take for you to get a higher level of motivation?"); and 3) a 'confidence ruler', which asks about a person's confidence in his/her own capacity to change towards the target behavior. Digital applications of this conversational method have proved to be effective in achieving positive intentional and behavioral outcomes (Shingleton \& Palfai, 2015).

To increase the 'feel' of an actual conversation, we include a picture (of a young female) to visualize the 'person' talking to the participant. We use personal pronouns like " I " and "you" in conversation; and talk is individually tailored by the system throughout the conversation based on responses of the - non-digital conversational partner. In the future, we would like to develop a more sophisticated dialogue system, capable of reacting to natural language input. Previous research has shown that technological social agents - like robots - are able to induce behavior change by providing interactive feedback with regard to for instance sustainability-related behavior like energy conservation (Ham \& Midden, 2014). However - to our knowledge - no research has yet looked into computerized agents that are active in the field of plantbased eating. We used survey-builder Qualtrics to design a straightforward, tree-based conversational system with feedback based on answers on - for the most part - multiple choice questions.

Table 1: Example of tree-based conversation with Eliza

| "When are you planning to make changes to your diet?" |  |  |
| :---: | :--- | :--- |
| Participant's answer | Eliza's answer |  |
| $\bullet$ | Within a week | "That's pretty soon, good to |
| • | Within a month | hear! Can I ask you more?" |
| $\bullet$ | Within 3 months | "You're taking your time, |
| • | Within a year | but that's OK! Are there any <br> ways to potentially speed up <br> this process for you?" |

## Method

## Participants

Three-hundred-and-seventy-one Dutch participants took part in the research. Participants were recruited from social media, mailing lists and the researchers' personal networks. Data from participants who had a vegetarian or vegan diet or failed to complete the questionnaire - were excluded from analysis. Two-hundred-and-eighty participants remained. Of this sample, $76 \%$ was female $(\mathrm{N}=212)$ and $24 \%$ male ( $\mathrm{N}=68$ ). Participants' mean age was 26 years ( $\mathrm{SD}=9.9$ ), ranging from 17 to 65 . Male and female participants were dispersed evenly across four conditions (15-20 men and 5560 women in each condition).

## Measures

Disengagement Belief Strength The strength of the various disengagement beliefs was measured by asking participants about the extent they (1) totally disapprove - (7) totally approve of fourteen disengagement beliefs about eating meat (i.e. "Without meat you cannot be healthy"; "Lions eat meat too"). These fourteen disengagement beliefs were formulated based on a belief elicitation study in which twenty-three participants stated the most important reasons for them to keep eating meat. In the present study, participants were asked which three of these fourteen beliefs were the most important reasons for them to keep eating meat. Subsequently, they received tailored feedback based on the answers they provided. This feedback was framed as a short text in a what-if question format (i.e. "You state that meat is too tasty. That is hard to deny! But what if you find out that some meat substitutes are quite good and sometimes even as good as real meat. Would you then be open to change your current diet towards a more plant-based diet?"). When a participant answered "no", the dialogue system would give similar 'what-if' feedback for the second and/or third reason, until the participant either answered "yes" or all three reasons were addressed. Note that all responses of the dialogue system consisted of valid arguments, based on scientific findings.

MI module In the full MI version, participants were explicitly asked for their approval to talk about their dietary habits ("In this program, I will talk about the advantages of having a plant-based diet [...] Are you open to talk about your own eating habits and possible changes to it?"). When participants did not consent, there was a short feedback page after which the experiment ended. As we described above, motivation to change towards a plant-based diet was measured by asking one's motivation on scales ranging from (0) No motivation at all - (10) very highly motivated. (e.g. "It looks like reducing your meat consumption is not that high of a priority for you! Could you tell me why?") A similar procedure was used for measuring how much participants trusted their own capacity to perform the requested behavior (self-efficacy).

Attitude and Behavioral Intention Attitude was measured by evaluating the following statement on a semantic differential scale: "If I would change my current diet to a vegan diet, that would be...": i.e. good-bad; foolish-wise; unnecessary-necessary. In addition, participants evaluated several statements on a seven-point scale ranging from (1) strongly disapprove - (7) strongly approve (i.e. "A diet without animal product is more environmentally friendly."). Behavioral intention towards three kinds of behavior was measured: going completely or partially vegan; going completely or partially vegetarian; going completely or partially organic where meat was concerned. These intention measures were weighted and summed into one intention-score that indicated their willingness to change their diet towards a more - or less - plant-based diet (the higher, the more willing).

Evaluation questions At the end of the session, we asked 1) whether participants felt they were addressed in a nice manner, and 2) whether they liked to communicate with Eliza by means of evaluating statements on a Likert-type scale: (1) completely disagree - (7) completely agree.

## Procedure and Design

When starting the dialogue system, participants saw a picture of a young girl who was introduced as "Eliza". She asked if they cared to join her in a conversation about their eating habits. Subsequently, participants were asked about their gender, age, education and actual eating habits. Next, participants received information about several benefits of a plant-based diet. In three of the four conditions the disengagement belief handling module ('DBH') was included to address the participant's most focal beliefs about eating meat. Two of the four versions also included a motivational interviewing module ('MI'), either a full (with an explicit consent question) or partial (without an explicit consent question) module. A fourth version did not include DBH and MI modules and served as - baseline - control condition. Table 2 shows how the modules were combined in the different versions of the system that were used in this study.

Table 2: Experimental conditions

|  | Full MI | Partial <br> MI | DBH | Control |
| :--- | :---: | :---: | :---: | :---: |
| Consent | + | - | - | - |
| MI | + | + | - | - |
| DBH | + | + | + | - |
| INFO | + | + | + | + |

Note. MI = Motivational Interviewing; DBH = Disengagement Belief Handling; Consent $=$ consent question; $\mathrm{INFO}=$ information on plant-based diet.

## Analysis

We used between-groups univariate Analysis of Variance to investigate the patterns of results for Attitude, Intention and Evaluation. Condition was one factor, with four levels (Full MI, Partial MI, DBH and Control), and Sex of Participant the other factor (male versus female). This latter factor has consistently been shown to influence behavioral outcomes concerning reduction of meat consumption (e.g. Cooney, 2014). In the analysis on Evaluation there were only three levels of Condition, as the Control condition did not feature a conversation with Eliza.

## Results

Table 3 shows the means for attitude towards adopting a plant-based diet, and the composite scores for intention to reduce meat consumption per condition.

Table 3: Means and Composite Scores (plus standard errors) of intention and attitude

|  | Intention |  |  |  |
| :--- | :--- | :--- | :--- | :--- |
| Attitude |  |  |  |  |
| Condition | Men | Women | Men | Women |
| Full MI | 95.45 | 99.67 | 5.56 | 5.62 |
|  | $(7.95)$ | $(5.24)$ | $(.21)$ | $(.14)$ |
| Partial MI | 95.67 | 106.80 | 5.21 | 5.56 |
|  | $(10.72)$ | $(5.24)$ | $(.28)$ | $(.14)$ |
| DBH | 80.65 | 101.72 | 4.74 | 5.45 |
|  | $(8.89)$ | $(4.80)$ | $(.23)$ | $(.12)$ |
| Control | 65.95 | 102.23 | 5.11 | 5.77 |
|  | $(7.76)$ | $(4.41)$ | $(.20)$ | $(.11)$ |

Note. MI = Motivational Interviewing; DBH = Disengagement Belief Handling

## Effects of Condition and Sex on Attitude

A Univariate Analysis of Variance showed a significant main effect of Condition on Attitude towards adopting a more plant-based diet $(\mathrm{F}(3,269)=2.67, \mathrm{p}=.048)$. Attitude scores of participants in the Control ( $\mathrm{M}=5.44, \mathrm{SE}=.12$ ) and Full MI ( $\mathrm{M}=5.59, \mathrm{SE}=.12$ ) condition were significantly higher than Attitude scores of participants in the DBH condition ( $\mathrm{M}=5.10$, $\mathrm{SE}=.13$ ). In addition, there was a main effect of Sex on Attitude $(\mathrm{F}(1.269)=11.54, \mathrm{p}=.001)$. Women ( $\mathrm{M}=5.60$, $\mathrm{SE}=.06$ ) scored significantly higher on attitude measures than men ( $\mathrm{M}=5.16, \mathrm{SE}=.06$ ) regardless of exposure to experimental condition. No interaction effect of Condition x Sex was found (p-value>.23).

## Effects of Condition and Sex on Intention

A Univariate Analysis of Variance showed a marginally significant main effect of Condition on Intention to adopt a more plant-based diet $\mathrm{F}(3,272)=2.29, \mathrm{p}=.078$. In addition, there was a main effect of Sex on Intention. Men ( $\mathrm{M}=84.44$, $\mathrm{SE}=4.56$ ) scored significantly lower on intention to adopt a more plant-based diet than women ( $\mathrm{M}=102.61, \mathrm{SE}=2.47$ ), $\mathrm{F}(1,272)=12.74, \mathrm{p}=.000$. The interaction of Condition x

Sex was found to be marginally significant $(\mathrm{F}(3,272)=2.2$, $\mathrm{p}=.09$ ).

Further exploration of these effects showed that intention scores were only significant between conditions for male participants $(\mathrm{F}(3,64)=2.85, \mathrm{p}=.044)$ but not for female participants $(\mathrm{F}(3,208)=.332, \mathrm{p}=.80)$. A post-hoc test showed that intention scores of men who were exposed to the Control condition ( $\mathrm{M}=66.0$, $\mathrm{SE}=7.8$ ), were significantly lower than mean intention scores of men who were exposed to either the full MI condition ( $\mathrm{M}=95.5, \mathrm{SE}=8.0$ ), $\mathrm{p}=.011$; or the partial MI condition ( $\mathrm{M}=95.67, \mathrm{SE}=10.8$ ), $\mathrm{p}=.030$. Intention scores between men in the DBH condition and the control condition did not differ.

## Evaluation questions

Table 4 shows the mean scores about the participants' appreciation for the way they were addressed by Eliza and the extent they liked talking to her.

Table 4: Means (plus SE) of appreciation and liking

|  | Appreciation |  | Liking |  |
| :--- | :--- | :--- | :--- | :--- |
| Condition | Men | Women | Men | Women |
| Full MI | 5.26 | 5.33 | 4.42 | 4.04 |
|  | $(.32)$ | $(.21)$ | $(.32)$ | $(.20)$ |
| Partial MI | 4.91 | 5.23 | 4.46 | 4.18 |
|  | $(.43)$ | $(.22)$ | $(.42)$ | $(.21)$ |
| DBH | 5.53 | 5.02 | 4.73 | 4.06 |
|  | $(.36)$ | $(.19)$ | $(.36)$ | $(.19)$ |

Note. MI = Motivational Interviewing; DBH = Disengagement Belief Handling

In general, participants felt they were addressed in a nice manner: mean scores ranged from 4.9 to 5.5 (maximum 7). A $3 \times 2$ ANOVA was carried out - no evaluation questions about Eliza were asked in the control condition - which showed no significant main or interaction effects (p-values > .37). Participants also seemed to like to communicate with Eliza, though the marginally significant main effect of Sex of Participant $(\mathrm{F}(1,182)=3.39, \mathrm{p}=.067)$ suggested that male participants enjoyed talking to Eliza a little bit more ( $\mathrm{M}=4.54$, $\mathrm{SE}=.21$ ) than female participants $\quad(\mathrm{M}=4.09$, $\mathrm{SE}=.12$ ). No other effects were significant (p-values > .77).

## Discussion

The aim of this research was to find out 1) whether it would be effective to design a dialogue system to promote plantbased diets, and 2) which elements or modules contribute to the persuasive power of the system. To this end, four versions of a computer-based dialogue system were developed, which 'talked' about the benefits of plant-based diets and provided - individually tailored - conversations based on different persuasive strategies.

Most importantly, we saw positive effects of incorporating persuasive strategies in a dialogue system. This implicates the usefulness of using a dialogue system to
promote sustainable behavior concerning the promotion of adopting a (more) plant-based diet.

We discovered effects of the different versions on behavioral intention towards adopting a plant-based diet. These effects were only present for men. Women were in general more willing to change their diet, regardless of the condition they were assigned to. So contrary to expectations, men seemed to be most sensitive to persuasion in the area of moving towards a plant-based diet. Men who were exposed to the Full MI and the Partial MI conditions which both contained a motivational interviewing module showed higher intentions to adopt a more plant-based diet than men in the control condition. The DBH condition that only contained disengagement belief handling did not significantly differ from the control condition.

Apparently, if we restrict our persuasive attempt to mere argumentation, we will not get far, at least not with our male conversational partners. This conclusion is underscored by the findings regarding participants' attitudes. Incorporating an argumentational component even seems to negatively affect those: attitude scores were significantly lower in the argumentation-only ( DBH ) condition than in the Control condition for both men and women. Because a DBH module is included in all experimental conditions, it is still possible that DBH is effective, but only in combination with a motivational module. Future research including an 'only MI' condition could perhaps answer that question.

A second important finding concerns the effects of Sex of the Participant. Our results support the notion that men and women think differently about adopting a more plant-based diet and that they are persuaded by different means (e.g. Cooney, 2014). However, as we said, the outcome was not quite as we anticipated, as we expected that women would be more susceptible to persuasion in this area. What our results do suggest is that women are generally more likely to have or adopt a plant-based diet. While it is true that in this research only men were positively affected by two versions of the intervention, women showed more positive attitudes and higher intentions to adopt a more plant-based diet than men overall.

Of specific interest is that there was also a (trend towards a) main effect of Sex on the scores of one of the evaluation questions, when participants were asked whether they had enjoyed talking to Eliza. Men had enjoyed the conversation with Eliza more than women. Perhaps if we would use a picture of a young male, this 'Elisus' would work better with a majority of female participants. We will tackle this issue in a future version of the present experiment.

Future studies in our lab will focus on a number of issues. First of all, we will perform a replication of this study in a different participant group to gauge the extent to which we can generalize the specific findings of this study

Second, we measured intention immediately after participants were exposed to the intervention. It is very likely the case that interventions need much more time before they have a detectable effect. Especially with difficult behaviors like changing dietary habits, the
occurrence of what is sometimes called 'sleeper effects' seems very plausible (Kumkale \& Albarracín, 2004).

In addition, as in most studies, the present research measured behavioral intention and not actual behavior. While intention is thought to be a potent predictor of actual behavior (Fishbein \& Ajzen, 2010), being able to measure and predict actual behavioral outcomes is the ultimate goal of persuasion research. We would like to use some form of longitudinal design, where we measure - self-reported eating behavior over a longer period.

Finally, the present research measured the effects of a single intervention. In the real world, people are often exposed more than once to the same, or related persuasive information - they read advertisements in newspapers and magazines, see posters, look at commercials etc. Perhaps we need multiple exposures to create more persuasive results.

In conclusion, then, our research suggests that a dialogue system can induce behavior change in the field of a plantbased life-style. However, strategy-wise, only giving people arguments in trying to persuade them is not going to work. People, especially men, may want to feel their own autonomous motivation, which can be fueled by a supporting dialogue based on - for instance - elements from motivational interviewing. Future research should test designs that incorporate different combinations of persuasive strategies (and pictures/avatars); multiple exposures to/conversations with the system; over a longer time span; and should measure actual consumption behavior instead of intention as outcome.

# Pseudoneglect and development: Age-related spatial bias in bisection and drawing 

Yordanka Zafirova, Asenia Giagtzidou, Dara Vassileva, Elena Andonova<br>(jovasileva@abv.bg, nia.giagtz@gmail.com, daravassileva@gmail.com, eandonova@nbu.bg)<br>Department of Cognitive Science and Psychology, 21 Montevideo Street<br>Sofia, 1618, Bulgaria

#### Abstract

The numerous studies on pseudoneglect have generated inconsistent results and disagreement concerning the underlying mechanisms. Most research supports the hypothesis that hemispheric lateralization is the main reason for the persistent leftward bias in spatial tasks. Findings on the influence of reading direction, handedness and participant age are largely contradictory. As a result of brain maturation adults usually perform with significant leftward bias. However, both hemispheric activation and scanning habits exert an influence on space representation, which varies across age groups. Preschoolers, middle school children and adults were tested on the line and word bisection tasks and on house-person-tree drawing tasks. The analysis of their performance produced results consistent with an explanatory account that the direction of the spatial bias shifts leftwards in the course of development.

Keywords: pseudoneglect, line bisection, age differences, house-person-tree drawing task

## Introduction

Cognitive processes have their limitations that may lead to distortion in perception or judgment. Different biases arise when cognitive resources are challenged, but are also partially rooted in the cultural context and can be learned implicitly, including our ability to navigate through space and construct adequate spatial representations of the close environment. The temporal and spatial structure of the viewing behavior is independent from the goal of the task and is attributed to the horizontal asymmetries of the visual and attentional systems.

The hemispatial neglect syndrome is a neuropsychological disorder where patients have difficulties processing stimuli from the contralesional hemispace. The condition is generally due to impairment of the ability to direct attention and movement, although it might as well be attributed to the inability to form spatial representations (Bisiach, 1996). Patients with left visuospatial neglect bisect horizontally presented lines to the right of their objective center. In contrast, neurologically normal people usually perform the task with significant leftward bias. This exploratory inclination to look slightly to the left of the center of the presented stimuli is known in the literature as pseudoneglect (Bowers \& Heilman, 1980).

Pseudoneglect is typically interpreted in terms of the hemispheric lateralization of the brain and has two complementary components - visual and motor. The visual component incorporates the scanning habits and the attentional and perceptual effects, while the motor
component refers to the overdriven movements, like directional hypometria, perceptual motor activation and cueing (Macdonald-Nethercott, Kinnear, \& Venneri, 2000). In one of the first studies on pseudoneglect leftward errors were made only in the paper-and-pencil version of the line bisection task and not in the computer version of the task (Luh, 1995). This result supports the contribution of the above mentioned motor factor to the leftward spatial bias. Both hemispheres are engaged in directing attention to the contralateral space, but as the right hemisphere is generally more active during spatial tasks this could lead to subsequent enhanced attendance to the left visual hemispace. This was demonstrated in a cancellation task designed to deliberately activate the left or the right hemisphere (Vingiano, 1991). A more recent fMRI study also showed increased activation in the right intra-parietal sulcus and lateral peristriate cortex during judgment and performance of line bisection tasks (Cicek, Deouell, \& Knight, 2009).

In a series of eye-tracking experiments on viewing behavior in exploring complex scenes participants demonstrated a marked initial leftward bias that was independent of the category of the presented images (Ossandon, Onat, \& Konig, 2014). It is generally accepted that people tend to scan the visual field in the direction that they read. Opposite reading habits give rise to opposite spatial bias when performing the line bisection task - left-to-right readers bisect the lines to the left of their veridical center, while right-to-left readers deviate to the right (Chokron \& Imbert, 1993). In a similar study the line bisection performance of adults, 8-year-olds and preschoolers coming from cultures with opposite reading habits was compared and differences were found in all groups (Chokron \& De Agostini, 1995). Usually the developmental shift in the observed bias in line bisection is from right to left, as demonstrated in an experiment with 4-5 and 10-12 years old children (Dellatolas, Coutin, \& De Agostini, 1996).

There is evidence that with the maturation of the corpus callosum during puberty, spatial processing shifts from the contralateral to the right hemisphere. Right-handed prepuberty children showed rightward bias in line bisection tasks when using their right hand and a leftward bias with their left hand. The adult and puberty groups bisected the lines to the left with both hands (Hausmann, Waldie, \& Corballis, 2003). Another study also showed that learned directionality and movement preferences have little influence on placement of single object on a page. Both

French and Moroccan dextral children manifested similar leftward bias in a draw-a-tree task, supporting the advantage of brain lateralization over learned cultural habits, including reading direction (Picard \& Zarhbouch, 2014).

Both neglect and pseudoneglect, despite the difference in the underlying neurological mechanisms, have similar behavioral manifestation and are assessed with the same tasks, such as line and word bisection, drawing or bisecting a simple figure and exploration of complex scenes. Basically, both lines and words are bisected to the left of their objective center by adults, in accordance with the hemispheric activation hypothesis and the reading direction hypothesis. However, the effect is more pronounced in word bisection showing that an additional mechanism might be involved. In a series of experiments with lines and orthographic strings (words, pseudowords, symbols), lines were bisected always to the left, while words yielded a different result depending on their length - short ones (3-4 letters) were bisected with a general right-side bias (Arduino, Previtali, \& Girelli, 2010).

As the beginning of the word is more informative than its end, oculomotor behavior shows that attention is usually directed to the left of the word center, while trying to access the mental lexicon in establishing a matching cohort. According to the Attentional scaling hypothesis, proposed by Fischer (1996), orthographic strings are processed differently than other symbolic or pictorial material. Word bisection is biased toward the beginning of the horizontally presented words, depends on their length and the ease of lexical access - Hebrew-American bilinguals showed a greater leftward bias in their second language (English) than native English readers (Fischer, 1996). Both English and Hebrew readers showed greater leftward bias for words and pseudowords than for lines (greatest for low-frequency words), and people with developmental dyslexia deviated more to the left than controls (Gabay, Gabay, Henik, Schiff, \& Behrmann, 2015). Interestingly, dyslexic children have been reported to show inversed pseudoneglect in line bisection tasks, shifting their subjective center to the right of the veridical one (Michel, Bidot, Bonnetblanc, \& Quercia, 2011).

There are numerous studies on pseudoneglect with inconsistent results as well as disagreement concerning the underlying mechanisms. The goal of the current study was to combine explicit and implicit measures to dissociate the attentional component in spatial processing. We tested three age groups - preschoolers, sixth-graders and adults on line and word bisection tasks and draw-a-house-person-tree tasks. In accordance with previous studies, we used paper-and-pencil tasks and only long and low-frequency words.

As different spatial tasks supposedly tap into different aspects of spatial awareness, we compared performance on active (implicit) and passive (explicit) spatial tasks across three developmental stages with different reading expertise (see Barrett, Kim, Crucian, \& Heilman, 2002 for a discussion on the difference of implicit and explicit tasks). Both the hemispheric activation and the directionality
hypotheses predict that right-handed preschool children would exhibit a right spatial bias in all tasks, because of the prevalence of the motor component in spatial judgments and their inability to read. Sixth-graders should have mixed results due to already established reading habits but incomplete brain lateralization. Adults were expected to have a strong leftward bias, especially in the word bisection tasks, in accordance with the Attentional scaling hypothesis.

## Method

In order to address the research questions above, we carried out an experimental study protocol consisting of a series of five tasks used in previous research on pseudoneglect in three population age groups - preschool children, middle school children, and young adults. The experimental tasks were line bisection, word bisection, and drawing a house, a person, and a tree on a blank sheet of paper in landscape orientation. The dependent variable was the degree of lateral (left or right) spatial bias in participants' performance.

Participants were asked to perform two passive (line and word bisection) and three active spatial tasks (drawing a simple figure). Line bisection is the most widely used and rigid measure for neglect in clinical settings, and for pseudoneglect in neurologically normal people, and is more connected to attention. The word bisection task is thought to activate semantic processing together with the spatial representations. Drawing reflects higher order cognitive functions - instead of passive judgment, it involves the ability to plan and execute a simple task in peripersonal space. We hypothesized that with age the direction of the bias should shift from right to left, and this would be reflected in the performance of the middle school group.

## Participants

60 Bulgarian speaking participants ( 22 men) took part in the study. The preschool group consisted of 19 children (8 boys), with a mean age of 4 years and 4 months ( $M=53.37$, $S D=3.47$, range 49-59, calculated in months). The middle school group consisted of 20 children ( 4 boys), with a mean age of 148 months ( 12 years and 3 months), $S D=3.65$ and range 139-154 months. The adults were 21 ( 10 men), with a mean age of 28 years, $S D=11.02$ and range $18-51$ years. All adults gave their written informed consent before the study. Informed written consent for the children was given by their parents.

All participants underwent assessment for handedness, given that some studies report a significant influence of handedness on bisection and drawing tasks (e.g. Jewell \& McCourt, 2000; Picard \& Zarhbouch, 2014). Only righthanded participants' data were considered further. From the analyses were excluded data from two preschoolers who used predominantly their left hand in the drawing tasks (in accordance with Kastner-Koller, Deimann, and Bruckner, 2007), two participants from the 12 -year-old group who self-reported as left-handed; three adult participants who self-reported as ambidextrous but reported predominant use of their left hand on the handedness questionnaire.

Thus, statistical analyses were performed on the data from 17 preschool children ( 7 boys), 18 middle-schoolers ( 4 boys) and 18 adults ( 9 men). The mean age of the adult and middle school groups remained the same, and a t-test showed no significant difference between the age of the recruited and the analyzed groups of preschoolers ( $p=$ .890). None of the preschool children had reading or writing habits.

## Stimuli

Two types of stimuli were used in the study - five straight horizontal lines and ten words, presented on two separate sheets of paper A4 format, portrait orientation. The lines and the words were printed in advance, while the drawing tasks were executed on blank sheets of paper format A4 with landscape orientation. The lines had a mean length of 10.9 $\mathrm{cm}(S D=2.2)$, and were positioned to the left or to the right side of the sheet, in a way that no two lines was exactly below each other. Only very long and low frequency words were chosen for the task. The mean length of the words in characters was $13.4(S D=2.1)$, or $3.9 \mathrm{~cm}(S D=0.7)$ and their mean objective frequency was 0.19 ( $S D=0.23$, range $0.00-0.59)$. Objective frequency data for the Bulgarian words (Simov, Osenova, Kolkovska, Balabanova, \& Doikoff, 2004) was converted into frequency score per million and 10 -base logarithm of the score was taken with one added to the score per million to avoid the undefined $\mathrm{Lg}(0)$. The words had an odd number of characters in order to avoid an overlap between their orthographic and physical center. For the same reason a handwriting script and not block letters, was used. The words were written in Segoe Script, bold, font size 13, again on different positions to the left or to the right of the A4 sheet.

Table 1: Means and SDs (in parentheses) of the line and word length in centimeters; word length in number of characters and their objective frequency (Simov et al., 2004)

|  | Length in cm | Length in characters | Frequency |  |
| :---: | :---: | :---: | :---: | :---: |
| Words | $3.9(0.7)$ | $13.4(2.1)$ | $0.19(0.23)$ |  |
| Lines | $10.9(2.2)$ |  |  |  |
|  |  |  |  |  |
|  |  |  |  |  |

## Procedure

All participants had to perform line and word bisection, and also draw a house, a person and a tree on three separate sheets of paper. The order of the line and word bisection tasks and the drawing tasks was counterbalanced for the adults and the middle-schoolers. Preschoolers performed the tasks in random order. The sheets of paper were placed one by one in front of the participants and taken away after the execution of each task. Participants were asked to cross the middle of the lines and words as fast and as accurately as possible, and to draw a house, a person and a tree, on their own terms. For the 4 -year-olds the instructions were more detailed, as the experimenter had to be sure that they understood the task well.

## Results

The performance on the active and passive tasks was measured with two different types of indices. For the analyses of the line and word bisection data, a Percent deviation score was calculated as the difference between the left bisected part and the true half, divided by the true half and multiplied by 100 ((left bisected-half)/half*100) (see Fujii, Fukatsu, Yamadori, \& Kimura, 1995; Failla, Sheppard, \& Bradshaw, 2003).
Also, a novel drawing bias index was developed that took into account both the size of the drawing and its deviation from the center. First, the distance between the two outmost points on the lateral axis of the drawing was divided by two. The distance from this central point $\mathrm{C}_{1}$ to the outer points was taken as the drawing`s radius R. Each Bias index was calculated as the proportion of the shortest distance ( $\perp$ ) from $\mathrm{C}_{1}$ to the sheet's midline $\mathrm{C}_{2}\left( \pm \perp \mathrm{C}_{1} \mathrm{C}_{2}\right.$, negative values coded left), and the absolute sum of $\pm \perp \mathrm{C}_{1} \mathrm{C}_{2}$ and R .

$$
\text { Drawing Bias Index }=\frac{ \pm \perp C_{1} C_{2}}{\left| \pm C_{1} C_{2}+R\right|}
$$

This calculation yielded values between -1 and +1 , with zero for the centrally positioned objects. For both measures negative values indicated left bias and positive values indicated right bias.

## Preschool children

The data of 17 four-year old children from the preschool age group were subjected to analyses of Bias for each of the five tasks. Table 2 shows the means, standard deviations, and range of values for Line Bisection and Word Bisection Bias.

Table 2: Means, standard deviations, and range for Deviation Percent Score (Line/Word Bisection) in 4 year olds.

| Experimental <br> Task (Bias) | M | SD | Min | Max |
| :--- | :---: | :---: | :---: | :---: |
| Line Bisection | 6.88 | 11.84 | -12.83 | 30.20 |
| Word Bisection | 6.05 | 9.47 | -16.20 | 22.18 |

Note: Negative values correspond to a Left side preference.
In the Line Bisection Task, children's choices were significantly biased towards the right-hand side of the lines, as seen in the percent deviation score, $M=6.88, S D=$ $11.84, t_{(16)}=2.40, p=.03$. Children's performance in the Word Bisection Task was similarly biased rightwards, $M=$ $6.05, S D=9.47, t_{(16)}=2.63, p=.02$.

The drawing placement choices of the preschool children were analyzed in terms of the House bias index, Person bias index, and Tree bias index, respectively.

One-sample t-tests evaluated whether children's drawings were positioned with significant lateral bias. Table 3 shows the means, standard deviations, and range for each drawing task.

Table 3: Means, standard deviations, and range for the drawing tasks bias indices in preschool children.

| Experimental <br> Task: Bias Indices | M | SD | Min | Max |
| :--- | :---: | :---: | :---: | :---: |
| Draw a House | .24 | .54 | -.83 | .90 |
| Draw a Person | -.01 | .56 | -.82 | .93 |
| Draw a Tree | .11 | .49 | -.73 | .71 |

Note: Negative values correspond to a Left side preference.
There was no lateral bias in the Draw-a-house task, $M=.24$, $S D=.54, t_{(16)}=1.79, p=.09$, the Draw-a-person Task, $M=$ -. $01, S D=.56, t_{(16)}=.11, p>.1$, or the Draw-a-tree Task, $M$ $=.11, S D=.49, t_{(16)}=.96, p>.1$. In neither of the three object drawing tasks did children's object placements deviate reliably from the sheet's midline.

## Middle school children

The data of 18 twelve-year olds from the middle school age group were analyzed for Bias for each of the five tasks. Table 4 shows the means, standard deviations, and range for the Line Bisection and Word Bisection Bias measures.

Table 4: Means, standard deviations, and range for Deviation Percent Score (Line/Word Bisection) in the middle school group.

| Experimental <br> Task (Bias) | M | SD | Min | Max |
| :--- | :---: | :---: | :---: | :---: |
| Line Bisection | .22 | 4.94 | -9.69 | 9.25 |
| Word Bisection | -.97 | 9.71 | -26.09 | 12.31 |

Note: Negative values correspond to a Left side preference.
In both bisection tasks, twelve-year olds' choices were not reliably biased to one of the sides, all $p$ 's $>.1$.

The drawing choices of the 12-year olds were analyzed in a similar way to the data of the preschool children. Onesample $t$-tests yielded a reliable lateral bias for the Person and Tree Bias index measures. Table 5 shows the means, standard deviations, and range for each drawing task.

Table 5: Means, standard deviations, and range for the drawing tasks bias indices in 12-year old children.

| Experimental <br> Task: Bias Indices | M | SD | Min | Max |
| :--- | :---: | :---: | :---: | :---: |
| Draw a House | -.06 | .17 | -.39 | .21 |
| Draw a Person | -.40 | .14 | -.60 | -.13 |
| Draw a Tree | -.13 | .15 | -.41 | .15 |

Note: Negative values correspond to a Left side preference.
The analyses revealed no lateral bias in the Draw-a-house task, $p>.1$, but we found a reliable Left bias in the Draw-aperson and Draw-a-tree tasks, $t_{(17)}=11.87, p<.001$, and $t_{(17)}$ $=3.59, p=.002$, respectively.

## Adult group

The data of 18 adult participants were analyzed for Bias. Table 6 shows the means, standard deviations, and range for the Line Bisection and Word Bisection Bias measures.

Table 6: Means, standard deviations, and range for Deviation Percent Score (Line/Word Bisection) in adults.

| Experimental <br> Task (Bias) | M | SD | Min | Max |
| :--- | :--- | :---: | :---: | :---: |
| Line Bisection | -1.21 | 5.49 | -13.10 | 7.25 |
| Word Bisection | -.83 | 3.21 | -8.45 | 4.78 |

Note: Negative values correspond to a Left side preference.
In neither task, did adults' performance show any lateral bias, p's > .1.

The drawing choices of the adults were analyzed in terms of the House, Person, and Tree bias indices. Table 7 shows the means, standard deviations, and range for each object drawing task.

Table 7: Means, standard deviations, and range for the Draw-a-House, Draw-a-Person, and Draw-a-Tree indices, in the adult group.

| Experimental <br> Task: Bias Indices | M | SD | Min | Max |
| :--- | :---: | :---: | :---: | :---: |
| Draw a House | -.27 | .26 | -.72 | .25 |
| Draw a Person | -.45 | .22 | -.77 | .03 |
| Draw a Tree | -.25 | .21 | -.58 | .13 |

Note: Negative values correspond to a Left side preference.
In all three object drawing tasks, adults exhibited a reliable Left bias: in the Draw-a-house task, $M=-.27, S D=.26, t_{(17)}$ $=4.23, p=.001$, in the Draw-a-person Task, $M=-.45, S D=$ $.22, t_{(17)}=8.79, p<.001$, and in the Draw-a-tree Task, $M=-$ $.25, S D=.21, t_{(17)}=5.07, p<.001$.
In summary, we found a reliable Right bias in preschool children's performance on the two bisection tasks, and a reliable Left bias in adults' performance on the drawing tasks. Twelve-year olds had no lateral bias on the bisection tasks, and a reliable Left bias on two of the three drawing tasks. In addition, in order to evaluate whether their performance differed from each of the other age groups we analyzed their performance measures in combination with the other groups in separate multiple analyses of variance on the bisection tasks and on the drawing tasks. A MANOVA revealed a significant main effect of age group in line and word bisection $\left(F(4,98)=3.75, p=.007 ; \eta_{p}^{2}=.133\right)$. A post-hoc analysis (Scheffé) revealed that the difference was between the adults and the preschoolers ( $p=.016$ for the line bisection task; and $p=.05$ for the word bisection task). No difference was found between the performance of the middle school children and either of the other two groups (Figure 1).

Figure 1. Percent deviation line and word scores as a function of age group. Positive values indicate deviation to the right and negative values indicate deviation to the left.

Error bars denote .95 confidence intervals. $* p<.05$.
A MANOVA showed a significant main effect of age group in the drawing tasks $\left(F(6,96)=4.73, p<.001 ; \eta_{p}^{2}=\right.$ .228). Post-hoc analysis (Scheffé) revealed that the adults and the preschoolers performed differently in all drawing tasks - in the draw-a-house task $(p=.001)$, in the draw-atree task $(p=.006)$ and in the draw a person task $(p=.003)$. Middle school children differed from preschoolers only in the draw-a-person task $(p=.01)$. Again, no difference was found between the performance of the middle school children and the adults (Figure 2).

Figure 2. Drawing bias index as a function of age group. Positive values indicate deviation to the right and negative values indicate deviation to the left. Error bars denote .95 confidence intervals. ${ }^{* * *} p<.001 ; * * p=<.01 ; * p<.05$.

## Discussion

The present study showed spatial bias in different cognitive spatial tasks across three age groups. Interestingly, the direction of the demonstrated bias depended significantly on the nature of the tasks. In the passive tasks (line and word bisection), results showed bias only for the
preschool group, and in the active (drawing) tasks - only for the middle school children and the adults. This suggests that implicit and explicit tasks might reflect different types of spatial processing. Furthermore, with development the direction of the bias was indeed shifted from right to left, but also across the tasks. Generally, all participants deviated more to the left in the implicit tasks. One explanation would be that the explicit instruction in the bisection task made participants more attentive, resulting in overdriven movements for the preschoolers because of the pervasive motor component. Another speculation would be that a certain familiarity effect could enhance the ability to form object representations in the peripersonal space, resulting in difference in performance.

Preschoolers exhibited significant rightward bias in the line and word bisection tasks, consistent with reports of previous studies (Dellatolas et al., 1996; Dobler, Manly, Atkinson, Wilson, Ioannou, \& Robertson, 2001). As reported by Dellatolas et al. (1996), when four-year-old children use their right hand, a low degree of hemispheric interaction due to callosal immaturity may be the reason which leads to enhanced left hemisphere involvement, shift of attention to the right side and rightwards overestimation.

The 12-year-old middle school children were not reliably biased in the bisection tasks. As reported by Hausmann et al. (2003), there is a robust developmental step to the adult pattern of pseudoneglect between the ages of 10-12 and 1315. In their study, a group of $10-12$ year old children demonstrated a symmetrical neglect for the line bisection task, whereas their eldest group (13-15 year olds) showed a leftwards bias. As proposed by Hausmann et al. (2003), this developmental step can be attributed both to corpus callosum maturation and hormonal change during puberty.

Furthermore, for the adult group, the line and word bisection task showed no significant bias although the overall mean scores indicated a leftward directionality.

In order to assess the leftward bias we used implicit measures of visual-spatial computation as in the person-treehouse drawing task (Barrett et al., 2002). As expected, the adult group demonstrated a leftward bias for all three types of object drawings, similar to the results in the study of Barret et al. (2002). The middle-schoolers` drawings also showed a leftward bias though to a smaller degree. This leftward bias is consistent with previous studies using the draw-a-person task (Heller, 1991) and the draw-a-tree task (Picard \& Zarhbouch, 2014) and indicates that at this age the right hemisphere asymmetric activation is evident and reading habits affect spatial attention.

Notably, Barrett et al. (2002) reported that reading habits (left to right or right to left) could not reverse the leftward bias in the house-tree-person drawings of adults. In our study we found that preschoolers exhibited no lateral bias and tended to place their drawings in the middle of the page. Thus, when reading habits are not established and there is no imbalanced left hemispheric activation, children's perceptual right space is not attenuated.

## Conclusion

The present study used both implicit and explicit tasks in three age groups with different reading skills. Age had significant effect in all tasks, but results depended on the nature of the tasks. Adults differed from preschoolers in all tasks. Middle school children performed like the adults, and differed from the preschoolers in only one of the implicit tasks. These results are consistent with previous studies stressing the importance of corpus callosum maturation in the the asymmetric activation of the right hemisphere, as well as the importance of the reading habits.

Unlike previous research, we did not find significant spatial bias for the adults and the middle school children in the explicit tasks. One explanation might be the enhanced executive control over motor performance. This would mean that when attention is engaged, pseudoneglect might be attenuated with maturation. However, due to the small sample sizes, not definite conclusion can be made.

Notably, in the present study was used a novel index to assess the spatial bias in the drawings` placement, taking into account not only the deviation of the drawing but its size. That is why it is difficult to compare our results with earlier results. Subsequent studies are planned with 7-8 year old children and illiterate adults in order to examine further the influence of brain maturation and scanning habits on the spatial representation of the immediate surroundings.

# Is Red Fire Warmer than Blue Fire? Colored Thermal Words in a Stroop Task 

Yordanka Zafirova<br>Department of Cognitive Science and Psychology, New Bulgarian University, Bulgaria<br>Armina Janyan<br>Research Center for Cognitive Science, New Bulgarian University, Bulgaria

#### Abstract

In many languages there are concepts for warm and cold colors. Research on color-temperature correspondence and their interaction is quite scarce, and based mostly on subjective measures. It is still unknown whether and to what extent colors bear the thermal information. The current study explored the relationship between warm and cold colors (red and blue) and thermal aspects of the word semantics (sun, snow), using the Stroop paradigm in a color categorization task. It was hypothesized that if colors activate the thermal meaning then Stroop effect should occur. The results suggested a colortemperature compatibility effect - faster responses when associated color and thermal meaning corresponded (e.g. sun presented in red). This provides important information on the automaticity of thermal activation during word processing, and on the strength of conceptual associations in color perception. It was suggested that words induced mental simulation of the thermal concepts, together with the associated color.

# The Redundancy Effect in Human Causal Learning: Evidence Against a Comparator Theory Explanation 

Tara Zaksaite (gintare.zaksaite@plymouth.ac.uk)<br>School of Psychology, Plymouth University, Plymouth, UK<br>Peter M. Jones (peter.m.jones@plymouth.ac.uk)<br>School of Psychology, Plymouth University, Plymouth, UK

#### Abstract

The blocking effect, canonical in the study of associative learning, is often explained as a failure of the blocked cue to become associated with the outcome. However, this perspective fails to explain recent findings that suggest learning about a blocked cue is superior to a different type of redundant cue. We report an experiment designed to test the proposal that blocking is not a failure of association, but a performance effect arising from a comparator process (Denniston, Savastano, \& Miller, 2001). Participants received A $+\mathrm{AX}+\mathrm{BY}+\mathrm{CY}-$ training containing a blocked cue X and another redundant cue Y , before rating outcome expectancies for individual cues. These ratings were inconsistent with the association-failure view. After subsequent A- Y+ training, participants rated cues again. Ratings in the second test were inconsistent with the comparator theory. Our data suggest that neither perspective is likely to provide a complete account of causal learning.

Keywords: associative learning; comparator theory; redundancy effect; blocking; cue competition

## Introduction

In a typical causal learning task, participants are required to learn which cues cause an outcome. Many such tasks involve presentation of more than one cue on each trial, and this typically results in cue competition. That is, learning about a cue is dependent to some extent on accompanying cues. Probably the best-known example of cue competition is blocking (e.g. Dickinson, Shanks, \& Evenden, 1984). In a blocking task, participants receive trials on which cue A is paired with an outcome (denoted A+) and trials on which A is presented alongside a second cue, X , and paired with the outcome (AX+). Blocking is said to have occurred if learning about $X$ is restricted by the presence of $A$, relative to a control condition in which A+ trials are omitted. Learning about X is therefore influenced by the presence and associative history of A . This finding is analogous to classic demonstrations of blocking in nonhuman animals (e.g. Kamin, 1969).

Following the discovery of cue competition effects, Rescorla and Wagner (1972) outlined an elegant and muchcited model according to which an outcome will only support learning if it is surprising. Surprise is equivalent to prediction error, or the discrepancy between the outcome that is expected and the outcome that occurs. When an unexpected outcome occurs, the resulting prediction error enables the formation of an association between any cues
present and the outcome. Critically however, outcome expectancy is based on all the cues that are present rather than individual cues. To illustrate this, consider the blocking effect. On AX+ trials, expectancy of the outcome is based on the extent to which it is predicted by both A and X . Because A is established as a predictor of the outcome on A+ trials, the outcome is expected on AX+ trials and little learning can take place. Learning about X is therefore 'blocked' by the presence of A. If A were not separately paired with the outcome, blocking would not occur. Informally, we can say that X is blocked because it is informationally redundant; it indicates no change in the outcome that is predicted by A. According to the RescorlaWagner model, this is operationalized as a failure by X to become associated with the outcome.

This description of blocking as a failure of association formation has been called into question by a recent result comparing learning about a blocked cue with another kind of redundant cue. Uengoer, Lotz, and Pearce (2013) compared learning about the blocked cue X with cue Y from a BY+CY- discrimination. Here, the outcome was predicted by B and its absence was predicted by C . We refer to the common cue, Y , as an uncorrelated cue because it is paired with both the presence and the absence of the outcome. Uengoer et al. gave participants $\mathrm{A}+\mathrm{AX}+\mathrm{BY}+\mathrm{CY}-$ training, followed by test trials on which they were asked to rate outcome expectancy for each cue. The Rescorla-Wagner (1972) model predicts that learning about X should be blocked by A, as described above. The prediction for Y is perhaps more complex, but the model predicts that the strength of the association between Y and the outcome will increase overall during training. This results from the use of a combined prediction error in determining learning, as follows: On BY+ trials, the associations between B and Y and the outcome should strengthen. On CY- trials, the association between Y and the outcome should lead to expectation of the outcome, and its non-occurrence will in turn lead to decreases in the extent to which both C and Y predict the outcome. As a consequence, C should be established as an inhibitor of the outcome. This will enable Y to maintain its association with the outcome to some extent. Informally, we can say that Y could be a cause of the outcome if its absence on CY- trials is explained by the preventative status of C . The Rescorla-Wagner model, then, predicts that Y will become better associated with the outcome than will X. Contrary to this prediction, Uengoer et
al.'s participants rated $X$ as a more likely cause of the outcome than Y. This finding is known as the redundancy effect (for corresponding results using rats and pigeons, see Jones \& Pearce, 2015; Pearce, Dopson, Haselgrove, \& Esber, 2012).

## Comparator theory

While the redundancy effect is not predicted by the Rescorla-Wagner (1972) model, it perhaps makes intuitive sense because X is consistently paired with the outcome. Y, on the other hand, is paired with the outcome only intermittently. Ignoring any effect of cue competition, we might expect X to become better associated with the outcome than Y. Accordingly, Uengoer et al. (2013) considered whether their results might be better accounted for by supposing that blocking occurs not because X fails to become associated with the outcome, but because of an additional process that acts during the test. According to comparator theory (Denniston, Savastano, \& Miller, 2001), association formation is non-competitive and driven by an individual prediction error for each cue. Cue competition is then accounted for by a comparator process that operates at test to influence performance. This process compares the associative status of the target cue with that of any cues that have previously been presented alongside the target. This results in a decrease if companion cues have a strong association with the outcome, and an increase if the association is weak. In the case of X, outcome expectancy will be reduced because A is strongly associated with the outcome, and blocking will occur. This model also predicts the redundancy effect, because association formation is governed by each cue's relationship with the outcome. X should be better associated with the outcome than Y, because Y is only followed by the outcome on $50 \%$ of trials. The comparator theory therefore seems like a promising candidate for explaining both blocking and the redundancy effect.

However, two attempts have been made to test this account and both have cast doubt on its validity. Jones and Pearce (2015) conducted an experiment in which rats were given $\mathrm{A}+\mathrm{AX}+\mathrm{BY}+\mathrm{CY}$ - training, where each cue was an auditory or visual stimulus and the outcome was the delivery of a sucrose solution. Rats were subsequently tested in extinction with $\mathrm{B}, \mathrm{X}$, and Y. A larger response was elicited by X than Y , demonstrating the redundancy effect. Responding was also higher for B than for X . Jones and Pearce suggested that this was important, because it allowed a further test of the comparator theory. According to this theory, because B and X were both consistently paired with the outcome, they should have become associated with the outcome to the same extent. The larger response for B than for X at test must therefore have been the result of the comparator process. Because B had been presented alongside Y, which was only weakly associated with the outcome, the response to B was left largely intact. For X, however, the response was moderated because X had been trained alongside A, which was strongly associated with the
outcome. To test this account, rats were given A- Y+ training. Following this, they were again tested with B and X . The comparator theory now predicts greater responding for X than for B , but the results closely resembled those from the first test. B elicited more responding than X despite revaluation of the comparator cues A and Y , apparently in contradiction of the theory. An objection may be raised, however, because of the nature of the outcome used in this experiment. Miller and Matute (1996) suggested that, once a target cue becomes associated with an outcome of motivational significance, the target cue itself acquires motivational significance. As a result, attempts to deflate responding to the target cue by further conditioning of an associate cue may be unsuccessful. In the experiment reported by Jones and Pearce, the appetitive outcome is likely to have had substantial motivational significance. It is therefore possible that responding to $B$ was unaffected by Y+ training, not because the comparator theory is incorrect but because the manner in which it was tested was inadequate. Urushihara and Miller (2010) noted that such revaluation effects are difficult to observe in nonhuman animals because of the use of motivationally significant outcomes, but occur frequently in human causal learning.

There also exists a test of whether the comparator theory can account for the redundancy effect in humans, reported by Uengoer et al. (2013). Since blocking is dependent on a comparison between X and A , it follows that revaluation of A should increase outcome expectancy for X . In one experiment, following initial $\mathrm{A}+\mathrm{AX}+\mathrm{BY}+\mathrm{CY}-$ training and subsequent individual cue testing, participants were given A- training and a further test. They found that outcome expectancy for X was equivalent for the two tests, contrary to the predictions of the comparator theory. This conclusion should be treated with caution, however. The crucial comparison is between outcome expectancy for X during the first and second tests. This means that the results are likely to have been contaminated to some extent by order effects. In the present paper, we report an experiment intended to provide a fairer test of the comparator theory. The experiment is conceptually similar to the Jones and Pearce experiment, except that it used human participants and a causal learning task. It therefore combines the better aspects of the existing evaluations of the comparator theory described above, while eliminating the shortcomings. The use of human participants should provide ideal conditions for observing revaluation effects and, because the adequacy of the comparator theory can be assessed by comparing B and $X$ in the same test, the confounding effect of order present in the Uengoer et al. experiment is avoided.

## A test of the comparator theory

The design of this experiment is summarized in Table 1. Stage 1 of the experiment was designed to establish the causal status of B, X, and Y. Each participant received four types of trial: A+, AX+, BY+, and CY-. Following Uengoer et al. (2013), training was embedded in a variant of the classic allergist task (Aitken, Larkin, \& Dickinson, 2000).

On each trial, participants were shown one or two food pictures and asked to predict whether they would lead to stomach ache in a fictional patient, Mr. X. After participants made their predictions, they received feedback on whether stomachache did (+) or did not (-) occur. After the completion of Stage 1, a test stage was administered in which participants were shown the five individual food cues and asked to rate the likelihood of stomach ache for each food using a rating scale. These ratings served as the measure of outcome expectancy for each cue. We expected these ratings to resemble those obtained by Uengoer et al. That is, we expected ratings to be higher for X than for Y (the redundancy effect) and to be higher for B than for X . We also expected ratings to be high for A and low for Y . After this test, participants received further training in Stage 2. This training was designed to revalue A and Y , and consisted of A- and Y+ trials. Following this training, outcome expectancies were again measured in the same way as in the earlier test. If the comparator theory (Denniston, Savastano, \& Miller, 2001) is correct, ratings for X should be higher than ratings for B in this test. Alternatively, if the outcome expectancy for B was higher than for X at Test 1 because of a difference in the strength of associations formed between these cues and the outcome during Stage 1, then ratings should still be higher for B than for X at Test 2.

Table 1: The design of the experiment.

| Stage 1 | Test 1 | Stage 2 | Test 2 |
| :--- | :--- | :--- | :--- |
| A+ | A | A- | A |
| AX + | B | $\mathrm{Y}+$ | B |
| BY+ | C |  | C |
| CY- | X |  | X |
|  | Y |  | Y |
| 8 blocks | 2 blocks | 8 blocks | 2 blocks |

## Method

Participants The participants were 50 Plymouth University undergraduate students studying Psychology. They received course credit for their participation in this experiment. They were aged $18-53$ years $(M=21.86, S D=7.1)$ and five were male.

Materials The experiment was run using computers attached to 22 -inch monitors with a $1920 \times 1080$ resolution. The experiment was designed, cues presented and responses recorded, using E-prime 2.0 software (Psychology Software Tools, PA, US).

The cues were five images of foods on a white background, each measuring $300 \times 300$ pixels. The foods were: apple, cherry, grape, lemon and strawberry. Foods were randomly assigned to serve as each cue ( $\mathrm{A}, \mathrm{B}, \mathrm{C}, \mathrm{X}$, Y ) for each participant. Outcomes were stomach ache, signified by text and a sad face on a red background, and no stomachache, indicated by text and a happy face on a green
background. Cues and outcomes were presented on a black background with white text. Participants responded using the mouse.

Procedure Each participant was initially asked to read onscreen instructions that were identical to those used by Uengoer et al. (2013). In the first stage of the experiment participants were presented with eight blocks of trials. Each of the four trial types ( $\mathrm{A}+, \mathrm{AX}+, \mathrm{BY}+, \mathrm{CY}-)$ were presented once per block, and were randomized within each block. Each trial started with the presentation of either one or two images of foods, below the phrase "The patient ate the following food(s):" The sentence "Which reaction do you expect?" was presented below the images. Participants responded by clicking one of two response buttons placed at the bottom of the screen. The left-hand button was labelled "No stomach ache", and the right-hand button was labelled "Stomach ache". As soon as the participant responded, the response buttons and the sentence above them were replaced by a statement and image showing the outcome of the trial. When the outcome was stomach ache, the statement was "The patient has stomach ache" and the picture of a sad face was shown. When the outcome was no stomach ache, the statement was "The patient has no stomach ache", and the picture of a happy face was shown. This feedback display remained on the screen for 3 s and was then followed by the next trial.

After the completion of Stage 1, Test 1 began. Here the participants were instructed to judge the probability with which specific foods will cause stomach ache in the absence of feedback. On each trial a single food was presented on the screen below the sentence "What is the probability that the food causes stomach ache?" Participants responded by clicking on an 11-point rating scale ranging from 0 (Certainly not) to 10 (Very certain). After participants chose a rating for each food, a blank screen was shown for 1 s . Each food that appeared in Stage 1 was presented twice, with the order of trials randomly determined for each participant. For each participant, the average of the two outcome expectancy ratings was calculated and used in subsequent analyses.

Participants then received further training in Stage 2. Training consisted of eight blocks of two trial types (A-, $\mathrm{Y}+$ ) appearing once per block in a random order. The procedure for this stage was otherwise identical to Stage 1. Test 2 then measured final outcome expectancies, using the same procedure as Test 1 .

## Results

We applied an inclusion criterion of $60 \%$ correct predictions in Stage 1, commonly used in similar work (e. g. Le Pelley \& McLaren, 2003). Four participants failed to meet this, and are excluded from all subsequent analyses. The remaining 46 participants learned readily, and made $98 \%$ correct responses during the final block of trials of Stage 1. These participants also made correct predictions on $98 \%$ of trials
during the final block of Stage 2. Our analyses here focus on the critical test data.

Mean ratings from Tests 1 and 2 are shown in Figure 1. The pattern of results in Test 1 closely resembles those obtained by Uengoer et al. (2013), with higher ratings for X than for Y , and higher ratings for B than for X . For the comparator theory, the crucial comparison is between B and X at Test 2. As for Test 1, ratings for B were higher than for X. A two-way ANOVA with test and cue variables was conducted. This revealed a significant effect of test, $F(1,45)$ $=6.59, p=.014, \eta_{\mathrm{p}}^{2}=.128$, a significant effect of cue, $F(4$, 180) $=80.76, p^{<}<.001, \eta_{\mathrm{p}}{ }^{2}=.642$, and a significant interaction, $F(4,180)=207.85, p<.001, \eta_{\mathrm{p}}{ }^{2}=.822$. To explore this interaction, simple effects analyses were used to compare ratings from Tests 1 and 2 for each cue. Ratings differed between tests for $\mathrm{A}, F(1,45)=431.15, p<.001, \eta_{\mathrm{p}}{ }^{2}$ $=.905$, for $\mathrm{B}, F(1,45)=29.30, p<.001, \eta_{\mathrm{p}}^{2}=.394$, for C , $F(1,45)=23.28, p<.001, \eta_{\mathrm{p}}^{2}=.341$, and for $\mathrm{Y}, F(1,45)=$ 359.38, $p<.001, \eta_{p}^{2}=.889$. Ratings for X did not differ between tests, $F<1$.

Separate analyses were conducted to test the most informative comparisons. Firstly, in order to check that the redundancy effect was obtained, we used a within-subjects $t$-test to compare ratings for X and Y at Test 1. Ratings for X were significantly higher than for $\mathrm{Y}, t(45)=7.58, p<$ .001. Secondly, to confirm that the revaluation of A and Y was successful, we conducted a two-way ANOVA comparing ratings for A and Y in the two tests. We found an effect of cue, $F(1,45)=6.37, p=.0151, \eta_{\mathrm{p}}{ }^{2}=.124$, an effect of test, $F(1,45)=5.12, p=.029, \eta_{p}^{2}=.102$, and importantly, a significant interaction, $F(1,45)=559.83, p<$ $.001, \eta_{\mathrm{p}}^{2}=.926$. Exploring this interaction, we found that ratings for A were higher than for Y at Test $1, F(1,45)=$ $559.62, p<.001, \eta_{\mathrm{p}}^{2}=.926$, but that ratings were higher for Y than for A at Test $2, F(1,45)=112.41, p<.001, \eta_{\mathrm{p}}^{2}=$ .714. The revaluation of A and Y was therefore successful. Thirdly, to test the predictions of the comparator theory, we conducted a similar two-way ANOVA to compare ratings for $B$ and $X$ at Test 1 and Test 2 . We found an effect of cue, $F(1,45)=46.82, p<.001, \eta_{\mathrm{p}}^{2}=.510$, an effect of test, $F(1$, $45)=21.40, p<.001, \eta_{\mathrm{p}}^{2}=.322$, and a significant interaction, $F(1,45)=18.81, p<.001, \eta_{\mathrm{p}}^{2}=.295$. Exploring the interaction, we found that ratings for B were higher than for X at both Test $1, F(1,45)=62.86, p<.001, \eta_{\mathrm{p}}^{2}=.583$, and Test 2, $F(1,45)=16.52, p<.001, \eta_{\mathrm{p}}^{2}=.268$. This disconfirms the predictions of the comparator theory. If outcome expectancies for B and X were determined by a combination of direct associations with the outcome and comparison with Y and A respectively, then ratings for X should have been higher than for B at Test 2. One notable feature of the data that might suggest some role for a comparator process is the change in ratings for B between the two tests. Participants rated B as a less likely cause of the outcome after Y+ training than they did before, which is consistent with the comparator theory. However, an opposite effect was observed for C . Ratings for C were higher at Test 2 than at Test 1, which is the opposite change
to that predicted by the comparator theory. It therefore seems likely that these changes are not the result of a comparator process, but rather a general decrease in certainty at Test 2 . Since A and Y had been revalued in Stage 2, some participants may have assumed that associations learned during Stage 1 were no longer reliable.

Figure 1: Mean ratings for Test 1 and Test 2, for each cue. Error bars show the standard error of the mean.

## Discussion

The experiment reported here was designed to test an explanation of the redundancy effect based on the comparator theory (Denniston, Savastano, \& Miller, 2001). Following A+AX+BY+ CY- training, participants were asked to rate the probability of the outcome occurring for each individual cue in Test 1. Ratings were higher for X than for Y; we therefore replicated the redundancy effect (Uengoer et al., 2013). This finding is consistent with the comparator theory, which states that the strength of the association formed between a cue and an outcome is determined by an individual (i.e. non-competitive) prediction error. Since $X$ was consistently paired with the outcome and Y was not, it follows that X should have become better associated with the outcome than Y . Participants also gave higher ratings for B than for X during Test 1. Again, this is consistent with the comparator theory. Although the theory predicts that each of these cues will have become associated with the outcome to the same extent, it also states that outcome expectancies should have been moderated by the comparator process at test. Specifically, outcome expectancy for X should have been reduced because it had been trained alongside A, which was strongly associated with the outcome. Any reduction in outcome expectancy for $B$ should have been smaller, because it had been trained alongside Y, which was only weakly associated with the outcome. However, the comparator theory is not consistent with the results of Test
2. Following Stage-2 A- Y+ training, participants again rated the probability of the outcome occurring for each cue. Ratings for B were again higher than for X . The comparator theory, however, predicts the opposite pattern of results. This is because, although the associations with the outcome should have remained unchanged for both B and X , the associative status of their comparator cues had changed. We therefore conclude that the comparator theory cannot account for our results. Of course, this conclusion relies on the assumption that Stage-2 training was successful in revaluation of A and Y . This is apparent in the higher ratings given for Y than for A at Test 2.

Our results are also difficult to reconcile with the model of learning proposed by Rescorla and Wagner (1972). Because it describes learning as being the result of a combined prediction error, X should have failed to become associated with the outcome and should have been rated as a less likely cause of the outcome than Y at Test 1. In other words, the Rescorla-Wagner model fails to account for the redundancy effect because it incorrectly predicts that learning about the blocked cue will be prevented. However, Vogel and Wagner (2017) have suggested a way in which the prediction of blocking can be modified to accommodate the redundancy effect. Their modification is based on the assumption that each cue shares some common features, denoted K. The training given in Stage 1 here could therefore be re-described as AK+ AXK+ BYK + CYK-. K should become associated with the outcome, with two consequences that are relevant for interpreting the redundancy effect. Firstly, because K is present on CYKtrials, overexpectation of the outcome is increased and the weakening of the association between Y and the outcome on these trials is more substantial than when K is omitted. Secondly, When XK is presented at test, outcome expectancy is boosted by K ; the model can therefore predict greater outcome expectancy for XK as a result of including the common features. Combination of these two changes allows the model to predict the redundancy effect. This version of the model also makes an interesting prediction regarding the effect of adding further trial types to Stage-1 training. Because the extent to which K becomes associated with the outcome is critical, adding extra trials on which the outcome does not occur (e.g. DK-) should reduce the influence of common features and eliminate the redundancy effect. This prediction remains untested. If it is correct, it would lend support to an account that provides a way to reconcile the Rescorla-Wagner model with the redundancy effect.

Another possibility is that learning is governed by quite different rules. Not all models of learning make such strong predictions about the restriction of learning about blocked cues. Pearce's $(1987,1994)$ configural model, for instance, predicts substantial outcome expectancy for blocked cues. According to this model, participants learn about configural representations that include all cues present on a given trial, rather than each cue entering into its own association with the outcome. In the case of blocking, participants would
come to associate A with the outcome on A+ trials, and to associate AX with the outcome on AX+ trials. Outcome expectancy for X alone would then be determined by generalization from AX, based on their similarity. Outcome expectancy for X would therefore be weaker than for AX , but considerably stronger than it would have been without any training. However, Pearce at al. (2012) note that the theory is unable to predict the redundancy effect because it predicts that outcome expectancy for Y will be higher still. As with the Rescorla-Wagner (1972) model, it is possible that some modification of the configural model would alter this prediction, but it is not clear at present what that modification might be.

Whether cues are learned about individually or as configurations, the redundancy effect might be accommodated if we suppose that the amount of attention paid to blocked and uncorrelated cues changes during training. For instance, it is commonly assumed (Le Pelley, 2004; Mackintosh, 1975) that cues are processed to the extent that they have predictive value. Since blocked and uncorrelated cues are both redundant, we might expect the amount of attention they are paid to be reduced. In order to explain the redundancy effect, however, we need to propose that this reduction in attention differs in magnitude for blocked and uncorrelated cues. If we suppose that participants learn quickly that Y is irrelevant during $\mathrm{BY}+$ CY- training, then we might expect substantial decreases in the amount of attention paid to Y and a weak association between Y and the outcome as a result. Attention to X, on the other hand, might be maintained for longer, allowing a stronger association to form between X and the outcome. In an attempt to evaluate this claim empirically, Jones and Zaksaite (2017) monitored participants' eye gaze during A+ AX + BY + CY- training. The duration of eye gaze for each cue has been used extensively as a measure of overt attention in learning tasks (e.g. Beesley \& Le Pelley, 2011). Jones and Zaksaite found that participants spent more time looking at Y than at X , but that this was likely to have been a consequence of differing trial durations. When X and Y were presented on the screen together in a subsequent stage of training, gaze was equivalent for each. This experiment therefore failed to provide any evidence that the amount of attention paid to blocked and uncorrelated cues differs.

In addition to associative accounts of blocking, others (e.g. Lovibond, Been, Mitchell, Bouton, \& Frohardt, 2003) have argued that blocking is the result of inferential reasoning. According to this view, blocking occurs because participants do not have independent evidence that the blocked cue causes the outcome (i.e. training trials on which X is presented without A ). However, since participants also lack evidence that the blocked cue does not cause the outcome, they should be uncertain about the causal status of $X$ and blocking should be relatively weak. This uncertainty might be enhanced because the magnitude of the outcome is fixed, meaning that compound presentation of two causal cues would lead to the same outcome as either cue alone. Lovibond et al. provided support for this position by
showing that blocking is enhanced when the magnitude of the outcome varies in accordance with the number of causes present, allowing participants to infer that the blocked cue is not a cause of the outcome. In light of this account, we should consider whether the intermediate ratings for X in the present experiment were the result of an intermediate level of learning, or of uncertainty about its causal status. An unpublished experiment from our laboratory suggests that this might be a promising approach. In addition to rating the probability of the outcome for each cue, participants rated their confidence in these judgments. Confidence ratings were lower for blocked than for uncorrelated cues, suggesting that the redundancy effect might be due at least in part to uncertainty about X .

## Conclusion

We have considered theories that account for learning by using individual and combined prediction errors. While combined prediction error models (e.g. Rescorla \& Wagner, 1972) are difficult to reconcile with the redundancy effect, individual prediction error does not result in cue competition effects such as blocking, unless an additional process is invoked. We tested a theory that includes such a process (Denniston, Savastano, \& Miller, 2001), but found that it was not consistent with the results of Test 2 . We suggest two lines of future enquiry. Firstly, data should be collected that evaluate the predictions arising from Vogel and Wagner's (2017) addition of common features to simulations of the Rescorla-Wagner model. While the cues used in the present experiment are likely to have shared some common features, we cannot currently evaluate the claim that learning about these features enables the redundancy effect to occur. Secondly, since neither combined nor individual prediction errors seem capable of producing our results, attempts should be made to evaluate some combination of the two. In particular, any models containing both kinds of prediction error should be tested against the idea that cue competition occurs because of inferential reasoning processes.

# Modeling Semantic Fluency Data as Search on a Semantic Network 

Jeffrey C. Zemla (zemla@wisc.edu)<br>Joseph L. Austerweil (austerweil@wisc.edu)<br>Department of Psychology, University of Wisconsin-Madison, 1202 W. Johnson Street<br>Madison, WI 53706 USA

#### Abstract

Psychologists have used the semantic fluency task for decades to gain insight into the processes and representations underlying memory retrieval. Recent work has suggested that a censored random walk on a semantic network resembles semantic fluency data because it produces optimal foraging. However, fluency data have rich structure beyond being consistent with optimal foraging. Under the assumption that memory can be represented as a semantic network, we test a variety of memory search processes and examine how well these processes capture the richness of fluency data. The search processes we explore vary in the extent they explore the network globally or exploit local clusters, and whether they are strategic. We found that a censored random walk with a priming component best captures the frequency and clustering effects seen in human fluency data.

Keywords: memory; search; semantic networks; fluency

## Introduction

One important task for the human mind is to retrieve knowledge from memory when it is needed. To investigate how the mind solves this task, psychologists have used the semantic fluency task (Bousfield, \& Sedgewick, 1944), in which participants generate as many unique items as they can from a category (e.g., "Name as many animals as you can") in a fixed amount of time (e.g., one minute). Semantic fluency data are richly structured. For example, researchers have found a frequency effect: Items that occur more often in the world are also produced more often in fluency lists. Under the assumption that knowledge is represented as a semantic network, we evaluate a number of possible process models of memory retrieval by determining how well they can reproduce the rich structure of human fluency data.

A debate has emerged as to whether a censored random walk over a semantic network (Abbott, Austerweil, \& Griffiths, 2015) or a strategic search in a high-dimensional space (Hills, Jones, \& Todd, 2012) better describes how the mind retrieves knowledge from memory. Central to the debate has been one property of fluency data: People tend to retrieve items in clusters in a manner consistent with optimal foraging (Hills et al., 2012). This is the tendency to search in memory within a cluster (sub-category) until the gains from further search in that cluster are outweighed by the benefits of switching to a new cluster. Both models can retrieve items in a manner consistent with optimal foraging. One issue in resolving this debate is that the semantic network account has only made computational-level claims and qualitative comparisons to human data. To advance the debate, we explore different possible search processes and compare their retrieval behavior to human retrieval behavior
by examining two traditional effects seen in semantic fluency data: frequency and clustering effects. We test processes that vary in the extent that they search strategically and explore the network.

The semantic fluency task is often scored by a simple count of the number of items named. While healthy controls typically have no trouble generating many items, patients with memory deficits such as Alzheimer's disease or semantic dementia recall fewer items (Troyer, Moscovitch, Winocur, Leach, \& Freedman, 1998). In addition, items that are typical of a category are reported more frequently than items that are atypical (Henley, 1969). For instance, cat is more likely to be named by a participant than lynx. This is particularly pronounced in patients with memory deficits, who often only recall items that are frequent in natural statistics (Sailor, Antoine, Diaz, Kuslansky, \& Kluger, 2004). Another well-studied property of semantic fluency data is clustering (Troyer, Moscovitch, \& Winocur, 1997). Healthy control participants tend to cluster items together in recall. For example, a participant may list cat, dog, and hamster in sequence because all three items belong to a common sub-category: pets.

In this paper, we evaluate how well different search processes on a semantic network reproduce frequency and clustering effects found in human fluency data. To do so, we first describe several search processes. Next, we measure frequency and clustering performance in humans using previously collected semantic fluency data (Zemla, Kenett, Jun, \& Austerweil, 2016). Then, we implement several network search procedures on a standardized semantic network and calculate those same measures for comparison.

## Memory Retrieval as Search

A model of memory retrieval is a search process over some representation. A search process begins with a cue (e.g., a category label) and uses that cue to locate relevant information (e.g., category members). A crucial component to any search process is the procedure used to navigate the representation (i.e., how the next item in search is determined). Search processes vary in whether they are local or global, or have aspects of both. A local search process will move from the current location to one nearby (in the representation) using information associated with the current location. A global search process may move from the current location to one far away using information encoded across the representation. Search is typically performed in conjunction with some executive process, to determine the relevance of the information encountered. For example, when searching through memory for "animals", it
is necessary to recognize that some items in the search path are not animals, and that some animals have already been found. This executive process does not need to be overt; in the search processes described below, it is assumed that search can traverse over items without conscious awareness and without being reported. In addition, search processes vary in whether they are strategic or not. Strategic search processes involve greater use of working memory and executive functioning to determine where to direct search next. Note that these dimensions are meant to help organize search processes and are idealized (e.g., most search processes are not purely local or global).

From behavioral evidence alone, it is difficult to infer properties of human search. For example, clustering in semantic fluency data has been taken as evidence of a strategic search process that leverages local cues (Troyer et al., 1997). To list animals we may start search at a random animal, say elephant. At this point, it may be more efficient to limit search to only African animals, as these items are more accessible. Once search exhausts its store of African animals, we switch back to a global search of any animal. This strategic cluster-and-switch process produces clustered fluency data as seen in participants. However, the switch between global and local cues does not need to be strategic if the underlying memory representation is organized in clusters (Abbott et al., 2015). Under this view, even a simple search process can produce clustered data simply by listing items in the order they are encountered in memorythe burden of efficiently retrieving items is built into the representation, rather than the process.

In this paper, we assume semantic memory is best represented as a semantic network and evaluate different search processes on it. Without specifying both a representation and a process, it is not possible to make claims from behavioral results (Abbott et al., 2015). We do so as a first step towards resolving the semantic network vs. space debate.

## Search Processes Over a Semantic Network

In this section, we define a semantic network and outline different possible search processes on it. Some processes, such as node degree search (NDS), rely on global cues, selecting the next item independent of the current item. Others, such as cluster-based depth first search (CbDFS) or the censored random walk (CRW), exploit local clusters by constraining search to nearby nodes. Most processes use a mixture of these cues, including three variations of the CRW which implement random jumping ( $\mathrm{CRW}+\mathrm{RJ}$ ), strategic jumping (CRW + SJ), and priming (CRW + PV) We also implement a basic spreading activation model (SA), which has been conceptually influential in the history of semantic networks (e.g., Collins \& Loftus, 1975). Figure 1 illustrates how the search processes are approximately distributed over the local-global dimension, and Figure 2 depicts a hypothetical semantic network and a possible search outcome for each search process.

Figure 1. Search processes ranked in terms of how far they tend to move on each step. Note that the ordering is given for the parameter values used in the paper and the precise ordering depends on the parameter values (e.g., CRW+RJ is more global-like when the jump probability is close to 1 ).

Figure 2. (top) A hypothetical network. (bottom) Example observed search paths for each method.

Semantic networks A common way to represent knowledge in memory is using a semantic network. A semantic network consists of nodes and edges. A node encodes a specific item in memory, such as dog or cat. Two nodes are connected to each other via an edge whenever those two items are semantically similar. For instance, $\operatorname{dog}$ and cat may be connected by an edge because they are both pets, but $d o g$ and elephant are unlikely to be connected.

In this work, we examine a semantic network that is both undirected and unweighted. Undirected means that if there is an edge between camel and horse, search could go from camel to horse or horse to camel (even though people might be more likely to say horse after camel than vice versa). Unweighted means that all edges imply the same amount of relatedness between two nodes. For example, if the network has one edge connecting horse and pony and another edge connecting horse and camel, the network encodes that a horse is as related to a pony as it is to a camel. Nodes sharing an edge are called neighbors. Although these assumptions may seem unrealistic, previous work found that a random walk over an undirected and unweighted semantic network captures optimal foraging behavior (Abbott et al., 2015). These distinctions may influence the clustering and frequency properties of semantic fluency data, but using directed and weighted edges increases the complexity of model substantially. So, we use an undirected network without weights and determine whether fluency data can be approximated by different search processes over it.

Node Degree Search (NDS) Node degree search selects nodes with probability proportional to a node's degree (the number of edges connected to a node). This corresponds to the relative frequency each node is visited by an "infinite" length random walk, which is a predictor of phonetic fluency data (Griffiths, Steyvers, \& Firl, 2007). Nodes with a large degree have many neighbors, and are typically encountered more frequently than nodes with a small degree. This search process chooses items based on their approximate frequency within the network regardless of the current location. Thus, it is a global and non-strategic process.

Cluster-based Depth First Search (CbDFS) Cluster-based depth-first search is equivalent to traditional depth-first search, except that the primary unit is a node and its neighbors (cluster) rather than a single node. Search begins at a starting node and outputs all of the neighbors of that node (in random order), skipping any node that has already been output. The process then moves to the most recently output node that has new neighbors and outputs those neighbors. Search is local, always emitting the current node's nearest neighbors and traversing one edge at a time.

Censored Random Walk (CRW) A censored random walk (Abbott et al., 2015) begins at a starting node and proceeds to follow a random walk, outputting each node the first time it is traversed (subsequent traversals over the same node are not output, i.e., they are "censored"). It is a local search process because it only depends on the neighborhood of the current node and can only move to a neighbor of the current node. However, because it only outputs the nodes it observes for the first time, items adjacent in its output may be far apart on the network. Nonetheless, it is much more likely to output a sequence of nodes that are close (in network space).

Censored Random Walk with Random Jumps ( $\mathbf{C R W}+\mathbf{R J}$ ) A censored random walk with random jumps is equivalent to a CRW with one key exception: At each step, the walk may jump to another node in the network (possibly one unconnected to the current node) with probability $\theta_{\mathrm{RJ}}$. (Goñi et al., 2010). The target node is chosen proportional to the node's degree (number of edges). As such, nodes that have more edges are more probable jump targets. As with the CRW, this search process is partially local, but due to random jumps, it has a global component. The decision to switch between local and global cues is random, and not a strategic decision.

Censored Random Walk with Strategic Jumps ( $\mathbf{C R W}+\mathbf{S J}$ ) A censored random walk with strategic jumps is similar to one with random jumps, except jump points are not chosen at random. Rather, the jumps occur after encountering $\theta_{\text {SJ }}$ censored nodes. The number of censored nodes is a proxy for time spent without outputting a new item, and is as a metacognitive cue that the current cluster is
exhausted. As with the CRW+RJ, this model will switch between local and global search. However unlike the random jump model, this switch is strategic: the switch is performed when there is evidence that the local cluster has been exploited sufficiently.

Censored Random Walk with Priming Vector (CRW+PV) One artifact of collecting multiple fluency lists from the same individual is that they are not independent. This is particularly pronounced when multiple lists are collected during a single session, as in our data set (Zemla et al., 2016). This results in search being biased by transitions made in a previous search (priming effects).

The censored random walk with priming vector attempts to capture this by biasing transitions toward those transitions produced in the previous list. Search is still a random walk, but whenever it reaches a node present in the previous list, with probability $\theta_{\mathrm{PV}}$ it transitions to the next observed node in the previous list (if such a transition exists) and with probability $1-\theta_{\mathrm{PV}}$ it moves to a random adjacent node. This search is primarily local, and does not have a strategic component.

Spreading Activation (SA) Classic models of semantic networks (e.g. Collins \& Loftus, 1975) explain priming effects using spreading activation. Each node has an activation value attached to it. An initial activation value of 1.0 is given to the starting node, with all other nodes given an activation of 0.0 . Activation spreads between all nodes through edges, decaying as it propagates through the network with proportion $\theta_{\mathrm{SA}}$ at each step. At each step, after performing a batch update of all node activation values, the search process chooses a node with probability proportional to its activation value. This node is then assigned an activation of 1.0. Note that we bound all activation values to be between 0.0 and 1.0. As activation begins to spread throughout the network, search quickly resembles global search as every node's activation eventually reaches and stays at 1.0. Once this happens, the search returns unobserved nodes with uniform probability.

## Experiment and Simulation Details

In this section, we describe the previous data used to evaluate the search processes, as well as the simulation and parameter fitting procedures.

## Human Data

We use human data from a previously reported experiment (Zemla et al., 2016). In their study, twenty participants were recruited from Amazon's Mechanical Turk. Each participant performed the semantic fluency task three times for three categories (animals, vegetables, and fruit). Participants entered items as they came to mind and hit "Enter" after each item, which notified the participant that the item was recorded and cleared it from the screen. Participants were instructed not to repeat an item within a list, but could repeat items across lists. Categories were pseudo-
randomized so that no participant received the same category twice in a row and each triad of lists contained each category once. For each list, participants were asked to generate as many items as they could from the category in three minutes (with a visible timer). We only analyze the results for the animal category. The data were cleaned after collection, correcting any spelling mistakes, removing pluralizations, and standardizing synonymous animals.

## Simulations

Following previous work (Abbott et al., 2015), we used the University of South Florida (USF) free association data to construct a semantic network (Nelson, McEvoy, \& Schreiber, 2004). This network was constructed by pooling the free association data of 149 participants. Given a set of cue words, participants were asked to generate the first word that came to mind. A semantic network was constructed by drawing edges between each cue-response pair. For our simulations, we used only the largest connected component of the animal subset of the USF network. This network contains 160 nodes, 786 edges, and has an average node degree of 4.91 .

Simulated fluency data was generated for each participant using every search process. The simulated data were yoked to real participant data in two ways: First, the simulated fluency lists were matched in length to real participant lists. For instance, if a participant generated lists containing 25, 30 , and 35 items, a corresponding set of simulated fluency lists would also contain 25, 30, and 35 items. Second, the yoked list always started with the first item of the participant's real list. In some cases, participants generated items that were not in the USF network. For these cases ( $15 \%$ of items), the simulated lists were instead seeded with a close semantic neighbor (as judged by the first author). For example if a participant list started with beagle (not in the USF network), the yoked list would start with dog.

This seeding process ensures that the lists explore different parts of the USF network when applicable. Moreover, it mimics the strong primacy effects seen in the experimental data: thirteen of twenty participants started at least two lists with the same animal, six of whom started all three lists with the same animal. Removing this constraint is likely to overestimate the extent to which participants are able to generate novel animals from list to list. One hundred yoked data sets (sets of three lists, matched for length) were generated for each participant. Clustering and frequency metrics were calculated as the average across all 100 data sets for each participant.

## Parameter fitting

Four of the seven search processes contained one free parameter. The best-fit parameter was found using a grid search which minimized the maximum z-score compared to the human data across all clustering and frequency measures (described below). CRW + RJ, CRW + PV, and SA models searched parameters 0.0 through 1.0 in intervals of 0.05 . For CRW + RJ, the best fitting parameter was 0.0 (no jumping)
and so we chose the second best fit for comparison. The best fit parameters were $\theta_{\mathrm{RJ}}=.6, \theta_{\mathrm{SJ}}=1, \theta_{\mathrm{PV}}=.75$, and $\theta_{\mathrm{SA}}=.25$. CRW, NDS, and CbDFS have no free parameters.

## Quantifying Cluster and Frequency Effects

Although there are many possible statistics based on clusters and frequency, we opt for simple, transparent measures to evaluate and compare the above search processes.

Clustering The clustering of fluency data is evaluated with three measures: cluster size, number of cluster switches, and number of cluster types. Cluster size is the average number of items output from a given cluster before switching to a new cluster. The number of cluster switches is the average number of times a participant switches clusters within a list.

Clusters are determined by assigning each animal to different categories as coded by Troyer et al. (1997) and extended by Hills et al. (2012). We have further extended this coding scheme by including any animals in the data that were not in the coding scheme ( $14 \%$ of animals). Because each animal may belong to multiple categories, determining cluster switch points can be done in multiple ways. We used a fluid switch measure, which counts a cluster switch as any two adjacent items that do not share any categories.

Our third cluster-based statistic is the number of unique cluster types. This is calculated by counting the total number of categories within a list (counting all categories to which an item belongs). Intuitively, the number of unique clusters appears to measure the same thing as cluster switches-but note that a cluster switch does not imply switching to a novel cluster. That is, a participant may switch back and forth between the same two clusters. Nonetheless, participant cluster switches and number of cluster types are highly correlated ( $\mathrm{r}=.74, p<.001$ ).

Frequency We evaluate frequency effects in three ways: the number of unique animals named (unigrams), the number of unique ordered pairs of animals named (bigrams), and the distribution of unigrams. The number of unigrams and bigrams was counted across all three lists. Finally, we calculated the distribution of unigrams in the data: How many items appeared only once, twice, or three times?

## Results

Because simulations were performed on an idealized (USF) semantic network, our discussion of the results focus on the relative patterns of fit. Figure 3 shows error bars (standard error of the mean) to help gauge quantitative fit.

Cluster Size Figure 3a depicts cluster sizes for participants and search processes. On average, participants generated clusters with 2.1 items (SD .44). Processes that behaved like global search (node-degree search and spreading activation) strongly underestimated cluster sizes. Cluster-based depth first search also underestimated cluster size, despite using a local search procedure. This is surprising because clusters are close in a semantic network.

Figure 3. Each clustering and frequency measure is shown for the human data (left) and each search process. (a) Average cluster size per list, (b) Average number of cluster switches per list, (c) Average number of cluster types per list, (d) Number of unique unigrams across three lists, (e) Distribution of unigrams across three lists, (f) Number of bigrams across three lists

The censored random walk produced clusters close in size to the actual human data. Variations of the CRW that included a priming vector ( $\mathrm{CRW}+\mathrm{PV}$ ) or strategic jumps (CRW+SJ) showed very little difference in cluster size compared to the CRW. However the censored random walk with random jumps (CRW+RJ) produced smaller clusters, as compared to CRW and compared to human data. Abbott et al. (2015) had previously explored censored random walks with and without random jumps and found no discernible difference with respect to optimal foraging. Our results suggest that when cluster size is taken into account, the random jump model fits worse.

Cluster Switches Figure 3b shows the average number of cluster switches for participants and search processes. Participants switched clusters an average of 16.85 times per list (SD 5.71). The pattern of cluster switches mimicked the inverse of cluster size-models that underestimated the cluster size overestimated the number of cluster switches. This is not surprising, as participant cluster size and cluster switches are negatively correlated in the data ( $\mathrm{r}=-.45, p=$ .045). Again, processes that relied strictly on global (NDS, SA ) or local (CbDFS) cues overestimated the number of cluster switches. In contrast, the CRW, CRW+SJ, and CRW+PV all closely resembled human performance. However the CRW+RJ suffered from the inclusion of random jumps, overestimating the number of cluster switches.
Number of Cluster Types Figure 3c shows the number of cluster types for participants and search processes. Participants produced an average of 16.7 cluster types per list (SD 2.7). In contrast to the cluster size and switch data,
counting the average number of cluster types per list produced a different pattern of results. Search processes that behaved more like global search (NDS, SA, CRW+RJ) performed closest to the actual data, while other search processes tended to underestimate the number of cluster types encountered.

Of course, processes that rely on global cues will tend to have more breadth than processes that rely on local cues. It is interesting that our participants were able to generate a breadth of cluster types resembling global search, but switch clusters less often (as expected by local search). This suggests that participants try to exploit local clusters, but that when they do switch, they tend to avoid old clusters.

Number of Unique Items (Unigrams) Figure 3d plots the average number of unique items listed by participants and the search processes. Across three lists, participants generated an average of 54.4 unique items (SD 19.8), though an average of 99.4 token items (SD 29.9). CRW+PV and CbDFS both produced lists containing a similar number of unique items as the human participants. Both of these models do so by limiting exploration in different ways. CbDFS will tend to generate similar fluency lists on successive trials as there is no mechanism to make longdistance transitions within the network. CRW + PV will tend to produce similar lists because it will make the same transitions as it has in previous lists with high probability.

Distribution of Unigrams Figure 3e depicts the distribution of unigrams for participants and the search processes. On average, participants listed 23.2 items once, 17.3 twice, and 13.9 three times (SDs 16.3, 7.1, 6.1). The large number of
items listed twice and three times is indicative of priming effects from earlier lists. CRW + PV was the only search process that produced a similar distribution of unigrams (in particular, the large number of items produced three times). The other search processes strongly overestimate the number of items that appear only once, and strongly underestimate the number of items that appear three times.

Number of Bigrams Figure 3f plots the number of bigrams produced by participants and the search processes. Participants listed 87.1 unique bigrams (SD 28.4). Nearly all models produced a similar number of bigrams as people, except for CRW +PV , which produced too few bigrams. Because CRW+PV often follows the same transitions as in previous lists, fewer unique bigrams are generated.

## General Discussion

We explored whether several search processes on a semantic network adequately captured the frequency and clustering effects seen in semantic fluency data. We found that local search processes captured the average cluster sizes and number of clusters, but failed to capture the number of cluster types produced by people. A priming component to the search process is needed to capture the unigram frequency statistics, but this priming component interferes with producing the appropriate number of bigrams. Although none of the search processes captured human behavior on every measure, the censored random walk with priming performed well across many.

More broadly, the censored random walk model (CRW), and its variations that include strategic jumping (CRW+SJ) or recent memory (CRW+PV), captured much of the clustering behavior seen in human data. Search processes that heavily favored only global or local search tended to produce too many cluster switches and underestimate cluster size. Thus, people balance between local and global search. While previous research was not able to discriminate between the CRW model with or without jumps (Abbott et al., 2015), our results suggest that a random jumping model does not capture human performance well.

The search processes were less successful at modeling frequency effects in the data, though CbDFS and CRW +PV produced the best fits. Overall, this suggests that for our experimental procedure-collecting multiple fluency lists from a single participant in a single setting-the censored random walk with priming vector produces the closest fits to human data with respect to clustering and frequency effects. Its performance may be improved by including a strategic component, where it jumps to unvisited nodes or clusters after censoring multiple items in a row. Future research should investigate this and whether the different processes also replicate optimal foraging.

The current work is limited in several ways. It relies on the validity of the USF semantic network, and the assumption of unweighted and undirected edges (De Deyne, Navarro, \& Storms, 2013). This network is constructed from an aggregate of participants, and does not reflect the
variability across participants. While these may not be unreasonable assumptions, we have established a baseline to compare additional search processes in the future. One possibility is to use crossvalidation: with enough lists from each participant, some lists could be used to estimate an individual's semantic network using U-INVITE (Zemla et al., 2016), while the remaining lists are used to evaluate the search processes.

#### Abstract

In this study, we explored the impact of the decision agency (Student vs. Tutor) and granularity (Problem vs. Step) across students with different levels of incoming competence (High vs. Low). Students were randomly assigned to four conditions and split into High and Low groups based on their pre-test scores. All students used the same Intelligent Tutoring System (ITS) called Pyrenees, followed the same general procedure, studied the same training materials, and worked through the same training problems. The only substantive differences among the four conditions were decision agency and granularity. That is: who decided to present an example or to solve a problem: the student or the ITS tutor; and was the decision made problem-by-problem or step-by-step? Our overall results showed that there were significant different impacts of the decision agency and granularity between High and Low students on learning performance. More specifically, for High students granularity was the more dominant factor in that step level decisions can be more effective than problem level decisions regardless of the decision agency; for Low students there was a significant interaction effect in that: Low students benefit significantly more when they were making problem-level decisions than making step-level decisions, but no significant difference was not found when the decisions were made by the tutor. Much to our surprise, both High and Low groups showed strong decision-making preference for problem solving over worked example at both problem and step levels.

Keywords: Aptitude Treatment Interaction, Pedagogical decisions, granularity, student-centered learning,

## Introduction

Certain learners are less sensitive to learning environments and can always learn; while others are more sensitive to variations in learning environments and may fail to learn. In order to fully honor their promises, effective learning environments should exhibit an aptitude-treatment interaction (ATI), that is, its instruction should match to the aptitude of the learner (Cronbach \& Snow, 1977). Intelligent Tutoring Systems (ITSs) are powerful educational technologies that support learning by providing step-by-step support and contextualized feedback adapted to individual learners and ITSs have demonstrated great success in many complex domains (Koedinger \& et al., 1997; Vanlehn, 2006). In our work, we explored the possibility of improving the effectiveness of ITSs from two perspectives: decision agency and granularity. Here we split students into High and Low groups based on their incoming competence and investigated the impact of these two perspectives on ATI: how the decision agency and granularity would impact students' learning across the High and Low groups.
Decision Agency: ITSs are generally designed to support users' learning by providing instructions, scaffolded problem-solving practice and on demand help. Most of existing ITSs are tutor-centered. The tutor is responsible for
selecting the next action to take at any given time. Each of these decisions affects student's successive actions and performance. In learning literature, the skills used to make such decisions are generally referred to as pedagogical skills. More formally, Chi et al. defined pedagogical skills are those "involve skillful execution of tactics, such as giving explanations and feedback or selecting the appropriate problems or questions to ask the students" (Chi, Siler, \& Jeong, 2004). Most ITSs generally employ fixed pedagogical policies that do not adapt to users' needs. For example on most ITSs students are asked to solve a series of training problems while research showed that studying worked examples can be more effective than solving problems and the former generally takes much less time (McLaren \& Isotani, 2011).

On the other hand, previous research showed that it is desirable for students to experience a sense of control over their own learning. For example, Cordova and Lepper (Cordova \& Lepper, 1996) found that offering student choices over their learning could lead to significantly better learning outcome than those who were not offered. Letting students make decisions during the tutorial process should make them feel that they are actively directing their own learning process and not just passively following it. Furthermore, prior research suggested that offering student learning choices often exhibits an ATI effect: students with different levels of competence should be offered with different choices. For example, Young split learners into High vs. Low based on survey results and found that the performance difference between the High and Low learners was significantly greater under learner's control than under system control (Young, 1996). In this paper, we provided the students with different yet both reasonable choices and let them decide how they would like to study the materials and our goal is to investigate how these choices would impact their learning differently across High vs. Low students.

Granularity: Tutoring in domains such as math and science can be viewed as a two-loop procedure (Vanlehn, 2006). In the outer loop, the tutor makes tasks or problem-level decisions such as deciding what problem to solve next, while the inner loop controls step level decisions such as whether or not to give a hint. In educational literature, 'steps' often refer to the application of a major domain principle such as Newton's Third Law of Thermodynamics. Solving a complete problem generally involves applying many individual principles in a logical order. In theory, problem-level decisions are at a larger grain size and thus once students make one 'big' decision, they can focus on comprehending an example or solving a problem. However, such "big" decision
might not be very sensitive to students' specific moment-bymoment needs. For example, offering a complete worked example to students facing difficulty with a single principle may rob them of the chance to exercise other skills. When making step-level decisions, by contrast, students may be better able to tailor their decisions to their immediate needs and current knowledge level. However, making fine-grained decisions often requires more sophisticated decision-making skills. Prior research has shown interleaving worked examples with problem solving in both problem level and step level could result in improved learning performance comparing to doing problem solving only (Van Gog et al., 2011; Salden et al., 2010). However, it remained unclear how worked example and problem solving tasks should be provided to maximize the tutoring effectiveness. Therefore, in this paper, we are going to examine the impact of different decision granularity across learners with different incoming competence.

In this study, we strictly controlled the content to be equivalent for all participants by: 1) using an ITS which provides equal support for all learners; and 2) investigating on tutorial decisions that cover the same domain content at both problem and step levels, in this case Worked Examples (WE) versus Problem-Solving (PS). In WE, students were given a detailed example showing the expert solution for the problem or step. In PS, the students were tasked with solving the same problem or step using the ITS.

Previously we investigated the impact of granularity on the effectiveness of students' pedagogical decisions by comparing students' decisions against tutor's random yet reasonable decisions. Overall, our results showed that there was a significant interaction effect between decision agency (Tutor vs. Student) and granularity (Problem vs. Step) on learning. We found that step level decisions can be more effective than problem level decisions but the students were more likely to make effective pedagogical decisions at problem level than at step level (Zhou et al., 2016). In this paper, we further investigate the impact of decision agency and granularity across students with different levels of incoming competence. Following prior research, we divided students into High and Low groups based on their pretest scores and our primary research question is: would the impact of decision agency and granularity on learning differ between the High and Low students?

## Background

WE/PS, vs. FWE: A number of researchers have examined the impacts of problem-level PS, problem-level WE, vs. Faded Worked Example (FWEs) (Renkl et al., 2002; Schwonke et al., 2009; Najar et al., 2014; Salden et al., 2010). FWEs interleave problem-solving steps with worked example steps within a single problem. Renkl et al. compared WE-PS pairs with FWE using a fixed fading policy (Renkl et al., 2002). In that study the number of example steps and problem-solving actions were strictly equal between the conditions. They found that FWEs with fixed fading policy significantly outperformed the WE-PS pairs, but no significant time-on-task differences were found. Schwonke et
al. compared FWE with a fixed fading policy to tutored PS (Schwonke et al., 2009). Over the course of two studies, they found no significant differences between the two conditions in terms of their learning outcomes. However the FWE group spent significantly less time on task than the tutored PS group. Najar and colleagues compared FWE with an adaptive fading policy to WE-PS pairs. They found that the FWE condition significantly outperformed the WE-PS condition in their learning outcomes and spent significantly less time on task (Najar et al., 2014). Finally, Salden et al. compared three conditions: FWE with a fixed fading policy, FWE with an adaptive fading policy, and PS-only (Salden et al., 2010). They found that the adaptive FWE group outperformed the fixed FWE who, in turn, outperformed PS-only and there is no significant time-on-task differences among three groups.

Thus prior researchers have shown that FWEs with effective pedagogical polices can outperform fixed WE-PS pairs. It has also been shown that the former may need significantly less time on task than the latter. However all of these studies relied on hand-coded tutor pedagogical polices whereas in this study, we investigated how students with different levels of incoming competence would differ on pedagogical decision-making at both problem and step level.
Students Pedagogical Decision on ITS: Prior research on student problem-level decision-making has primarily focused on decisions of choosing instructional content, e.g. problem selection, but not how, e.g. WE vs. PS. Mitrovic et al. showed that learners, even college students, often make poor problem selections (Mitrovic \& Martin, 2003). Long et al. compared the impact of joint student/system control again full system control over problem selection (Long \& Aleven, 2014). In joint control, the system adaptively selects the problem type while the students select the individual problems. They found no significant difference on learning between the joint control groups and the full control group. In another study, Long et al. augmented a ITS with features that help students develop effective problem selection strategies with shared student/system control and compared its effectiveness with full system control ITS (Long \& Aleven, 2016). They found that students in the shared control group learned significantly better than those in the full system control group. The results for student step-level pedagogical decision-making are inconclusive. Aleven \& Koedinger studied students' help-seeking behaviors in the Cognitive Tutor (Aleven \& Koedinger, 2000). They found that students cannot use hints effectively in that they tended to wait too long before asking for hints. Roll et al. by contrast examined the relationship between students' help-seeking patterns and their learning (Roll et al., 2014). They found that asking for help on challenging steps was generally productive while help abusing behaviors were correlated with poor learning. Finally, Wood et al. found that learners with high prior knowledge can exhibit more effective help-seeking behaviors than those with low prior knowledge learners(Wood \& Wood, 1999).

Therefore prior research on students' decision suggests that
students can benefit substantially from effective pedagogical decision-making. Yet they often lack the necessary metacognitive skills to do so. On the other hand, help in ITSs is generally provided on demand, and some students might never need to request. In this study, we controlled for this possible conflict by focusing on WE/PS decisions, and by examining both problem and step-level decision-making. By letting both High vs. Low students make pedagogical decisions, we can fully investigate the impact of decision agency and granularity on learning across students of different levels of incoming competence.

## Our Approach

We will investigate the impact of students' pedagogical decisions on learning by comparing students' decisions to tutors' random decisions at either problem or step level in order to avoid the impact of possibly misguided pedagogical policies. This study is $2\{$ Student, Tutor $\} \times 2$ \{Problem, Step $\}$ design with four conditions: 1) Stud ${ }_{P r o b}$ : problem-level student decisions; 2) Stud $d_{\text {Step }}$ : step-level student decisions; 3) Tut Prob : problem-level random tutor decisions and 4) Tut Step: steplevel random tutor decisions.

## Methods

Participants: This study was conducted in the undergraduate Discrete Mathematics course at the Department of Computer Science at NC State University in the Fall of 2015. 279 students participated in this study, which was given as their final homework assignment.
Conditions: The students were assigned to the four conditions via balanced random assignment based upon their course section and performance on the class mid-term exam. Since the two tutor-random decision groups were already compared in our prior study (Zhou et al., 2015) and the primary goal of this work is to examine the nature and effectiveness of students' pedagogical decision-making and ATI effect, we assigned twice more students to the two studentdecision groups, Stud ${ }_{\text {Prob }} \&$ Stud $_{\text {Step }}$, than the two tutorrandom groups, Tut $_{\text {Prob }} \&$ Tut $_{\text {Step }}$. The final group sizes are as follows: $N=92$ for Stud ${ }_{\text {Prob }}, N=93$ for Stud $_{\text {Step }}, N=47$ for Tut $_{\text {Prob }}$, and $N=47$ for Tut Step.

Due to the holiday break, preparations for final exams, and length of the experiment, 212 students completed the experiment. 11 students were excluded from our subsequent analysis because they performed perfectly on the pretest. The remaining 201 students were distributed as follows: $N=70$ for Stud $_{\text {Prob }} ; N=59$ for Stud $_{\text {Step }} ; N=38$ for Tut Prob $; N=34$ for Tutstep. A $\chi^{2}$ test examining the relation between condition and completion rate showd no significant difference: $\chi^{2}(3)=1.159, p=0.763$.
Probability Tutor -Pyrenees Pyrenees is a web-based ITS for probability. It covers 10 major principles of probability, such as the Complement Theorem and Bayes' Rule. Pyrenees provides step-by-step instruction, immediate feedback and on-demand hints prompting students with what they should
do next. As with other systems, help in Pyrenees is provided via a sequence of increasingly specific hints. The last hint in the sequence, the bottom-out hint, tells the student exactly what to do. For the purposes of this study we incorporated four distinct pedagogical decision modes into Pyrenees to match the four conditions.

Procedure In this experiment, students were required to complete 4 phases: 1) pre-training, 2) pre-test, 3) training on Pyrenees, and 4) post-test. During the pre-training phase, all students studied the domain principles through a probability textbook, reviewed some examples, and solved certain training problems. The students then took a pre-test which contained 10 problems. The textbook was not available at this phase and students were not given feedback on their answers, nor were they allowed to go back to earlier questions. This was also true of the post-test.

During phase 3 , students in all four conditions received the same 12 problems in the same order on Pyrenees. Each primary domain principle was applied at least twice. The minimum number of steps needed to solve each training problem ranged from 20 to 50 . The steps included variable definitions, principle applications and equation solving. The number of domain principles required to solve each problem ranged from 3 to 11 . For the FWE problems, the $S t u d_{\text {Step }}$ students were asked to make decision only on two types of steps: principle selection and principle application. To apply a principle, students need to first choose the principle they will use (principle selection) and then write the appropriate equation to apply it (principle application). We evaluated the students' decisions on both types of steps in our analysis below. The only procedural differences among the four conditions were the decision agency: Student vs. Tutor and the granularity of the decision: Problem vs. Step. Apart from this, the system was identical.

Finally, all of the students took a post-test with 16 problems. Ten of the problems were isomorphic to the pre-test problems given in phase 2. Note that the rest of six questions are non-isomorphic complicated problems.

Grading Criteria: The test problems required students to derive an answer by writing and solving one or more equations. We used three scoring rubrics: binary, partial credit, and one-point-per-principle. Under the binary rubric, a solution was worth 1 point if it was completely correct or 0 if not. Under the partial credit rubric, each problem score was defined by the proportion of correct principle applications evident in the solution. A student who correctly applied 4 of 5 possible principles would get a score of 0.8 . The One-point-per-principle rubric in turn gave a point for each correct principle application. All of the tests were graded in a doubleblind manner by a single experienced grader. The results presented below were based upon the partial-credit rubric but the same results hold for the other two. For comparison purposes, all test scores were normalized to the range of $[0,1]$.

Table 1: Learning Performance

| High Group Students |  |  |  |
| :--- | :--- | :--- | :--- |
| Cond | Pre | Iso Post | Overall Post |
| Stud Prob $(31)$ | $.851(.059)$ | $.909(.111)$ | $.843(.143)$ |

## Results

We split students into High and Low groups based on their pre-test scores. Using a median split of 0.75 and students were divided into: High $(n=99)$ and Low $(n=102)$ groups. As expected, the High group scored significant higher than the Low group: $t(199)=17.462, p<0.0001, d=2.464$. The numbers in the parentheses in the first column of Table 1 shows the numbers of High vs. Low students across the four conditions. No significant difference was found among the four conditions on the distribution of High vs. Low students: $\chi^{2}(3)=1.1879, p=0.7559$.

Fortunately, random assignment balanced the four conditions and this balance persisted even with the groups were subdivided into High and Low. The second column in Table 1 shows the pretest scores of High and Low groups. A one-way ANOVA test on students' pre-test score shows that there is no significant difference among the four conditions: $F(3,197)=1.969, p=0.12$, or the four conditions in High group: $F(3,95)=0.581, p=0.629$ or the four conditions in the Low group: $F(3,95)=0.449, p=0.719$.

## Learning Performance

Table 1 shows a comparison of the pre-test, isomorphic posttest ( 10 isomorphic questions), and overall post-test scores among the four conditions, showing the mean (and SD) for each score.

To investigate the impact of decision agency and granularity on learning performance across High and Low students, two three-way ANOVAs were conducted using decision agency (tutor vs. student), granularity (problem vs. step), and incoming competence (High vs. Low) on the isomorphic post-test scores and the overall post-test scores respectively. For the isomorphic post-test scores, there is a significant three-way interaction effect: $F(1,193)=4.079$, $p=0.045$, a significant two-way interaction effect on decision agency and granularity: $F(1,193)=5.324, p=0.022$, a significant main effect on incoming competence: $F(1,193)=$ 26.23, $p<0.0001$ and a marginal interaction effect on granularity and incoming competence: $F(1,193)=2.854, p=$
0.093. For the overall post-test scores, there is a significant two-way interaction effect on decision agency and granularity: $F(1,193)=4.415, p=0.037$, a significant main effect on incoming competence: $F(1,193)=38.96, p<0.0001$ and a marginal significant interaction effect on granularity and incoming competence: $F(1,193)=3.521, p=0.062$. Overall, our results showed that the impact of decision agency and granularity on learning performance differs significantly between the High and the Low groups. Next we will examine the learning performance of High and Low groups separately.
High Groups A repeated measure analysis using test type (pre-test vs. isomorphic post-test) as factors and test score as the dependent measure showed a main effect for test type $F(1,95)=34.74, p<0.0001$. Thus, overall the High students learned significantly by training on Pyrenees. However, further comparisons on the condition by condition basis revealed that: no significant improvement was found from pre-test to isomorphic post-test for the High Tut Prob group: $F(1,19)=1.817, p=0.194$, but the remaining three High groups showed significant improvement: $F(1,30)=$ $6.385, p=0.017$ for $\operatorname{Stud}_{\text {Prob }} ; F(1,27)=22.58, p<0.0001$ for Stud $_{\text {Step }}$ and $F(1,19)=16.37, p=0.0007$ for Tut Step . This suggests that random problem level pedagogical decisions may not be very effective for High students.

To fully compare the learning performance among the four High groups, a two-way ANOVA analysis using decision agency and granularity as factors was conducted on the overall post-test scores. Our results showed while there is no significant interaction effect, there is a significant main effect on granularity: $F(1,95)=5.504, p=0.021$, that is, the step level decisions are significantly more effective than problem level decisions across the decision agencies. More specifically, the two step level decision groups, Stud Step and Tut $_{\text {Step }}$ scored significantly higher than the Tut Prob group: $t(38)=-2.263, p=0.029, d=0.716$ for the Tut Step group and $t(46)=-2.749, p=0.009, d=0.805$ for the Stud ${ }_{\text {Step }}$ group respectively. For isomorphic post-test scores. Twoway ANOVA analysis showed a marginal main effect on granularity: $F(1,95)=3.563, p=0.062$. Pairwise t-tests showed the StudStep group outperformed the Tut Prob group significantly: $t(46)=-2.178, p=0.035, d=0.638$ and the Tut Step group tended to outperform the Tut Prob group: $t(38)=-1.757, p=0.087, d=0.556$. Therefore, our results showed that step-level decisions are more effective for High group students than problem-level ones.
Low Groups A repeated measure analysis using test type as the repeated factor shows that Low group students learned significantly after training on Pyrenees. $F(1,98)=200.01$, $p<0.0001$. In fact, all four groups made significant improvement from pre-test to isomorphic test: $F(1,38)=117.99$, $p<0.0001$ for Stud $_{\text {Prob }} ; ~ F(1,30)=63.89, p<0.0001$ for Stud $_{\text {Step }} ; F(1,17)=8.537, p=0.010$ for Tut $_{\text {Prob }}$; and $F(1,13)=39.98, p<0.0001$ for Tut Step . This suggests that for Low students, the basic practice and problems, domain exposure, and interactivity of Pyrenees might help students

Table 2: Student Decisions

| Problem Level Decisions |  |  |  |
| :--- | :--- | :--- | :--- |
| Competence | WE | PS | Total |
| High | $1.55(1.31)$ | $8.45(1.31)$ | 10 |
| Low | $1.56(1.48)$ | $8.44(1.48)$ | 10 |
| Step Level Decisions |  |  |  |
| Competence | WE | PS | Total |
| High | $21.14(24.34)$ | $115.07(27.03)$ | 136 |
| Low | $18.84(17.28)$ | $114.26(16.84)$ | 133 |

to learn even when the problem- and step-level decisions are made randomly.

A two-way ANOVA analysis using decision agency and granularity on isomorphic post-test showed a significant interaction effect across the four Low groups: $F(1,98)=5.819$, $p=0.018$. Post hoc Pairwise t-test reveals that the Stud $d_{\text {Prob }}$ Low group scored significantly higher than the Stud Step Low group: $t(68)=2.591, p=0.012, d=0.624$. For overall posttest, our two-way ANOVA showed a marginal interaction effect: $F(1,98)=3.591, p=0.061$. Pairwise t -tests showed a trend that the $S_{t u d_{\text {Prob }}}$ group outperformed the $S_{t u d_{\text {Step }}}$ group: $t(68)=1.903, p=0.061, d=0.458$. Therefore, our results showed that Low group students benefited more from making problem level decisions than step level ones and no significantly difference was found between the two tutor decision groups: Tut Prob and Tut Step.

To summarize, our results showed that: 1) for the High group, step level decision was more effective 2) for the Low group, letting students make problem level decisions can be more beneficial than letting them make step level decisions.

## Student Pedagogical Decisions and Training Time

Student Decisions Much to our surprise, our analysis on students' decision-making preference revealed that both High and Low Groups are far more likely to choose problem solving than worked examples. For the tutor decision groups, our random policies generated a balanced 50-50 selection of WE and PS. Table 2 shows the number of pedagogical decisions made by students at both problem level and step level. Columns 2 and 3 show the average number of worked examples and problem-solving decisions made by each group. We required all students to solve two problems in order to familiarize them with Pyrenees. Therefore each student in problem-level condition made or received 10 problem-level decisions. Within each of the 10 problems, there are 6 to 24 step-level decisions. Therefore each student in step-level condition made or received about 135 step level decisions. In the following, we will compare the decision making preference across High and Low groups.

We compared the percentage of WEs students selected among different groups. For problem level decisions, both High and Low groups selected around $15 \%-16 \%$ of WEs on average. That is, both groups chose significantly less WEs than the two corresponding tutor groups: $t(49)=8.717, p<$
$0.0001, d=2.500$ for the High groups and $t(55)=-10.668$, $p<0.0001, d=3.040$ for the Low groups. The results for step level decisions are similar. High group students chose an average of $15.52 \%$ WE steps; while Low group students chose $14.16 \%$. Again, both groups chose significantly less WEs than the two corresponding tutor decision groups: $t(46)=8.920, p<0.0001, d=2.612$ for the High groups and $t(43)=10.27, p<0.0001, d=3.308$ for the Low groups. The results suggested that students were significantly more likely to choose PS than WE at both levels.

Training Time Given that our results showed that the type of student decisions was not impacted by granularity and our preliminary results showed that similar patterns were found across the two different granularities on the training time. In the following, we will combine the step and problem level decision groups and mainly focus on the impact of the decision agency on time on task for High vs. Low students.

Despite the fact that students selected more PS, surprisingly, not all of them spent more time on learning comparing to those received equal number of PS and WE from the tutor. Table 3 shows the average total training time on Pyrenees (in seconds). A two-way ANOVA analysis examining the effect of incoming competence and decision agency shows a marginal significant interaction effect: $F(1,196)=3.345$, $p=0.069$. More specifically, while no significant difference was found between the two High groups, there is a significant difference between the two Low groups in that the student decision group spent significantly more time on training than the tutor decision group: $t(99)=-2.272, p=0.025, d=0.490$.

Since student decision groups chose more PS than WE and PS is generally more time consuming than WE, we further investigated the impact of decision agency on training time by comparing the average time on each WE step and PS step. The third and fourth columns in Table 3 shows the average amount of time students spent on each WE and PS steps respectively. For the average WE step time, no significant difference was found among the four groups. For the average time on PS steps, a two-way ANOVA on decision agency and incoming competence showed a significant main effect of decision agency: $F(1,196)=14.53, p=0.0002$. That is the student decision groups spent significantly less time on each PS step than the tutor decision groups. Pairwise t-test showed that this difference is significant for both High and Low groups: $t(97)=6.118, p<0.0001, d=1.253$ for the

Table 3: Time Results

| High Group Students |  |  |  |
| :--- | :--- | :--- | :--- |
| Cond | Total | WE | PS |
| High $_{\text {Stud }}$ | $7977(1811)$ | $9(10)$ | $35(8)$ |
| High $_{\text {Tut }}$ | $8041(2503)$ | $8(5)$ | $51(18)$ |
| Low Group Students |  |  |  |
| Low $_{\text {Stud }}$ | $8612(2428)$ | $9(9)$ | $39(10)$ |
| Low $_{\text {Tut }}$ | $7457(2179)$ | $9(7)$ | $50(16)$ |

High group and $t(99)=3.888, p=0.0002, d=0.839$ for the Low group. Therefore, students worked faster on PS steps when they made decisions than when tutor decided.

## Discussion

In this study, we investigated the impact of decision agency (student vs. tutor) and granularity (problem vs. step) on learning across students with different levels of incoming competence (High vs. Low). Students were randomly assigned to four experiment conditions and split into High and Low groups based on their pre-test scores. Our results showed that all four Low groups and three out of four High groups (except the High Tut Prob group) learned significantly after training on Pyrenees. In general, the Low students learned more than their High peers. This suggests that the training of Pyrenees is generally effective especially for low students.

We found that there were significantly different impacts of decision agency and granularity across High and Low students. For the High ones, granularity is the more dominant factor in that the two step-level groups significantly outperformed the two problem-level decision groups on the overall post-test. For the Low groups, there is a significant decision agency and granularity interaction effect: while no significant difference was found between the two Low tutor decision groups, the Low Student Problem-level group learned significantly more than the Low Student Step-level group. The results suggest that for High students step level decisions can be more effective than problem level decisions, but for Low students making problem level decisions are more beneficial than making step level ones.

Surprisingly, both High and Low students selected more problem solving than worked example at both problem and step level. However, students worked faster on PS steps when they selected them than received them. A potential explanation is that the control of their own learning process produced increases in motivation and depth of engagement. Currently, we are applying Reinforcement Learning (RL) to induce effective pedagogical policies based on which we will derive a methodology for teaching effective pedagogical decisionmaking strategy. After that, we will augment our ITS with decision-making development features to help students learn those strategies and examine its effectiveness.

# Information Seeking as Chasing Anticipated Prediction Errors 

Jian-Qiao Zhu (j.zhu@warwick.ac.uk)<br>Wendi Xiang (wendi.xiang11@gmail.com)<br>Elliot A. Ludvig (e.ludvig@warwick.ac.uk)<br>Department of Psychology, University of Warwick<br>Coventry, UK CV4 7AL

#### Abstract

When faced with delayed, uncertain rewards, humans and other animals usually prefer to know the eventual outcomes in advance. This preference for cues providing advance information can lead to seemingly suboptimal choices, where less reward is preferred over more reward. Here, we introduce a reinforcement-learning model of this behavior, the anticipated prediction error (APE) model, based on the idea that prediction errors themselves can be rewarding. As a result, animals will sometimes pick options that yield large prediction errors, even when the expected rewards are smaller. We compare the APE model against an alternative information-bonus model, where information itself is viewed as rewarding. These models are evaluated against a newly collected dataset with human participants. The APE model fits the data as well or better than the other models, with fewer free parameters, thus providing a more robust and parsimonious account of the suboptimal choices. These results suggest that anticipated prediction errors can be an important signal underpinning decision making.

Keywords: information seeking; early resolution of uncertainty; anticipated prediction errors; forward sampling.

## Introduction

Humans and other animals have a strong preference for informative options. They are inherently curious and will explore unknown options, even sacrificing rewards to resolve an uncertain outcome early. Sometimes the search for predictive information can be independent of profit and have no effect on the delivery of primary rewards, as if consuming information itself was rewarding (Wyckoff, 1952; Prokasy, 1956; Bromberg-Martin \& Hikosaka, 2009; Iigaya, Story, KurthNelson, Dolan, \& Dayan, 2016). On occasion, this information seeking can lead to seemingly suboptimal behaviors with animals preferring options with lower expected values (Spetch, Belke, Barnet, Dunn, \& Pierce, 1990; Roper \& Zentall, 1999). In this paper, we develop a new computational model of this information-seeking behaviour based on the idea that animals' choices reflect both the expected rewards and the anticipated prediction errors from any upcoming cues.

This preference for advanced information has been widely observed across species, including rats (Prokasy, 1956; Chow, Smith, Wilson, Zentall, \& Beckmann, 2016), pigeons (Spetch et al., 1990), starlings (Vasconcelos, Monteiro, \& Kacelnik, 2015), monkeys (Bromberg-Martin \& Hikosaka, 2009, 2011; Blanchard, Hayden, \& Bromberg-Martin, 2015), and humans (Iigaya et al., 2016). In some cases, animals even give up food or water for advance information about impending rewards, even though these advanced signals do not change the eventual reward. For example, pigeons reliably choose an alternative that provides delayed access to food $50 \%$ of the time over one that always provides the same
amount of food with the same delay, but only when an immediate cue is provided, which signals to the pigeons whether or not food will eventually be available on that trial (Spetch et al., 1990; Gipson, Alessandri, Miller, \& Zentall, 2009). The choice of the $50 \%$ option is clearly suboptimal in terms of reward-intake maximization. Similarly, when choosing between delayed, probabilistic rewards, monkeys and humans will prefer an option that informs them about the eventual outcome of that trial over one that leaves the resolution of uncertainty to the time of reward delivery (Bromberg-Martin \& Hikosaka, 2009, 2011; Iigaya et al., 2016).

In addition to the presence of advance information, a few variables have proven critical to the emergence of this suboptimal choice (see McDevitt, Dunn, Spetch, and Ludvig (2016) for review). First, the contingencies between the predictive cues and the outcomes is important because it influences the amount of uncertainty resolved by the cues: The more information conveyed by the predictive cues, the more preferred the associated choice target (Bromberg-Martin \& Hikosaka, 2009). Second, humans and other animals also exhibit a preference for earlier advanced notice of the eventual outcome. Increased information seeking has been found in the case of longer delays (Spetch et al., 1990; Iigaya et al., 2016). Third, the subjective value of advance information scales with the reward magnitude of the potential outcomes (Blanchard et al., 2015). Finally, aversive outcomes can sometimes produce outright information avoidance in human subjects, as in the Ostrich effect (Karlsson, Loewenstein, \& Seppi, 2009).

Given this rich set of empirical findings, we endeavored to build a computational model that can capture as many of these empirical results as possible, but first we briefly review the existing computational models for this information-seeking behaviour.

## Existing Computational Models

The apparent departures from optimality observed when advance information is available poses a significant computational challenge to standard models of reinforcement learning (RL) (Niv \& Chan, 2011). Previous research has explored several possible extensions and refinements to the usual RL framework, including the information bonus model (Bromberg-Martin \& Hikosaka, 2011), the disengagement model (Beierholm \& Dayan, 2010), and the anticipatory utility model (Iigaya et al., 2016). The information bonus model encapsulates the idea that receiving advance information acts as if it were a primary reward. This information bonus has alternatively been operationalized as either a free parameter
(Bromberg-Martin \& Hikosaka, 2011) or as the Shannon entropy of the reward probability (Bennett, Bode, Brydevall, Warren, \& Murawski, 2016). These ideas successfully explain the observed preference for more informative options (Bromberg-Martin \& Hikosaka, 2009). Formalizing the information bonus as the Shannon entropy, however, fails to deal with, for instance, the fact that animals prefer to observe more even when the number of bits they receive by doing so is less (Roper \& Zentall, 1999). On the other hand, without using Shannon entropy, the information bonus cannot capture the relationship between information seeking and probability, which resembles an inverse U-shaped function (Green \& Rachlin, 1977).

The anticipatory utility model is a recently proposed alternative model for these data, which formalizes the economic idea of savouring (Loewenstein, 1987; Iigaya et al., 2016). According to this model, animals are hypothesized to enjoy or savour the anticipation of guaranteed rewards to come. Anticipatory utility alone, however, cannot explain why the delay to reward would influence how much the informative option is preferred (Spetch et al., 1990; Iigaya et al., 2016). This limitation emerges because delay renders anticipatory utility less rewarding at the same speed as the primary reward. To rectify this, an additional boosting mechanism was introduced to enhance anticipatory utility, and thereby slow down effect of discounting future rewards (Iigaya et al., 2016). The full model, including this boosting mechanism, explains a wide range of information-seeking behaviours, including many of the properties of sub-optimal choice. One challenge for the anticipatory utility model is how such a mechanism could be learned locally, as the computations require full knowledge of the eventual time to reward in advance (Niv \& Chan, 2011).

## The Anticipated Prediction Error Model

Given these limitations on prior models, here, we develop an alternative formalism centered around the idea of anticipated prediction errors (APE). According to the APE model, animals draw one-step samples of their anticipated futures from a simple model of the world and calculate the prediction error that would be associated with that sample. These anticipated prediction errors are then treated as though they were rewarding in and of themselves, reminiscent of how momentary subjective well-being correlates with prediction errors (Rutledge, Skandali, Dayan, \& Dolan, 2014). These samples are biased such that futures which contain positive prediction errors are more likely to be sampled. This forward sampling (i.e. anticipation) from the current state using imagined experiences and learned environmental dynamics, such as developed in the Dyna-2 architecture (Silver, Sutton, \& Müller, 2008), can provide useful anticipatory signals that guide decision making. The critical difference between the APE model and the standard RL model is that the APE model maintains two separate valuation systems: one estimated from actual experience (model-free), and the other estimated through this forwardsampling process (model-based). The prediction errors gen-
erated via the forward traces are called anticipated prediction errors (APEs). Together with the conventional value functions, these APEs drive the preference to seek or avoid certain future states. The bias in the sampling process toward positive prediction errors can even induce suboptimal choices.

## Model Specification

We extend the standard Temporal-difference (TD) model (Sutton \& Barto, 1998) where agents are assumed to estimate an action-value function for each experimental stimulus:

$$
\begin{equation*}
Q\left(s_{t}, a_{t}\right)=\mathbb{E}\left[\sum_{k=1}^{\infty} \gamma^{k} r_{t+k-1}\right] \tag{1}
\end{equation*}
$$

where $t$ indexes time, $s_{t}$ specifies the state visited at time $t$, $r_{t}$ indicates the immediate reward delivered at time $t$, and $\gamma \in$ $[0,1)$ is a discount factor, which devalues delayed rewards. This action-value function represents the expected discounted future reward. In TD learning, this action-value function is estimated through a simple incremental update mechanism:

$$
\begin{equation*}
Q\left(s_{t}, a_{t}\right) \leftarrow Q\left(s_{t}, a_{t}\right)+\alpha \delta_{t+1} \tag{2}
\end{equation*}
$$

where $\alpha$ is the learning rate and $\delta$ is the reward prediction error (RPE), calculated as follows:

$$
\begin{equation*}
\delta_{t+1}=r_{t+1}+\gamma \max _{a} Q\left(s_{t+1}, a\right)-Q\left(s_{t}, a_{t}\right) \tag{3}
\end{equation*}
$$

This RPE signal represents the difference between the value of the current state-action pair and the value of the best next-state-action plus the reward achieved in the transition. Thus, RPEs are triggered by each state transition; the mechanics of the APE model hinge on the transition from choice to the predictive cues which reveals what the eventual outcomes will be on that trial. In particular, a good cue, which resolves reward uncertainty appealingly, will generate positive RPEs, whereas a bad cue will generate negative RPEs. The RPEs will be zero in response to non-predictive cues, once the values are well learned.

Here, we define anticipated prediction errors (APE) as the perceived discrepancy between the current state (what it is like at present) and an anticipated future state (how it would be in the future) (see Figure 1). Formally, if there is no immediate primary reward delivered during the trajectory from state $s$ to $s^{\prime}$ (e.g., the transition from choice state to cue states in the information choice task), then the value of APE in state $s$ when anticipating future state $s^{\prime}$ is defined as the product of prediction errors between the two states and the transition probability:

$$
\begin{equation*}
A P E\left(s^{\prime} \mid s, a\right)=T\left(s^{\prime} \mid s, a\right) \times\left[\gamma_{s s^{\prime}}^{D_{a^{\prime}}} \max Q\left(s^{\prime}, a^{\prime}\right)-Q(s, a)\right] \tag{4}
\end{equation*}
$$

where $D_{s s^{\prime}}$ is the time taken to travel from $s$ to $s^{\prime}$, and $T\left(s^{\prime} \mid s, a\right)$ is the transition probability from $s$ to $s^{\prime}$ by taking action $a$. In the simulations here, this travel time is always taken to be 1 , but the formulation is more general.

$\longmapsto$ choice $\longmapsto$ cue period $\longrightarrow$, outcomes $\longrightarrow$

Figure 1: Formal representation of the information-choice task as a Markov Decision Process (MDP). Two offers (red and blue circles) are presented and the animal must choose one of them. A cue then appears after this initial choice, which is either informative (green $S^{+}$indicates a rewarding outcome, and yellow $S^{0}$ indicates a neutral outcome) or uninformative (black $S^{*}$ leaving the animal in a state of uncertainty). Following a delay ( $T_{\text {delay }}$ ), the animal obtains the outcome (reward or no reward). The anticipatory signals proposed by the APE model are illustrated as purple dashed lines.

Note that this computation relies on the samples generated based on the learned environment dynamics. The primary assumption of the APE model is that humans and other animals treat APEs as though they were rewarding, whereby positive APEs are reinforcing and negative APEs punishing. The APEs are positive when the anticipated value of the future sampled state is better than value of the present state and negative in the opposite case. These quantities can also be understood as measurements of the pleasure (displeasure) one derives from anticipating the good cue (bad cue). Furthermore, attention weights are assigned to each individual APE, specifying the relative likelihood that a particular future state will be sampled. Accordingly, the decision value $\bar{Q}$ of taking action $a$ is defined as the weighted sum of APEs for anticipated future outcomes plus the value function for the corresponding state:

$$
\begin{equation*}
\bar{Q}(s, a)=\sum_{s_{k} \in \mathcal{S}} w_{k} A P E\left(s_{k} \mid s, a\right)+Q(s, a) \tag{5}
\end{equation*}
$$

where $\mathcal{S}$ denotes the set of all possible future states after taking action $a$ at the state $s$ that a subject can attend to.

Given the decision values of both the cued and the uncued options, the softmax function is then used to compute the probability of choosing the cued option:

$$
\begin{equation*}
P(a)=\frac{e^{\beta \bar{Q}(s, a)}}{\sum_{a^{\prime} \in \mathcal{A}} e^{\overline{\bar{Q}}\left(s, a^{\prime}\right)}} \tag{6}
\end{equation*}
$$

where $\mathcal{A}$ is the set of all possible actions at state $s$, and $\beta$ is an inverse temperature parameter, which controls the degree of exploration.

## Experiment

We conducted an empirical experiment to evaluate the quality of the APE model in comparison with the informationbonus model discussed above. In the experiment, people were repeatedly given a choice between an informative or non-informative option, where the outcomes were delayed 20s. Outcomes were either positive (erotic images), neutral (images of objects) or negative (aversive images). Good trials involved positive or neutral images, Mixed trials involved positive or negative images, and bad trials involved negative or neutral images. These outcomes were always delivered with 50/50 odds on each trial. Qualitatively, the APE model predicts that people will seek information in the positive and mixed cases, but not the negative cases. This prediction emerges from bias toward sampling future states with positive outcomes. The information bonus model would expect equivalent information seeking in all cases, as the amount of information present is equal in all three types of choices.

## Methods

Participants Eighty human participants were recruited from the Warwick University SONA system. All participants gave informed consent and were paid a flat rate of 5 pounds for their participation.

Task Participants performed the experiment on Windows PCs running PsychoPy (Peirce, 2007). The task was a simple two-alternative forced choice between an uncued target (Keep It Secret), which was followed by a non-predictive cue, and a cued target (Find Out Now), which was immediately followed by predictive cues that signalled the eventual outcome. Choosing either the cued or the uncued option did not alter the odds nor the eventual outcomes. The only difference between the two options was the presence or absence of advance information about those eventual outcomes. After choice, the cue was present for 20 seconds in all trials. The outcome image was presented immediately at the end of this cue. To ensure participants viewed the image, they had to press a randomly selected key (indicated on the image proper) to advance to the next trial.

The experiment consisted of three different conditions in terms of the valence of eventual outcomes. In the Good condition, the gamble included $50 \%$ erotic images and $50 \%$ neutral images (as illustrated in Figure 2). In the Bad condition, the gamble included $50 \%$ aversive images and $50 \%$ neutral images. In the Mixed condition, the gamble included $50 \%$ erotic images and $50 \%$ aversive images. The images used in the experiment were previously validated in the International Affective Picture System (Lang, Bradley, Cuthbert, et al., 1999). Sixteen images from the "EroticCouple" category were selected as positive images for heterosexual subjects and another 16 images from "Mutilation" category were selected as the aversive images. Images were chosen as the rewards
so that they could be consumed immediately, as opposed to monetary rewards (Crockett et al., 2013). All participants completed 16 interleaved trials for each condition, making 48 trials in total. Participants were informed about the nature of the potential outcomes before the experiment started.

Figure 2: Human information choice task. The diagram illustrates the Good condition, which contains a gamble of $50 \%$ erotic and $50 \%$ neutral images. The experiment also tested a Bad condition ( $50 \%$ aversive and $50 \%$ neutral images) and a Mixed condition (50\% erotic and 50\% aversive images).

## Results

A total of 69 heterosexual participants ( 48 female and 21 male) completed the task. Eleven participants were excluded (6 non-heterosexual, 4 did not disclose their sexual orientation, and 1 did not complete the task). Only the data from the last nine trials per condition are reported here.

As shown in Figure 3, participants chose the cued option on average $42.8 \% \pm 8.2 \%, 60.2 \% \pm 7.6 \%$, and $71.8 \% \pm$ $6.5 \%$ in the Bad, Mixed, and Good conditions respectively. Choices in the Good condition and the Mixed condition were significantly higher than chance responding (Good: $t(68)=6.72, p<0.001, d=1.143$; Mixed: $t(68)=2.68, p=$ $0.009, d=0.456$ ). In the Bad condition, people chose the informative slightly below chance, but not significantly so $(t(68)=-1.75, p=0.085, d=-0.297)$. There were, however, considerable individual differences in the preferences for advance information (dashed grey lines in Figure 3). This pattern of responses qualitatively agree with the predictions of the APE model, but not the information-bonus model.

## Model Comparisons

Next, we attempted a quantitative model comparison, fitting both the APE model and the information-bonus model to the individual choice proportions in the current dataset.

To fit the APE model to the data, first note that the expected rewards for both options are held constant in the ex-

Figure 3: Mean percentage of choosing cued option (Find Out Now) in the Bad, Mixed, and Good conditions. Error bars indicate $\pm$ SEM in mean choice proportions. The dashed black line indicates the $50 \%$ choice probability. The dashed grey lines are individual choice probabilities.
perimental task, $Q($ cued $)=Q$ (uncued). In addition, receiving non-predictive cues leaves participants equally uncertain about the eventual outcomes, and thus sampling from those states does not generate any anticipated prediction errors, $A P E\left(S^{*} \mid\right.$ uncued $)=0$. This analysis suggests that only the APEs related to the predictive cues determine choices in the current task. Following this logic, from equation (5), we can calculate differences in the action values of the cued and uncued options in the Good, Bad, and Mixed conditions, respectively as follows:

$$
\begin{align*}
\Delta \bar{Q}_{\text {Good }} & =w^{+} A P E\left(S^{+} \mid \text {cued }\right)+w^{0} A P E\left(S^{0} \mid \text { cued }\right)  \tag{7}\\
& =\left(w^{+}-w^{0}\right) \frac{\gamma^{T} R}{4}  \tag{8}\\
\Delta \bar{Q}_{\text {Bad }} & =w^{-} A P E\left(S^{-} \mid \text {cued }\right)+w^{0} A P E\left(S^{0} \mid \text { cued }\right)  \tag{9}\\
& =\left(w^{0}-w^{-}\right) \frac{\gamma^{T} R}{4}  \tag{10}\\
\Delta \bar{Q}_{\text {Mixed }} & =w^{+} A P E\left(S^{+} \mid \text {cued }\right)+w^{-} A P E\left(S^{-} \mid \text {cued }\right)  \tag{11}\\
& =\left(w^{+}-w^{-}\right) \frac{\gamma^{T} R}{2} \tag{12}
\end{align*}
$$

where $T$ is the length of the delay, $R$ is the absolute magnitude of rewards or punishment, and $S^{+}, S^{-}, S^{0}$ are the cues indicating positive, negative, or neutral outcomes. The weight factors are associated with their corresponding future states. Note that only the differences in weights matter for model behavior.

Any individual differences are reflected by the weight pa-
rameters in the APE model. The APE model predicts no preference for advance information when $w^{+}=w^{-}=w^{0}$. We hypothesize that the differences in weights for various future outcomes give rise to information seeking or avoidance behaviors. The preferences for advance information would arise, for instance, in the Mixed condition if the model weights $S^{+}$more heavily than $S^{-}: w^{+}>w^{-}$.

As described above, the information-bonus model (Bromberg-Martin \& Hikosaka, 2011) assumes that information has an intrinsic value, $r_{\text {info }}$, which in our setting was delivered upon each state transition to an informative cue state. This model would predict the differences in decision values as follows:

$$
\begin{equation*}
\Delta \bar{Q}=r_{\text {info }} \tag{13}
\end{equation*}
$$

for all situations where information is sometimes available. We also considered a potential extension to the informationbonus model which would assign different values to different types of information: $r_{\text {info }}^{+}, r_{\text {info }}^{-}, r_{\text {info }}^{0}$ for viewing reward predicting cues, punishment predicting cues, and neutrality predicting cues respectively.

## Model Fitting

The models were fit to the the data using hierarchical Bayesian modeling (Huys et al., 2011), in which the maximum a posteriori estimate of each parameter $h_{i}$ for each participant $i$ is calculated. These parameters are treated as a random sample from a Gaussian population distribution with means and variance $\theta=\left\{\mu_{\theta}, \Sigma_{\theta}\right\}$. Model comparison was based on the integrated Bayesian Information Criteria (iBIC) scores with an uninformative prior. As such, we analyzed the log likelihood $p(D \mid M)$ of each model directly:

$$
\begin{align*}
p(D \mid M) & =\int p(D \mid \theta) p(\theta \mid M) d \theta  \tag{14}\\
& \approx-\frac{1}{2} \mathrm{iBIC}  \tag{15}\\
& =\log p\left(D \mid \theta^{M L}\right)-\frac{1}{2}|M| \log |D| \tag{16}
\end{align*}
$$

where $|D|$ is the number of choices made by all participants, and $|M|$ is the number of parameters fitted. We compute the $\log p\left(D \mid \theta^{M L}\right)$ as the sum of integrals over individual parameters:

$$
\begin{align*}
p\left(D \mid \theta^{M L}\right) & =\sum_{i} \log \int p\left(D_{i} \mid h\right) p\left(h \mid \theta^{M L}\right) d h  \tag{17}\\
& \approx \sum_{i} \log \frac{1}{K} \sum_{k=1}^{K} p\left(D_{i} \mid h_{k}\right) \tag{18}
\end{align*}
$$

where the integrals are replaced by a sum over samples from the empirical prior. This step ensures that we evaluate how well the model fits the data only using information about the group parameters.

As a result, the iBIC penalizes for model complexity, and the model with the lowest iBIC is taken as the best-fitting
model. As shown in Table 1, the best-fitting APE model vastly outperformed the different information-bonus models. We use the iBIC score of the best fitted model as a baseline and derive the differences in iBIC as $\Delta \mathrm{iBIC}$.

Table 1: Quality of model fit to behavioral data

| Model | Free parameters | Model iBIC | $\Delta \mathrm{iBIC}$ |
| :--- | :--- | :--- | :--- |
| APE | $w^{+}-w^{-}, w^{-}-w^{0}$ | 2065.1 | 40.4 |
| APE | $w^{+}-w^{-}, w^{-}-w^{0}, \gamma$ | 2126.3 | 101.6 |
| APE | $w^{+}-w^{-}, w^{-}-w^{0}, \beta$ | $\mathbf{2 0 2 4 . 7}$ | $\mathbf{0 . 0}$ |
| APE | $w^{+}-w^{-}, w^{-}-w^{0}, \beta, \gamma$ | 2137.2 | 112.5 |
| Info Bonus | $r_{\text {info }}$ | 2361.5 | 336.8 |
| Info Bonus | $r_{\text {info }}, \beta$ | 2430.8 | 406.1 |
| Info Bonus | $r_{\text {info }}^{+}, r_{\text {info }}^{-}, r_{\text {info }}^{0}$ | 2098.8 | 74.1 |
| Info Bonus | $r_{\text {info }}^{+}, r_{\text {info }}^{-}, r_{\text {info }}^{0}, \beta$ | 2081.0 | 56.3 |

## Discussion

We have introduced a novel model of information-seeking in choice, which assumes that preferences are driven by anticipated prediction errors (APEs) accumulated through simulated forward trajectories. These APEs are treated like rewards, which combined with a bias toward sampling trajectories with positive outcomes, leads to information seeking in situations with potential positive outcomes. The model was compared against an information-bonus model through a novel empirical experiment, whereby people were given the opportunity to get early information about rewarding or aversive outcomes. As the APE model predicted, and contrary to the information-bonus model, people only sought early information for positive outcomes. Quantitative model selection supported these conclusions.

In addition to better fitting the novel dataset, the APE model provides potential insights into other types of information-induced sub-optimal choices (McDevitt et al., 2016). For example, the positive APE scales with the probability of reward (larger with lower probabilities), providing a mechanism through which a lower probability reward could be preferred to a higher probability one, as sometimes observed in animals (Spetch et al., 1990; Roper \& Zentall, 1999; Gipson et al., 2009). In addition, unlike an information bonus, the APE is sensitive to the magnitude of reward and would grow with larger rewards leading to greater preference for informative options, as observed with information-seeking in monkeys (Blanchard et al., 2015). Future work will require direct simulation of these other findings, as well as further comparison to existing models, including the different information-bonus models (BrombergMartin \& Hikosaka, 2011; Bennett et al., 2016) and the anticipatory utility model (Iigaya et al., 2016).

The current experimental protocol only involved a shallow decision tree, and the corresponding APE model presented here only used one-step anticipation. For decision
trees with high branching factors and/or larger depths, however, it would be computationally intractable to sample from all possible forward trajectories. For example, one recent study used a four-stage information-seeking game, and observed systematic deviations from the optimal strategy (Hunt, Rutledge, Malalasekera, Kennerley, \& Dolan, 2016). This type of task poses yet another computational challenge for all the models discussed here. The APE model, which already involves look-ahead experiences, is readily adaptable to incorporate other, more sophisticated, planning algorithms such as Monte-Carlo tree search (Coulom, 2006). This potential extension of the model to more complex tree search remains a question for further research.

#### Abstract

The relationship between confidence and accuracy has been modeled many times. This paper compares and contrasts three decision-making mathematical models (2DSD, Poisson, RTCON2) of confidence and investigates how each model predicts the effects of interruptions on accuracy, decision response time, confidence, and confidence response time.

Keywords: 2DSD; Poisson model; RTCON2; confidence; accuracy; interruptions; response time; decision-making

## Introduction

In 2016, the U.S. Justice Department released guidelines for law enforcement on how to collect confidence judgments for witness identification ("Justice Department Issues New Guidance On Securing Eyewitness IDs," 2016). These evidence-based guidelines consider the role memory plays in confidence judgments.

Memory researchers have found that the more an item is rehearsed in memory, the more confident a person will be in the accuracy of that retrieval (Busey, Tunnicliff, Loftus, \& Loftus, 2000). For witnesses, repeating a testimony prior to trial is not uncommon. As a result, by the time a trial occurs, the confidence a witness has about their testimony has increased beyond the confidence of their first testimony (Wixted, Mickes, Clark, Gronlund, \& Roediger III, 2015).

Inflated confidence is a concern for the justice system because of the often replicated finding that the relationship between accuracy in memory and confidence is positive (DeSoto \& Roediger, 2014; Dunlosky \& Metcalfe, 2008; Roediger \& DeSoto, 2014; Roediger III \& Desoto, 2012; Roediger III \& DeSoto, 2014; Wixted et al., 2015). Because this positive relationship is often noticed by laypersons, jury's mistake inflated witness confidence for accuracy. The Justice Department encourages law enforcement to guard against inflated confidence by recording confidence during
the first testimony so as to better reflect the accuracy that the testimony happened as described.
.Although this policy change at the U.S. Justice Department is likely to result in higher quality evidence in courtrooms, formally modeling the relationship between confidence and accuracy has been very difficult because it has been hard to determine when confidence judgments begin. There have been many attempts to model the relationship between confidence and accuracy (see Dunlosky \& Metcalfe, 2008; Pleskac \& Busemeyer, 2010; Ratcliff \& Starns, 2013 for a review). It seems intuitive that the process of forming a confidence judgment should begin after some choice has been made. However, Petrusic \& Baranski (2003) showed that when a confidence judgment was required, participant's response times for the primary choice were longer than when the confidence judgment was not required. Petrusic \& Baranski (2003) interpreted this finding to mean that at least some of the processing for a confidence judgment occurs during the primary judgment. As a result, many researchers have attempted to extend previous models of primary choice to account for confidence judgments.

Three of the most popular models to attempt to explain confidence judgments are 2DSD (Pleskac \& Busemeyer, 2010), the Poisson model (Merkle \& Van Zandt, 2006; Van Zandt \& Maldonado-Molina, 2004), and RTCON2 (Ratcliff \& Starns, 2009, 2013). Each model relies on sequential sampling to determine the selection of a choice. Sequential sampling models assume that information is collected from memory or sensory input and summatively translated to evidence towards a particular choice.

Evidence collection through sequential sampling is a common theme across all three models. According to each model, choice is based on the collection of evidence. Evidence is collected until a threshold is reached for one of
the choice alternatives. Crossing a threshold and the subsequent response (e.g key-press) is the decision time for a primary choice. The primary choice is the evidence accumulation and response to questions like "Did you see item ' $A$ ' or item ' $B$ ' before?' Confidence time is the time it takes to make a confidence judgment about the probability that the primary choice was correct. The confidence judgment is a secondary choice in response to questions like "How would you rate your confidence on a Likert scale of 1 to 6 ?" Thresholds are variable and so can be determined in a trial-by-trial and person-to-person basis (Audley, 1960; D. Vickers, 1970; Douglas Vickers, 2014).

Below is a description of each of the three models. The goal is to briefly summarize each model and highlight how each model suggests confidence judgments are calculated from evidence accumulation and how primary choice may relate to confidence judgments (when specified).

## 2DSD

The 2-stage-dynamic-signal-detection theory (2DSD) was first introduced by Pleskac \& Busemeyer in 2010 and suggests that confidence judgments involve post-decision processing of the primary choice. 2DSD is specifically adapted to a 2-alternative forced-choice task (2AFC).

In the 2DSD model, participants make a primary choice by collecting evidence that pushes a single counter towards one choice alternative or the other. When the counter reaches a criterion for one alternative, a primary choice is made. If a decision is prompted before a threshold is passed, the alternative choice that is closest to the counter is selected.

After a primary choice is made, evidence continues to be collected for a confidence judgment. Evidence continues to accrue for the single counter until evidence passes a threshold for a particular confidence judgment and a secondary choice is made. Each possible confidence response has a separate threshold. Similar to primary choice, if a choice is prompted before a threshold is passed; the confidence judgment that is closest to the counter is selected.

According to 2DSD decision time for primary and secondary choice is the product of drift rate. Drift rate is determined by the quality of the evidence collected. Because drift rate towards one alternative or the other determines how fast a choice is made, response time is a function of the quality of the evidence.

2DSD extends the idea that high drift rates lead to fast choices to confidence judgments. The often replicated finding that there is a negative relationship between confidence judgments and response times (Baranski \& Petrusic, 1998; Petrusic \& Baranski, 2003) suggests that lower drift rates will produce lower confidence responses.

## Poisson Model

The Poisson model was introduced by Pike (1971;1973) and modified for confidence by Merkle \& Van Zandt, (2006). The Poisson model assumes that in a 2AFC task,
there is one counter of evidence for each of the possible primary choice alternatives. Counters accrue evidence for each alternative. Whichever counter reaches its respective choice threshold first is the primary choice. If the decision is prompted, whichever counter is closest to the criterion threshold is selected.

After the primary choice is made, evidence collection stops and a secondary choice for confidence is ready to be made. In the Poisson model, confidence is a function of the difference in evidence between counters. If the difference between the collected evidence is large, confidence is high. If the difference between the collected evidence is small, confidence is low.

The idea of confidence being generated by separate counters was made most popular by the balance of evidence hypothesis (D. Vickers, 1970; Douglas Vickers, 2001, 2014). The balance of evidence hypothesis suggests that the difference in evidence between counters is scaled to produce a confidence response. The Poisson model is unclear about whether or not confidence is scaled immediately after a choice is made or a computation is required first.

According to the Poisson model, decision time for the primary choice is the sum of the time to retrieve each piece of evidence and increment the winning counter. The model does not specify confidence as a second choice that is calculated as a post-decision. However, Van Zandt \& Maldonado-Molina (2004) have suggested that additional evidence collection and post-processing could occur after a primary choice but may not always be necessary.

## RTCON2

RTCON2 is a model of making confidence judgments only and not of primary choice (see Ratcliff, 1978 for their diffusion model of primary choice). As a result, it is unclear from RTCON2 how primary choice influences confidence judgments.

RTCON2 suggests that there is a separate counter for each of the possible confidence responses. A confidence judgment is selected when a counter reaches a predefined threshold. According to RTCON2, participants do not have access to the amount of evidence each counter has accrued and therefore can only make a choice when a counter has reached a threshold. In addition, because people do not have access to the evidence, there is no comparison between the amount of evidence for different confidence judgments.

Importantly RTCON2 differs from the original RTCON (Ratcliff \& Starns, 2009) in that each counter for a confidence judgment is affected by the behavior of other counters so as to maintain no net difference. As a result, if evidence facilitates an increment in one counter, the other counters decrease so as to have a net zero effect.

Similar to 2DSD, RTCON2 also uses higher drift rates to explain faster response times and higher confidence responses.

## Memory

One major component of the 2DSD, Poisson model, and RTCON2 models is their reliance on memory for their evidence counters. A sufficient model should be able to predict what happens when memory quality changes.

Many researchers have investigated the relationship between accuracy and confidence by manipulating memory (see Dunlosky \& Metcalfe, 2008 for a review). One wellresearched way of manipulating memory is using interruptions. A long history of research has shown a decrease in task performance (e.g increased response time, decreased accuracy, increased time to return to the task) following an interruption (Altmann \& Trafton, 2007; Altmann, Trafton, \& Hambrick, 2014; Cades, BoehmDavis, Trafton, \& Monk, 2011; Gillie \& Broadbent, 1989; Trafton, Altmann, \& Ratwani, 2011; Trafton, Jacobs, \& Harrison, 2012).

More recently, confidence in the accuracy of a memory has been shown to be lower after an interruption (Aguiar, Zish, McCurry, \& Trafton, 2016; Zish, Hassanzadeh, McCurry, \& Trafton, 2015). In an experiment we replicate these findings and discuss the predictions of each of the three models.

## Model Predictions

All of the models suggest that decision-making is the result of some form of sequential evidence collection. There are two primary differences between each of the models. First, decisions are either the result of the use of one counter for evidence (2DSD) or multiple competing counters (Poisson and RTCON2). Second, confidence judgments are the result of the winning counter choosing the confidence response (2DSD and RTCON2) or the winning counter choosing the time when the delta between multiple counters is used to calculate confidence (Poisson).

The number of counters (one or multiple) and the role of the counter (choosing a response or calculating the delta between counters) results in testable predictions for how interruptions will affect performance.

For all three models accuracy should be lower after an interruption because drift rates will experience more fluctuations when the quality of the evidence collected decreases. Fluctuations in drift rates can result in an error if noise allows for evidence to increment towards the incorrect choice threshold.

Drift rates also drive response time for all three models. Any decrease in the drift rate should increase response time. Because interruptions increase the amount of time to retrieve an item from memory, interruptions should increase decision response times and confidence response times.

As for confidence, 2DSD and RTCON2 predict that confidence decreases whenever drift rate decreases. Although 2DSD relies on one counter and RTCON2 uses multiple counters, both models suggest that confidence is chosen when one counter crosses a threshold for a confidence judgment. Alternatively the Poisson model uses two counters where confidence is the delta between the two
counters. An interruption is likely to slow the increment of both counters equally. Therefore, the Poisson model predicts that confidence should be no different after an interruption trial than a non-interruption trial.

Given the predictions of these three models, the number of counters clearly does not matter when it comes to predicting accuracy or response time. The primary difference between the predictions of the three models is whether or not confidence will be the same after an interruption trial as compared to a non-interruption trial.

## Methods

## Participants

Fifty-five George Mason University undergraduates participated for course credit.

## Tasks

Primary Task The primary task consisted of a simulated stock exchange where participants filled out Buy and Sell orders. Each order had 12 widgets that needed different information about the state of the stock market and the Buy or Sell request (e.g Stock Symbol, Exchange, Transaction Type).

To begin, participants were presented with an autoselected Buy or Sell request at the bottom of the screen (colored gray) and a red arrow designating which of the 12 widgets required information first. The red arrow's location was randomized so that participants learned to start from multiple widgets.

Participants located and selected a "Start" button on the side of the widget designated by the red arrow. Selecting "Start" would teleport the widget to the bottom middle of the screen so that it became the main focus of the task.

Participants would use information from the gray-colored request and the stock market information along the middle of the screen to fill in the widget with the correct information. When the correct information was selected from the widget's dropdown menu, the widget would return to its original place on the screen (Figure 1). Participants repeated the process by finding information for the next widget. Widgets were completed left-to-right and top-down.

A trial ended when the active order was replaced by another auto-selected Buy or Sell request.

Figure 1: Primary task with auto-selected order and widget.
Interruption Task For half of the trials, participants were given a secondary task that served as an interruption. The interruption lasted for 20 -seconds after completing an order. The interruption consisted of a series of addition problems. Addition problems completely occluded the screen until the secondary task was complete. Participants were instructed to complete the addition problems as quickly and as accurately as possible.

Signal Position Question After a trial ended or after a trial and interruption ended, participants were presented with a facsimile of the stock order screen. A blue arrow pointed to one of the 12 widgets with the question: "Is the arrow pointing to the next correct step?" Participants would respond by clicking the word "Yes" in the top left corner or the word "No" in the top right corner (Figure 2). Once the participant made a selection, they were presented with the next order to complete with a new Buy or Sell request.

The placement of the blue arrow was evenly split between the next correct or incorrect step.

Figure 2: Signal Position Question with a blue arrow pointing at a possible next correct step.

Confidence Question Once the signal detection question was complete, the screen was replaced with a question that asked: "How confident are you that the [widget name] was the next correct step?" The participant selected a button on the bottom of the screen that represented their confidence on a scale of 1 through 6 with 1 being "Not at all Confident" and 6 being "Entirely Confident."

## Design

The study was a 2 factor (interruption/non-interruption) repeated measures design.

Each participant had 32 interruptions across 64 trials. The order of screens participants saw was the primary task for 25 completed widgets, a 20 -second secondary task after half of the trials, a signal position question, and a confidence question.

The 64 trials were equally divided between $2,3,4$, and 5 completed widgets in length. The length of the trial was varied to reduce the likelihood that participants could prepare for an interruption and/or signal position question.

Each participant had half of the signal position arrows pointing to the next correct step.

## Procedure

Participants filled out an approved IRB consent form as well as biographical information. Participants were seated approximately 47 cm from the computer monitor. The task was first described using screenshots of the primary and secondary tasks as well as the signal position and question.

Three practice trials were completed that were each 12 widgets long. This was to give the participant the opportunity to experience the order of the widgets before being given partial orders to fill. The experimenter provided the opportunity for participants to ask clarifying questions about the behavior of the task. Participants could begin once the experimenter left the room and were debriefed and dismissed once finished.

## Measures

Behavioral data based on mouse clicks was collected for all participants in addition to screen recordings. Accuracy for identifying the next correct step in the task, response time (RT) for identifying the next correct step in the task, confidence in identifying the next step of the task, and response time for the confidence judgment were calculated.

## Results

Fifty-five participants made 3176 correct responses and 3520 confidence responses.

## Behavioral Results

A within-subjects ANOVA between interruption and noninterruption trials show that interruptions hurt performance metrics for accuracy $(\mathrm{F}(1,54)=132.4, \mathrm{MSE}=0.59, \mathrm{p}<.05$, $\left.\eta^{2}=.56\right)$, confidence $(\mathrm{F}(1,54)=135.7, \mathrm{MSE}=22.813, \mathrm{p}<$ $\left..05, \eta^{2}=.73\right)$, decision response time $(\mathrm{F}(1,54)=134.8$, MSE
$\left.=78,277,425, \mathrm{p}<.05, \eta^{2}=.75\right)$, and confidence response time $\left(\mathrm{F}(1,54)=30.47, \mathrm{MSE}=844,342, \mathrm{p}<.05, \eta^{2}=.11\right)$. A summary of the means of each performance metric across interruption condition can be found in Table 1.

Table 1: Means of performance measures.

| Performance Metric | Interrupted <br> Trials | Non- <br> Interruption <br> Trials |
| :--- | :--- | :--- |
| Accuracy | $82.9 \%$ | $97.5 \%$ |
| Confidence | 4.95 | 5.86 |
| Decision RT (ms) | 4493.96 | 2806.82 |
| Confidence RT (ms) | 1492.30 | 1317.08 |

## Empirical Data and Model Predictions

All three models predicted the decrease in accuracy, the increase in decision response time, and the increase in confidence response time that appeared after an interruption trial compared to a non-interruption trial. Most importantly, only 2DSD and RTCON2 predicted a decrease in confidence after an interruption.

## Discussion

In this paper we describe three sequential-sampling models of decision making and apply their predictions to the results of an experiment.

2DSD used one counter to make a primary choice and then subsequent post-decision processing to provide a confidence judgment once the single counter passed a threshold. The Poisson model used two counters to make a primary choice where the first counter to cross a threshold determines the time when a delta between the two counters is calculated for confidence. Finally, RTCON2 is a multiple counter confidence-only model where the winning counter crosses a threshold that informs the confidence judgment.

We compared the predictions of these three models to the results of an experiment where participants completed a task in a simulated stock market. Participants were interrupted $50 \%$ of the time and then asked to choose if a widget was the next correct step of the task followed by a confidence judgment.

This study replicated the results of many other interruption-based studies in that performance suffered after an interruption. An addition to previous work is that confidence response times are slower following an interruption.

In terms of model predictions, all three models can account for a decrease in accuracy after an interruption. All three models suggest that accuracy is a function of the fluctuations in the drift rate. Counters can reach the threshold for the incorrect choice first when there is more noise in the drift rate, particularly when the thresholds are lowered. To fully explain a decrease in accuracy after an interruption, each model would need to explain why there is
more noise in drift rate and/or lower choice thresholds after an interruption trial than a non-interruption trial.

A strength of each model is a fairly comprehensive explanation for decision response time and confidence response time after an interruption. All three models suggest that response times are a function of the speed of evidence collection. As a result, anything that reduces the speed of evidence collection should reduce response time. While no link has been produced that shows that quality of evidence decreases after an interruption, there is certainly a large amount of literature showing interruptions increase retrieval time (Altmann \& Trafton, 2007; Altmann et al., 2014; Cades et al., 2011; Trafton et al., 2011, 2012). An increase in retrieval time would slow down evidence collection and lead to longer decision and confidence response times.

As for confidence only 2DSD and RTCON2 were able to predict lower confidence judgments after an interruption. In both models confidence decreases when the drift rate is lower. Therefore, interruptions are likely to lower the drift rate.

The Poisson model is unclear about explaining a change in confidence after an interruption. Confidence in the Poisson model is driven by the balance of evidence hypothesis and calculated by scaling the delta between the counters. According to the Poisson model, confidence after an interruption should stay the same as before an interruption because both counters in a 2 AFC would be affected by the interruption equally. Thus, the Poisson model does not predict the difference in confidence found in this study.

This paper compared and contrasted three mathematical models of decision making. The 2DSD, Poisson model, and RTCON2 can explain changes in accuracy with drift rate but do not provide a clear mechanism to explain the effect of interruptions. However, each model does have a fairly robust explanation of decision response times and confidence response times via speed of evidence collection. As for confidence judgments, it is easier for models to explain changes in confidence judgments when there is a single counter that chooses a response than models that use multiple counters to calculate the delta between alternatives.

# Simulation and heuristics in flexible tool use 

Kelsey Allen<br>Massachusetts Institute of Technology, Cambridge, MA, US

Kevin Smith
Massachusetts Institute of Technology
Josh Tenenbaum
Massachusetts Institute of Technology

#### Abstract

Humans are remarkably flexible tool users. We not only recognize a wide range of existing tools, but also produce new tools by seeing objects in new ways, or by making or repurposing objects to solve a problem confronting us. Here we study the cognitive processes supporting flexible tool use, including deciding what makes a good tool, and how it should be used. Participants played a video game which requires selecting an object from a set of options and placing it in a virtual physical scene in order to accomplish goals such as tipping another object over or launching it into a container. People appear to use a combination of simulation-based planning and experience-based heuristics: fast heuristics drive the initial selection and placement of a candidate tool, and that solution can then be refined by several rounds of mental simulation interspersed with trial-and-error experimentation to rapidly converge on goal-satisfying solutions.

# Predicting Preschool-Aged Children's Behavior Regulation from Attention Tasks in the Lab 

Chelsea Andrews<br>University of Wisconsin Madison<br>Emily Coates<br>Ripon College<br>Kristine Kovack-Lesh<br>Ripon College<br>Vanessa Simmering<br>University of Wisconsin - Madison

#### Abstract

One challenge in studying cognition over the lifespan is designing tasks that measure the same construct in different age groups and relate reliably to real-world outcomes. The current study confronts this challenge by testing a new paradigm to assess attention in preschool-aged children for comparison with other measures. Children completed the new "Pop-the-Bubbles" paradigm plus Flanker and Visual Search tasks, for comparison with parental reports of behavioral regulation. Correlations between behavioral regulation and measures from both Flanker and Pop-the-Bubbles suggest that children's ability to ignore irrelevant stimuli in these lab tasks relates to their ability to behave appropriately in everyday situations. Further development of Pop-the-Bubbles for eye-tracking and a color version of Flanker are underway to test these relationships more extensively in young children.

# Why do we punish negligent behaviors? 

Sarin Arunima

Harvard University

Cushman Fiery<br>Harvard University

#### Abstract

Prior research suggests that negligent harms are punished because of the resulting negative outcomes. Under this account, negligent but completely harmless acts should not be punished. An alternative possibility is that negligence is punished as a way of modifying future thought and behavior. Across three studies we find support for this second proposal. Study 1 demonstrates that punishment is assigned to negligent agents, irrespective of whether or not a harm actually occurs. Study 2 demonstrates that non-negligent agents who cause harm are punished less than negligent agents who do not cause harm. Study 3 shows that the punishment of harmful negligent actions is only judged to be successful when it results in the agent ceasing to act negligently, and not when it results in the harm ceasing to occur. Together, these results suggest that a primary function of punishment in cases of negligence is modify future thought.

# When I say 'Black Lives Matter,' why do some people hear 'Others Lives Matter Less'? 

E. Malemma Azumah<br>Agnes Scott College

Jason Shepard<br>Agnes Scott College

#### Abstract

The statement "Black lives matter" is commonly construed as implying other lives matter less, even though the statement does not explicitly reference other lives. Bias is a common explanation for this construal. However, other factors may contribute. We hypothesized that the linguistic structure of "Black lives matter" plays an important role. "Black lives matter" takes the form of a generic, or statements in which a property is attributed to members of a set (e.g., "lions have manes"). Generics are often interpreted as implicit comparisons (e.g., "lions are more likely to have manes than other animals"). We report two experiments in which we find evidence that the statement "Black lives matter" is often construed as an implicit comparative claim, similarly to other generics. This research contributes to our understanding of generics, while providing a novel explanation for why when I say "Black lives matter," some people hear "Other lives matter less."

# The Use of Ambiguous Messages as a Strategy to Appeal to Multiple Decision Makers 

Devika Banerji<br>Purdue University, West Lafayette, IN, United States<br>Torsten Reimer<br>Purdue University, West Lafayette, IN, United States<br>Chris Roland<br>Purdue University, West Lafayette, IN, United States

#### Abstract

Messages that are tailored to specific audiences (matched messages) are typically more persuasive compared to messages that are crafted for a general audience (Hirsh, Kang, \& Bodenhauser, 2012). However, tailoring messages can have the effect that messages are less persuasive for audiences for which they were not tailored (mismatched messages; Sillince, Jarzabkowski, \& Shaw, 2012). Eisenberg (1984) introduced the concept of strategic ambiguity to appeal to multiple audiences simultaneously. We systematically compared effects of matched/mismatched tailored messages with the effects of ambiguous messages on multiple-criteria choice behavior. We found evidence that ambiguous messages can be used under certain conditions to simultaneously appeal to multiple audiences within the context of credit card choices. Using the financial control typology developed by Shefrin and Nicols (2014) to define different audiences, the study ( 154 participants) provided some support for the use of ambiguity as a tool for tailoring messages to diverse credit-card holders.

# Social wayfinding in complex environments 

Iva Barisic<br>ETH Zurich, Zurich, Switzerland

Tyler Thrash
ETH Zurich, Zurich, Switzerland
Victor R. Schinazi
ETH Zurich, Zurich, Switzerland

## Christoph Hoelscher

ETH Zurich, Zurich, Switzerland

#### Abstract

Wayfinders in a group can be influenced by various factors, including other group members and environmental structure, but social wayfinding is an underexplored topic. This experiment investigated differences in wayfinding decisions between individuals and groups and their dependence on environmental structure. Participants navigated through a train station with or without market stalls, either as individuals or as groups. There was a significant main effect of environmental structure on task efficiency, and an inconclusive interaction between environmental structure and group membership on task efficiency $(\mathrm{p}=0.05)$. Because of heterogeneity of variance, we conducted targeted t -tests. T-tests revealed that groups were slower than individuals with market stalls $(\mathrm{p}=0.02)$ but not without $(\mathrm{p}=0.91)$. There was significant main effect of the environmental structure on number of turns. The main effect of group membership on number of turns and the interaction were not significant. We will analyze walked and Levenstein distance as wayfinding efficiency indicators.

# Projecting space into the future: peripersonal space remaps in anticipation of an object manipulation 

Anna Belardinelli<br>University of Tübingen<br>Johannes Lohmann<br>University of Tübingen

Martin Butz<br>University of Tübingen

#### Abstract

Manipulation planning relies on anticipatory processes, aimed at achieving the desired goal state, such as a grasp. This implies that peripersonal space is remapped to the anticipated grasp posture on the targeted object. Vibrotactile-visual interactions were probed at different times during a grasp-and-place task. Thumb or index finger were stimulated concurrently with a visual distractor on the to-be-grasped object. Object orientation (upright/upside down) afforded a thumb-up or thumbdown grasp, inverting the congruency between haptic and visual stimulation. Response times about which finger was stimulated show the expected crossmodal congruency effect already before motion onset, with shorter times when the visual distractor and the future position of the stimulated finger overlapped. Moreover, eye-tracking data show that the tactile stimulation influences the gaze in anticipation of the upcoming grasp. Thus peripersonal hand space is mapped into the future, predictively mediating between tactile and visual perceptions as a function of the final state.

# Characterizing Human-Machine Teams with Process Algebras 

Leslie Blaha<br>Pacific Northwest National Laboratory, Richland, Washington, USA<br>Robert Jasper<br>Pacific Northwest National Laboratory, Richland, Washington, USA

#### Abstract

We conceptualize human-machine (computer, robot) teams as concurrent processes. Such a conceptualization means: (1) the human and machine agents have a common goal or mission; (2) each agent may have different subtasks within the goal space; (3) they do not have a shared memory, but (4) they do have a means of communicating with each other. Process algebras, such as communicating sequential processes (Hoare, 1977), are formal languages for describing the ways in which two concurrent processes interact through message passing across information channels. In this research, we enumerate the ways in which human-machine interactions can be structured, such as strictly serial, parallel, and cascade-like architectures. We use process algebras to characterize the interactions in candidate architectures. We discuss design implications for active and interactive machine learning systems.

# Bottom-up attentional cueing in category learning in children 

Nathaniel Blanco<br>Ohio State University<br>Vladimir Sloutsky<br>Ohio State University

#### Abstract

Young children tend to differ from adults in how they learn new categories. In comparison to adults (who rely on selective attention and tend to form explicit rules), children distribute attention widely, forming similarity-based category representations. But, when attention is explicitly directed toward the rule with top-down feedback, children exhibit rulebased classification-though memory performance still indicates distributed attention. Little is known, however, how bottom-up attentional cueing affects the category representations that children form. In our experiment 4 -year-olds learned to classify alien creatures composed of binary features. A single "deterministic" feature perfectly predicted category membership, while other features were probabilistically predictive. We manipulated the saliency of the deterministic feature, making it grow and shrink. This manipulation was remarkably effective at facilitating category learning and rule-based classification, but recognition memory still showed evidence of distributed attention. These results help elucidate the important role of attentional processes in the development of categorization.

# Infusing Cognitive Science Content in Teacher Preparation 

Julie Booth<br>Temple University

#### Abstract

Surprisingly, foundational knowledge about cognitive science (CS) is not included in all teacher preparation programs or required for certification in all states. Here, I examine the impact of infusing CS content into teachercandidates' coursework by providing half of the pedagogy instructors with professional development on big ideas in CS (memory/attention/transfer/problem solving/practice/expertise) and encouraging them to use the materials to deliver mini-lectures on these topics and discuss their relevance to instructional practice. Control instructors did not receive PD or CS materials. In both experimental and control classes, CS knowledge was measured at the beginning and end of the semester; we also collected lesson plans where teacher-candidates explained their reasoning for each instructional decision. We saw no CS knowledge improvement, but teacher-candidates exposed to CS reduced their use of folk reasons (e.g., buzz words such as learning styles, concrete thinking, active learning, etc.) when planning lessons compared with peers in control classes.

# Using Analogical Processing to Categorize Musical Patterns 

Janet Bourne<br>Bates College, Lewiston, Maine, USA<br>Elliot Chun<br>Bates College, Lewiston, Maine, USA

#### Abstract

Participants often categorize musical melodies ("themes") based on perceptual features (e.g. loudness, fastness) instead of structural or relational features (e.g. pitch, rhythm) (Lamont \& Dibben, 2001; Ziv \& Eitan, 2007). In the present study, we investigate whether within-category analogical comparison (Markman \& Gentner, 1993) influences participants to categorize musical themes based on relational features, a prediction from structure-mapping theory (Gentner, 1983). Participants completed a forced-choice triad task where they had to choose whether one theme (relational match) or another (perceptual match) best fit the target theme. In a "no-compare" condition (between-subjects), participants heard one target theme. In a "compare" condition, participants heard and compared two target themes. Initial results indicate that participants who compared two themes chose more relational matches. We found this result for Western Classical themes and popular music chord progressions. These results and their implications are discussed with respects to analogical processing and musical categorization.

# How infants map nonce phrases to scenes with objects and predicates. 

Angelica Buerkin-Pontrelli<br>University of Pennsylvania<br>Daniel Swingley<br>University of Pennsylvania

#### Abstract

When infants hear sentences containing unfamiliar words, are some language-world links (such as noun-object) more readily formed than others (verb-predicate)? What if the context renders verb-predicate and noun-object interpretations equally plausible? We examined 14-15-month-olds' capacity for linking semantic elements of scenes with simple bisyllabic nonce utterances. Each syllable either referred to the object, or the object's motion. Infants heard the syllables in either a VSor SV-consistent order. Learning was tested using 2AFC language-guided looking. Infants learned the nouns and verbs equally well, showing no bias favoring nouns. In all conditions, infants learned the meaning of the utterance-final syllable, but not the initial one, suggesting that noun or verb biases played a smaller role than utterance position when noun- and verb-learning were equally supported by context.

# No Tranfer of Training in Simple Addition 

Jamie Campbell

University of Saskatchewan, Saskatoon, SK, Canada

Yalin Chen
University of Saskatchewan, Saskatoon, SK, Canada

#### Abstract

Several researchers have proposed that skilled adults may solve single-digit addition problems (e.g. $3+1=4,4+3=7$ ) using a fast counting procedure. Practicing a procedure often leads to transfer of learning and faster performance of unpracticed items. Such transfer has been demonstrated using a counting-based alphabet arithmetic task (e.g., B+4 = C D E F) that indicated robust RT gains when untrained transfer problems at test had been implicitly practiced (e.g., practice $\mathrm{B}+3$, test $\mathrm{B}+2$ or $\mathrm{B}+1$ ). Here we constructed analogous simple addition problems (practice $4+3$, test $4+2$ or $4+1$ ). In three experiments ( $n=108$ ) there was no evidence of generalization for these items, but there was robust speed up when the items were repeated. The results are consistent with direct retrieval of addition facts from long-term memory rather than a counting procedure.

# Vowel Harmony as a Distributional Learning Problem 

## Spencer Caplan

University of Pennsylvania, Philadelphia, Pennsylvania, United States
Jordan Kodner
University of Pennsylvania, Philadelphia, Pennsylvania, United States

#### Abstract

Vowel harmony is a class of phonotactic restrictions in which vowels in a language are divided into two or more subclasses, and words must contain only vowels from only one such subclass regardless of intervening consonants. Languages worldwide (Turkish, Finnish, Mongolian, Warlpiri, but not English) exhibit vowel harmony. The opacity of such potentially long distance alternations poses a challenge for the learner. Nevertheless, infants are sensitive to vowel harmony alternations at as young as seven months. We present a computational model for vowel harmony acquisition. By normalizing transitional probabilities over the vowel tier, and making minimal assumptions about the phonology, we successfully determine which test languages have harmony processes and correctly categorize their vowels into harmonizing classes. Using universal typological patterns to inform the search space, we find that phenomena which appear opaque can be captured by simple distributional learning.

# A comparative assessment of embodied and computational topic extraction 

James Carney<br>Department of Psychology, Lancaster University, Lancaster, Lancashire, United Kingdom

#### Abstract

Word embedding algorithms like word2vec (Mikolov et al., 2013) have enabled advances in topic modelling by training shallow neural networks on the co-occurrence of words in corpuses of sentences. However, it is not clear how this process reflects human cognition. This poster will compare the results of document classification using the word2vec skipgram model and the 20k sensorimotor word norms collected by the presenter and colleagues (Lynott \& Connell 2013; Carney et al., in prep.) (These latter norms establish how concepts are processed by way of perceptual and motor schemes, and thus offer a useful proxy for human conceptual classification.) The results of the comparison will generate insights into the different ways in which higher-order concepts are inferred, and allow systematic biases in concept formation to be identified. It will also allow for machine learning processes to be finessed so as to more accurately reflect human-level modes of cognition.

# Mapping hand to world; Development of iconic representation in gesture and homesign 

Erica Cartmill<br>University of California Los Angeles

Lilia Rissman
University of Chicago
Miriam Novack
Northwestern University
Susan Goldin-Meadow
University of Chicago

#### Abstract

In both gesture and sign, objects and events can be represented by reproducing some of their features iconically. Iconic gestures do not typically appear until well into children's second year of life, suggesting that the cognitive and/or communicative resources required are not trivial. Here we investigate how manual iconicity develops in two different communicative systems. Using longitudinal video corpora, we compare the emergence of manual iconicity in 52 hearing children learning a spoken language (co-speech gesture) to a deaf child creating a manual communication system (homesign). We focus on the shape of the hand, asking how handshape use changes between age 1 and 5 , and how handshape choice relates to semantic content. We find broadly similar patterns of handshape development in co-speech gesture and homesign. This suggests that the cognitive building blocks underlying children's ability to iconically map forms to meanings are shared across vastly different communicative systems.

# One-shot word learning under high and low sentential constraints in adult L2 learners of Chinese 

Jenn-Yeu Chen<br>National Taiwan Normal University<br>Yu-Shu Huang<br>National Taiwan Normal University

#### Abstract

New words were embedded in high- and low-constraint sentences and presented three times in a random order to adult learners of Chinese as a second language. The learners explained the meaning of each word in their native languages and their answers were scored by other native speakers. The overall accuracy was .47 with no effect of constraint or frequency. When the data were limited to those words the learners reported having no prior encounters with and those sentences they reported comprehending, the accuracy was .45 . The results demonstrated fast mapping of word learning in adult L2 learners but indicated that extended mapping was necessary to achieve ultimate attainment. The results are also consistent with Krashen's (1982) "comprehensible input" and " $i+1$ " hypothesis.

# Comparing Human Use of Fast \& Frugal Tree with Machine-Learning Tree 

Yee Siang Chng<br>UNIVERSITY COLLEGE LONDON, LONDON, LONDON, United Kingdom

#### Abstract

Previous studies have shown that the predictive accuracy of fast and frugal decision trees (FFTs) is comparable to decision trees generated by machine-learning (Martignon et al., 2008). FFTs are thought to be useful decision tools that are cognitively plausible to internalise, as opposed to complex machine-learning algorithms. Nonetheless, there seems to be a lack of behavioural studies in the literature to support such a claim. In this between-group experiment, we examined the human use of an FFT versus a C 4.5 algorithm tree when completing a car evaluation task. Participants had to learn the rules of their given tree before making evaluations based on their memory. Preliminary results show that FFTs may indeed be easier to use, even when the number of cues for both trees are the same. Interestingly, participants who were successful in using the C 4.5 tree exhibited tree pruning strategies, resulting in a heuristic similar to an FFT.

# Incorrect responses salience affects strategy use in a figural analogy task 

Iwona Ciechanowska<br>Jagiellonian University, Krakow<br>Bartlomiej Kroczek<br>Jagiellonian University, Krakow<br>Adam Chuderski<br>Jagiellonian University, Krakow

#### Abstract

Previous studies of multiple-choice analogy problems suggested that some people use a more efficient but also harder constructive strategy (they build the complete representation of analogy), whereas others tend to use a less effective but simpler response elimination. We tested whether salience of incorrect options (five per figural analogy problem) affected strategy use. Salient options in 18 problems missed many features from the (sixth) correct option; options in 18 non-salient problems missed only few features. When controlling for working memory capacity, eye tracking yielded strongly correlating patterns of data that suggested, in line with previous reports, large individual variance in strategy use. However, participants overall spent $50 \%$ less time analyzing salient than non-salient options, suggesting that salience promoted the constructive strategy. This conclusion was supported by pupil size significantly predicting accuracy on problems with salient options, but not on those with non-salient options (which additionally yielded lower accuracy).

# Learning Object Names from Visual Pervasiveness: the Visual Statistics Predict 

Elizabeth Clerkin<br>Indiana University, Bloomington, IN, United States

Chen Yu<br>Indiana University

Linda Smith<br>Indiana University

#### Abstract

Recent analysis of a corpus of infant-perspective head-camera images found an extremely right-skewed frequency distribution of objects present in 8 - to 10 -month-old infants' visual environments (Clerkin, et al., 2017). Furthermore, the objects most pervasively present in these scenes have names normatively acquired first by learners of English. New analyses show that the names for these objects occur only sparsely in infants' environments, and object name frequency is not correlated with object visual frequency. Therefore, we designed a simple associative model simulating word-object co-occurrence in order to investigate how visual pervasiveness without high-frequency naming could lead to learning of word-object correspondences. With random sampling from distributions reflecting the actual frequency of words and objects in infants' environments, we find that the most frequent objects have a distinct advantage over less frequent objects in their conditional probability. This suggests visual experience with objects may be the principal predictor of early word-referent learning.

# Relations Between Intuitive Biological Thought and Scientific Misconceptions 

John Coley<br>Northeastern University

Nicole Betz
Northeastern University
Jessica Leffers
Northeastern University

Yian Xu<br>Northeastern University

Michal Fux<br>Northeastern University

Kristin de Nesnera
San Francisco State University
Kimberly Tanner
San Francisco State University

#### Abstract

Students enter educational settings with complex and well-established intuitive conceptual understandings of the world, which have important educational consequences. In biology, intuitive thinking can be characterized in terms of cognitive construals (anthropocentric, teleological, and essentialist thinking, Coley \& Tanner, 2015). We examined relations between intuitive thinking and biological misconceptions, and how formal biology education might influence such relations. 137 biology and non-science majors completed measures of anthropocentric, teleological, and essentialist thinking, and indicated agreement/disagreement with common misconceptions and explained their responses. Teleological thinking (but not anthropocentric or essentialist thinking) predicted teleological misconceptions. Anthropocentric and teleological thinking (but not essentialist thinking) predicted anthropocentric misconceptions. Agreement with essentialist misconceptions was unrelated to intuitive thinking. Similar patterns for non-majors and majors suggests formal biology education may have little influence on relations between intuitive reasoning and misconceptions. These findings demonstrate a clear impact of intuitive thinking on learning biology at the university level.

# A picture falls under many categories: How ancient mathematical marks became extinct 

Peter Coppin<br>Perceptual Artifacts Lab, Faculty of Design, OCAD University and the Department of Mechanical and Industrial Engineering, University of Toronto<br>Daemon Retren<br>Perceptual Artifacts Lab, Faculty of Design, OCAD University

Ambrose Li<br>Perceptual Artifacts Lab, OCAD University

#### Abstract

The development of mathematical marking conventions from prehistory to the present is characterized by a trend from conventions with more iconic relationships to concrete structures of the physical world (such as more pictorial ancient land surveying marks) to marking systems with less-iconic relationships to physical structures (that represent numbers, operations, infinity, and other more abstract concepts). We propose how certain constraints of perception-cognition induced conventions that made more-iconic (pictorial) marks controversial. These became too conceptually ambiguous to convey more abstract conceptual categories during the formalization of mathematics: Iconic properties of ancient proto-mathematical conventions recruited lower level perceptual capabilities developed to perceive-act in a concrete world of occluded surfaces-edges and were suitable for conveying concrete structures (such as landforms during surveying). However, these were too conceptually ambiguous to convey more abstract conceptual categories that emerged when mathematics was formalized because a (pictured) concrete structure can fall under many possible conceptual categories

# ANCHORING is amodal: evidence from a signed language. 

Qatherine Dana<br>Dep. of Psychology, Northeastern University, Boston, MA, United States<br>Diane Brentari<br>Dep. of Linguistics, University of Chicago<br>Outi Bat-EI<br>Dep. of Linguistics, Tel-Aviv University<br>Iris Berent<br>Dep. of Psychology, Northeastern University

#### Abstract

Modern linguistic theory posits the existence of universal constraints. But whether these constraints concern language structure, generally, or speech, specifically, is unknown. To address this question, here we ask whether the constraints identified in spoken languages transfer to sign languages. ANCHORING (McCarthy \& Prince, 1993) is a putatively universal constraint on reduplication. ANCHORING requires that the final element of a suffixed reduplicant match the final element of the base (e.g., pana 'chase' —>panana, 'run' not panapa). Here, we examine whether ANCHORING is likewise operative in a signed language. In our experiments, native ASL signers rated novel reduplicated forms: either ones consistent or inconsistent with ANCHORING (i.e., ABB vs. ABA , where A and B are syllables). Results showed that signers reliably favored ABB forms over ABA. These findings show for the first time that ANCHORING constrains a sign language. This conclusion is consistent with the existence of amodal linguistic principles.

# Don't forget to bind: Memory binding and interference in development 

Kevin Darby<br>The Ohio State University, Columbus, OH, USA<br>Vladimir Sloutsky<br>The Ohio State University, Columbus, OH, USA

#### Abstract

This work investigates the development and causes of memory interference effects. Specifically, we measured proactive and retroactive interference effects in children and adults when learning multiple sets of contingencies, as well as individuals' memory binding for the same contingencies. We measured proactive interference by examining memory for a second set of contingencies after learning a first set, and retroactive interference by examining memory for the first set of contingencies after learning the second set. We measured memory binding by presenting participants with partial information about each contingency and measuring their accuracy and pattern of errors when asked to identify the completed contingency. Results indicate that both children and adults experienced substantial interference effects, but children were more prone to interference and substantially worse at memory binding. Additionally, individuals' memory binding abilities were predictive of the magnitude of interference effects, suggesting that memory binding is an important mechanism modulating memory interference.

# Developmental Changes in Visual Scene Statistics 

Christina Deserio<br>Indiana University, Bloomington, IN, United States<br>Jason Gold<br>Indiana University, Bloomington, IN, United States<br>Swapnaa Jayaraman<br>Indiana University, Bloomington, IN, United States<br>Rowan Candy<br>Indiana University, Bloomington, IN, United States<br>Linda Smith<br>Indiana University, Bloomington, IN, United States

#### Abstract

Mature visual experience is tuned by inputs to the developing visual system. However, little is known about the low-level statistics of available visual input as infants interact with the world in rapidly changing ways. Recent studies of the contents of infant-perspective scenes (sampled from a corpus of over 5 million head camera images) indicate that these contents change dramatically over the first year of life. Faces, ceilings, wall edges, and high-contrast patterns characterize younger babies (below 3 months), while more crowded images characterize older babies. These differences suggest possible developmental changes in lower-level visual statistics. After analyzing a sample of infant-perspective scenes from 4- to 10 -week-old infants, and from 28- to 34-week-old infants, we found that mean Feature Congestion and Subband Entropy-measures of visual clutter in natural scenes-increase with age. The full analyses include spatial frequency, orientation, contrast, and clutter measures across $1,821,021$ frames.

# Speed and accuracy trade-off of semantic composition involving highlighting and adjustment 

Diana Dimitrova<br>University of Cologne, Cologne, Germany<br>Brian McElree<br>New York University, New York City, USA<br>Petra Schumacher<br>University of Cologne, Cologne, Germany

#### Abstract

In a Speed-Accuracy-Tradeoff (SAT) paradigm we investigated how adjective type and polarity modulate the online semantic composition of noun phrases (NPs). 22 German speakers read sentences like "The tradesman - buys - a real diamond". Enriched adjectives ("real/fake") highlighted or adjusted the noun's meaning, whereas non-enriched adjectives ("white/flawed") simply specified a property. Adjectives had positive ("white/real") or negative polarity ("flawed/fake"). Upon the display of critical NPs, participants indicated by a series of key presses if the sentence was correct. For the SAT response function we computed the (i) asymptote (response accuracy as d'), (ii) rate (response speed) and (iii) intercept (point when accuracy departs from chance). Accuracy was significantly lower for semantically enriched vs. non-enriched NPs, suggesting that highlighting and adjusting certain properties during composition is costly. Polarity affected temporal dynamics with negative NPs showing a slower rate than positive NPs, indicating that negative information is processed in more depth.

# A Neurodynamical Model of How Prior Knowledge Influences Visual Perception 

Dražen Domijan<br>University of Rijeka

Mateja Marić<br>University of Rijeka

#### Abstract

Recent behavioral studies showed that prior knowledge can directly influence visual perception. In the current work, we offer an explanation of the observed findings based on the adaptive resonance theory (ART). The ART neural network was designed to solve the problem of catastrophic forgetting during learning in non-stationary environment. In the ART, stability of learning is achieved by matching bottom-up sensory signals with top-down expectations. Resonant state that corresponds with conscious perception develops in the network when the bottom-up and top-down signals are closely aligned. On the other hand, mismatch produces global reset signal that clears the traces of erroneous top-down expectations. Therefore, prior knowledge can influence conscious perception only when it already closely matches with sensory signals. We performed computer simulations with real-time implementation of the ART circuit that confirm our analysis. Simulations also showed how observed behavioral findings arise from response bias.

# Couples Emotion Dynamics During Conversations Involving Stress and Enjoyment 

Nicholas Duran<br>Arizona State University

Ashley Randall<br>Arizona State University

#### Abstract

While conversing face-to-face, romantic partners are thought to form a coupled and co-regulatory system, unintentionally shaping each other's emotional states on a moment-by-moment basis. What has been less explored, however, are the ways in which this coupling is modulated by high-level interpersonal factors, such as discussing topics that are stressful for one or both partners. We provide an initial exploration by examining the emotion ratings of 42 romantic, heterosexual couples during conversations involving stress or enjoyment. Ratings were generated via continuous dials (sampled every second) as participants watched video playback of their interactions. The resulting time series were assessed for time-lagged patterns of emotional coupling using cross recurrence quantification analysis. Initial results show that for topics that involved a mutual sense of stress or enjoyment, overall coupling was high, but this coupling was largely disrupted once the stress was more asymmetrically experienced.

# Information Signatures in Children's Language Environment 

Steven L. Elmlinger<br>Cornell University

Drew H. Abney<br>Indiana University

David W. Vinson
University of California, Merced
Linda B. Smith
Indiana University

Chen Yu<br>Indiana University

#### Abstract

In auditory statistical learning, children are sensitive to the transitional structure of their language environment. Variability and stability of utterances in the language environment are important properties of statistical learning but are currently understudied across laboratory and naturalistic research contexts. In this study, we quantify variability and stability in the language environment of children as measured by amount of information within the temporal structure of caregivers' utterances. In this work we present a new method for understanding information signatures in the temporal structure of parent-child free play contexts and document information signatures of caregiver utterances at multiple timescales. Our results suggest information signatures of parental utterances increase across development (9-24 months), but decrease within individual play sessions (5-6 minutes). We speculate that the dynamics of information signatures varies across multiple timescales. Possible implications of the observed information signatures inherent in caregivers' naming of objects to their young children are explored.

# The acquisition of verb morphology in Polish and Finnish: Model and experiment 

Felix Engelmann<br>University of Manchester, Manchester, United Kingdom<br>Joanna Kolak<br>University of Manchester, Manchester, United Kingdom<br>Sonia Granlund<br>University of Liverpool, Liverpool, United Kingdom<br>Ben Ambridge<br>University of Liverpool, Liverpool, United Kingdom<br>Julian Pine<br>University of Liverpool, Liverpool, United Kingdom<br>Anna Theakston<br>University of Manchester, Manchester, United Kingdom<br>Elena Lieven<br>University of Manchester, Manchester, United Kingdom

#### Abstract

Usage-based approaches suggest that language acquisition is a function of the statistical properties of the input. We compare predictions from neural network models with results of two elicited-production experiments on verb inflection with children in the morphologically complex languages Polish and Finnish. Three-layer neural networks were trained to produce person/number-inflected present-tense verb forms in Polish and Finnish from phoneme representations of verb stems using frequency information from child-directed speech corpora. Simulated acquisition in both languages was affected by token frequency and phonological neighbourhood density (PND) as well as an interaction such that low-frequency forms benefited more from PND than high-frequency forms. Suffix errors showed overgeneralisation and substitutions of low-frequency forms with higher-frequency forms. The model predictions are consistent with our empirical findings, except for the frequency X PND interaction. We discuss the experimental and simulated data and their implications.

# What makes a joke funny: Analysing joke humor through single-word ratings. 

Tomas Engelthaler

University of Warwick

## Thomas Hills

University of Warwick

#### Abstract

The appreciation of humor is a universal phenomenon and a key aspect of cognition. It has been studied in the context of jokes, where the incongruity in expected and observed context results in the perception of humor. The present study examines how the humor appreciation of single words relates to the humor of the whole joke - is a joke simply a sum of its parts? Using a novel dataset of single-word humor ratings, collections of jokes from the JESTER database were analyzed. A multiple regression analysis showed joke length and individual word arousal were the best predictors of joke funniness. Longer jokes with fewer individually arousing words were found funnier. Individual word humor did not contribute to the humor of the overall joke. These findings suggest the cognitive aspects of humor are likely driven by broader semantic context, whereas appreciating humor on a per-word basis links to separate factors.

# What's on your wandering mind? The content of mind wandering during textand film comprehension 

Myrthe Faber<br>University of Notre Dame, Notre Dame, Indiana, United States<br>Sidney Dmello<br>University of Notre Dame

#### Abstract

What do we think about when our mind wanders? We asked 88 students to read an instructional text and watch a film (each 20 minutes) and report whenever they found themselves zoning out. Each time they did, we asked them to report their thoughts and what, if anything, triggered them. We then categorized these thoughts ( 1208 in total) based on their content, and found that in contrast with previous studies, only $17 \%$ involved prospection whereas $33 \%$ consisted of autobiographical and semantic memory retrieval. This discrepancy might be driven by the rich content of stimuli: $71 \%$ of autobiographical and semantic retrieval was explicitly triggered by the text or film, compared to $28 \%$ of prospection. Latent semantic analysis revealed that memories were more similar to their triggers than prospective thoughts, suggesting that a substantial proportion of mind wandering is driven by the content of our environment.

# Interaction with a robot changes human motor behavior 

Laura Fademrecht<br>Max Planck Institute for Biological Cybernetics, Tübingen, Germany<br>Tobias Meilinger<br>Max Planck Institute for Biological Cybernetics, Tübingen, Germany<br>Stephan Streuber<br>École Polytechnique Fédérale de Lausanne, Lausanne, Switzerland<br>Aurelie Saulton<br>Max Planck Institute for Biological Cybernetics, Tübingen, Germany<br>Heinrich Bülthoff<br>Max Planck Institute for Biological Cybernetics, Tübingen, Germany<br>Rouwen Cañal-Bruland<br>Friedrich-Schiller-University Jena, Jena, Germany<br>Stephan de La Rosa<br>Max Planck Institute for Biological Cybernetics, Tübingen, Germany

#### Abstract

Social judgments about other people are often made based on visual appearance. In this study, we investigated whether visual appearance of an interaction partner influences action coordination in social interactions. In a novel interactive augmented reality setup participants interacted (i.e. carried out a high-five) with a life-sized 3D avatar that was either humanlooking or robot-looking. Importantly, the kinematics of the avatars were identical for both appearances. We examined whether motion trajectories of a high-five action and other motion trajectory parameters such as velocity, radial error, synchrony, and variability were modulated by the visual appearance of the avatar. Results showed that participants carried out the high-five faster and applied different motion trajectories for the human-looking than for the robot-looking avatar. These findings suggest that visual appearance does not only influence social judgments but also the immediate behavior towards the interaction partner.

# The differential effects of transmission and interaction on linguistic variation 

Olga Feher<br>University of Edinburgh<br>Kenny Smith<br>University of Edinburgh

#### Abstract

Variation in natural language is constrained: languages tend to lose competing variants over time, and where variation persists, its use tends to be conditioned on grammatical or sociolinguistic context. We had adult participants learn and communicate with artificial languages exhibiting unpredictable variation in plural marking. Using an iterated learning procedure, the languages produced by participants were used as training languages for other participants. We passed on either the language produced during a post-training recall test (Recall condition) or the language used while communicating with another participant (Interaction condition). We found that alignment during interaction leads to the elimination of variability: in Interaction chains, one plural marker typically came to dominate. However, in Recall chains, variation became conditioned on linguistic context, rather than being eliminated. This suggests that the pattern of restricted, conditioned variation in natural language reflects the combined influences of biases in learning, recall and interaction.

# Production of morphologically complex words as revealed by a typing task: Morphological influences on keystroke dynamics 

Laurie Feldman<br>SUNY Albany \& Haskins Labs<br>Rick Dale<br>UC Merced<br>Jacolien van Rij<br>U Groningen, NL<br>\section*{David Vinson}<br>UC Merced

#### Abstract

In a production by typing task, with extraneous factors (e.g., length) controlled, measures such as latency to initial keystroke as well as mean inter keystroke interval typically vary systematically according to the word's lexical properties. Conventionally, lexical effects in production tasks get interpreted as evidence of cascaded processing between central and peripheral levels. We compare mean and distribution of keystroke latencies within the same stem as it undergoes affixation in sets such as DEPRESS, DEPRESSION, DEPRESSIVE. Novel is the comparison of stems that differ with respect to number of affixes like SUPER, SUPERIOR, SUPERIORITY. Results provide new insights into the ways in which morphological structure can influence purportedly peripheral motor processing.

# Probability matching as a cognitive basis of cultural drift 

Vanessa Ferdinand<br>Santa Fe Institute, Santa Fe, New Mexico, USA

#### Abstract

In the field of cultural evolution, cognitive agents are either seen as perfect imitators who reproduce cultural variants veridically (e.g. Boyd \& Richerson 1985) or as imperfect imitators who transform the variants as they replicate them (e.g. Sperber 1996). In this poster, I explain how the transformative view of cognition applies to not only to the generation of variants, but also to the way we learn frequency distributions. Probability matching is a widely-observed human behavior where learners reproduce a frequency distribution over variants with a small amount of error and is equivalent to WrightFisher drift when the variance in error is binomial/multinomial. However, humans and learning algorithms can produce error distributions that are non-binomial/non-multinomial, which constitute a broader class of drift processes than those that exist in genetic evolution or in perfect-imitator models of cultural evolution.

# Is gender-fair langauge needed? How grammatical gender influences representations of discourse referents 

Evelyn Ferstl<br>Centre for Cognitive Science, University of Freiburg<br>Lena Dietsche<br>Centre for Cognitive Science, University of Freiburg

#### Abstract

The use of gender-fair language is an important measure to boost gender equality. However, there is wide-spread scepticism as to the usefulness of avoiding male bias in language, even in gendered languages. For instance, in German all nouns carry grammatical gender, and role names are considered generic, even when their gender is masculine. We used a sentence-picture matching task to test whether male references in language induce gendered representations. After presenting a sentence with a role name, a picture of a person was shown. In 48 trials, the factors gender of the role name (masculine vs. feminine) and sex of the person in the picture (woman vs. man) were crossed. The results of 40 participants showed that women after masculine referents were more readily accepted than men after feminine referents, but reaction times increased. Thus, readers interpret some masculine forms as generic, but only with considerable cognitive effort.

# Introducing a New JavaScript Framework for Professional Online Studies. 

Holger Finger<br>University of Osnabrueck<br>\section*{Dorena Diekamp}<br>University of Osnabrueck<br>Caspar Goeke<br>University of Osnabrueck

#### Abstract

New possibilities such as online crowdsourcing (Amazon Mechanical Turk), open data repositories (Open Science Framework), and online analysis (Ipython notebook) offer rich possibilities to improve, validate, and speed up research. However, until today there is no cross-platform integration of these subsystems. Furthermore, implementation of online studies still suffers from the complex implementation (server infrastructure, database programming, security considerations etc.). Here we present LabVanced, a JavaScript framework that constitutes methodological innovation by combining three essential aspects for online research. With our framework studies can be implemented in an intuitive graphical user interface without programming. Second, the framework takes care about participant recruitment and third, it outlines options for data visualizations and statistical analysis. Additionally, the framework can be used for sharing not only the recorded data, but also the study design and the analysis. In summary, we introduce a new powerful JavaScript framework for improving and accelerating online research.

# How to communicate uncertainty in severe weather forecasts? 

Nadine Fleischhut<br>Max Planck Institute for Human Development<br>Stefan Herzog<br>Max Planck Institute for Human Development<br>Ralph Hertwig<br>Max Planck Institute for Human Development

#### Abstract

Communicating uncertainty to lay audiences is as challenging as indispensible if people are to understand medical test results, gains from financial investments, or weather warnings.

Compared to risk communication in the medical domain, there is so far only limited evidence on how to best communicate uncertainty for continuous quantities, such as financial returns or wind speeds (Spiegelhalter et al., 2011).

The poster presents results from a longitudinal study investigating this question within a real-life setting. We implemented different representations communicating probabilistic weather forecasts within an online information system operated by the German National Weather Service. The system is used by fire brigade coordination centers throughout Germany to prepare for severe weather conditions.

By analyzing web usage and search behavior, we investigate which representations users rely upon under real operational constraints. We link the analysis to tests which representations are best understood and could thus aid emergency managers in their decisions.

# Developing Visual Closure in Infancy 

Samuel Forbes<br>University of Oxford

Kim Plunkett

University of Oxford

#### Abstract

Visual closure is the ability to complete a picture from partial information. In children it is a requisite in many skills such as fluent reading, and is also used in many tests of colour vision. Here we present a test of visual closure in infants across two age groups, $1 ; 4$ and $1 ; 7$, both to test their abilities in visual closure, but also as a prototype for a colour vision test for younger infants. The results of the study show evidence of development in visual closure abilities across those two ages, suggesting that visual closure is a perceptual ability that continues to develop in the second year of life. The results of this study are discussed in terms of perceptual development in infants and toddlers, and have consequences for both medical and scientific understanding of visual closure in children.

# Executive Functions and Academic Achievement in a High-Poverty Sample 

Gill A. Francis (1)<br>University of Cambridge<br>Zewelanji Serpell (2)<br>Virginia Commonwealth University<br>Teresa Parr (3)<br>Ashley Parr LLC<br>Michelle R. Ellefson (1)<br>University of Cambridge

#### Abstract

Research exploring cognitive theories of executive function (EF) report positive associations with academic outcomes, but whether such general cognitive theories generalise to when children are exposed to social or economic poverty contexts require more in-depth investigating. This study explores associations between EF and academic achievement for an ethnic minority sample aged 8-10 years, from high poverty, urban backgrounds. EF skills were measured using stop-signal (inhibition), continuous performance (sustained attention), task-switching (cognitive flexibility), spatial span (working memory) and Tower of Hanoi (planning). In addition, we included a popular standardized test of academic ability commonly used by schools to measure literacy, numeracy and science skills and the Raven's Progressive Matrices task to measure general cognitive ability. EF is differentiated in this sample and is linked to academic achievement. The role of important mediators like cognitive ability are considered in the context of children with high-poverty urban backgrounds.

# Neural Phase Synchrony on Understanding Meanings of Symbols 

Masayuki Fujiwara<br>Japan Advanced Institute of Science and Technology<br>Takashi Hashimoto<br>Japan Advanced Institute of Science and Technology<br>\section*{Guanhong Li}<br>Japan Advanced Institute of Science and Technology<br>Jiro Okuda<br>Kyoto Sangyo University<br>Takeshi Konno<br>Kanazawa Institute of Technology<br>Kazuyuki Samejima<br>Tamagawa University<br>Junya Morita<br>Shizuoka University

#### Abstract

The establishment of symbolic communication system, i.e., making a shared meaning system from meaningless signals, is studied in experimental semiotics (Galantucci, 2005). Local neural activities within a brain region during a symbolic communication task (Konno et al., 2013), where two participants try to establish a symbolic communication system from scratch, has been studied (Li et al, 2015). It is, however, not certain how information bindings between different brain regions is involved in a cognitive process associated with the establishment process. We analyzed EEG phase synchronization, as a measure of functional connectivity, of participants engaged in the symbolic communication task. We found the recruitment of fronto-occipital synchronization at 40 Hz frequency (gamma band), when a symbolic message was displayed, became fast when establishing a symbolic communication system. This finding suggests that frontal-occipital information binding by phase synchronization becomes efficiently used in the course of mutual understanding of symbolic messages.

# Jumping in Japanese: Converting linguistic instructions into physical performances 

Chie Fukada<br>Kyoto Institute of Technology<br>Noriyuki Kida<br>Kyoto Institute of Technology<br>Hiromichi Hagihara<br>Graduate School of Human and Environmental Studies, Kyoto University<br>Takatsugu Kojima<br>Shiga University of Medical Science

#### Abstract

This study explores the difficulties in physically realizing linguistic instructions concerning the action of jumping. We carried out a questionnaire on the understandability and physical feasibility of various jumping actions in Japanese, and then conducted an experiment in which participants were asked to jump according to these instructions. After the physical performances the participants were asked to rate the easiness of the actions in a second questionnaire, and the results of the two questionnaires were compared. The results show that the understandability of the instructions and the participants' beliefs about the physical feasibility of the instructions were closely correlated. However, the results of the two questionnaires did not correlate. The results suggest that although participants believe they can convert jump instructions into physical performances if the instructions are easy to understand, there are some gaps between the understandability of the linguistic instructions and the physical realization of them.

# The Price of Fear: Developing a behavioural assessment of fear-related avoidance incorporating dynamic response measures. 

Santiago Garcia-Guerrero

National University of Ireland, Galway<br>Denis O’Hora<br>National University of Ireland, Galway

Arkady Zgonnikov
National University of Ireland, Galway

#### Abstract

In economics, "willingness to pay" reflects subjective value which has been employed to price goods, and more recently, negative outcomes. The current project proposes a protocol for the behavioural assessment of fear-related avoidance based on how much an individual is willing to pay to avoid their fears.

The proposed protocol consists of a "card game" interface in which participants make choices in several stages. During baseline, participants chose between two decks that provide differential point rewards. Across a series of experimental blocks, feared stimuli (e.g. a spider image) were presented in addition to rewards when the richer deck was chosen. Rewards were then manipulated, in a staircase fashion, to establish the value of the feared stimulus. Mouse and eye movements were tracked in an attempt to track cognitive processes during decision-making and avoidance. Preliminary results indicate sensitivity of the protocol, and strengths and weaknesses will be discussed.

# On the road to ... somewhere? Change-blindness in event description tasks is informative about the interrelation between visual perception and language planning 

Johannes Gerwien<br>Heidelberg University, Heidelberg, Germany<br>Ines Marberg<br>Heidelberg University, Heidelberg, Germany

#### Abstract

The visual processing of complex event stimuli and the planning of utterances to describe them happen rapidly and partly overlap in time, posing a challenge to researchers on vision and language: How exactly do the processes interact? As a test case we investigate how sudden content-changes in visual scenes affect speakers of different languages. In a novel approach, we elicit event descriptions from naturalistic video stimuli of motion events consisting of two segments (240ms each), each followed by a mask ( 80 ms ). A potential change-blindness situation regarding the presence/absence of the goal of motion is created. We exploit typological differences between French and German regarding the verbal encoding of goal-orientation. Analyses of the linguistic data (content and timing) reveals a language-specific effect regarding how subjects accommodate to seemingly unnoticed changes (e.g., distribution of hesitations, temporal onsets of words). Furthermore, we find differences in overt change detection frequency depending on conditions.

# Mental computations underlying morphosyntax acquisition 

Heidi Getz<br>Georgetown University<br>Elissa Newport<br>Georgetown University

#### Abstract

Research in theoretical linguistics has shown that human languages require abstract and highly detailed grammatical representations. However, we understand surprisingly little about the mechanisms through which these representations are acquired. What kinds of statistical relationships would learners need to compute to construct representations like those posited by linguistic theory? We created miniature languages containing patterns found in natural languages and also patterns not found in natural languages. We showed that complex word-order contingencies are acquired only when they correlate with morphological patterns like those in natural languages. We then asked how learning changes when the statistical evidence for these patterns is manipulated. These experiments illuminate the nature of learners' computations and the units over which they are performed.

# Computational Modelling of Embodied Semantic Cognition: A Deep Learning Approach 

Ajitesh Ghose<br>Centre for Cognition, Computation and Modelling Department of Psychological Sciences, Birkbeck, University of London Malet Street, London, WC1E 7HX, United Kingdom<br>Rick Cooper<br>Centre for Cognition, Computation and Modelling Department of Psychological Sciences, Birkbeck, University of London Malet Street, London, WC1E 7HX, United Kingdom

#### Abstract

Barsalou's $(1999,2003)$ perceptual symbol systems hypothesis describes how semantic knowledge is grounded in sensorimotor experience. According to the theory, knowledge is acquired through sensorimotor simulations. This challenges the classical view supported by the disembodied cognition hypothesis, which generally favours an abstract and symbolic system. We propose a unified perspective, in which, the embodied cognition hypothesis, with a particular focus on the semantic domain, is provided with a mechanistically tractable computational framework based on the parallel distributed processing (PDP) paradigm. A critical difference between the current approach and previous mechanistic accounts of embodied cognition is that the current approach avoids using hand-coded representations and instead, relies on an agent-based simulation with environmental interaction for the creation of situated inputs and outputs, supplemented with supervised and unsupervised deep learning mechanisms, from which semantic cognition emerges.

# The Perceived Duration of Vast Spaces 

Devin Gill<br>University of Utah, Salt Lake City, UT, USA<br>Jeanine Stefanucci<br>University of Utah, Salt Lake City, UT, USA

#### Abstract

Experiencing awe may make us believe we have more time (Rudd, Vohs, \& Aaker, 2012). Awe can be evoked by encountering a vast experience (Keltner \& Haidt, 2003), for example an endless ocean or large mountains (Klatzky, Thompson, Stefanucci, Gill, \& McGee, 2017). Vast environments may lead to distortions in perceived time that are reported after awe experiences. Participants reproduced the perceived duration of images of natural environments that varied in vastness and estimated the degree awe they would experience in those spaces. Results show that as actual duration increased, perceived duration of the image decreased, whereas estimated awe increased. The perceived duration of highly vast images was underestimated less than other images. Participants reported they would experience more awe in highly vast images compared to low and medium vast images. These findings suggest that distortions of time associated with awe may be related to the vastness of the environment.

# The role of spatial skills in mathematics cognition: Evidence from children aged 5-10 years 

Katie Gilligan<br>UCL Institute of Education, London, United Kingdom<br>Alex Hodgkiss<br>UCL Institute of Education, London, United Kingdom<br>Michael Thomas<br>Birkbeck College, University of London<br>Emily Farran<br>UCL Institute of Education, London, United Kingdom

#### Abstract

While there is evidence of associations between spatial skills and mathematics, relatively few studies explore these associations in children aged 5-10 years. I will present findings from longitudinal and cross-sectional studies to highlight the importance of spatial skills as both longitudinal and concurrent predictors of mathematics. First, secondary data analysis of the Millennium Cohort Study indicates that spatial performance at both 5 and 7 years is a significant predictor of mathematics at age $7(\mathrm{~N}=12099)$. Second, cross-sectional findings from children aged $5-10$ years $(\mathrm{N}=156)$, suggest that spatial skills explain 10$12 \%$ of the variation in standardised maths performance and approximate number sense, even after accounting for vocabulary skills. That is, spatial scaling was a significant predictor of mathematics for all age groups, while the role of mental rotation and mental folding varied with age. These findings have implications for the design of mathematics interventions customised for specific developmental stages.

# Investigating the predictions of a memory-based account of statistical learning 

Sandrine Girard<br>Carnegie Mellon University<br>Erik Thiessen<br>Carnegie Mellon University

#### Abstract

Statistical learning (SL) refers to the ability to extract statistical regularities from the environment. Many researchers believe that SL arises as a consequence of the way that information is stored and accessed in memory (Thiessen, Kronstein, \& Hufnagle, 2013). Accordingly, manipulations that influence memory should have similar effects in SL experiments. In the current study, participants were presented with artificial languages that varied along two dimensions known to impact memory: number of distractors in the input and timing of presentation (e.g., spaced vs. massed). Participants' performance was clearly influenced by these manipulations; for example, the ability to segment a word (e.g., "dupona") differed as a function of whether there was one frequent competitor (e.g., "dugalo") or several less frequent competitors (e.g., "dugalo," "dufalu," "dumiso"). Experimental results were compared to two memory-based computational models of SL (PARSER and TRACX). Implications of the experimental results and model comparisons will be discussed.

# Motor Fluency Effects on Causal Judgment: The Role of Grip-Strength Asymmetries and Spatial-Numeric Associations 

Kelly Goedert<br>Seton Hall University<br>Daniel Czarnowski<br>Seton Hall University

#### Abstract

Human understanding of causation may be grounded in our experience of physical forces in the world. We investigated whether right-handers, who exert greater force with their right than left hands, judge candidate causes on the right side as more causal. In two experiments, subjects simultaneously learned about a moderately effective and an ineffective cause on a trial-by-trial basis. Subjects rated the moderately effective cause as more causal when it appeared on the right side of space. This effect was also present in subjects' trial-by-trial predictions, but the effect reversed with a left-right reversal in the spatial-numeric mapping of the causal judgment scale. The results are not consistent with the notion that our understanding of causation is grounded in our ability to exert force. However, they are consistent with influences of motor fluency and polarity correspondence on judgment.

# Comparison of directed gaze during vocalizations in bonobo and human infants 

Ulrike Griebel<br>The University of Memphis, Memphis, TN, USA<br>Josep Call<br>Max Planck Institute for Evolutionary Anthropology. Leipzig, Germany<br>Eugene Buder<br>The University of Memphis, Memphis, TN, USA<br>D. Kimbrough Oller<br>The University of Memphis, Memphis, TN, United States, USA

#### Abstract

A crucial step in language evolution was likely joint attention with alternating gaze between vocalizing individuals and an object. This triadic interaction likely formed a foundation for labeling of objects. We have argued that vocalizations used for "social glue" - flexible low intensity and low arousal vocalizations given during e.g. grooming, keeping in contact with the group, etc. - are a probable source of raw material for first labels. It is critical that these vocalizations be socially directed, by gaze contact. We longitudinally investigated directed gaze during vocalizations in low arousal interactions during the first year in three bonobo mother-infant pairs and compared them with 9 human mother-infant pairs. We found that bonobo infants directed their gaze to a conspecific during vocalizations only $8 \%$ of the time while human infants directed it $44 \%$ of the time.

# How does of initial inaccuracy benefit cross-situational word learning? 

Chris Grimmick<br>New York University<br>George Kachergis<br>Radboud University<br>\section*{Todd Gureckis}<br>New York University

#### Abstract

Both children and adults are able to extract several intended word-referent mappings from a series of scenes containing multiple words and objects. Known as cross-situational learning, this ability is thought to be an important means of acquiring language. Proposed models of this ability range from hypothesis-testing accounts to associative accounts, but most formal models assume learners store one or more feasible word-referent mappings per experience, and that the correct mappings emerge through consistent co-occurrence. These theories would all predict that presenting unambiguous evidence for a correct pair would benefit learning, but recent evidence indicates the reverse is true: giving unambiguous evidence for incorrect pairs improves subsequent cross-situational learning (Fitneva and Christiansen, 2015). With some nuances, we replicate these results, and show why future models may need to include an error-driven learning mechanism to explain word learning.

# On the Detection of "Alternative Facts" in Environmental Messages: The Effects of a Sequential versus a Simultaneous Presentation Format 

Mona Guath<br>Uppsala University, Uppsala, Sweden<br>Peter Juslin<br>Uppsala University, Uppsala, Sweden

#### Abstract

Reasonable rational information processing is important in people's in everyday decision-making. A number of features affect how environmental messages are processed, including the presentation format and the reliability of the information source. One way to measure the importance assigned to the source reliability is to frame the question in terms of Bayes' theorem (Hahn \& Harris, 2009). In two online experiments, we investigated how people process environmental messages in a Bayesian integration task where the participants rate the probability of an energy crisis. The information about the prior, likelihood ratio, and source reliability were presented either sequentially or simultaneously. The results showed that, as prescribed by Bayes' theorem, participants integrated the sentences multiplicatively. However, with sequential presentation they assigned more weight to source reliability, and this effect remained when the source reliability was presented next to last, suggesting that participants assigned more weight to the source regardless of its position.

# Exploring inductive bias of visual scenes 

Jessica Hamrick<br>University of California, Berkeley, Berkeley, CA, USA<br>David Bourgin<br>University of California, Berkeley, Berkeley, CA, USA<br>Thomas Langlois<br>University of California, Berkeley, Berkeley, CA, USA<br>Tom Griffiths<br>University of California, Berkeley, Berkeley, CA, USA

#### Abstract

When people encode a representation of a scene, they do not necessarily represent the exact locations and orientations of the constituent elements. Instead, people rely on preexisting inductive biases to simplify their encoding of new scene configurations. We investigated people's inductive biases in their memory for configurations of simple 2D shapes (such as circles, triangles, etc.) using a serial reproduction paradigm (Bartlett, 1932). This paradigm establishes an iterative process in which information is transmitted through a chain of people (like the "telephone" game). In our experiment, we asked people to memorize configurations of simple shapes (which were either generated at random or by other participants) and then asked them to reproduce those configurations. In analyzing the final generation of reproductions, we found that people have strong preferences for the scale of individual shapes, as well as the alignment, distance, overlap, and relative rotation between pairs of shapes.

# Choosing while Losing: The Effects of Valence and Relative Magnitude on Decision Dynamics. 

Avril Hand<br>National University of Ireland, Galway, Ireland<br>Denis O'Hora<br>National University of Ireland, Galway, Ireland<br>Rick Dale<br>University of California, Merced, USA<br>Petri Piiroinen<br>National University of Ireland, Galway, Ireland

#### Abstract

Framing decision options as gains or as losses affects how we evaluate those options. The current study assessed the effects of gain- and loss-framing on the acquisition of outcome values across decisions and on the dynamics of computer mouse responses to those decisions. In a series of 36 decisions per block, four arbitrary symbols were presented, two of which were assigned high points (e.g., 20) and two of which were assigned low points (e.g., 5). Participants ( $\mathrm{N}=86$ ) learned to choose high values and avoid low values when values were positive and to choose low values and avoid high values when they were negative. Loss-framed outcomes (i.e., negative valence) were learned faster and more reliably. Response trajectories following acquisition were slower, more curved and exhibited greater vacillation when choosing between two poor outcomes. These effects were stronger when poor outcomes were negatively valenced.

# The Relationship between Anxiety, Mind Wandering and Task-switching: A Diffusion Model Analysis 

Andree Hartanto<br>Singapore Management University<br>Hwajin Yang<br>Singapore Management University

#### Abstract

The current study aims to examine the mechanisms underlying the negative impact of anxiety on task-switching. To do so, we employed a stochastic diffusion model analysis along with a thought-probe technique in task-switching paradigm. Across 152 participants, we found state anxiety was associated to higher switch costs in nondecision time but not drift rate parameter of diffusion model, implying that the locus of task-switching impairment in anxious individuals is pertinent to the efficiency of task-set reconfiguration but not proactive interference processes. Furthermore, we found boundary separation parameter - which quantifies conservative decisional styles - heightened as a function of anxiety, supporting the existence of compensatory strategy in anxious individuals. Lastly, we found that impaired performance by anxiety was not attributed to the frequency of worrisome thoughts during task-switching. These findings elucidate several theoretical assumptions on the relationship between anxiety and task-switching.

# Do people behave dishonestly easily? 

Hajimu Hayashi

Kobe University

#### Abstract

This study examines whether dishonest behaviors occur easily. In 60 trials, 100 undergraduate students viewed 20 dots on a square divided into right and left sides and had to decide which side contained more dots within one second (developed by Gino et al., 2010). In with-reward condition, participants received 0.1 point for each left decision and 1 point for each right decision, and they received more sweets depending on points. Therefore, this asymmetrical payment structure triggered motivation to dishonestly report more right-side dots, even when there are actually more left-side dots. The results demonstrate that participants decided at greater frequencies that more dots were on the right side in with-reward condition than in without-reward condition, indicating dishonest behaviors occurred. Furthermore, participants with greater right-side frequencies in with-reward condition showed lower points on a morality scale. These results suggest dishonest behaviors occur easily and are related with a decline in morality.

# Hierarchical Processing of Response Production and Categorisation 

Liusha He<br>Centre for Cognition, Computation and Modelling Department of Psychological Sciences, Birkbeck, University of London, London, London, United Kingdom

Rick Cooper
Birkbeck, University of London, London, England, United Kingdom

#### Abstract

Early research on categorisation suggested that verbalizable and nonverbalizable category-learning are qualitatively different. Toward this end, the implementational-level model (COVIS-COmpetition between Verbal and Implicit Systems) of categorisation assumes that category-learning involves separate but parallel sub-systems. Specifically, for verbalizable tasks abstract category-labels are learned by a hypothesis-testing sub-system, while for nonvertbalizable tasks response position is learned by a procedural-learning sub-system. However, recent research has revealed that: 1) regardless of category structure, reversal learning is easier than learning novel categories; 2) qualitative difference between verbalizable and nonverbalizable tasks disappears when automaticity has developed; and 3) control of automatic categorisation is different from both proposed sub-systems. These challenges suggest a fundamental revision of the mechanisms of categorisation. Contrary to the separate, parallel-processing sub-systems theory, we argue that categorisation involves hierarchical-processing sub-systems of responseproduction and category-label association. This framework, when combined with Supervisory Attentional System theory, may facilitate the unification of human categorisation.

# Where are you? The Effect of Uncertainty and its Visual Representation on Location Judgments in GPS-like Displays 

Mary Hegarty<br>University of California, Santa Barbara

Alinda Friedman<br>University of Alberta

Alexander P. Boone<br>University of California, Santa Barbara, Santa Barbara, CA, USA

Trevor J. Barrett
University of California, Santa Barbara

#### Abstract

Two experiments revealed how non-experts interpret visualizations of positional uncertainty on GPS-like displays and how the visual representation of uncertainty affects their judgments. Participants were shown maps with representations of their current location; locational uncertainty was visualized as either a circle (confidence interval) or a faded glyph (indicating the probability density function directly). When shown a single circle or faded glyph, participants assumed they were located at the center of the uncertain region. In a task that required combining two uncertain estimates of their location, the most common strategy - integration - was to take both estimates into account, with more weight given to the more certain estimate. Participants' strategies were not affected by how uncertainty was visualized, but visualization affected the consistency of their responses. The results indicate that non-experts have an intuitive understanding of uncertainty and that the best visualization method is task dependent.

# Semantic Bootstrapping in Frames: A Computational Model of Syntactic Category Acquisition 

John Hewitt<br>University of Pennsylvania<br>\section*{Charles Yang}<br>University of Pennsylvania

#### Abstract

Semantic Bootstrapping in Frames: A Computational Model of Syntactic Category Acquisition According to the semantic bootstrapping hypothesis, children map certain (prototypical) semantic concepts to syntactic categories (e.g., objects as nouns, actions as verbs), which are then used to learn other elements of language. We report a computational model of syntactic category acquisition that combines semantic bootstrapping with the distributional learning of language. The model has access to a small set of "seed" words, with labeled categories. It then iteratively constructs syntactic frames from the seeds; sufficiently frequent frames are used to categorize non-seeded words which then contribute to the construction of additional frames, including frames that incorporate category information. The model is online and effective. Simulation on child-directed English corpus shows that with only 100 seed words, classification precision exceeds $70 \%$.

# Tangible rhythm: Sensorimotor representations of metrical structure and learning musical rhythm with gesture 

Courtney Hilton<br>The University of Sydney, Sydney, NSW, Australia<br>Micah Goldwater<br>The University of Sydney, Sydney, NSW, Australia<br>Michael Jacobson<br>The University of Sydney, Sydney, NSW, Australia

#### Abstract

When we listen to music, we can mentally control how we perceive the beat. This ability is thought to be subserved by sensorimotor imagery, having top-down effects on attentional-allocation and perception. Here, we examine whether imagined "up and down" gestures can support an internal generation of metrical accent in rhythmic sequences. We also examine how this type of motor imagery interacts with either metrically congruent or incongruent auditory imagery. This is explored using EEG with a frequency-tagging approach, quantifying the strength of metrical accent with the amplitude of beat-related SSEPs. Gesture supports our ability to think and learn by fostering an alignment between sensorimotor representations and more abstract conceptual structure. Therefore, the imagined gestures may act as a bridge between perceptual and action-oriented understandings of metrical structure and the more abstract conceptual ones that musicians struggle with in their training. These imagery strategies may then be beneficial to music education.

# Eye movement-based probabilistic models for physical scene understanding 

Eghbal Hosseini<br>Massachusetts Institute of Technology<br>Eli Pollock<br>Massachusetts Institute of Technology<br>Tobias Gerstenberg<br>Massachusetts Institute of Technology

#### Abstract

Humans make prediction about physical environments and future events through inference. Previous research has proposed that a common sense engine implementing probabilistic programming is used to build an internal model of the environment, and simulations of that internal model are used for inferences. Battaglia et al.(2013) have demonstrated an application of this formulation in physical scene understanding and stability judgment in the case of block tower. Here we augment this formulation by including the subjects' eye movements as a process of sampling the environment, and propose that the underlying common sense model guides gaze toward sampling the features of the space with relevant information for the judgments about stability. We compare a base probabilistic model with one that takes the statistics of the saccades into account, and argue that the additional information improves the model predictions about subjects' judgment.

# Data Driven Eye Gaze Path Segmentation 

Joseph Houpt<br>Wright State University, Dayton, Ohio, USA<br>Mary Frame<br>Miami University, Oxford, Ohio, USA<br>Leslie Blaha<br>Pacific Northwest National Laboratory, Richland, Washington, USA

#### Abstract

The first stage of analyzing eye-tracking data is commonly to code the data into sequences of fixations and saccades. This is usually automated using simple, predetermined rules for classifying ranges of the time series into events, such as "if the dispersion of gaze samples is lower than the threshold, then code as a fixation." More recent approaches incorporate additional eye-movement categories in automated parsing algorithms, particularly glissades, by using time-varying, data-driven thresholds. We describe an alternative approach using the beta-process auto-regressive hidden Markov model (BP-AR HMM). The BP-AR-HMM offers two main advantages over existing frameworks. First, it provides a statistical model for eye movement classification rather than a single estimate. Second, the BP-AR-HMM uses a latent process to model the number and nature of the types of eye-movements and hence is not constrained to predetermined categories. We present comparisons between BP-AR-HMM parsing and standard analyses on multiple datasets.

# Case Markers Facilitate Abstraction of Syntax among Mandarin-speaking preschoolers 

Dong-Bo Hsu<br>National Taiwan Normal University, Taipei, Taiwan, Taiwan, R.O.C.

#### Abstract

In light of the studies that investigate when and how English-speaking young children exhibit adult-like abstraction of syntax, this study explores these issues by examining Mandarin-speaking preschoolers ranging from 2- to 5-year-olds' comprehension of the Mandarin SVO-, ba-, long-passive, and short-passive constructions using the forced-choice pointing paradigm. The results indicated that at the age of 2, Mandarin preschoolers exhibited abstraction of syntax in these four constructions. These results went against the predictions of accounts derived from the structure mapping account and from the competition model. Instead, Mandarin ba- (used in the ba-construction) and bei-markers (used in the long- and short-passive constructions) play an important role in Mandarin-speaking young children's demonstrations of abstraction of syntax.

# An Exploratory Study on Remote Associates Problem Solving: Evidence of Eye Movement Indicators 

Po-Sheng Huang<br>Hsuan Chuang University, Hsinchu, Taiwan, R.O.C.<br>Shu-Ling Peng<br>National Cheng Kung Univeristy, Tainan, Taiwan, ROC<br>Jon-Fan Hu<br>National Cheng Kung Univeristy, Tainan, Taiwan, ROC

#### Abstract

Remote associates problems (RAP) have been widely used to measure creative processes. However, studies have rarely explored the RAP processes. The main purpose of this study was to record eye movements while solving RAP. The results show that: (1) The mean fixation duration increases throughout the problem-solving process, which indicates that more problem solvers encounter impasses. This result supports the "impasse encounter" phase of insight. (2) During the initial period of problem solving, individuals display more regression counts in the fixation region than in the key region, which supports that the impasses are caused by inappropriate initial representation. (3) During the middle period of the process, the time individuals spend gazing at the key region increases, while the time spend at the fixation region decreases. This supports the "impasse resolution and insight" phase of insight.

# Processing of Filler-gap Dependency in Island Constraints and its Relation to Working Memory for Non-native Speakers of English 

Kuan-Jung Huang<br>National Cheng Kung University, Tainan, Taiwan<br>Jon-Fan Hu<br>National Cheng Kung Univeristy, Tainan, Taiwan, ROC<br>Anastazija Rajkovic<br>National Cheng Kung University, Tainan, Taiwan

#### Abstract

Whether non-native speakers' on-line processing can be native-like remains a hot issue. Recently many have shown that qualitatively native-like processing is attainable, especially for learners with high proficiency. However, most of the studies recruited learners who had been immersed to the English-speaking country. The current study investigated processing of fillergap dependency and island constraints for Chinese learners of English as a second but foreign language. We also attempted to look into individual differences by taking different variables into account. The results showed that native-like active gap-filling strategy positively correlated with L2 proficiency, native-like island effect negatively correlated with age of acquisition, but neither one correlated with working memory capacity. These findings lent more support to the grammar-based account for island effects, though future studies adopting more precise measure of working memory would be needed. The study also called for further investigation into L1 background on processing islands in an L2.

# Linguistic processes in translation: Eye-tracking reveals differential effects of phrase order and lexical choice 

Xin Huang<br>University of Macau<br>Wei (sophia) Deng University of Macau<br>University of Macau

## Defeng Li

University of Macau

#### Abstract

What are the processes underlying the judgments of translation? And what is the role of language proficiency? This study addresses these questions by examining how Chinese-English bilinguals evaluate poetry translations. Participants were shown haikus in Chinese and the corresponding English translations and were asked to rate the translation quality. The English translations ranged from literal to free style and differed in two source text factors - phrase order and lexical choice. Results indicated an interaction between translation style and language proficiency, with the high proficiency bilinguals giving free translations higher ratings. Furthermore, the analyses of eye movements revealed that, (a) in contrast to low proficiency bilinguals, high proficiency bilinguals tended to integrate discourse information regardless of intra-text re-ordering, and (b) among the good quality translations, the phrase order effect was more prominent than the lexical effect. These findings suggest the interplaying roles of language proficiency and linguistic factors in translation.

# How reactivation strength affects memory updating 

Scully Iiona<br>Lehigh University<br>Hupbach Almut<br>Lehigh University

#### Abstract

Memory reactivation induces plasticity, rendering reactivated memories susceptible to interference. The current study examined whether the method and strength of reactivation modulates retroactive interference effects. Two days after learning AB word pairs, memory for these pairs was either not reactivated, moderately reactivated (presentation of A cues in an unrelated task), or strongly reactivated (restudy of AB pairs or cued recall of B targets). Immediately afterwards, participants either learned AC word pairs, DE word pairs, or performed an unrelated distractor task. Cued recall of target words was tested two days later. Strong reactivation before learning new material protected memory from retroactive interference and intrusions, whereas moderate reactivation resulted in both. This finding suggests that strong reactivation enhances event-based distinctiveness, counteracting memory modification. Results are discussed in reference to the testing effect literature and the reconsolidation account, and implications for educational practice are outlined.

# An fNIRS Hyperscanning Study on Brain-Brain Interactions of a Dyad during a Joint Sentence Reading Task 

Erdinc Isbilir<br>Middle East Technical University, Ankara, Ankara, Turkey<br>Murat Perit Cakir<br>Middle East Technical University, Ankara, Turkey<br>Fred Cummins<br>University College Dublin<br>Hasan Ayaz<br>Drexel University

#### Abstract

Existing studies in cognitive neuroscience predominantly focus on a single participant's behavioral and brain responses. Lack of an interactive context for joint action particularly limited social neuroscience studies to simulated social contexts. Advances in portable brain imaging technologies have made it practical to simultaneously monitor the brain activity of two or more people in an interactive context to investigate neural correlates of social interaction. In this study, the relationship between behavioral synchrony and inter-brain coherence is investigated during simultaneous reading of matching and mismatching sentences in different auditory conditions. A dual-fNIRS hyperscanning setup was used to obtain simultaneous recordings of hemodynamic activity from the prefrontal cortices of the participants while they jointly read-aloud the sentences displayed on their screens. The results suggest that the level of inter-brain coherence in the right superior cortex tends to increase depending on the level of behavioral synchrony among the participants.

# Pre-term infants exhibit impaired prediction and learning in Audio-Visual association paradigm 

Sagi Jaffe-Dax<br>Princeton University

Alex M Boldin<br>Princeton University<br>Nathaniel D Daw<br>Princeton University<br>Lauren L Emberson<br>Princeton University

#### Abstract

Forming reliable predictions about upcoming events are both essential to and the product of successful learning. Using fNIRS recording of cortical hemodynamics, we measured infants' prediction of upcoming visual events that were preceded by auditory cues in infants who are at-risk for poor development due to premature birth and their full-term peers. We compared prediction and learning across groups by fitting their occipital cortex response (which we assumed to reflect the magnitude of the prediction error) to a reinforcement learning model with a dynamic learning rate. We found that preemies had a lower learning rate than full-terms. These findings shed light on the origins of the developmental difficulties associated with prematurity.

# Endpoints and Midpoints in Event Perception 

Yue Ji

University of Delaware

Anna Papafragou<br>University of Delaware

#### Abstract

Events unfold over time, i.e., they have a beginning and endpoint. Previous studies have illustrated the importance of endpoints for the perception and memory of various events (Lakusta \& Landau, 2005, 2012; Papafragou, 2010; Regier \& Zheng, 2009; Strickland \& Keil, 2011; Zacks \& Swallow, 2007). However, this work has not compared endpoints to other potentially salient points in the internal temporal profile of events (e.g., midpoints). Building on the "picky puppet task" (Waxman \& Gelman, 1986), we presented 4-to-5-year-old children and adults with a puppet that liked clips of events containing brief screen blanks that disrupted either the midpoint or the endpoint of the event. Both children and adults learned the puppet's preferences better (as evidenced by their extension to novel events) when the puppet liked midpoint compared to endpoint interruptions. These findings suggest a bias for event endpoints that is present from an early age.

# Dynamic and multiplexed networks for working memory 

Elizabeth Johnson<br>University of California, Berkeley<br>Robert Knight<br>University of California, Berkeley

#### Abstract

Working memory (WM) provides the neurobiological infrastructure for human cognition. Dominant models posit that prefrontal cortex (PFC) supports WM by coordinating control over distributed memory representations. In two studies, multimodal electrophysiology data reveal that PFC control over WM is rhythmic, fundamentally dynamic, and not altogether necessary. Direct brain recordings ( $\mathrm{n}=10$ ) demonstrate that PFC and medial temporal lobe (MTL) theta-band rhythms direct a complex system of higher-frequency neural activity across regions, uncovering initial support for bidirectional PFC-MTL interactions related to WM demands. Then, data from patients with unilateral PFC damage ( $\mathrm{n}=14$ ) challenge dominant models on the central role of PFC (note $8 \%$ accuracy decrease in patients). In healthy controls ( $\mathrm{n}=20$ ), delta-theta-band rhythms precess from PFC toward parieto-occipital sites, concurrent with alpha-beta-band rhythms precessing in the opposite direction. All PFC effects are diminished with unilateral damage, revealing an independent posterior WM mechanism. These results reveal that rapid, parallel processing governs WM.

# Improving Perceptual Reasoning in School Children through Chess Training 

Ebenezer Joseph<br>Madras University, Chennai, Tanilnadu, India<br>Sumathi Chandrasekaran<br>Emmanuel Chess Centre - DST Project, Chennai, Tamilnadu, India<br>Uma T.r.<br>Emmanuel Chess Centre,Chennai, Tamilnadu, India<br>Veena Easvaradoss<br>Women's Christian College, Chennai, Tamilnadu, India

#### Abstract

Perceptual reasoning is the ability that incorporates fluid reasoning, spatial processing, and visual motor integration. Several theories of cognitive functioning emphasize the importance of fluid reasoning. Tasks that require fluid reasoning involve the process of manipulating abstractions, rules, generalizations, and logical relationships. A pretest-posttest with control group design was used, with 43 ( 28 boys, 15 girls) children in the experimental group and 42 ( 26 boys, 16 girls) children in the control group. The sample was selected from children studying in two private schools from South India, which included both the genders. The experimental group underwent weekly one-hour chess training for one year. Perceptual reasoning was measured by three subtests of WISC-IV INDIA. Pre-equivalence of means was established. Statistical analyses revealed that the experimental group shows statistically significant improvement in perceptual reasoning compared to the control group. The present study establishes a correlation between chess learning and perceptual reasoning.

# Measuring Demand Avoidance with the Demand Selection Task: Challenges and Opportunities 

Ion Juvina<br>Wright State University<br>Jeffrey Nador<br>Wright State University<br>Othalia Larue<br>Wright State University<br>Randall Green<br>Wright State University<br>Brandon Minnery<br>Wright State University

Assaf Harel<br>Wright State University

#### Abstract

When given the chance to choose between two tasks, one will more likely choose the easier, less demanding task. This effect has been shown in various domains and referred to as the law of minimum effort or demand avoidance. Kool and colleagues $(2010,2013)$ designed the demand selection task (DST) and showed that most of their participants exhibited clear demand avoidance. We attempted to replicate and extend their results in a series of three studies. Here we argue that DST confounds demand detection and demand selection, which weakens its ability to reliably measure demand avoidance in different populations. In our first study, most participants did not show reliable demand avoidance and those who showed it had higher working memory capacity. The following two studies aimed to de-confound the two processes. We define a new measure of demand avoidance that affords a more robust estimation of demand avoidance in different populations.

# Optimizing Mathematic Learning: Effects of Continuous and Nominal Practice Format on Transfer of Arithmetic Skills 

Charles Kalish<br>University of Wisconsin-Madison, Madison, Wisconsin, USA<br>Rui Meng<br>University of Wisconsin-Madison, Madison, Wisconsin, USA<br>Ayon Seng<br>University of Wisconsin-Madison, Madison, Wisconsin, USA<br>Percival Matthews<br>University of Wisconsin-Madison, Madison, Wisconsin, USA

#### Abstract

Should we give learners a lot of practice with a few problems, or a little practice with a variety of problems? The best practice set depends on the way people are learning. We describe two models people employ when learning arithmetic problems. We show that features of the task environment influence model use. When problems are presented in a purely symbolic format, people learn an item-specific model. When the task format linked problems to representations of magnitudes, people learn a continuous model. We also test the effects of different practice sets on learning. In both formats people learned the practice sets well with a few repeated examples. With a continuous magnitude format people showed better transfer with a wide variety of practice problems. Variety led to poor learning in the symbolic format. In ongoing research we are attempting to identify the optimal practice set for each type of learning model.

# Priors, informative cues and ambiguity aversion 

Lauren Kennedy<br>University of Adelaide

Amy Perfors<br>University of Adelaide

## Daniel Navarro

University of New South Wales

#### Abstract

Ambiguity aversion, or the preference for options with known rather than unknown probabilities, is a robust finding within the decision making literature (see Camerer \& Weber, 1992, for a review). There are some suggestions this averseness is due differences in the inferred prior distribution (Güney \& Newell, 2015). In this study we investigated the relationship between prior distributions and information cues on decision making and participants' judgments of underlying distribution. We used three different prior cues; a positive underlying distributional cue, a negative underlying distributional cue, and a neutral cue. We also used five different information cues which varied both the bias of the information and the degree of ambiguity. Whilst we found that both prior and information manipulations had the expected impact for participants' judgments of underlying distributions, they only impacted the decisions participants made in some cases. There were also interesting interactions between the prior and information manipulations.

# Moral Judgments in Trolley Like Dilemmas: An Eye-Tracking Study 

Vjeran Keric<br>New Bulgarian University

## Evgeniya Hristova

New Bulgarian University

#### Abstract

Previous research suggests that participants may be susceptible to confirmation bias after making decisions in moral dilemmas. We manipulated the type of moral dilemmas (personal or impersonal) and the framing of the question prompting participants to respond (emphasizing saving five people or sacrificing one person). The actors in the dilemmas were represented by a series of silhouettes. Eye tracking data revealed that both manipulations had an effect on participants' gaze. Further analysis of utilitarian choices has shown that there were no framing effects of the prompting question when the dilemmas were impersonal. The data suggests that participants' subsequent gaze patterns are sensitive to both how the situation is described and the framing of their hypothetical actions. Taken together, our results provide some support to the claim that confirmation bias may arise after making moral decisions.

# Word retrieval decline in midlife: a voxel-based morphometry study 

Vanja Kljajevic

University of the Basque Country, Vitoria \& IKERBASQUE, Basque Foundation for Science, Bilbao, Spain

#### Abstract

There is currently little understanding on whether significant word retrieval difficulties appear during midlife and if so, whether they relate to decrease in grey matter (GM) density that accompanies aging. To answer this question, we studied retrieval of proper names in 125 cognitively healthy middle-aged persons ( $49.7, \pm 3.2$ ) comparing their performance on a tip-of-the-tongue (TOT) task with that of 86 young persons $(25.4, \pm 3.5)$ from the Cam-Can data repository (http://www.mrccbu.cam.ac.uk/datasets/camcan/). The middle age (MA) group was worse in word retrieval ( $\mathrm{U}=23950.5, \mathrm{p}=0.003$ ) and had less GM volume in a range of left fronto-temporal areas relative to the young group, but there were no statistically significant correlations between volumes of the regions known to be implicated in word retrieval and MA's TOT scores. Thus, midlife word retrieval decline is not associated with GM volume reduction; more likely it is due to changes in connectivity.

# The relationship between verbal route descriptions and personal characteristics of empathy 

Takatsugu Kojima<br>Shiga University of Medical Science

#### Abstract

Empathy is important for good verbal navigation instructions. The present study examined the relationship between verbal route descriptions and personal characteristics of empathy using a verbal navigation task and the Japanese Interpersonal Reactivity Index (IRI-J). In the verbal navigation task, participants were presented a maze map and were instructed to provide verbal route instructions to reach a goal, to a person who is lost in the maze. Then, the participants answered a questionnaire about their own navigation abilities and responded to the IRI-J. The descriptive data were objectively evaluated with reference to the following three points: types of spatial description (survey or route), consideration for the other person's point of view, and unambiguity of instruction. We analyzed the relationships between the descriptive traits and scores on the two questionnaires, and found that the three points were good predictors for some empathy-related factors measured by the IRI-J.

# Explanatory Completeness: Evidence from Causal Chains 

Joanna Korman<br>Navy Center for Applied Research in Artificial Intelligence, Naval Research Laboratory, Washington DC, USA<br>\section*{Sangeet Khemlani}<br>Navy Center for Applied Research in Artificial Intelligence, Naval Research Laboratory, Washington, DC, USA

#### Abstract

Explanations have no bound in principle, but in practice, people prefer explanations that are complete (Zemla et al., 2017), and the explanations that they generate are bounded (Miyake, 1986). We tested reasoners' ability to assess whether some explanations are incomplete. Participants in three experiments received explanations, i.e., chains of causal events, e.g., A causes B causes C. Their task was to choose questions relevant to links in the chain. Some explanations contained "breaks" in the chain, whereas others did not. Participants in three studies were able to detect the breaks, and preliminary data suggest that they assess explanations with breaks as less complete than those without breaks. Many participants also chose to ask questions about the initial event in a causal chain (e.g., A in the chain above), suggesting that such initial events are themselves seen as incomplete. The studies reveal a novel pattern in reasoners' ability to formulate explanations.

# Different alternative explanations can render different information relevant to explaining an event 

Barbara Koslowski<br>Cornell University<br>Francoise Vermeylen<br>Cornell University

#### Abstract

Scientific reasoning includes deciding whether information is relevant to explaining an event. In some cases, seeing information as relevant requires having a background theory or explanation that can make sense of the information. College students were shown a possible explanation for an event, along with two pieces of possibly relevant information (Infol and Info2), and one of two possible alternative explanations (Alt1 or Alt2). Info1 was seen as more relevant when Alt1 rather than Alt2 was presented; Info2 was seen as more relevant when Alt2 rather than Alt1 was presented. In addition, relevance ratings of the information increased as did initial ratings of the Alternative. People from different backgrounds might bring with them different alternative theories that can hinder the understanding of why some information is relevant and other information not. In addition, finding the initial alternative compelling might enable people to better assess the relevance of additional information.

# One-shot Learning and Classification in Children 

Eliza kosoy<br>MIT, cambridge<br>\section*{Brenden Lake}<br>New York University, New York City, NY, USA<br>Josh Tenenbaum<br>MIT, Cambridge

#### Abstract

People can often generalize concepts from just a single example, while machine learning algorithms typically require hundreds. Lake, Salakhutdinov and Tenenbaum (2016) studied this ability in the domain of handwritten characters, and proposed a model for one-shot learning of new concepts based on inferring compositionally structured generative models, and transfer (or learning to learn) from familiar concepts. Lake et al showed that their model fit well with the classifications and drawings of adults, but provided no direct evidence for the role of learning to learn which presumably occurs mostly in children learning to draw. Here we study the drawing and classification abilities of children ages 3-5, asking whether their ability to classify novel objects and handwritten characters is related to their ability to infer an appropriate motor program for drawing or tracing characters. Preliminary results suggest at least a weak relationship between these abilities, independent of age.

# Mentioning atypical properties of objects is communicatively efficient 

Elisa Kreiss<br>University of Osnabrueck<br>Robert X.d. Hawkins<br>Stanford University<br>Judith Degen<br>Stanford University<br>Noah Goodman<br>Stanford University

#### Abstract

What governs how much information speakers include in referring expressions? Atypical properties of objects are more likely to be included in referring expressions than typical ones. E.g., speakers are more likely to call a blue banana a "blue banana" and a yellow banana a "banana". A unified account of this phenomenon is lacking. When should a rational speaker mention an object's color? Reference production is modeled within the Rational Speech Act framework. Utterances ("banana", "blue", and "blue banana") are taken to have a graded semantics: rather than assuming all bananas are equally good instances of "banana", we empirically elicited object-utterance typicality values for all possible utterances. Pragmatic speakers select utterances proportionally to the probability that a literal listener using a graded semantics will select the intended referent. We evaluate the proposed model on a dataset of freely produced referring expressions collected in an interactive reference game experiment via the web.

# Why Would 'Same' Go With 'Same'? Exploring New Factors Required For Relational Reasoning 

Ivan Kroupin<br>Harvard University<br>Susan Carey<br>Harvard University

#### Abstract

Relational Match to Sample (RMTS) is a common test of relational reasoning involving matching cards based on the relations "same" and "different". Children below the age of five fail RMTS, even with corrective feedback. Given that success on RMTS depends on the ability to represent and compare "same" and "different", such failure has been interpreted as indicative of the absence of these abilities (Penn, Holyoak \& Povinelli, 2008; Hochmann, Mody \& Carey, 2016).

In the current studies three, four and five-year-old children were provided explicit instructions on RMTS. Results show success in all groups, including three-year-olds - two years earlier than previous work. This suggests the ability to represent and compare "same" and "different" emerges significantly earlier than spontaneous success on RMTS, undermining previous interpretations. More generally, this work begins to explore the nature of the development which allows existing relational reasoning capacities to be spontaneously deployed in RMTS.

# When reading is harder than a mother kucker: Top-down effects of the taboo-ness on novel word pronunciation 

Sarah Kucker<br>University of Wisconsin Oshkosh<br>Lynn Perry<br>University of Miami, Coral Gables, Florida, United States

#### Abstract

When pronouncing novel/unknown words, readers often use prior experience with similar, neighbor words. Comparison to neighbors can be helpful for unknown or novel words (wug is like pug), but it can also lead to errors (pint is not like mint). We investigate whether pronunciation can be affected by top-down influences, specifically the perceived taboo-ness of a known neighbor. While orthographic similarity typically biases novel-word pronunciation to be similar to a known word, taboo-ness might bias pronunciation away from a likely one. Adults read aloud words from three lists- novel words that were neighbors to taboo words, novel words that were neighbors to benign words, and known control words. All known neighbors and controls were frequency matched. Results show differences in the correspondence between pronunciation of novel words and known neighbors depending on the relative taboo-ness of the known neighbor. Findings suggest that perceived taboo-ness has top-down influences on reading.

# Effects of Variable Response-Stimulus Interval (RSI) On Sequence Learning 

Sneha Kummetha

Cognitive Science Lab, International Institute of Information Technology, Hyderabad, India
Anuj Shukla
Cognitive Science Lab, International Institute of Information Technology, Hyderabad, India

## Raju Bapi

Cognitive Science Lab, International Institute of Information Technology, Hyderabad, India and School of Computer and Information Sciences, University of Hyderabad, Hyderabad, India

#### Abstract

The objective of this study was to investigate the effects of varying Response-to-Stimulus interval (RSI) on sequence learning by systematically varying it across three different groups (Group1: 0-300ms, Group2: 400-700ms and Group3: 8001100 ms ) and to assess the implicitness and explicitness of the knowledge acquired through such learning. Serial Reaction time task followed by generation task and recognition task were used for this purpose. Results of the SRT task showed learning in all the three groups and the results of the free generation task and recognition task revealed that the sequence learning was implicit in Groups 1 and 2 while it was explicit in Group3. These results were discussed in the context of a recent theoretical framework that proposes conditions in which a switch from implicit to explicit knowledge acquisition is facilitated.

# Object Understanding: Exploring the Path from Percept to Meaning 

Kenneth Kurtz<br>Binghamton University<br>Daniel Silliman<br>Binghamton University

#### Abstract

This research addresses the generation of meaningful interpretations of real-world perceptual stimuli. According to a widespread framework we will call the features-first view, a stimulus is initially encoded via semantically-laden, symbollike properties that are compared to stored category representations to find the best match. Alternative theoretical perspectives challenge the features-first view, but there has been no direct empirical test. In our experiment, participants were shown photographic images of everyday objects and asked to judge as quickly as possible whether a provided verbal descriptive matched the picture. We tested different levels of delay between image and descriptive and found evidence that basic-level category labels were verified faster than clearly manifested descriptions of physical or functional properties. Accordingly, people know the category of the stimulus before knowing its semantic properties. The present evidence suggests that the category is used to achieve a property-level description of the meaning of the stimulus, not vice-versa.

# Effect of Touch-produced Sounds on Surface Texture Perception 

Jinhwan Kwon<br>Department of Informatics, The University of Electro-Communications<br>Suguru Hata<br>Department of Informatics, The University of Electro-Communications<br>Natsumi Komoto<br>Department of Informatics, The University of Electro-Communications<br>Maki Sakamoto<br>Department of Informatics, The University of Electro-Communications

#### Abstract

Texture is an important source of information for distinguishing surface properties. We are able to perceive various textural properties of surfaces from tactile or visual inputs. However, it is unclear how touch-produced sounds influence the various surface texture perceptions. In this study, we examined whether the touch sounds produced by different surface textures influence the various surface perceptions. Consequently, the surface textures with high height and wide interval resulted in rough, bumpy, soft and cool perceptions and the surface textures with the low height and narrow interval resulted in smooth, flat, hard and warm perception. Also, there were statistically significant differences in these measures between two surface texture groups. Furthermore, significantly positive correlations were found in "rough - smooth", "bumpy - flat", "sticky slippery", "wet - dry" and "unpleasant - pleasant" measures between touch-produced sounds and actual touch. This indicate that the touch-produced sounds influence various surface perceptions.

# Identifying Causal Direction in the Two-Variable Case 

Pablo León-Villagrá<br>University of Edinburgh, Edinburgh, United Kingdom<br>Christopher Lucas<br>University of Edinburgh, Edinburgh, United Kingdom

#### Abstract

One of the key characteristics of human cognition is the ability to learn causal structure from data. An influential thread of research into causal learning relies on causal graphical models as a theoretical foundation, and emphasizes the role of prior knowledge, interventions, and statistical independence as tools with which people learn causal structure. What if these sources of information are all absent, as in the problem of identifying causal direction from observations of just two variables? Most work has either ignored this problem or asserted that it is inherently unsolvable. However, recent machine learning algorithms can sometimes infer causal directionality in this setting, by exploiting simple assumptions about the relationship between causes and the noise observed in their effects (Mooij, et al 2016). We investigate whether humans are able to exploit these assumptions or others in order to infer the causal connection between two statistically dependent variables.

# Intolerance to uncertainty is associated with diminished exploration 

Jennifer Lenow<br>Department of Psychology, New York University, New York, NY, USA<br>Nathaniel Daw<br>Princeton Neuroscience Institute, Princeton University, Princeton, NJ<br>Elizabeth Phelps<br>Department of Psychology, New York University, New York, NY, USA

#### Abstract

Across diverse cognitive and behavioral domains, humans confront a fundamental tension between exploiting current knowledge about the environment and exploring the environment in order to acquire new knowledge. Individuals differ idiosyncratically in how they balance this explore/exploit tradeoff, although the sources of these individual differences have not been systematically studied. In the current study, we sought to do so, in terms of trait-level affective phenotypes. Specifically, we investigated whether intolerance to uncertainty (IU), characterized by a negative disposition toward uncertainty, predicted both random and directed exploration in a two-armed bandit task which manipulated decision horizon. We found that greater IU was associated with diminished exploration, both random ( $\mathrm{p}<0.001$ ) and directed ( $\mathrm{p}<0.05$ ). These results suggest the importance of explicitly considering affective states and dispositions in human decision-making and also have psychiatric implications, to the extent that IU is a transdiagnostic dimension central to a range of anxiety-related disorders.

# Interplay between semantic and emotional information in visual scene processing 

Anaïs Leroy<br>Laboratoire d'Anthropologie et de Psychologie Cliniques Cognitives et Sociales, Université Côte d'Azur, France<br>Sylvane Faure<br>Laboratoire d'Anthropologie et de Psychologie Cliniques Cognitives et Sociales, Université Côte d'Azur, France<br>Sara Spotorno<br>Institute of Neuroscience and Psychology, University of Glasgow, UK

#### Abstract

We examined whether and how image's semantics and emotion content interact during visual processing. In each trial, we briefly presented two emotional or neutral images (a scene context and an object), manipulating the semantic consistency and the emotional consistency of the pair. Participants categorised one image semantically or emotionally. Semantic categorisation was overall better than emotional categorisation, but reduced in emotional compared to neutral images, and especially in negative images. Emotional categorisation was better for positive than neutral or negative images; moreover, it was facilitated by emotional consistency and, for accuracy in context images, by semantic consistency. Our results show easiness of semantic compared to emotional categorisation. They suggest that semantic and emotion processes are interdependent, although emotional influence on semantic processing seems stronger than the counterpart, with in particular an interfering effect of aversive images. Conversely, image's attractiveness seems beneficial when evaluating the quality of the emotional content.

# The effect of binaural beats on inhibition 

Kimery Levering<br>Marist College, Poughkeepsie, NY<br>Molly Poinan<br>Marist College, Poughkeepsie, NY<br>\section*{Kristin Jay}<br>Marist College, Poughkeepsie, NY

#### Abstract

A binaural beat is the perceptual experience that occurs when two tones of slightly different frequencies are presented dichotically, creating the experience of a third tone corresponding to the difference in frequencies. Many temporary cognitive effects have been linked to the presentation of a binaural beat, including increased working memory capacity. In the present study, a version of the flanker test was used to investigate the effect of short-term alpha wave binaural beat stimulation on inhibition processes specifically. Participants were presented with 10 minutes of either mid-alpha range binaural beats combined with a recording of waves or only the sound of waves. After this, participants completed a flanker test. The difference between reaction times of congruent and incongruent trials on the flanker task was significantly lower in the binaural beats condition than the wave condition, suggesting that even brief exposure to binaural beats aids in the inhibition of irrelevant stimuli.

# Perception of others: Representation of immigrant groups in newspaper articles 

Ying Li

University of Warwick

Thomas Hills<br>University of Warwick

#### Abstract

Immigrants always have difficulties in integrating into a local society, and sometimes these difficulties come from the fact that they are subconsciously regarded as someone from the outside. How they are represented in the main stream media could reflect people's perceptions towards the 'otherness' of different social members. We analyzed the representation of 29 US immigrant groups in newspaper articles in 2 related studies. The favorability of an immigrant groups is highly associated with its perceived social distance (reflected through usage of concrete language) in our research. To further understand what caused the positive or negative image of immigrants, we applied Latent Dirichlet Allocation to identify topics associated with immigrant groups. We also investigated into how these news topics differ in terms of lingual social distance and favorability. The results provide both qualitative and quantitative insights in how the image of immigrants are reproduced in social media.

# Modelling the dynamics of integrating context into perception: in good and in poor readers 

Itay Lieder<br>ELSC, Hebrew University<br>Vincent Adam<br>Gatsby Computational Neuroscience Unit, UCL<br>Maneesh Sahani<br>Gatsby Computational Neuroscience Unit, UCL<br>Merav Ahissar<br>ELSC, Hebrew University

#### Abstract

Individuals implicitly learn the statistics of environmental stimuli. We used "contraction bias", the tendency to perceive stimuli closer to the estimated mean of similar previous stimuli, to characterize the dynamics of these implicit inference processes. Using a simple auditory discrimination task we found that listeners build a rich representation of the distribution of past stimuli, and yet over represent very recent events. This combined pattern allows both learning of the stable environment, and flexibility to fast changes.

We further characterized populations who have difficulties in acquiring specific expertise, i.e. specific developmental disorders, focusing on reading (dyslexia) and non-verbal communication (high functioning ASD, autism spectrum, individuals) disability, respectively. We found that the pattern of their perceptual inference differs from controls'. Both underweight previous events. However, dyslexics' implicit memory decays fast and they underweight earlier events, whereas ASD individuals underweight recent events. This pattern parallels, and perhaps underlies, their strengths and weaknesses.

# The Effects of Familiarity and Typicality on Naming Objects and Faces 

Yu-Ching Lin<br>National Cheng Kung Univeristy, Tainan, Taiwan, ROC<br>Jon-Fan Hu<br>National Cheng Kung Univeristy, Tainan, Taiwan, ROC<br>Shu-Ling Peng<br>National Cheng Kung Univeristy, Tainan, Taiwan, ROC<br>Shulan Hsieh<br>National Cheng Kung Univeristy, Tainan, Taiwan, ROC

#### Abstract

It is found that when we name an object or a face, we often use basic level name (e.g., dog) rather than a name at superordinate level (e.g., animal) or subordinate level (e.g., Labrador). In addition, although abundant evidence generally suggested that both familiarity and typicality influence object recognition, how each of the two factors involves categorization in terms of naming is not fully investigated yet. The present studies were performed to examine the familiarity and typicality effects on naming either an object or a face. Names for basic, superordinate, and subordinate levels were prepared for testing the speed and correctness of object/face identification. As a result, familiarity, not typicality, induced a down-shift pattern for naming. In contrast, typicality led to overall faster responses. The findings of the study indicated that familiarity and typicality have dissimilar effects on categorization by naming.

# The Effect of CSAL AutoTutor on Deep Comprehension of Text in Low-Literacy Adult Readers 

Anne Lippert<br>University of Memphis<br>Breya Walker<br>University of Memphis<br>Raven Davis<br>University of Memphis<br>Qinyu Cheng<br>University of Memphis

## Zhiqiang Cai

University of Memphis

## Danielle Clewley

University of Memphis

## Genghu Shi

University of Memphis

## Arthur Graesser

University of Memphis

#### Abstract

It is well documented that reading strategies of low-literacy readers are suboptimal when text requires deeper levels of comprehension. Deep comprehension demands causal or goal-oriented reasoning and functional conceptual knowledge. Alternatively, shallow comprehension entails recall of definitions or text features without necessitating a coherent understanding of the text. The Center for Adult Literacy (CSAL) AutoTutor is an interactive intelligent tutoring system designed to foster deep and shallow comprehension in low-literacy readers. The present work represents the first empirical study of the effect of CSAL AutoTutor on comprehension type in low- and high-literacy readers. Community members and students interacted with CSAL Autotutor and then were assessed on recall ability for the structure (shallow) and meaning (deep) of sentences from lesson text. Preliminary analysis suggests CSAL AutoTutor promotes comparable deep level comprehension in low- and high-literacy readers. Implications for CSAL AutoTutor as a literacy intervention and future goals are discussed.

# Adaptive response priors in context-dependent decision-making 

Olga Lositsky<br>Princeton University, Princeton, NJ, USA<br>Michael Shvartsman<br>Princeton University<br>Robert C. Wilson<br>University of Arizona<br>Jonathan D. Cohen<br>Princeton University

#### Abstract

Context (such as our location or current goal) informs everyday decisions, both by predicting stimuli and determining relevant responses. How do we develop priors that are general enough to apply in various contexts yet specific enough to maximize reward in a given context? We investigated this using the AX-CPT, a task in which a cue determines which button to press for a probe that appears seconds later. We manipulated the frequency of the probe given the cue across participants and built a diffusion model to estimate how the cue informs participants' priors for the decision. We found that participants' context-dependent priors were closer to each other and less extreme than those predicted by a model that maximizes reward rate given the true stimulus frequencies. However, participants' priors were optimal given their subjective frequency estimates, which showed that they averaged response probabilities across cues when the cues made sufficiently similar predictions.

# Comprehension of Chinese Classifiers in Preschool Children 

Yu-Han Luo<br>National Cheng Kung University, Tainan City, Taiwan, R.O.C<br>Jon-Fan Hu<br>National Cheng Kung Univeristy, Tainan City, Taiwan, R.O.C

#### Abstract

The present research aimed to investigate children's comprehension of Chinese classifiers. Sixty-five Chinesespeaking children between the ages of 4 and 6 recruited in Taiwan participated in the experiment. The results indicate that children can make generalization based on their understanding of classifiers instead of solely relying on classifier-noun associations. The results also show that the participants performed equally on both shape-based and feature-shared classifiers, which suggests that children not only use shape salience to learn Chinese classifiers, but are also sensitive to other relations between objects classified by the same Chinese classifier. Besides, the complex patterns in the results imply that in spite of the exposure to classifiers, the semantic transparency between classifiers and objects varies considerably in both semantic types of classifier, which might be the primary reason that some classifiers are more difficult for children to acquire.

# Cumulative response probabilities: Estimating time course of lexical activation from single-point response times 

Sahil Luthra<br>University of Connecticut, Storrs, Connecticut, USA<br>James Magnuson<br>University of Connecticut, Storrs, Connecticut, USA

#### Abstract

An aim of research on spoken word recognition is to characterize the influence of various lexical characteristics (e.g., word frequency, neighborhood size) on lexical access. Dynamics can be coarsely estimated from single-point measures like naming or more directly assessed using time course measures like fixation proportions over time in the visual world paradigm (e.g., Tanenhaus et al., 1995). We propose that cumulative response probabilities (CRPs) over time may allow a new characterization of the activation dynamics of lexical access from single-point measures. We assume that the timing of responses in a naming task reflects probabilistic sampling of underlying continuous activation dynamics that can be recovered by CRPs. We applied CRP analyses to visual word recognition data collected for 40,481 words from 472 participants (the English Lexicon Project; Balota et al., 2007) and report initial efforts to validate this new approach.

# Guardian and Daily Mail Readers' Implicit Attitudes to Immigration 

Dermot Lynott<br>Lancaster University, UK<br>Michael Walsh<br>University of Stuttgart, Germany<br>Tony McEnery<br>Lancaster University, UK<br>Louise Connell<br>Lancaster University, UK<br>Liam Cross<br>University of Buckingham, UK

#### Abstract

The implicit association test (IAT) measures bias towards often controversial topics (race/religion), while newspapers typically take strong positive/negative stances on such issues. In a pre-registered study, we developed and administered an immigration IAT to readers of the Daily Mail (typically anti-immigration) and Guardian (typically pro-immigration) newspapers. IAT Materials were constructed based on co-occurrence frequencies from each newspapers' website for immigration-related terms (migrant) and positive/negative attributes (skilled/unskilled). Target stimuli showed stronger negative associations with immigration concepts in the Daily Mail corpus compared to the Guardian corpus, and stronger positive associations in the Guardian corpus compared to the Daily Mail. Consistent with these linguistic distributional differences, Daily Mail readers exhibited a larger IAT bias, revealing stronger negative associations to immigration concepts compared to Guardian readers. This difference in overall bias was not explained by other variables, and raises the possibility that exposure to biased language contributes to biased implicit attitudes.

# How and when does the syllable become a reading unit? Developmental evidence in French children 

Norbert Maïonchi-Pino<br>Université Clermont Auvergne - LAPSCO - CNRS UMR 6024, Clermont-Ferrand, France<br>Virginie Loiseau<br>Université Clermont Auvergne - LAPSCO - CNRS UMR 6024, Clermont-Ferrand, France

#### Abstract

French beginning readers might rely on syllables during reading acquisition. However, no in-depth developmental study has been carried out to determine how and when the syllable becomes this prelexical and segmental unit used in the time course of reading acquisition. We recruited 800 French-speaking children distributed in grade 1-5. We used a lexical decision task in a visual masked priming paradigm and a visual identification task. We manipulated the initial syllable frequency, the initial bi/trigram frequency, and the initial syllable structure (CV; CVC). Our main results describe a clear developmental course. The syllable-based effects are early (G1) and sustainably observed (G5), and primarily depend on the syllable frequency. From G2, we found the systematic, automatic use of the syllable as prelexical and segmental unit but the syllable frequency has facilitatory syllable-based effects in the task with lexical access, while it has inhibitory effects in the task without lexical access.

# Epistemically Suspect Beliefs can be partly explained by individual's propensity towards contradiction 

Yoshimasa Majima<br>Hokusei Gakuen University, Sapporo, Hokkaido, JAPAN

#### Abstract

Studies on epistemically suspect beliefs (ESB) have suggested that individual's analytic cognition suppresses unwarranted beliefs, however, our previous studies also showed that an inhibitory effect of analytic cognition was higher among Westerners than Easterners. Rather, intuitive cognition was a common predictor of beliefs between two cultures. Among several cultural differences in cognitive style, we suspect that tendency towards dialectic thinking, i.e., tolerance for contradiction may contribute cultural differences on ESB. The present study aimed to explore this possibility and investigated the association between beliefs and other cognitive measures including individual's cognitive abilities, thinking dispositions, personality traits and propensity towards dialectic thinking. The results showed that the ESB resulted from our intuitive cognition for the most part, and that the effect of culture diminished whilst controlling individual's tendency towards dialectic thinking and style of causal cognition. The cultural difference in a relationship between beliefs and cognitive style was discussed.

# Practicing an auditory working memory task recruits lower-level auditory areas in a task-specific manner 

Tamar Malinovitch<br>Hebrew University of Jerusalem<br>Philippe Albouy<br>Montreal Neurological Institute, McGill University, Montreal<br>Merav Ahissar<br>Hebrew University of Jerusalem<br>Robert Zatorre<br>Montreal Neurological Institute, McGill University, Montreal

#### Abstract

We studied the impact of the trained auditory task on the pattern of behavioural improvement, and its relation to the underlying neural mechanisms. Specifically, we asked whether training with tone retention and manipulation (working memory, WM) transferred to pitch discrimination and vice versa, and whether training modified the brain areas that underlie task performance. Training substantially improved performance, but did not transfer across tasks, even when using the same stimuli. Pre and post training fMRI scans revealed that WM training enhanced activity in bilateral auditory cortices, but not in frontal areas that are initially associated with higher cognitive functions. These results suggest that training-induced improvement is associated with back-tracking along the reverse hierarchy in a task specific manner, as predicted by the Reverse Hierarchy Theory of perceptual learning (Ahissar \& Hochstein, 2004). Thus, low-level areas are recruited, but there is no general upgrade in WM or in auditory skills.

# Do Relationality and Aptness Influence Conventionalization? 

Francisco Maravilla<br>Northwestern University, Chicago, IL, United States

Dedre Gentner

Northwestern University

#### Abstract

The conventionalization of figurative comparisons is one source of lexical evolution. For example, anchor once only meant a device for mooring a ship, but may now be used to describe any source of stability or confidence. Our goal is to understand this process. Following the Career of Metaphor framework, figurative mappings are interpreted through a structure-mapping process, rendering common structure salient. As figurative terms become conventionalized, (1) the figurative sense becomes associated with the base term; and (2) there is shift from simile form to metaphor form. In two studies we investigated psycholinguistic properties that may influence this process: relationality and aptness. We use relative preference for the metaphor form as an estimate of degree of conventionalization; by determining the preferred form for a set of figuratives, we find evidence that both aptness and relationality influence this process. We speculate that figurative comparisons may give rise to new relational terms.

# Mutual Exclusivity Revisited - When Pragmatics overrides Novelty 

Hanna Marno<br>Central European University, Budapest, Hungary<br>Dan Sperber<br>Central European University, Budapest, Hungary; Institut Nicod, Paris, France

#### Abstract

Children typically apply a novel label to a novel object, rather than to a familiar object; a phenomenon called Mutual Exclusivity (Markman et al., 2003). A recent explanation is that children tend to associate novel stimuli together (Horst et al., 2011). We show that pragmatic factors may override novelty. In our study two-year-old children first played with a novel object together with E1. Then E1 left the room and E2 brought another three novel objects for the child to manipulate on his/her own. Finally, E1 came back and requested the child to give her the 'Bitye'. Most children chose the first object, with which they had a common history with E1, even though it was the least novel. This suggests that children understand a novel word by considering to which object the speaker is most likely to have intended to refer.

# Search Your Feelings, Luke: Emotional Fluency Predicts Well-being and Emotional Intelligence 

Masitah Masitah<br>University of Warwick

Ying Li
University of Warwick

Thomas Hills<br>University of Warwick

#### Abstract

How we feel reflects a combination of recalled and recognized emotions. All existing self-report measures are based solely on recognized emotions. To understand the influence of recalled emotions, we developed a new method to recover human emotional states based on emotional free association, in a task we call the emotional fluency. The present work investigated the differences between recall and recognition in human emotional states. We compared the emotional fluency task with self-report measures, including PANAS, WEMWBS, and the Emotional Intelligence Scale. Using language statistics computed from the emotional fluency task, we developed multiple models for predicting self-report measures. We find that while recalled emotions can predict recognized emotions, they highlight important problems with existing recognition measures, including emotional coverage and the difference between availability and accessibility. We also investigate the search process in emotional memory, supporting the role of unbiased memory sampling and higher emotional intelligence and mental well-being.

# Children's reasoning about data sets 

Amy Masnick<br>Hofstra University, Hempstead, NY, US<br>Bradley Morris<br>Kent State University, Kent, Ohio, USA

## Christopher Was

Kent State University

#### Abstract

When reasoning about several numbers, past work has shown that adults mentally summarize data sets and reason based on set characteristics such as the mean and variance (Morris \& Masnick, 2015). In the current study, we asked 10- and 12 -year-old children to look at two columns of numbers (framed as the distances two golfers drove a golf ball, when doing so repeatedly), and to choose which golfer hit the ball farther. We examined reaction time, accuracy, and eye movements, in addition to self-reported strategy use. We found children reasoned using some of the same summary characteristics as adults, though less consistently, and had more varied strategy uses. For example, some children focused only on one number in each set, a pattern not seen in adults. These findings suggest that instruction building on these intuitions may help develop children's numerical cognition skills.

# Attention Modulation Effects on Visual Feature-selectivity of Neurons in Brain-inspired Categorization Models 

Saeed Masoudnia<br>Cognitive Robotics Lab, Control and Intelligent Processing Center of Excellence, School of Electrical and Computer Engineering, College of Engineering, University of Tehran, Tehran, Iran.

Abdol-Hossein Vahabie<br>School of Cognitive Sciences, Institute for Research in Fundamental Sciences (IPM), Tehran, Iran.<br>Majid Nili Ahmadabadi<br>Cognitive Robotics Lab, Control and Intelligent Processing Center of Excellence, School of Electrical and Computer Engineering, College of Engineering, University of Tehran, Tehran, Iran. School of Cognitive Sciences, Institute for Research in Fundamental Sciences (IPM), Tehran, Iran.<br>Babak Nadjar Araabi<br>Cognitive Robotics Lab, Control and Intelligent Processing Center of Excellence, School of Electrical and Computer Engineering, College of Engineering, University of Tehran, Tehran, Iran. School of Cognitive Sciences, Institute for Research in Fundamental Sciences (IPM), Tehran, Iran.

#### Abstract

Most Brain-inspired Visual Object Recognition Models(BVORMs) do not consider local and global reciprocal connections in visual pathway. We addressed this weakness and implemented an attention modulation mechanism based on feedback connections in BVORMs, where feature-selectivity is shaped and modulated by categorization of objects based on their visual features. This modification is inspired by the top-down neuromodulatory signals that make changes in post-synaptic activities of the feature-selective neurons. We also incorporated an implicit memory unit in BVORMs to accumulate recent Hebbian synaptic plasticity's of the neurons in each task. This mechanism guides the top-down feature-based attention modulation to retrieve the interrelated feature-selectivity pattern for each task.HMax and CNN models were used as two BVORMs and tested on a visual categorization problem: natural versus artificial objects in CALTECH-256. Based on experimental results, our proposed modifications not only increased their biological-plausibility but also significantly improved their categorization accuracies compared to the original models.

# Simple and Complex Working Memory Tasks Allow Similar Benefits of Information Compression 

fabien mathy<br>Université Côte d'Azur<br>mustapha chekaf<br>Université Côte d'Azur<br>Nelson Cowan<br>University of Missouri, Columbia

#### Abstract

Because complex span tasks were designed to create a demanding concurrent task, the average span is usually lower ( $4 \pm 1$ items) than in simple span tasks ( $7 \pm 2$ items). One possible reason for the higher span of simple span tasks is that participants can take profit of the spare time to chunk a few stimuli into $4 \pm 1$ groups. It follows that the respective spans of these two types of tasks could be equal (at around $4 \pm 1$ ) when regularities are absent. We therefore predicted an interaction between task and chunkability, supporting a single higher span for a simple span task using chunkable items. However, observation of the spans in the non-chunkable vs. chunkable series refuted the idea that chunking is important solely in simple spans. Indeed, information compression processes contributed to performance levels to a similar extent in simple and complex span tasks.

# Causal asymmetry and the intuitive physics of collision events 

Ralf Mayrhofer<br>University of Göttingen<br>Michael Waldmann<br>University of Göttingen

#### Abstract

In the Michotte (1963) launching scenario, an object (X) moves toward a resting object (Y), eventually colliding with $i t$. In the moment of contact, X stops und Y starts moving - creating the strong impression that X caused Y 's motion and that X exerted a force on Y (but not vice versa). These asymmetries contradict the (symmetrical) laws of Newtonian mechanics, which are at the heart of the popular "noisy Newton" theories of intuitive physics. As an alternative, we propose that inferences in physical scenarios operate over pre-Newtonian representations that are based on the asymmetrical concept of impetus, a motive force that keeps objects moving and that is transferred and reflected in object collisions. We present a formal model of impetus and show that, unlike noisy Newton theories, it provides an explanation of asymmetrical judgments. Other related findings can also be modeled (e.g., biases in mass judgments).

# The development of interpersonal regret and its relation to prosocial choice 

## Teresa McCormack

Queen's University Belfast

## Brian Uprichard

Queen's University Belfast

#### Abstract

We examined whether children feel regret when their failure to make a prosocial choice negatively affects a peer. Five-to-six-year-olds and 7-to-9-year-olds played a game in which they completed a sticker sheet to win a prize. Children then decided whether to donate a spare sticker to another child; most children did not donate. Children discovered that the next child did not have enough stickers to win a prize, and rated their emotions. At this point, children did not know whether the next child could have been able to win the prize if they had donated the sticker in question. This counterfactual information was then provided, and children rated whether they felt happier, sadder, or the same as before. Only the 7-to-9-year-olds' responses suggested that they experienced interpersonal regret. We also showed that experiencing interpersonal regret in the sticker task resulted in children making more prosocial choices in a separate task.

# Interactive and embodied repair: Displaying, recognizing, and negotiating misalignment in an emerging language context 

Ashley Micklos<br>Max Planck Institute for Psycholinguistics, Nijmegen, The Netherlands

#### Abstract

As problems of understanding arise in conversational interaction, we must find a means to indicate to our interlocutor the reason for our misunderstanding. However, we are simultaneously constrained by social interactive practices that limit face threat and adhere to epistemic rights. Thus, the challenge is to communicate our own misunderstanding - as specifically as possible - while avoiding explicitness. This challenge may be increased in contexts of language emergence in which alignment is necessary to promote communicative efficiency and conventionalization. Participants in novel communication tasks relied on certain gesture-driven other-initiated repair strategies to gain interactive alignment. The embodied display of cognitive and interactive misalignment cues the interlocutor to repair in a way that reflects their own understanding of the repair initiation and trouble source. The breakdown of intersubjectivity - and its subsequent re-building - is observed in the negotiation of evolving signal-meaning matches through interactive repair sequences.

# Misalignment increases abstraction of referring expressions 

Gregory Mills<br>University of Groningen, Groningen, Netherlands<br>Gisela Redeker<br>University of Groningen

#### Abstract

A central finding in dialogue research is that interlocutors rapidly converge on referring expressions which become progressively contracted and abstract. However there is currently no consensus on which mechanisms underpin convergence: The interactive alignment model (Pickering and Garrod, 2009) favours alignment processes, the grounding model (Clark, 1996) prioritizes positive feedback, while Healey (2002) demonstrates the importance of miscommunication in identifying differences of interpretation.

To investigate convergence we report a variant of the maze-task in which both participants are given misaligned instructions: One participant is primed with instructions that conceptualize the maze as consisting of horizontal vectors (e.g ." 4 th row, 2nd square"); the other is primed with instructions that conceptualize the maze as consisting of vertical vectors (e.g ."3rd column, 2nd square"). Compared with a baseline, misaligned dyads converged on more abstract referring expressions. We argue this pattern is due to participants interactively combining their perspective with that of their partner.

# The spontaneous creation of systems of conventions 

Jennifer Misyak<br>University of Warwick, Coventry, UK<br>Nick Chater<br>University of Warwick, Coventry, UK

#### Abstract

We used a non-linguistic experimental paradigm to explore the instantaneous creation and adaption of novel communicative systems of conventions. Groups of participants played a computer game, in which they sent and interpreted minimal signals to obtain shared rewards within a virtual scene. Within groups, trials manipulated the space of possible signals that could be sent, and the set of meanings to be expressed (the range of cases for the locations and quantities of rewards). Between groups, initial conditions were manipulated through early exposure to different sets of communicative cases.

We observed participants spontaneously develop systems of conventions that were adapted to the full range of signal-meaning mappings encountered. Groups favoured systems optimised to their particular initial learning environment. These systems become entrenched and transferred to new signal-mapping environments to which they were not adapted.

# Refining the cognitive semantic web: The tensor method to represent the topographic emplacement of different word categories 

Eduardo Mizraji<br>Facultad de Ciencias, Universidad de la República, Montevideo, Uruguay<br>Andrés Pomi<br>Facultad de Ciencias, Universidad de la República, Montevideo, Uruguay

#### Abstract

A central problem concerning the organization of the cognitive semantic web is to understand how different categories of words are stored in the brain with a well-defined topographical organization. This topography is a natural construction that plausibly is strongly related with the syntactic and semantic organization of natural languages. An eloquent experimental evidence of the existence of a continuous semantic representation of object and action categories in the human brain has been published by Huth et al (Neuron $76: 1210,2012$ ). One of the ways to explain the emergence of a topographical organization in the brain cortex using neurocomputational models, is by means of Kohonen's self-organizing maps. Here we show that these topographies can be operationally represented with associative memories spatially organized by tensor contexts. We illustrate formally and numerically this fact. In addition, we show that, consistently with evidence from pathology, different semantic categories can be specifically damaged.

# Picture book reading in the lives of 18-30 month old children: A diary study 

Jessica Montag<br>University of California, Riverside

Linda Smith

Indiana University

#### Abstract

Picture book reading is a common activity in the lives of many children. This work describes the frequency and character of picture book reading in American homes. Seventy-seven monolingual English-speaking families with children between the ages of 18-30 months took part in a 5 -day diary study in which caregivers recorded details about picture book reading activities. This sample is characteristic of some laboratory samples but less nationally representative; $92.2 \%$ of caregivers held a college degree. Relative to previously reported averages, caregivers reported reading to children more often ( $6.8 \mathrm{x} / \mathrm{day}$ ), reported beginning reading at a younger age ( 2.2 months) and reported more books in the home ( 111.1 books). Caregivers reported both reading the book text and discussing the pictures with their children. These numbers suggest an extremely high upper-limit to the amount of language input some children receive from picture book reading. Consequences for language environments and language development will be discussed.

# Resemblance among similarity measures in semantic representation 

Maria Montefinese<br>Department of Experimental Psychology, University College London, London, UK<br>David Vinson<br>Department of Experimental Psychology, University College London, London, UK

#### Abstract

Similarity measures, extent to which two concepts have similar meanings, are key to understanding how concepts are represented, with different theoretical perspectives relying on very different sources of data from which similarity can be calculated. Experiential/embodied theories use verbal features or property ratings; distributional/relational ones use cooccurrence. Similarity may also be estimated from tasks like word-association, priming, and other rating studies. Often the different theoretical perspectives are placed in opposition; here we test the extent to which similarity representations based on different measures converge. We used Representational Similarity Analysis and multidimensional scaling on 31 similarity measures. Similarity in age-of-acquisition and word-length were related to similarity in naming and priming; and affective similarity and co-occurrence were also related. More importantly, representational resemblance was shown among embodied, distributional and association-based representations, demonstrating that different data sources are employed in a similar way in building meaningful conceptual representation.

# Effects of Question Format on Test-Taker Cognition 

Jung Aa Moon<br>Educational Testing Service<br>Irvin Katz<br>Educational Testing Service<br>\section*{Madeleine Keehner}<br>Educational Testing Service

#### Abstract

Technology-based, interactive test questions are common in large-scale assessments, yet how alternative question formats influence test-taker cognition is not well understood. In a series of studies, we investigated test-taker performance on isomorphic questions using alternative presentation layouts and modes of responding. Adult participants solved math problems in three formats, each of which regularly appear in many large-scale assessments: 1) forced-choice (explicit True-False options) presented in a table format, 2) check-all-that-apply (implicit True-False options) presented in a table format, and 3) check-all-that apply presented as separate questions. Participants' solution time and affirmative selection rate suggested different cognitive processes for the question formats, particularly when they were uncertain of their answers. We propose a cognitive model to account for the results and predict the impact of alternative question formats on test-takers. We discuss how principles of cognitive science and human-computer interaction provide direct implications for designing assessment questions and understanding test-taker cognition.

# Magnitude of metaphor and its effect on reasoning about immigration 

Karie Moorman<br>University of California, Merced<br>Teenie Matlock<br>University of California, Merced

#### Abstract

Metaphor is replete in discourse about immigration. Recent work shows that metaphoric framing can influence attitudes toward immigration (e.g., Landau et al., 2009). However, we know little about how and when specific information in the source domain drives this effect. Our study takes a novel approach, examining how varying intensity of information in the source domain frame influences attitudes toward immigrants and immigration in the U.S. We analyze various metaphors but we focus especially on intensity effects in the conceptual metaphor IMMIGRATION IS FLUID TRANSFER. For the FLUID TRANSFER source domain, we investigate how varying intensity of flow (e.g., rate) influences attitudes about immigration, including whether immigrants should have access to social services and what type of wall should be built, if at all. Our results make a valuable contribution to metaphor research by revealing what information within the source domain has the most (or least) robust effects on reasoning.

# Investigating the Impact of Sleep on Eyewitness Memory 

David Morgan<br>Royal Holloway, University of London<br>Jakke Tamminen<br>Royal Holloway, University of London<br>Laura Mickes<br>Royal Holloway, University of London

#### Abstract

How sleep impacts the accuracy of identifications that eyewitnesses make from lineups is unknown. For a comprehensive understanding of eyewitness performance, two types of eyewitness ID accuracy are considered: discriminability (the ability to distinguish innocent from guilty suspects) and reliability (the probability that the identified suspect was the offender). The well-known role sleep plays in memory consolidation should apply to an eyewitness's ability to discriminate, but not necessarily their reliability. That is what we investigated in a large-scale forensically-relevant experiment. We compared discriminability and reliability from sleep (sleep occurs between witnessing a crime and lineup test) and wake (remains awake between crime and lineup) conditions. Furthermore, theorists have long been using signal-detection models to understand recognition memory, but its use is new to the field of eyewitness ID research. Thus, we compared signal-detection models with different decision rules. Our findings shed light on the impact sleep has on eyewitness IDs.

# Impact of testimony and prior knowledge on children's beliefs about category homogeneity 

Kelsey Moty

Lehigh University

Amanda Brandone<br>Lehigh University

#### Abstract

Previous work has shown that preschoolers-in comparison to older children and adults-tend to view categories as homogeneous, generalizing properties of individuals broadly to all category members (e.g., this dax has wings, so all daxes do). Here, we explore whether the testimony used to describe category individuals as well as children's prior knowledge of categories attenuates their homogeneity expectations. Using a novel induction task, 4 to 7 -year-olds were asked to predict the distribution of properties among members of familiar/unfamiliar animal categories based on a single exemplar. Exemplars were introduced as "special" to half of participants. Preliminary findings $(\mathrm{N}=71)$ suggest that prior knowledge may contribute to beliefs about category homogeneity: responses for familiar animals varied appropriately given the real-world prevalence of each property whereas children overestimated the property's prevalence for unfamiliar animals. The complete dataset will speak to how language choice in testimony shifts children's beliefs about homogeneity.

# Learning to Consider Alternative Causes: Can Practice Make Us More Aware of Our Imperfection? 

Edward Munnich<br>University of San Francisco

Ana Maria Hoffmann<br>University of San Francisco

Nancy Ortega
University of San Francisco
Emma Weinberger
University of San Francisco

Dana-Lis Bittner

University of San Francisco
Jacqueline Tiongco
University of San Francisco
Jasmine West
University of San Francisco

#### Abstract

In hindsight bias, upon learning an outcome, one is overly confident that one would have "known it all along." Several researchers have been able to neutralize hindsight bias by prompting participants to consider alternative outcomes, but can we learn to avoid bias for novel outcomes, without prompting? Foresight participants read brief summaries of five psychology studies, and learned the mean performance of one group in each study. They estimated the other group's perfor-mance-reflecting their sense of the effect size—stated possible causes, and then learned the other group's mean performance. Hindsight participants learned both groups' mean performance at the outset, then indicated what they would have estimated. We asked whether (1) participants would show superior estimation and/or consideration of alternative causes for novel stimuli one week later, and (2) whether Foresight participants would benefit more given the feedback they received on the accuracy of their estimates.

# Bidirectional effect of emotional contagion for pain during face-to-face interaction 

Aiko Murata<br>Waseda University<br>Tatsuya Kameda<br>The University of Tokyo

Katsumi Watanabe<br>Waseda University

#### Abstract

The automatic contagion of emotion is considered crucial in interpersonal communication. In face-to-face interactions, people could be both the receiver and sender of emotional content. Thus, contagion may have bidirectional influences on the emotional states of individuals. However, many studies have mainly dealt with unidirectional contagion, such that the expression of pain in a target entails a reaction of pain in the observer. In this study, we demonstrated bidirectional emotional contagion in the experience of thermal pain during interaction. Firstly, we showed that the physiological responses of dyad members were correlated with each other when they could interact compared to when they were impaired to see each other. Further, we demonstrated that individuals showed higher or lower physiological responses when their partners experienced stronger or weaker stimuli respectively. Thus, people can develop similar physiological responses through interactions, and this effect seems to induce a change in the responsivity to stimuli.

# Agent's symmetry elicits egocentric transformations for spatial perspective-taking 

Hiroyuki Muto<br>Graduate School of Human Sciences, Osaka University Japan Society for the Promotion of Science<br>Soyogu Matsushita<br>Graduate School of Human Sciences, Osaka University<br>Kazunori Morikawa<br>Graduate School of Human Sciences, Osaka University

#### Abstract

Spatial perspective-taking is an ability to understand in which direction an object is located relative to an agent (e.g., another person or a chair). Previous studies showed that left/right judgments prompted an egocentric transformation strategy (i.e., mental rotation of the self) whereas front/behind judgments prompted other strategies (e.g., tracing a line of sight). To examine whether the symmetrical shape of an agent could affect the choice of strategies, we used as an agent a cuboid which has a prong on one of its sides. We labeled the prong side as the front (Experiment 1) or right (Experiment 2) of the agent, about which participants made left/right and front/behind judgments. The results revealed that egocentric transformations were more favored for judgments about directions along symmetrical than asymmetrical axes of the agent, regardless of whether the judgment was about left/right or front/behind. This suggests similar processing underlies left/right and front/behind judgments.

# Robot as Moral Agent: A Philosophical and Empirical Approach 

Shoji Nagataki<br>Chukyo University<br>Masayoshi Shibata<br>Kanazawa University

# Tatsuya Kashiwabata <br> Keio University 

Takashi Hashimoto
Japan Advanced Institute of Science and Technology

Takeshi Konno<br>Kanazawa Institute of Technology<br>Hideki Ohira<br>Nagoya University<br>Toshihiko Miura<br>University of Tokyo<br>Shinichi Kubota<br>Kanazawa University

#### Abstract

What is necessary for robots to coexist with human beings? In order to do so, we suppose, robots must be moral agents. To be a moral agent is to bear its own responsibility which others cannot take for it. We will argue that such an irreplaceability consists in its having an inner world - one which others cannot directly experience, just as pleasure and pain. And personality of a moral agent, which is to be irreducible to a mere difference of traits or features of individuals, is firmly rooted in such an inner world.

We will support our theses by referring to our experiment in which humans and robots interact with each other doing a coordination task. This experiment will provide an empirical analysis of the human-robot relationship with regard to learning mechanism, moral judgement, and the ascription of the inner world.

# Iconicity vs. Systematicity in Artificial Language Learning 

Alan Ks Nielsen<br>Max Planck Institute for Psycholinguistics<br>Julia Simner<br>University of Sussex<br>Simon Kirby<br>University of Edinburgh<br>\section*{Kenny Smith}<br>University of Edinburgh

#### Abstract

A foundational assumption in linguistics has been that words and their meanings are arbitrarily related; however, this position has been challenged recently. Experiments have shown that both systematic (where similar objects have similar labels) and iconic (words 'resemble' the objects they label) associations between words and objects facilitate learning. However, these two literatures remain confounded: the degree to which increased learnability is driven by iconicity rather than systematicity has not been disentangled. Here we present the results of two studies testing the differences in learnability between artificial lexica that are either conventionally systematic, or both systematic and cross-modally iconic. In the first study we find that both conventional and iconic systematic lexicons are equally learnable, but iconic mappings provide an early learnability advantage. In the second study we find that the presence of sound-symbolic associations for one dimension can interfere with the learning of conventional associations on another dimension.

# The space and time of contamination: Complete, continual, spreading effects 

Laura Niemi<br>Harvard University, Cambridge, MA, USA<br>Liane Young<br>Boston College, Chestnut Hill, MA

#### Abstract

People sometimes report feeling "totally" different (complete affectedness) and that "they'll never be the same again" (continual affectedness) after negative events. It's been proposed that complete, and continual negative effects characterize contamination or impurity. Meanwhile, whether impurity is a legitimate moral domain apart from harm has been debated in moral psychology. We address these matters using novel approaches from cognitive linguistics. First, according to a prominent theory of verb semantics, verbs that convey impurity (contaminate, taint) belong to a class that implies complete affectedness (the "fill" class), such that contaminated entities are seen as completely contaminated. Second, people rated perpetrators equally, and highly, "contaminated", "contaminating", and "injuring", whereas victims were rated straightforwardly "injured" (Turk; $\mathrm{n}=126$, replicated twice). For "contaminated" perpetrators, the taint carried on - they were continually "contaminating". In sum, impurity is distinct from harm: the process underlying impurity, contamination, involves inferences of complete, continual negative effects that spread.

# Construction of design activity index based on the value of artifact 

Kunio Nikata<br>Kanazawa College of Art<br>\section*{Kentaro Inomata}<br>Kwansei Gakuin University<br>Toru Sato<br>Kwansei Gakuin University<br>Keigo Kawasaki<br>Kanazawa College of Art<br>Noriko Nagata<br>Kwansei Gakuin University

#### Abstract

Digital personal fabrication refers to the creation of products using ICT-tools by individuals. In order to support the users of such tools who are untrained in design, it is necessary to develop a support system that makes it possible to use expert knowledge on designing products. For this study, we selected 26 items from the values that are considered important for design (e.g., unique, modern; Inomata et al., 2016), and investigated the design activities for realizing these values. Eighty professionals in design participated in the survey. Many design activities concerning shapes and colors were observed as ways to realize the values. In addition, various activities such as improvements on materials and motifs or advices to satisfy the practical design activity were observed. We created an index of the frequently used activities to realize each value and discussed its potential as an actual design support tool.

# Indirection Explains Flexible Tuning of Neurons in Prefrontal Cortex 

David Noelle<br>University of California, Merced

#### Abstract

The prefrontal cortex (PFC) is broadly seen as supporting cognitive flexibility - quickly adapting behavior in response to changing circumstances. Some PFC neurons appear to actively maintain rule-like information associated with the current task, with firing changing with task context. Some PFC neurons, however, have been found to exhibit activity related to specific stimulus features or action options, but the tuning of these neurons appears to dynamically change with task shifts (Duncan, 2001). Short-term synaptic plasticity has been proposed as the primary mechanism for rapidly adapting the response profiles of these cells. Using a computational cognitive neuroscience model of hierarchical structure in PFC (Kriete, Noelle, Cohen, \& O'Reilly, 2013), an alternative account is offered in which flexible neural tuning arises not from fast synaptic change but from a frontal representational scheme involving neurons that encode references to other PFC areas rather than directly encoding task relevant sensory/motor information.

# Five-Year-Old Children Transfer a Metacognitive Strategy to a Novel Task 

Allison O'Leary<br>The Ohio State University<br>Vladimir Sloutsky<br>The Ohio State University

#### Abstract

Previous work has demonstrated that interventions like 1) giving in-the-moment performance feedback and 2) providing a strategy rule can improve children's metacognitive learning. However, there is little evidence to suggest that this learning transfers to a novel task. We trained 5-year-olds' metacognitive control in a task requiring participants to select the easier of two games to acquire the highest amount of points. Compared to a control group who received no training, children who were trained to control behavior (by selecting an easier dot discrimination task) showed greater evidence of transfer to a novel task (by selecting an easier line length discrimination task). This suggests that the learned strategy rule (i.e., to select an easier task) was not stimulus-specific, and was abstract enough to apply to a novel task with new stimuli. In sum, 5 -year-olds were able to learn a strategy rule and spontaneously apply the strategy to a novel task.

# Do forgiving God primes strengthen support for state sanctioned punishment? 

Katherine O'Lone<br>Royal Holloway, University of London, LONDON<br>Ryan McKay<br>Royal Holloway, University of London

#### Abstract

Do forgiving God primes strengthen support for state-sanctioned punishment? Laurin et al (2012) found that beliefs in powerful, intervening Gods (both in general and when made salient) reduce people's endorsement of state-sanctioned punishment. In light of this, we investigated whether the manner in which God intervenes (via forgiveness or punishment) influences people's endorsement of state-sanctioned punishment.

Across four studies we explored a) whether priming participants with a forgiving God and b) whether salient, forgiving God beliefs increase endorsements of state-sanctioned punishment. The rationale being that a forgiving God will lead people to view punishment as a responsibility that lies with them rather than one outsourced to God. Our results revealed no evidence for effects of forgiving God primes or salient forgiving god beliefs on endorsements of state-sanctioned punishment. We discuss the implications of these findings for extant theories of religious prosociality and proportionality-based accounts of morality.

# Effects of motives of search and prior experiences on online browsing performance: Considerations from searchers cognitive load 

Kayoko Ohtsu<br>Waseda University<br>Takako Sakawaki<br>Waseda University

#### Abstract

The present study aimed to develop effective education methods of online search for unskilled college students. In the preparatory stage of the study, an experiment using simple browsing tasks was conducted to examine the effects of important factors of searching focusing on cognitive load. Under two conditions (Casual and Formal) promoting different motivations, search result lists were displayed to fifty-nine college students to look for two types of information: seeking statistical data (task A) and seeking views and opinions to answer open questions (task B). Analyses of each task using two factors (the conditions and their presentation orders) revealed that in task A, only when the Casual condition was first, the participants performed better in the Formal condition. In task B, only when the Formal condition was first, browsing time in the Casual condition was shorter. We assume that these effects are associated with the workload of browsing.

# Anticipatory Active Inference from Learned Recurrent Neural Forward Models 

Sebastian Otte<br>University of Tübingen, Tübingen, Baden-Württemberg, Germany<br>Theresa Schmitt<br>University of Tübingen, Tübingen, Baden-Württemberg, Germany<br>Martin V. Butz<br>University of Tübingen, Tübingen, Baden-Württemberg, Germany

#### Abstract

We demonstrate that inference-based goal-directed behavior can be done by utilizing the temporal gradients in recurrent neural network (RNN). The RNN learns a dynamic sensorimotor forward model. Once the RNN is trained, it can be used to execute active-inference-based, goal-directed policy optimization. The internal neural activities of the trained RNN essentially model the predictive state of the controlled entity. The implemented optimization process projects the neural activities into the future via the RNN recurrences following a tentative sequence of motor commands (encoded in neurons akin to recurrent parametric biases). This sequence is adapted by back-projecting the error between the forward-projected hypothetical states and desired (goal-like) system states onto the motor commands. Few cycles of forward projection and goal-based error backpropagation yield the sequences of motor commands that control the dynamical systems. As an example, we show that a trained RNN model can be used to effectively control a quadrocopter-like system.

# Application of fuzzy logic in dyslexia user modelling to design customizing assistive technology 

Tereza Pařilová

Masaryk University

## Eva Hladká

Masaryk University

#### Abstract

Cognitive psychology studies phenomena that cannot be directly observed. Scientific knowledge about the brain is extensive, but there is still a lot to be understood about its functions. Cognitive functions are weakened in dyslexic children; this is reflected in highly individual problems regarding the reading skills. Reading is a process which consists of decrypting graphic characters (perceptual level) and understanding the meaning of words (cognitive level). These levels cannot be separated. An approach - fuzzy logic - is used in order to address this issue and create a model of the dyslexic user, based on which technologies can be individually tailored to a particular dyslexic. We discusse the possibilities of the use of the mathematical apparatus for the categorisation of users with regard to their "black box". Further, we focuse on the development of new assistive technologies targeted at specific attention disorders, reading disorders, as well as information processing disorders.

# An Exploratory Study of the Influence of Pretend Play on Children's Self-Regulation and Language Skills 

Tanya Paes<br>University of Cambridge, Cambridge, Cambridgeshire, United Kingdom<br>Michelle Ellefson<br>University of Cambridge

#### Abstract

Recently, there has been increased interest regarding how pretend play contributes to children's cognitive development. This study examines the efficacy of a pretend play intervention on self-regulation and language skills of 4-to 5-year-olds and explores parents' perceptions about children's engagement in pretend play. The small-scale intervention includes eight 30minute sessions over 6 weeks, in groups of five children. Each session included: (1) shared storybook reading; (2) role-playing; and (3) review. During shared story-book reading the children were read two books with explicit phonological awareness and vocabulary instruction for 18 words in each book. Role-playing included providing the children with props, which allow for engagement in pretend play activities. Several measures were used pre- and post-intervention to evaluate children's self- regulation and language skills. The improvements that occurred in the intervention are considered alongside other cognitive and educational factors to better understand the role of pretend play in educational settings.

# Interpreting nonsignificant findings in psychological research 

Bence Palfi<br>University of Sussex, Falmer, United King

Aba Szollosi<br>University of New South Wales<br>Barnabas Szaszi<br>Eotvos Lorand University<br>Marton Kovacs<br>Eotvos Lorand University<br>Mark Zrubka<br>Eotvos Lorand University<br>Peter Szecsi<br>Eotvos Lorand University<br>Balazs Aczel<br>Eotvos Lorand University<br>\section*{Eric-Jan Wagenmakers}<br>University of Amsterdam

#### Abstract

In this study, we examined the current practice and alternative methods for interpreting nonsignificant findings in psychological research. The traditional null-hypothesis testing presents a challenge for researchers to interpret nonsignificant findings. We reviewed the abstracts of all empirical articles published in three high-esteem psychological journals in 2015 and selected those which referred to a nonsignificant result $(\mathrm{N}=134)$. We found that the majority of the statements interpreted the results only within the sample, yet in $23 \%$ the authors inferred from the results to the absence of an effect. Bayes factor analyses on these statistics indicated that the support of these results for the null-hypothesis is strong only in $4 \%$, moderate in $70 \%$ and anecdotal in $26 \%$. The results revealed that Bayes factor analysis can help researchers in interpreting nonsignificant results and also highlight that psychological studies with traditional sample sizes are unlikely to present strong evidence for the null-hypothesis.

# Perceived control in bounded-rational decision-making 

Saee Paliwal<br>Translational Neuromodeling Unit (TNU), Institute for Biomedical Engineering, University of Zurich and Swiss Federal Institute of Technology (ETH Zurich), Zurich, Switzerland<br>\section*{Frederike Petzschner}<br>Translational Neuromodeling Unit (TNU), Institute for Biomedical Engineering, University of Zurich and Swiss Federal Institute of Technology (ETH Zurich), Zurich, Switzerland<br>\section*{Ekaterina Lomakina}<br>Translational Neuromodeling Unit (TNU), Institute for Biomedical Engineering, University of Zurich and Swiss Federal Institute of Technology (ETH Zurich), Zurich, Switzerland<br>Klaas Enno Stephan<br>Translational Neuromodeling Unit (TNU), Institute for Biomedical Engineering, University of Zurich and Swiss Federal Institute of Technology (ETH Zurich), Zurich, Switzerland

#### Abstract

The amount of control perceived by an agent governs their ability to learn. Bounded rationality, or the idea that we are limited by the amount cognitive work we can perform, provides an appealing framework within which perceived control could be formulated. When modeling the world, the bounded-rational agent balances the trade-off between the utility and complexity of this constructed model in order to choose an optimal policy. Here, we present a novel formulation of behavioral control, bounded inference, which explicitly models control as the perceived constraint experienced by an agent during the inference process, employing a version of the free energy functional with an additional boundedness parameter as the variational principle of this constrained optimization. The utility of bounded inference is demonstrated in simulations that capture various characteristics of dysfunctional behavioral patterns as observed in a range of psychiatric disorders for which control beliefs play a central role.

# Applications of Cognitive Science to Enhancing Scholarly Communication 

Purav Patel<br>University of Minnesota - Twin Cities, Minneapolis, Minnesota, USA

#### Abstract

Learning from and building on the accomplishments of scholarly publications is often difficult. To address this challenge, this work leverages well-replicated cognitive science phenomena to promote people's understanding of research found in journal articles. It forms the conceptual groundwork for a digital platform through which users can author and learn from interactive multimedia documents that communicate research more effectively. One of the many recommendations is to reduce the split-attention effect by integrating text and graphics in figures. Doing so may help readers understand complex visuospatial representations. Encouraging active processing via comprehension questions and responsive simulations of experimental procedures embedded in articles may boost learning even more. To promote the creative extension of research, evidence-based brainstorming prompts that trigger analogical reasoning and episodic specificity induction should be adopted. If scholarly communication is centered on scientific principles like these, then the dissemination and dynamics of science may both advance.

# Novel metacognitive problem solving task 

Jwalin Patel<br>Faculty of Education, University of Cambridge<br>\section*{Amanda Aldercotte}<br>Faculty of Education, University of Cambridge

Teresa Parr
Ashley-Parr, LLC
Zewelanji Serpell
Department of Psychology, Virginia Commonwealth University
Michelle Ellefson
Faculty of Education, University of Cambridge

#### Abstract

Metacognition is important for decision making, problem solving and learning. Despite the widespread interest in metacognitive skills and their development, it is challenging to measure metacognitive skills in children. Some excellent qualitative and observational measures exist, but use metrics that are different from traditional metacognition tasks for adults. Some meta-cognition tasks of memory have been developed for children, but these only offer a narrow range of the skills involved in metacognition. Here, we compared performance on a meta-memory task for children with a new task of metacognition for problem solving. Our sample includes about 800 children aged $8-10$ years who were part of a larger study exploring the development of thinking skills. The results indicated similarities and differences between the memory and problem solving tasks, suggesting that the new task could be a bridge between existing qualitative and quantitative measures of metacognition in children.

# Comparing comparison indices: Assessing the validity of different magnitude comparison measures across presentation formats and age groups 

Marcie Penner-Wilger<br>King's University College at Western University<br>Aaron Cecala<br>Elizabethtown College<br>Melissa Elfers<br>King's University College at Western University

#### Abstract

Magnitude comparison tasks are used to assess the precision of numerical representations. Recent research, however, questions the validity of different measures of magnitude comparison. We investigated the validity of five performance measures: overall RT, overall accuracy, numerical ratio effect (RT), numerical ratio effect (accuracy), and Weber fraction. Kindergarten and university students completed symbolic and non-symbolic magnitude comparison tasks and a math skill measure. For children and adults, we calculated Chronbach's $\alpha$ separately for each presentation format. All values were in the unacceptable range, indicating that the different indices were not measuring the same construct. For children, a multiple regression predicting KeyMath scores from symbolic and non-symbolic indices showed that only non-symbolic overall accuracy and symbolic overall RT were predictors. For adults, a multiple regression predicting French Kit scores showed that only the symbolic numerical ratio effect (RT) was a predictor. No index demonstrated predictive validity across formats or age groups.

# Language input and development during a year in an early intervention classroom 

Lynn Perry<br>University of Miami, Coral Gables, Florida, United States<br>Emily Prince<br>University of Miami, Coral Gables, Florida, United States<br>Adriana Valtierra<br>University of Miami, Coral Gables, Florida, United States<br>Camila Rivero-Fernández<br>University of Miami, Coral Gables, Florida, United States<br>Mary Anne Ullery<br>University of Miami, Coral Gables, Florida, United States<br>Lynne Katz<br>University of Miami, Coral Gables, Florida, United States<br>\section*{Daniel Messinger}<br>University of Miami, Coral Gables, Florida, United States

#### Abstract

By the time they are three-years-old, children raised in poverty hear 30 million fewer words than their socioeconomically advantaged peers. This word gap predicts later school readiness outcomes and sets the stage for achievement gaps that can follow the child through life. Although parent speech has become a subject of increasing study and intervention, less is known about speech in childcare settings. We conducted a longitudinal study in an early-intervention classroom for $2-3$-year-old children from low-income, at-risk backgrounds. We examine the relationship between language input from teachers and peers and children's language skills over one year. Results show that vocabulary knowledge influences children's talkativeness in the classroom, and talkativeness and the amount of language they hear positively relates to increases in their language abilities. Our application of automated measurement provides new insight into the dynamics of the classroom language environment and consequences for language development in at-risk children.

# Early Visual Evoked Potentials (VEPs) in Infant Siblings of Children with ASD, ADHD and Age-Matched Controls 

Elena Serena Piccardi<br>Centre for Brain and Cognitive Development, Birkbeck University of London<br>Mark H. Johnson<br>Centre for Brain and Cognitive Development, Birkbeck University of London<br>Teodora Gliga<br>Centre for Brain and Cognitive Development, Birkbeck University of London

#### Abstract

Atypicalities in sensory perception are observed in individuals diagnosed with ASD and ADHD but have rarely been contrasted in experimental studies. In the visual domain, superior performance on visual search tasks and hypersensitivity to flickering lights have been cited as evidence of unusual sensory profiles.

To measure a reliable visual response, black-and-white checkerboards were presented under free-viewing conditions to three groups of 10 -month-olds: siblings of children with ASD ( $\mathrm{N}=47$ ), ADHD ( $\mathrm{N}=21$ ) and controls $(\mathrm{N}=18)$. Continuous EEG was recorded and VEPs time-locked to checkerboards presentation computed.

Analysis of VEPs amplitude and latency revealed statistically significant group differences in the first 200ms post-stimulus onset. Early components were enhanced in amplitude (P100) and delayed in latency (P100-N100) in at-risk infants compared to controls ( $\mathrm{p}<.05$ ).

Atypical VEPs to low-level information might index a domain-general aberration in at-risk populations. The nature of this atypicality will be further investigated by analyzing its association with background EEG.

# How does social touch modulate arousal states? An investigation in early development. 

Laura Pirazzoli<br>Birkbeck College, London, United Kingdom<br>Emily Jones<br>Birkbeck College, London, United Kingdom<br>Teodora Gliga<br>Birkbeck College, London, United Kingdom<br>Mark H. Johnson<br>Birkbeck College, London, United Kingdom

#### Abstract

Caregiver-infant interaction through touch was shown to have long-term effects on child's cognitive development, but the mechanisms are poorly understood. Our aim is to investigate how affective touch (slow gentle caressing) affects arousal states in young infants. Previous work showed that slow-touch decreases heart rate in 9-month-old infants.

We tested two groups of 6-months-old ( $n=26$ ) and 9 -months-old infants ( $n=23$ ). We measured heart rate and saccadic reaction time while infants performed a visual orienting task, where speed of re-orienting from a central fixation to a peripheral target was measured. During the experiment, infants received either slow or fast-touch on their back in blocked trials. We found no effects of touch on heart rate in either age-group, and only marginal effects of slow-touch on reaction times in 9-month-old infants. We are currently testing 2 months-old infants to investigate if these effects are observed earlier in life; these new results will be discussed.

# Hand, spoon or toothbrush? Towards the understanding of the neural underpinnings of affective touch in 5 months-old infants. 

Laura Pirazzoli<br>Birkbeck College, London, United Kingdom<br>Sarah Lloyd-Fox<br>Birkbeck College, London, United Kingdom<br>Mark H. Johnson<br>Birkbeck College, London, United Kingdom<br>Teodora Gliga<br>Birkbeck College, London, United Kingdom

#### Abstract

It is known that affective touch leads to broad cortical activations including posterior STS, key region of the social brain. Our goal is to discover if a similar pattern of activation can be observed in 5-months-old infants, or whether the development of this cortical specialization results from extensive postnatal experience.

Over two studies we used functional-Near-InfraRed-Spectroscopy (fNIRS) to compare social touch (a human caress) to non-social touch (a caress performed with a spoon in study $1-n=22$ - or with an electric toothbrush in study2-n=17-).

In study1 we found similar patterns of activation to the social and non-social stimulus. In study2 we report broad responses to the non-social stimulus, but, to our surprise, we found no activations to the human caress.

In light of these results we conclude that it is possible that at this age discrimination between social and non-social touch in the posterior temporal lobe is still undergoing specialization.

# Do we see things better when we know grammar? 

Fenna Poletiek<br>Leiden University<br>Maartje Van de Velde<br>Leiden University

#### Abstract

Language affects perception. But how? Recent findings (Boutonnet \& Lupyan, 2015; Bocanegra, Poletiek \& Zwaan, submitted) suggest a dissociation between perception that is mediated as compared to not mediated by language. One explanation is that language -that is combinatorial in nature- stresses the separate features of objects. We investigated the effect of combinatorial (two words) and non-combinatorial (one word) labels on the perceptual separation of features in visual recognition. Participants were trained to categorize meaningless objects with two dimensions: shape and height. Each category had either a one word name; or a two words name reflecting its features. Participants then were tested on new objects . Combinatorial labels enhanced categorization performance as compared to single labels. This suggests that language, by decomposing objects into parts, might drive dimension separation in vision as well.

# Patterns of Cortical Activation Correlate With Speech Understanding After Cochlear Implantation 

Luca Pollonini<br>University of Houston<br>Heather Bortfeld<br>University of California, Merced<br>Michael Beauchamp<br>Baylor College of Medicine<br>John Oghalai<br>Stanford University

#### Abstract

Cochlear implantation is a standard intervention for deafness, yet the ability of implanted patients to understand speech varies widely. To better understand this variability, we used functional near-infrared spectroscopy to image auditory cortex activation in response to different classes of sound and compared that to behavioral measures of speech perception. Both control and implanted participants with good speech perception exhibited greater cortical activity to natural speech than to unintelligible speech. In contrast, implanted participants with poor speech perception produced pronounced cortical activation across stimulus classes. Moreover, the ratio of cortical activation in response to normal speech relative to that of scrambled speech directly correlated with their comprehension scores, though not with auditory threshold, age, side of implantation, or time after implantation. Because implanted adults with low speech perception scores produced indistinguishable cortical activation across stimulus classes without preferential response to speech, we interpret this as demonstration of compensatory processing effort.

# Encouraging Fruit and Vegetable Consumption Through Intuitive Theory Building 

Derek Powell<br>Stanford University

Ellen Markman<br>Stanford University

#### Abstract

Although routinely informed of the benefits of fruits and vegetables, Americans eat far short of the recommended amounts. Instead of just telling people that fruits and vegetables are healthy, providing a compelling causal and teleological explanatory framework could increase both people's conviction about their health benefits and commitment to increasing the amount and variety of fruits and vegetables they consume. Our brief intervention: (1) emphasizes that fruits and vegetables have thousands of health-promoting phytochemicals, well beyond just vitamins, (2) describes clear causal mechanisms by which these foods ensure cellular health, (3) draws an analogy between the benefits of plant-based foods and the power of plantderived medicines, and (4) explains that plants contain abundant nutrients because they must manufacture these chemicals for their own survival. This novel intervention improved understanding and increased participants' intentions to eat more fruits and vegetables, illustrating how intuitive theories can shape motivation for behavioral change.

# Scientific Reasoning Ability in Middle Schoolers related to MasterMind Discovery Strategy 

Jean-Baptiste Quillien<br>University of Minnesota, Minneapolis, MN, United States<br>Keisha Varma<br>University of Minnesota, Minneapolis, MN, United States<br>Purav Patel<br>University of Minnesota, Minneapolis, MN, United States<br>Martin Van Boekel<br>University of Illinois at Urbana Champaign

#### Abstract

A study, investigating the relationship between scientific reasoning and the capacity to discover the strategy to play an hypothetico-deductive game (MasterMind), posits that students being able to discover Complex Strategies (vs. General Strategy, Feedback Related, No Strategy) were also, on average, performing higher on our measure of scientific reasoning, itself composed of evaluative, experimental and scientific knowledge measures. In addition to bridge the discovery of complex strategies with higher SR ability, the finding also suggests the necessity to integrate rule discovery exercises in curriculum to 1practice while 2- recognize valid reasoning procedures. Finally, inquiring about the middle schooler's capacity to recognize the most effective strategy, will help to assess the class level as a whole. Such assessment will help the teacher identify some needs and target effective lessons to explain and facilitate the transfer of CoV strategies to novel situations, as suggested by "real life" problem demands.

# Neural responses decrease while performance increases with practice: A neural network model 

Milena Rabovsky<br>Freie Universitaet, Berlin

Steven S. Hansen

Stanford University

James L. McClelland

Stanford University

#### Abstract

Why do neural responses decrease with practice? We used a predictive neural network model of sentence processing (St. John \& McClelland, 1990) to simulate neural responses during language understanding, and examined the model's correlate of neural responses (specifically, the N400 component), measured as stimulus-induced change in hidden layer activation, across training. N400 magnitude first increased and then gradually decreased over training while comprehension performance at the output steadily rose with practice. These results fit the developmental trajectory of N400 amplitudes. Importantly, they also address the reduction of neural activation with practice. In the model, the reduction is due to continuous adaptation of connection weights over training. As connection weights between hidden and output layer grow stronger, less hidden layer activation is necessary to efficiently modulate the output. This shift of labor from activation to connection weights might be an important mechanism contributing to the reduction of neural activation with practice.

# Age-related top-down and bottom-up guidance on eye movements when searching in real-world scenes 

Hanane Ramzaoui<br>Laboratoire d'Anthropologie et de Psychologie Cliniques, Cognitives et Sociales, Université Côte d'Azur, France<br>Sylvane Faure<br>Laboratoire d'Anthropologie et de Psychologie Cliniques, Cognitives et Sociales, Université Côte d'Azur, France<br>\section*{Sara Spotorno}<br>Institute of Neuroscience and Psychology, University of Glasgow, UK

#### Abstract

Efficient selection of targets is crucial in everyday activities across the lifespan. Studies reporting age-related decline have, however, typically utilised arrays of simple, unrealistic objects. Using real-world scenes, we investigated how reliability of scene semantics (consistent vs. inconsistent targets), target template specificity (name vs. precise picture) and target perceptual salience influence oculomotor search behaviour in older vs. young viewers. Aging resulted in slower search considering initial saccade latency, time and number of fixations to locate the target, and verification of object-template matching. No group differences emerged in accuracy and in search facilitation due to a pictorial template or a semantically consistent target. Target high salience enhanced efficiency in both groups, with stronger effects in older viewers. Aging seems therefore to lead to an overall search speed reduction not due to specific deficits in utilisation of scene semantic guidance or in target recognition, and possibly reduced by enhancing target perceptual guidance.

# The Long and Short of It: The Role of Verb Stem Vowel Duration in Sentence Processing 

Gwendolyn Rehrig
Rutgers University
Sten Knutsen
Rutgers University
Nicolaus Schrum
Rutgers University
Paul de Lacy
Rutgers University

Karin Stromswold<br>Rutgers University

#### Abstract

When native English speakers say active and passive sentences, verb stems are longer in passive sentences than in their active counterparts (Stromswold et al., 2002; Rehrig et al., 2015) because phrase-final lengthening and polysyllabic shortening cause the verb stem vowel to be longer in passives (Aveni et al., 2016; Mayro et al., 2016). Eye-tracking and gating studies of unaltered sentences revealed that listeners are able to predict whether a sentence is active or passive prior to hearing the inflection on the verb (Stromswold et al., 2002; 2016). To examine whether listeners use vowel duration in online sentence comprehension, we lengthened the vowel in half of the active verb stems and shortened it in half of the passive verb stems. Reaction times were longer for sentences with altered verb stem vowels ( $\mathrm{p}<.001$ ), consistent with listeners using verb stem vowel duration as a predictive cue in online comprehension.

# Recycling or Trash Bin? Modeling Consumers' Recycling Behavior in a Field Study 

Torsten Reimer<br>Purdue University, West Lafayette, IN, United States<br>Juan Pablo Ramirez<br>National University of Colombia, Bogota, Colombia<br>Chris Roland<br>Purdue University, West Lafayette, IN, United States<br>\section*{Devika Banerji}<br>Purdue University, West Lafayette, IN, United States

#### Abstract

What affects people's behavior when they dispose items? The distance hypothesis predicts that the number of misplaced items is a function of the distance of an appropriate bin. We categorized and mapped bins at 140 locations on the campus of a major research university in the Midwest and calculated the distances between adjacent bins. The distance hypothesis predicts that users dispose more recyclables in single, isolated trash bins than in trash bins that are paired with recycling bins. Likewise, it is expected that more trash items can be found in isolated compared to paired recycling bins. We conducted a field study that involved systematic comparisons of matched locations and focused on behavioral data that were obtained through systematic audits of trash and recycling bins. The study provided partial support for the distance hypothesis, which was supported for certain items. The role of item difficulty and weather conditions will be discussed.

# Is Neurocomputational Self-Organization a Core Mechanism of AGI Systems? 

Spyridon Revithis<br>University of New South Wales (UNSW), Sydney, NSW, Australia

#### Abstract

Artificial General Intelligence (AGI) is a term that describes a variant of a Strong AI revival in the mind sciences. Irrespective of its definition limits, and leaving aside the non-scientific metaphysical or philosophical aspirations, AGI studies the feasibility and implementation aspects of artificial systems that would have the capacity of domain non-specific (domaingeneral) human-level intelligence.

The importance of self-organization in natural neural systems as well as in neuromimetic computational systems, especially the class of Self-Organizing Map (SOM) neural networks, has been extensively demonstrated and supported in the literature. Neurocomputational self-organization exhibits unique characteristics, including non-deterministic epigenetic (post-genetic) behavior, which enable direct functional and structural comparisons with the neocortex more than most existing relevant computational mechanisms. If the problem of artificial general intelligence is approached from a biologically relevant computational standpoint then SOM mechanisms are currently a very strong candidate as a core component of a computational AGI system.

# Does a present bias influence exploratory choice? 

Alexander S Rich<br>New York University<br>Todd M Gureckis<br>New York University

#### Abstract

Balancing exploration and exploitation is difficult, and across a wide variety of situations under-exploration of uncertain alternatives appears prevalent. We propose that one possible cause of under-exploration is present bias, whereby immediate rewards (like those gained from exploitation) loom larger than future rewards (like those gained from exploration). This possible cause of under-exploration is not addressed by past studies, in which choices generally yield token rewards that are converted to money at the end of the experiment, removing the inter-temporal aspect of the decision-making process. To address this issue, we developed an exploratory choice task with immediately-consumed rewards. We then tested whether whether imposing a temporal delay before the consumption of rewards increased exploration by decreasing present bias, and report on our results.

# Everyday object affordance enhances automatic inhibitory control: an ERP study 

Stefania Righi<br>University of Florence<br>Giorgio Gronchi<br>University of Florence

## Lapo Pierguidi

University of Florence

## Maria Pia Viggiano

University of Florence

#### Abstract

High affordance stimuli are associated with an enhancement in the activation of the corresponding motor programs. Such over-activation of motor programs may imply a decrease in performances based on inhibitory control. However, recent data suggest that high affordance stimuli are associated with a widespread privileged neural activation that goes beyond motor representations. In this case, we can expect that high affordance objects will be associated to a higher level of flexibility in an oddball task with Go-NoGo procedure. By measuring ERPs, we observed that, in the case of high affordance objects, the amplitude of the N200 is decreased when the inhibition of the motor response is more difficult. Data suggests that high affordance objects facilitate inhibitory control, probably due to a higher activation of automatic attentional resources.

# Metacognitive Monitoring of Internal and External Storage and Retrieval 

Evan Risko<br>University of Waterloo, waterloo<br>Connor Gaspar<br>University of Waterloo, waterloo<br>Dave McLean<br>University of Waterloo, waterloo<br>Tim Dunn<br>University of Waterloo, waterloo<br>Derek Koehler<br>University of Waterloo, waterloo

#### Abstract

The ability to monitor our cognitive performance (i.e., metacognitive monitoring) is central to efficient functioning. Research investigating this ability has focused largely on tasks that rely exclusively on internal processes. However, our day-today cognitive activities often consist of mixes of internal and external processes. For example, we can offload memory demands onto external media (e.g., computers, paper). In the present investigation, we expand research on the metacognitive monitoring of performance to this domain. Specifically, we examine participant's ability to accurately monitor their performance in tasks that require them to rely on only their internal processes (e.g., short term memory to remember a series of letters) and tasks that require them to rely on both (e.g., paper and pencil to remember a series of letters). Results suggest that the former results in superior monitoring relative to the latter. Implications for understanding metacognition in more distributed cognitive domains will be discussed.

# From Concrete Examples to Abstract Relations: A model-based neuroscience approach to how people learn new categories 

Gareth Roberts<br>School of Psychology, University of Sydney<br>Micah Goldwater<br>School of Psychology, University of Sydney<br>Evan Livesey<br>School of Psychology, University of Sydney<br>Josue Giron<br>School of Psychology, University of Sydney<br>Tyler Davis<br>Department of Psychological Sciences, Texas Tech University

#### Abstract

The ability to form relational categories for objects that share few features in common is a hallmark of human cognition. However until recently, neuroimaging research largely focused solely on how people acquire categories defined by features. In the current electroencephalography (EEG) study, we examine how relational and feature-based category learning compare in well-matched learning tasks. Building on a previous functional magnetic resonance imaging study by our laboratory, we capitalise on the rich temporal information offered by EEG. Focusing on the neural dynamics of how people learn category memberships over individual trials in an experimental task, we investigate how these single trial dynamics modulate computational estimates from decision-making modelling frameworks. Specifically, by sorting participants’ individual trials by their position in the experimental sequence we observe striking relationships between EEG dynamics (e.g., frontal theta oscillations and P300 component) and feature-based and relational categorisation behaviour.

# Progress in building a machine that can ask interesting and informative questions 

Anselm Rothe<br>New York University<br>Brenden Lake<br>New York University<br>Todd Gureckis<br>New York University

#### Abstract

Asking creative questions is a hallmark of human cognition. In comparison, machine learning systems that attempt to mimic this ability are still extremely limited (e.g., current chatbots ask questions based on preprogrammed routines). In the present work, we developed a computational model of question generation. Based on a corpus of questions collected from online participants playing an information-seeking game, we designed a "grammar of questions." The grammar is powerful enough to represent all human questions we collected and thus defines the "question space." Given a particular context (game scenario), people are more likely to ask (generate) some questions that others. Our computational model predicts these likelihoods, that is, a probability distribution over the question space. In addition, the model can generalize to novel contexts. Key model ingredients are informativity, compositionality, and length of a question.

# Shifting backward to say what's front? Spatial referencing of dorsal object arrangements 

Annelie Rothe-Wulf<br>University of Freiburg, Freiburg, Germany<br>Andrea Bender<br>University of Bergen, Bergen, Norway<br>Julia Fischer<br>University of Freiburg, Freiburg, Germany<br>Nadine Lobmüller<br>University of Freiburg, Freiburg, Germany<br>Sieghard Beller<br>University of Bergen, Bergen, Norway

#### Abstract

When referring to spatial arrangements of two objects in the visual field, German native speakers prefer reflection as a subtype of the relative frame of reference. Whether this preference transfers to objects in one's back and whether a mental turn has to precede such dorsal references (turn hypothesis), has recently been explored in studies implementing questionnaires. However, the results hardly supported the turn hypothesis and rather suggested backward projection as an alternative strategy for dorsal references. To test the two assumptions more rigorously, a series of experiments implemented dorsal object arrangements in interview situations and induced dorsal perspectives via turning, shifting or reflecting the actual view of participants. Across experiments and conditions, backward projection consistently emerged as the preferred referencing strategy and only a small proportion of dorsal references accorded with the turn hypothesis. Participants' retrospective descriptions supported this pattern and suggested backward projection to be involved in dorsal referencing.

# The time course of Intentional Binding 

Miriam Ruess<br>Albert-Ludwigs-Universität Freiburg, Freiburg i. Br., Germany<br>Roland Thomaschke<br>Albert-Ludwigs-Universität Freiburg, Freiburg, Germany

## Andrea Kiesel

Albert-Ludwigs-Universität Freiburg

#### Abstract

Environmental stimuli caused by actions (i.e., effects) are perceived earlier than stimuli not caused by actions. This phenomenon is termed intentional binding (IB), and serves as implicit measure of sense of agency. We investigated the influence of effect delay and temporal predictability on IB, measured with the classic clock procedure as the bias to perceive the effect as temporally shifted towards the action. For short delays, IB increased with delay (Experiment 1: $200 \mathrm{~ms}, 250 \mathrm{~ms}, 300 \mathrm{~ms}$ ) and this initial increase declined for longer delays (Experiment 2: $100 \mathrm{~ms}, 250 \mathrm{~ms}, 400 \mathrm{~ms}$ ). These results extend previous findings showing IB to decrease with increasing delays for delay ranges of 250 ms to 650 ms . Further, the indication that IB, that is, sense of agency, might be maximal for different delays depending on the specific characteristics and context of action and effect, has important implications for human-machine interfaces.

# A positive attitude increases subjective life expectancy 

Susana Ruiz Fernández<br>Leibniz-Institut für Wissensmedien, Tübingen, Germany<br>Martin Lachmair<br>Leibniz-Institut für Wissensmedien, Tübingen, Germany<br>Juan José Rahona<br>Leibniz-Institut für Wissensmedien, Tübingen, Germany<br>Lotte Sophia Roessler<br>Leibniz-Institut für Wissensmedien, Tübingen, Germany<br>Peter Gerjets<br>Leibniz-Institut für Wissensmedien, Tübingen, Germany

#### Abstract

Subjective life expectancy (SLE) has been related to psychological variables, such as optimism. Based on previous studies where positive attitude was related with longer lifetime, the present study examined whether modifying participants' attitude would influence their SLE. Therefore, 50 participants were randomly assigned either to a positive or to a neutral attitude group. During one week, participants of the positive (neutral) group, had to choose the three most accurate positive (neutral) sentences (among 22) to describe their day. After this week, they had to estimate the probability of being $60,70,80$, or 90 years old (traditional measure) and to situate themselves on a line representing their lifetime (spatial based measure). Results show that 1) a more positive attitude increased SLE more than a neutral one, 2) the spatial based measure was sensitive to the intervention and 3) both measures correlated positively with participants' optimism.

# Probability matching in choice behavior influenced by virtual rewards 

Yuichi Saito<br>Graduate School of Engineering, Kogakuin University

Miyuki G. Kamachi<br>Faculty of informatics, Kogakuin University

#### Abstract

We recognize the amount of "reward" according to our choices. In repeated binary choice tasks, human behave according to the theoretical basis of "probability matching" (Shanks et al., 2002), which has been advocated in several studies. However, the quality of reward may influence their choice-behavior. It is acknowledged that the sensitivity of values for gains or losses differs among individuals because of risk aversion (Kahneman \& Tversky, 1979). We conducted a series of experiments to investigate how participants' choices change when the ratio of hit-items was set up. Virtual rewards, $-3 / 0,-3 /+3$, and $0 /+3$ point for each choice, were given to participants. The results showed that the choice-ratio of the weighted correct side was higher in conditions involving losses, suggesting that participants' choices indicate risk aversion even though rewards were virtual. Our results suggest that probability matching can be found only when people implicitly recognize their choices have no loss.

# ASR Systems as Models of Phonetic Category Perception in Adults 

Thomas Schatz<br>LSCP (ENS/EHESS/CNRS), Département d'Etudes Cognitives, Ecole Normale Supérieure, PSL Research University, France<br>Francis Bach<br>SIERRA Project-Team (ENS/INRIA/CNRS), Département d'Informatique, Ecole Normale Supérieure, PSL Research University, France<br>Emmanuel Dupoux<br>LSCP (ENS/EHESS/CNRS), Département d'Etudes Cognitives, Ecole Normale Supérieure, PSL Research University, France

#### Abstract

Adult speech perception is tuned to efficiently process native phonetic categories, causing difficulties with certain non-native categories. For example, Japanese has no equivalent of the distinction between American English $/ \mathrm{r} /$ and $/ \mathrm{l} /$ and native speakers of Japanese have a hard time discriminating between these two sounds. Here, we ask whether standard Automatic Speech Recognition (ASR) systems trained on large corpora of continuous speech can make correct quantitative predictions regarding such non-native phonetic category perception effects. By training an ASR system on language L1 and evaluating it on language L2, we obtain predictions for a native L1 speaker tested on L2 phonetic contrasts. Using a variety of L1 and L2, we show that ASR models correctly predict several well-documented effects. Beyond the immediate results, our evaluation methodology, based on a machine version of ABX discrimination tasks, opens the possibility of a more systematic investigation of computational models of phonetic category perception.

# Which test to perform? Modeling utility of medical tests: information gain, patient risk and financial costs 

Clara Schirren<br>Humboldt-Universität zu Berlin

Stefanie C. Hautz

AO Educational Institute

Wolf E. Hautz

Inselspital - Universitätsspital Bern
Juliane E. Kämmer
Charité Universitätsmedizin Berlin
Björn Meder
Max Planck Institute for Human Development, Berlin
Jonathan D. Nelson
Max Planck Institute for Human Development, Berlin

#### Abstract

In medical diagnosis, as in many cognitive domains, asking the right questions is crucial. Medical tests differ not only in the type of information they provide, but in their financial costs and physical risks to a patient. We develop a model that combines informational and cost constraints, describing specific medical scenarios of a patient with realistic symptoms. We then define a finite number of existing medical tests that are available in this situation. The tests differ in their sensitivity and specificity concerning different possible underlying diseases as well as in their financial costs and the physical risks they pose to a patient. Combining these, we compare the utilities of the different tests if performed alone as well as if performed in combination. We show how purely informational considerations are not adequate for the analysis of such a scenario; test costs and patient outcomes must also be taken into account.

# Intuitive system control: Challenging the standard model of dynamic decision making 

Wolfgang Schoppek<br>University of Bayreuth

#### Abstract

Dynamic decision making (DDM) is usually operationalized in a way that subjects explore and control computersimulated dynamic systems consisting of interconnected variables. Most authors in the field agree on a "standard model of DDM" that assumes that decision makers have to learn the causal structure of the system through appropriate explorative behavior before they can bring the system to given goal states. This strategy draws heavily on cognitive ressources, such as working memory. The standard model predicts that performance in DDM, as well as structural knowledge should be severely impaired when a second cognitive task has to be executed while exploring the system. An experiment with a dual task as the main factor revealed no differences in knowledge and performance between the conditions. Participants in both conditions appeared to rely on rudimentary structural knowledge and adopted intuitive strategies. We interprete the findings within a dual processing framework.

# Learning Temporal Generative Neural Codes for Biological Motion Perception and Inference 

Fabian Schrodt<br>University of Tübingen, Tübingen, Baden-Württemberg, Germany<br>Martin V. Butz<br>University of Tübingen, Tübingen, Baden-Württemberg, Germany

#### Abstract

We introduce a modular recurrent neural architecture, which learns distributed, generative temporal models of biological motion. It encodes modal visual and proprioceptive (angular) biological motions separately by means of autoencoders, structuring respective postures, motion directions, and motion magnitudes separately. The submodal encoders are interdependent by predicting each other's next autoencoder states temporally. As a result, distributed attractor states can develop from self-generated motions. We show that the architecture is able to synchronize its activities across modalities towards overall consistent action-encoding attractors. Moreover, the developing spatial and temporal structures can complete partially observable actions, e.g., when only providing visual information. Furthermore, we show that the network is capable of simulating whole-body actions without any sensory stimulation, thus imagining unfolding actions. Finally, we show that the network is able to infer the visual perspective on a biological motion. Thus, the neural architecture enables embodied perspective taking and action inference.

# The Sufficiency Principle: Predicting when children will regularize inconsistent language variation 

Kathryn D. Schuler<br>Georgetown University<br>Jaclyn E. Horowitz<br>Georgetown University

Charles Yang
University of Pennsylvania
Elissa L. Newport
Georgetown University

#### Abstract

Children exposed to inconsistent language variation regularize this variation in their productions (Hudson-Kam \& Newport, 2005). Existing demonstrations of regularization observe this behavior when the signal-to-noise ratio is greater-than-or-equal-to $40 \%$, but whether regularization occurs when the dominant form is less widespread has not been investigated. A recent computational model, the Sufficiency Principle, quantifies when a pattern is widespread enough to generalize (Yang, 2016): Let $R$ be a generalization over $N$ items, of which $M$ are attested to follow $R$. $R$ extends to all $N$ items iff: $N-M<N / \ln (N)$. To test this model, we exposed children to artificial languages in which the dominant form occurred either above or below this threshold for generalization. We found that, as predicted, children regularized only under circumstance in which the Sufficiency Principle threshold for generalization is met. Thus, regularization may be governed by a basic principle of generalization that is well captured by this model.

# Impaired phonological processing of lexical tones in Cantonese speakers with congenital amusia 

Jing Shao<br>The Hong Kong Polytechnic University<br>Xunan Huang<br>The Hong Kong Polytechnic University<br>Caicai Zhang<br>The Hong Kong Polytechnic University

#### Abstract

Congenital amusia is a lifelong musical disorder. It has been found that tonal-language speakers with amusia are impaired in lexical tone perception. But it has also been found that tonal-language experience compensates the deficit in certain scenario, reducing prevalence rate of amusia in speakers of a highly complex tonal-language - Cantonese. Thus it remains unclear whether lexical tone perception, especially its phonological processing, is impaired in Cantonese-speaking amusics. This study investigated the categorical perception of a continuum of lexical tone stimuli and pure tone analogues in Cantonesespeaking amusics and controls. The amusics showed reduced discrimination peak across the categorical boundary compared to controls in lexical tone condition, suggesting impaired categorical perception; in pure tone condition, the amusics showed inferior performance on both between- and within-category discriminations, suggesting a deficit in auditory pitch processing. These findings indicate that phonological processing of tone is impaired in Cantonese-speaking amusics, despite possible compensation effect.

# Discovering kinds of future-oriented thought using automated machine-learning techniques 

Jason Shepard<br>Agnes Scott College

Aiming Nie<br>Stanford University

Bridget Copley
CNRS/Universite Paris 8
Phillip Wolff
Emory University

#### Abstract

Humans have a remarkable ability to think about the future. Our abilities to think about the future are essential for the level of goal construction, planning, and execution of plans that is only observable in humans. Thinking about the future has also been found to be important for the development of sense of self and for health and well-being. In spite of the importance of future-oriented thought, very little empirical work has been conducted on the nature of future-oriented thought. In this research, we demonstrate how automated methodologies can be used to identify references to the future from natural text (Study 1) and how machine-learning techniques can be used to identify categories of future-oriented thought (Study 2). We also demonstrate how the categories that emerge from these analyses can help us better understand the relation between future-oriented thought and many of the positive outcomes associated with future-oriented thought (Study 3).

# The influence of word-order harmony on structural priming in artificial languages 

Kenny Smith<br>University of Edinburgh<br>Olga Feher<br>University of Edinburgh<br>Jennifer Culbertson<br>University of Edinburgh

#### Abstract

Structural priming occurs when interlocutors copy the syntactic structure of their partners' utterances, and is diagnostic of their underlying representations. We trained adult participants on an artificial 'alien' language in which nouns appeared with adjectives or numerals in two-word phrases; participants then used that language to communicate with an alien interlocutor. Input languages had variable word-order with the two modifier types tending to appear on the same side of the noun (harmonic) or on different sides of the noun (non-harmonic). Participants in all conditions acquired the dominant order of their input; however, structural priming only occurred within modifier types (e.g. encountering Numeral-Noun primed Numeral-Noun order only, not Adjective-Noun), even for participants exposed to harmonic input where both modifier types patterned the same way. This suggests that the abstract representations tapped by structural priming in rapidly-learnt artificial languages encode distinctions that are not based purely on distributional properties of the input.

# Recently rewarded task-irrelevant stimuli do not distract 2-year-olds during visual search 

Hayley K Smith<br>University of Massachusetts, Boston<br>Erik Blaser<br>University of Massachusetts, Boston<br>Zsuzsa Kaldy<br>University of Massachusetts, Boston

#### Abstract

In adults, stimuli associated with reward capture attention, even when task-irrelevant, resulting in distraction (Awh et al., 2012). Here we examine whether rewarded stimuli capture attention in 2 -year-old children. Toddlers ( $\mathrm{N}=46$, mean age: 28;10, range: 19;16-36;18) performed a visual search task where the target switched between blocks. Search arrays consisted of the current target, a previous target, and six feature conjunction distractors. On each trial, the current target was cued, and following a fixed search period, rotated as a reward. We used a Tobii T120 eye-tracker to record toddlers' eye-movements. Following a target switch, toddlers fixated the current target before the previous target, despite the previous target's recent reward history $\mathrm{F}(1,44)=31.183, \mathrm{p}<0.001$ ). Our study is one of the first to investigate the early development of reward-based attentional selection.

# Disambiguating Disfluencies: What Do Speech Disfluencies Tell Us About Speech Production? 

Mikhail Sokolov<br>Carleton University

John Logan<br>Carleton University

#### Abstract

Speech disfluencies occur frequently in spontaneous speech but their source is unclear. Disfluencies can take several forms, most commonly as verbalized disfluencies such as "um", "uh", and "so", as well as silent pauses. In the present exploratory study we examined the relationship between disfluencies as distinct entities, individual differences in working memory capacity, and linguistic markers of complexity. We found that disfluencies diverge in their relationship with these variables. The "um" disfluency was most closely related to working memory capacity and linguistic complexity. The "uh" disfluency was associated with infrequent word production. The "so" disfluency predicted of the number of words produced. Silent disfluencies were not related to working memory capacity. However, micro-pauses were related to word production, and macro-pauses were negatively correlated with the "so" disfluency. Results are discussed in terms of potential relationships between disfluencies and speech production processes.

# Phonological Competition during Spoken-Word Recognition in Infants and Adults 

Marlene Spangenberg<br>University of Oxford, Oxford, United Kingdom<br>Kim Plunkett<br>University of Oxford, Oxford, United Kingdom

#### Abstract

An ongoing debate concerns whether spoken word recognition happens in an incremental or continuous manner (Marslen-Wilson \& Zwitserlood, 1989; McClelland \& Elman, 1986). In the current study, participants ( 31 adults and 49 infants aged $24-30$ months) were presented with four images while they heard a sentence like "Look at the cat". Among the images was one object that rhymed with the spoken word, one object that shared its onset and two phonologically unrelated objects. Growth curve analysis of eye-tracking data revealed that adults preferentially fixated onset competitors over unrelated objects soon after word onset but did not preferentially fixate rhyme competitors. Fixations of the onset competitors were modulated by the degree to which the onsets of the three remaining competitors were phonologically similar to the spoken word. Infants showed no preference for either type of phonologically related competitor. The absence of a rhyme effect contradicts continuous theories of spoken word recognition.

# Word order rules in business name binomials 

Samuel Spevack
University of California, Merced, Merced, California, United States

## Patricia Lichtenstein

University of California, Merced, Merced, CA, US

Stephanie Shih

University of California, Merced

#### Abstract

Naming practices offer a window onto linguistic processes of productivity that rely on input from interacting streams of information. Previous studies have looked at proper personal names and binomial combinations of proper personal names to show that phonological features such as rhythm, semantic features such as gender, and corpus features such as word frequency play an important role in naming and ordering of names. In comparison to personal names, business names tend to be more diverse in terms of constituent structure, often incorporating binomial constructions that may or may not consist of proper names themselves. In this study, we investigate whether the ordering of binomials in business names reflects the features identified in previous work, with a focus on the following: syllable count, metrical stress, animacy, concreteness, word frequency, and binomial frequency. We report here on an initial analysis of data from the Yelp Dataset Challenge.

# The time course of colour guidance in realistic scene search 

Sara Spotorno<br>University of Glasgow, Glasgow, Scotland, United Kingdom<br>Ben Tatler<br>University of Aberdeen, Aberdeen, Scotland, United Kingdom

#### Abstract

Colour is a source of attentional guidance and object segmentation when viewing a scene. In an eye-tracking study, we examined its role during search of targets placed in consistent or inconsistent locations within realistic scene contexts. Both the target template and the whole scene were presented in full colour or grayscale. Colour presence did not influence early search, considering latency, direction or gain of the first saccade, but affected later phases, with longer scene scanning and more fixations required to locate the target in the grayscale condition, which also lengthened verification of template-object matching. These effects were enhanced in inconsistent scenes. Our results suggest that observers may not utilise colour cues when initiating scene inspection during search but also that colour information modulates efficiency of the search process in terms of attentional selection and object recognition, in particular when the context of the scene does not provide reliable high-level guidance.

# Perceptual decision making from correlated samples 

Oana Stanciu<br>Central European University, Budapest, Hungary<br>Mate Lengyel<br>University of Cambridge<br>Daniel Wolpert<br>University of Cambridge<br>Jozsef Fiser<br>Central European University, Budapest, Hungary

#### Abstract

The optimal perceptual decision making strategy for weighting serially presented information depends on the degree of sample dependence. Uniform weighting produces optimal estimates from independent samples, but increases in autocorrelation should be matched by increasing and symmetric overweighting of early and late samples in order to maintain optimal performance.

In the current experiment, participants $(\mathrm{N}=30)$ observed briefly presented sequences of eight dots and were asked to estimate their center of mass by dragging the cursor. The autocorrelation of the series was manipulated in two distinct blocks (either 0 or .7). Preliminary results show that the weight assignment to uncorrelated inputs did not differ significantly from the optimal uniform allocation. In contrast, in the high-dependence block participants used different weighting profiles - overweighting the first and/or last samples of the sequence. This suggests that humans flexibly adapt to changes in statistical structure in the predicted direction of optimality.

# Optimality of visual search under ambiguous stimuli 

Elina Stengård<br>Department of Psychology, Uppsala, Sweden<br>Ronald van den Berg<br>Department of psychology, Uppsala, Sweden

#### Abstract

A hallmark of optimal decision making is that cues are weighted by their reliability. Previous studies have reported evidence for reliability weighting in several human perceptual decision-making tasks in which sensory noise was the only possible source of errors. Here we use a target detection task to test whether optimality generalizes to situations where stimulus ambiguity is an additional source of uncertainty. Target and distractor orientations were drawn from distributions with different means and the level of ambiguity was varied through the amount of overlap between the two distributions. In line with previous studies, we found clear evidence for sensory reliability-weighting, regardless of the level of ambiguity. However, using a richer set of models than before, we also found that the estimated weights deviated from the optimal ones. Finally, we found no effect of ambiguity level on task efficiency, which suggests that subjects optimally accounted for this source of uncertainty.

# It is new, but will it be good? Context-driven exploration of novel options 

Hrvoje Stojic<br>University College London, London, London, United Kingdom<br>Eric Schulz<br>University College London, London, London, United Kingdom<br>Maarten Speekenbrink<br>University College London, London, London, United Kingdom

#### Abstract

How do people decide whether to try out novel options? We argue that they utilize contextual information to efficiently generalize from learned functional relations in order to decide between known or novel options. In a contextual multi-armed bandit task, in which rewards are a noisy function of observable features, we assess participants' preferences for newly introduced options. We show that participants preferably choose a novel option if its features indicate high rewards, but shun the option if its features indicate low rewards, a behavior that can only be explained by functional generalization. Moreover, we assess people's preferences for novel options that have medium rewards to test whether they prefer options less similar to experienced options, consistent with choices guided by uncertainty. Given that novel options normally come with observable features, we argue that contextual learning is a parsimonious yet powerful explanation of behavior in the face of novelty.

# Mathematical Symbol Recognition in Children 

Sandra Street<br>University of Wisconsin-Whitewater, Whitewater, WI, US

#### Abstract

In early mathematics development the development of symbolic skills is critical to math learning. Our mathematical system is based on Arabic number symbols which do not provide any semantic meaning relevant to the number words and symbols. In order to succeed in math one must be able to recognize and understand the meaning of numeric and other mathematical symbols. Little is known about the development of these symbolic skills. The current study examines $4-7$-year-old children's understanding and recognition of number and arithmetic symbols. The youngest children made significant errors in identifying numbers as well as confusing letter symbols with number symbols. Results reveal a developmental progression of numeric symbol recognition.

# Speaking in English, sorting in Chinese: interaction in L2 can reinforce existing categories in L1 

Ellise Suffill<br>University of Edinburgh, Edinburgh, Midlothian, United Kingdom<br>Holly Branigan<br>University of Edinburgh, Edinburgh, UK<br>Martin Pickering<br>University of Edinburgh, Edinburgh, UK

#### Abstract

How does interaction affect categorization, and how might this vary between native and non-native speakers? When people use shared labels to categorize objects, they categorize more similarly to each other. We investigated whether interaction leads non-native speakers to categorize in the same way as native speakers. In six rounds, L1-English and L2-English/L1Mandarin speakers individually categorized dishware using labels (BOWL, PLATE), then discussed their categories or an unrelated topic after each round. L2 speakers' categories shifted following category-relevant interaction with L1 speakers, but their categories did not become more L1-like. Unexpectedly, category-relevant interaction reduced alignment within pairs and within language groups; however, this effect was weaker in the L2 than L1 group. Hence, L2 speakers showed a stronger tendency than L1 speakers to use categories that were similar to other speakers from their language group. This suggests that interaction in an L2 can reinforce L2 speakers' categories in their L1.

# The effect of overt language use on category induction 

Justin Sulik<br>Max Planck Institute for Psycholinguistics, Nijmegen, Netherlands<br>Haily Merritt<br>Indiana University, Bloomington, IN, USA<br>Gary Lupyan<br>University of Wisconsin, Madison, WI, USA

#### Abstract

Successfully solving a problem should help people solve similar problems, but such generalization is often surprisingly limited. We investigated generalization performance when people explicitly verbalized solutions to open-ended categoryinduction "Bongard problems", compared to tacitly indicating that they had found a solution. In a Bongard problem people are presented with an array of items falling into two classes, and have to induce the basis for the classification by working out what (sometimes quite abstract) feature of the items is relevant, from a vast set of possibilities. We measured objective performance by testing people with new items, and observed how explicitly vs. tacitly expressed solutions affected generalization across concretely similar or abstractly similar problems. For the concretely similar problems, explicitness boosted transfer of correct solutions. For the abstractly similar problems, there was no evidence of transfer, though there was a general positive effect of explictness.

# Respecting UP and Despising DOWN: Emotional and Body-based Image in Japanese Verbs 

Tomohiro Taira<br>Osaka City University

#### Abstract

The aim of this study was to examine the image-schematic representations that arise from sentences referring to concrete/abstract action in Japanese verbs. We used a free positioning task that required the participants to draw the position of an object in a sentence referring to an agent's concrete/abstract action and a simple rating task that investigated the agent's need for body movement and emotional evaluation for the object. The results showed that the drawn object's position in not only a concrete but also an abstract action sentence is changed before and after the action. Further, the results indicated that the height and distance from the agent to the object in the sentence is related to the emotional evaluation of the agent for the object in the sentence.

# A time-series eye-fixation analysis of the similarity-compromise effect in multi-alternative choice 

Tsuzuki Takashi<br>Rikkyo University

Chiba Itsuki<br>National Institute of Advanced Industrial Science and Technology

#### Abstract

In decision-making tasks with two attributes and three alternatives, the similarity effect implies that, if the total expected utility is equal between two opposite alternatives (i.e., the target and competitor), the probability of the target being chosen decreases with the addition of the decoy similar to the target. This study demonstrated the similarity-compromise effect, wherein the probability of the target being chosen increased with the addition of the decoy, under the same conditions as the similarity effect, by setting all attribute values of three alternatives to broken numbers rather than rounded numbers. To determine the mechanism underlying this effect, we examined information acquisition patterns using eye-movement data collected from 37 undergraduates who made 10 hypothetical purchase tasks with two attributes and three alternatives. Timeseries analysis of fixation time for the three alternatives revealed dynamic temporal features distinct from those of attraction and compromise effects observed in our previous research.

# Relationship between four measures reflecting representations of fraction magnitude in adults: number line estimation, comparison, calculation of fractions, and immediate serial recall of fractions 

Yuki Tanida<br>Osaka University, Suita-city, Osaka, Japan<br>Yu Koshima<br>Osaka Prefecture University, Sakai, Osaka, Japan<br>Masahiko Okamoto<br>Osaka Prefecture University, Sakai, Osaka, Japan

#### Abstract

Our previous studies (presented at the London meeting of EPS in 2017 and submitted for ICPS 2017) suggested that immediate serial recall tasks access magnitude representation of fraction. A subsequent research task is to explore the intercorrelations among four tasks stimulating representations of fraction magnitude: an immediate serial recall task with fraction stimuli and three typical tasks, number line estimation, comparison, and calculation of fractions. The purpose of this study is to examine whether our new measure, the size of the magnitude similarity effect on immediate serial recall of fractions, relates to other typical measures for adults. The results from 36 university students showed a significant correlation between the size of the magnitude similarity effect and the RT of fraction calculation tasks but no correlations among any other tasks. This result suggests that it is necessary to reexamine what tasks could access the magnitudinal representation of fraction in adults.

# Slow Change: The Visual Context for Real World Learning 

Charlene Tay<br>Indiana University Bloomington, Bloomington, Indiana, United States<br>Linda Smith<br>Indiana University Bloomington, Bloomington, Indiana, United States<br>Chen Yu<br>Indiana University Bloomington, Bloomington, Indiana, United States

#### Abstract

The visual world can be a noisy and dynamic place. This poses problems for novice word learners who must map heard names to objects in scenes with their many potential referents. In this study, we consider how the visual stability and selectivity of scenes from the first-person perspective may simplify the learning problem. 12- and 30-month-old children wore head cameras and played with a large set of toys. Through analyzing head-camera video frame by frame, we measured the rate of change of scene information in the natural world of children in this context, and found that the visual world from the child's perspective changes continuously. However, this change is slow and incremental - tiny steps - even across increasingly larger timescales. We discuss the importance of understanding the dynamics of real world environments for understanding visual processing, sustained attention, and early object name learning.

# Effects of attention to emergent phenomena on rule discovery 

Hitoshi Terai<br>Kindai University<br>Kazuhisa Miwa<br>Nagoya University<br>Sho Yokoyama<br>Kindai University<br>Souta Fujimura<br>Kindai University<br>Gotaro Nakayama<br>Kindai University

#### Abstract

In this study, we focused on effects of finding of emergent phenomena in rule discovery. In the experiment, we used Conway's Game of Life, which generates high-order phenomena from fundamental rules. Our research question is to realize the effects of attention to emergent phenomena on finding the fundamental rules. The two experimental conditions (chaotic and static) differed only in initial states. In the chaotic condition, the initial state consisted some Methuselahs, which take long period until they become stable. On the other hand, in the static condition, the initial condition consisted many emergent patterns: still lifes and oscillators, which repeat same pattern in short period. We classified the hypotheses reported by the participants to either mentioning about emergent phenomena or not. This result revealed that people might see emergent phenomena not only in the static condition but also in the chaotic condition, which do not include the emergent patters.

# Scheduling system delays for optimal user performance: Don't predict time; let time predict! 

Roland Thomaschke<br>Albert-Ludwigs-Universität Freiburg, Freiburg, Germany<br>Lennart Koch<br>Albert-Ludwigs-Universität Freiburg, Freiburg, Germany<br>Miriam Ruess<br>Albert-Ludwigs-Universität Freiburg, Freiburg, Germany<br>Andrea Kiesel<br>Albert-Ludwigs-Universität Freiburg, Freiburg, Germany

#### Abstract

System delays affect user performance and experience when interacting with computers. We investigated the effects of different prediction relations between delay duration and response requirements on user performance. In one experiment, delay duration predicted, to different degrees ( $50 \%$ vs. $75 \%$ vs. $100 \%$ ), the following system response. Predictability substantially increased users' response speed, while adaptation was highly flexible, between different prediction regimes. In a second experiment, users' responses predicted system delay duration. Compared to the first experiment, users' response speed was moderately increased, while the adaptation was rather inflexible across different prediction regimes. In a third experiment, we directly compared both types of predictability. The results confirmed a stronger and more flexible adaptation effect when time predicted the system response, compared to when users' responses predicted time. These findings have important implications for scheduling data transmission rates across different users in internet-based parallel computing.

# Computational Foundations of Cultural Evolution: Modeling the Emergence of Systems from Higher-order Probabilistic Inference 

Bill Thompson<br>Max Planck Institute for Psycholinguistics

#### Abstract

Cumulative cultural evolution in humans is the process through which behaviours gain structure and complexity as they are transmitted from one generation of learners to the next. A central challenge in the cultural evolution literature is to understand how the unique computational principles of human cognition scaffold the emergence of complex behavioural systems. I explore how the human ability to make inferences at higher order levels of abstraction can lead to cultural complexity, in two ways: by allowing initially independent behaviours to gradually acquire group-like structure as new learners repeatedly impose an expectation for statistical dependence; and by allowing inferences in one domain to be rapidly transferred to new domains which share features at higher-order levels of abstraction. I model these processes in populations using a probabilistic cognitive model for the acquisition of vowel systems in human language.

# Counterfactual thoughts and judgments about morally good actions 

Shane Timmons<br>TRINITY COLLEGE DUBLIN, UNIVERSITY OF DUBLIN, IRELAND<br>Ruth Byrne<br>TRINITY COLLEGE DUBLIN, UNIVERSITY OF DUBLIN, IRELAND

#### Abstract

Evaluating the morality of an action is affected by thoughts about whether the outcome might have turned out differently. We report experimental results that show a moral action effect occurs for judgments about morally good actions. Participants read stories about a morally elevating situation, e.g., an agent is found to be a match as a bone-marrow donor for someone else. The agent decided to act or not to act, and the outcome turned out well or it did not turn out well. Participants created counterfactual thoughts and they also made judgments about whether the agent should have acted, and whether the agent was morally responsible for the outcome. The results show a moral action effect: participants judged that the action should have been taken, and that the agent was morally responsible for the outcome, when the agent acted compared to when they did not act, regardless of the outcome.

# Gradually ascending sound with accelerating automatic driving vehicle might change passengers' tension or anxiety: analysis of biometrical index. 

Akitoshi Tomita<br>University of Tsukuba<br>Etsuko Harada<br>University of Tsukuba, Tsukuba, Ibaraki, Japan<br>Kozue Miyashiro<br>University of Tsukuba, Tsukuba, Ibaraki, Japan<br>Satoshi Ando<br>University of Tsukuba<br>Maito Ohmori<br>University of Tsukuba<br>\section*{Hiroaki Yano}<br>University of Tsukuba

#### Abstract

When people ride an autonomous car, they might feel anxiety because they cannot know how it may move. Adding artificially augmented signals, which represent coming changes of the vehicle, it may be useful to reduce anxiety by change expectation. Thus we executed an experiment examining whether ascending sound could decrease passenger's anxiety, while riding on virtual autonomous car. In the experiment, participants saw 360-degree computer-graphics world through a head-mounted-display. The stimuli were views from a moving car with 2 speed ( 19 and $320 \mathrm{~km} / \mathrm{h}$ ), half of which was added ascending and descending sound at first / last 6 secs. Results of the heart-wave analysis as biometric index, i.e., index of sympathetic nervous (LF/HL), showed a marginal interaction between existence of sounds and the vehicle speed; while sounds reduced participants' anxiety with high-speed condition, they showed higher tension with sound at slow-speed conditions.

# Does sonority influence the syllable segmentation in visual identification? Evidence in French skilled readers. 

Méghane Tossonian<br>Clermont Auvergne University, LAPSCO-CNRS, UMR 6024<br>Norbert Maïonchi-Pino<br>Clermont Auvergne University, LAPSCO-CNRS UMR 6024

#### Abstract

Many studies focused on the importance of statistical and distributional properties to account for the prelexical and segmental role of syllable-sized units in silent reading in French. We explored how skilled readers segmented printed (pseudo)words when no reliable statistical cues were available around and within the syllable boundary. We were interested in how sonority, a universal phonological element, might be a reliable source for syllable segmentation. We tested 160 native French-speaking adults with pseudowords in which orthographic and phonological statistical properties were (quasi)null for the first three letters including the syllable boundary in a revisited version of the paradigm used by Treiman and Chafetz (1987). Five sonority profiles within the syllable boundaries along a continuum from legal to illegal clusters were designed. Our results showed that segmentation does not strictly depend on statistical cues; participants were also sensitive to the legality of the sonority profile to locate the syllable boundary.

# Poverty of materials makes recursive combination operation evolvable 

Genta Toya<br>Japan Advanced Institute of Science and Technology, Nomi, Ishikawa, Japan<br>Takashi Hashimoto<br>Japan Advanced Institute of Science and Technology

#### Abstract

Humans can use recursive combination operation in various behaviors; other primates, however, rarely perform this operation. In our previous research, using an evolutionary simulation of combination behavior, we showed that recursive combination was more adaptive than repetitive combination in cases where the robustness of production or the diversity of products was required. In this research, we examined the evolvability of recursive combination in combinatorial space parametrized by kinds of elemental materials and the number of elements per product. Recursive combination evolved in the region of low kinds of elemental materials and large number of elements per product. This region may be compared with the situation of the middle stone age when invented diversified tools with limited kinds of materials such as stone, bone, and woods. The recursive combinatorial operation could scaffold the evolution of general recursive combination abilities including language, technology, music, and mathematics.

# Fitting a Stochastic Model to Eye Movement Time Series in a Categorization Task 

Paul Tupper<br>Simon Fraser University<br>Thuan Pham Nguyen<br>Simon Fraser University<br>Yunlong Nie<br>Simon Fraser University<br>Jiguo Cao<br>Simon Fraser University<br>Liangliang Wang<br>Simon Fraser University

#### Abstract

Our goal is to develop an efficient framework for fitting stochastic continuous-time models to experimental data in cognitive psychology. As a simple test problem, we consider data from an eye-tracking study of attention in learning. For each subject, the data for each trial consists of the sequence of stimulus features that the subject fixates on, together with the duration of each fixation. We fit a stochastic differential equation model to this data, using the Approximate Bayesian Computation framework. For each subject we infer posterior distributions for the unknown parameters in the model.

# Gaze during utterances and silence in L1 and L2 Conversations 

Ichiro Umata<br>KDDI Research, Inc.<br>Koki Ijuin<br>Doshisha University<br>Tsuneo Kato<br>Doshisha University<br>Seiichi Yamamoto<br>Doshisha University

#### Abstract

Gazing activities during utterances and silence were analyzed in a face-to-face three party conversation setting in a native language (L1) and in a second language (L2). The function of each utterance was categorized according to the Grounding Acts defined by Traum (Traum, 1994) so that gazes during utterances could be analyzed from the viewpoint of grounding in communication (Clark, 1996). Factor analyses of gaze activities showed similar factor structures in L1 and L2 conversations: the first factor was characterized by speakers' gazes and gazes during silence, and another factor was characterized by listeners' gazes in each condition. Analyses of the participants based on the factor scores, however, showed different tendencies between the two conditions, suggesting that language proficiency affects gaze activities during utterances.

# Statistical Learning Contributions to Semantic Knowledge Development 

Layla Unger<br>Carnegie Mellon University, Pittsburgh, Pennsylvania, USA<br>Anna Fisher<br>Carnegie Mellon University, Pittsburgh, Pennsylvania, USA<br>Robert Powers<br>Carnegie Mellon University, Pittsburgh, PA, United States

#### Abstract

The organization of semantic knowledge according to relations between concepts influences many facets of higher cognition. Therefore, understanding the origins of relations knowledge is a key focus of cognitive development research. This study investigated the contributions of environmental statistical regularities to relations knowledge in preschool-age children. Using CHILDES to estimate co-occurrence between familiar items, we constructed triads consisting of a target, related distractor, and unrelated distractor in which targets and related distractors consistently co-occurred (e.g., sock-foot), belonged to the same taxonomic category (e.g., sock-coat), or both (e.g., sock-shoe). Using a Visual World paradigm, we then measured relations knowledge as the degree to which children looked at related versus unrelated distractors when asked to look for targets. The results revealed that co-occurrence, regardless of taxonomic relatedness, influenced whether participants looked significantly more at related versus unrelated distractors. These findings demonstrate that co-occurrence regularities between entities in the environment shape knowledge organization.

# Improving Number Foundations in Preschoolers: ANS versus Symbolic Knowledge 

Jo Van Herwegen<br>Kingston University London<br>Hiwet Costa<br>Kingston University London

Bethany Nicholson

Kingston University London
Chris Donlan
University of London

#### Abstract

The current study examined whether preschoolers who are low achievers (LA) on mathematical tasks benefit more from a training programme that focuses on magnitude comparisons or ANS abilities (PLUS games) compared to games that target symbolic knowledge (DIGIT games).

Twenty-four preschoolers played PLUS games and 21 children played DIGIT games 3 times per week for 5 weeks. Performance scores were compared to 25 typical control children who did not play any games. All children were assessed pre and post-intervention on Test of Early Mathematics (TEMA), a computerized ANS task, the Give a Number task (Wynn, 1990) to assess cardinality and a counting and Digit Recognition task.

The results showed that, although the DIGIT and PLUS groups performed lower than the Control group, both PLUS and DIGIT games improved mathematical abilities in LA children. These results suggest that there is a complex interaction between ANS, symbolic, and formal mathematical abilities.

# Biological and Artificial Perspectives on Metacognition 

Katherine Wagner<br>DePaul University, Chicago, Illinois, USA

#### Abstract

Metacognition may be broadly understood as awareness, monitoring, and regulation of an intelligent agent's own internal processing, a "thinking about thinking". The cognitive complexity and self-maintenance value of this introspective skillset has considerable current interest in the study of both biological and artificial intelligence, with intriguing parallels. Study of metacognition in some nonhuman species and Biologically-Inspired Cognitive Architecture (BICA) systems reflect evidence of, at best, an attenuated form of the elaborated human manifestation, with ongoing difficulties in operationalizing metacognitive components and traits. A linked exploration of these "inhuman" forms of metacognition may better clarify the locus of divergence from the human form and illuminate the role of the skill in supporting potentially emergent cognitive traits, from self-recognition to Theory of Mind understanding. The current review will take a comparative approach in assessing metacognitive systems in nonhuman biological and artificial agents in pursuit of clarity for future methodological and conceptual directions.

# Predicting Future Performance in an ITS system via Gradient Boosting Classification 

Breya Walker<br>University of Memphis, Memphis, TN, United States<br>Anne lippert<br>University of Memphis, Memphis, TN<br>Raven Davis<br>University of Memphis, Memphis, TN<br>Zhiqiang Cai<br>The University of Memphis, Memphis, TN<br>\section*{Cheng Qinyu}<br>The University of Memphis, Memphis, TN<br>\section*{Genghu Shi}<br>The University of Memphis, Memphis, TN<br>Arthur Graesser<br>The University of Memphis

#### Abstract

Gradient Boosting Classification (GBC) models are well known to machine learning and artificial intelligence. Having the ability to predict user performance is imperative to the outcomes and purpose of an intelligent tutoring system. The Center for the Study of Adult Literacy (CSAL) intelligent tutoring system aims to improve reading comprehension in low-literacy adult learners. A GBC was applied to preliminary data gathered from high-literacy adult readers ( $\mathrm{N}=1800$ observations). Our model was shown high accuracy in predicting users' correct/incorrect responses to our multiple choice items. Specifically, users' reaction times and order of question presentation are important features of the model to consider. Less important features are difficulty of the item and the users reading ability. Our next steps are to apply GBC to high-literacy college students, followed by low-literacy readers, as a test set. Our eventual goal is to predict correctness prior to scoring.

# Interactivity, Stereotype threat, and Working memory 

Anna-Stiina Wallinheimo<br>University of Surrey, Guildford, United Kingdom<br>Harriet Tenenbaum<br>University of Surrey, Guildford, United Kingdom<br>Adrian Banks<br>University of Surrey, Guildford, United Kingdom

#### Abstract

The purpose of the current study was to investigate the role of interactivity (the use of pen and paper) in defusing the impact of stereotype threat on difficult mental arithmetic tasks, covering all four operations of mathematics. Eighty-four 16-year-old girls from secondary schools in South East England (UK) participated in this study. Participants carried out (in an educational setting) difficult, multi-digit mental arithmetic tasks in a stereotype threat or control condition, crossed with interactivity or no interactivity. The primary dependent variables were the overall performance of the participants in accuracy, latency to solution, working memory, and mathematics anxiety. Increased interactivity enhanced mental arithmetic performance. Girls in the stereotype condition performed worse in the working memory test than the participants in the control condition. However, there was no causal role of working memory in reduced mathematics performance under stereotype threat. Reasons for this finding and recommendations for future studies are discussed.

# Judging Magnitude: Is there a Common Cognitive System for Different Types of Magnitude Judgments? 

Rylan J. Waring<br>University of Guelph

Lana M. Trick

University of Guelph

#### Abstract

It has been suggested that a common cognitive system is employed in magnitude judgments across multiple modalities (Walsh, 2003). To test this theory, we examined whether performance on magnitude judgments of number, surface area, duration, and loudness correlated with each other in both magnitude comparison (e.g., determine which is more), and magnitude estimation (e.g., if magnitude 1 value $=100$, estimate the value of magnitude 2) tasks. For magnitude comparison, significant correlations were observed between number, surface area, and loudness (but not duration) tasks (percent correct measured). Similar results were observed for magnitude estimation (mean absolute percent deviation of value estimates from correct measured). These results are indicative of a common cognitive system for at least some magnitude judgment modalities, and suggest that such a system may play a role not only in more-than/less-than magnitude judgments, but also in the process of assigning numerical values to magnitudes.

# Effects of Auditory-Feedback Delays and Musical Roles on Coordinated Timing Asymmetries in Piano Duet Performance 

Auriel Washburn<br>Stanford University<br>Matthew Wright<br>Stanford University

Takako Fujioka
Stanford University

#### Abstract

Recent research in human behavioral dynamics has demonstrated that co-actors often successfully achieve joint goals by adopting functionally asymmetric patterns of behavior. To better understand the evolution of such patterns in a naturalistic musical context, the current study examined how auditory-feedback delays and individual musical roles affect collective temporal stability and relative adaptability during duet performance. The delays between pianists were short (1040 ms ), bidirectional, and remained constant during a single trial, simulating those typical in internet-mediated performance. Preliminary results show increasingly reduced collective stability for longer delays along with a distinct pattern of asynchronies across the points where temporal synchrony would be expected, in which individuals exhibited consistent alternation between playing before or after their co-performer. Furthermore, asynchronies became greater when the two musical parts were less similar. Thus, emerging coordinative dynamics appear to be shaped both by asymmetries in co-performers' assigned roles and external constraints on shared information.

# What influences the impact of warning labels in decisions from description-plus-experience 

Leonardo Weiss-Cohen<br>University College London, London, London, United Kingdom<br>Emmanouil Konstantinidis<br>University of New South Wales<br>Maarten Speekenbrink<br>University College London<br>Nigel Harvey<br>University College London, London, London, United Kingdom

#### Abstract

Warning labels can be considered as descriptions added to repeated decisions-from-experience. Limited research so far has looked at the theoretical integration of decisions from descriptions and decisions from experience when the two are available concurrently. We explore how the presence and timing of such warning labels influence behaviour. We expected the provision of warning labels to subsequently reduce risk taking, and that more prior experience before the appearance of such labels would lead to stronger habit formation and reduce their behavioural impact. Instead, we show how the appearance of descriptions warning against risks can have a perverse effect of increasing risk taking. And counter-intuitively, we also observe that the amount of previous experience prior to the appearance of descriptions does not impact behaviour. Briefly presented warning labels also have the same effect as constantly present ones. All of these findings have strong implications on the design of effective warning labels.

# Later lexical development in bilinguals 

Anne White<br>KU Leuven - University of Leuven<br>Barbara Malt<br>Lehigh University<br>Steven Verheyen<br>Institut Jean-Nicod, PSL Research University, École Normale Supérieure<br>Gert Storms<br>KU Leuven - University of Leuven

#### Abstract

We investigated object naming in Dutch-French bilingual children to determine the developmental trajectory of the cross-language convergence in naming patterns shown by bilingual adults. We collected name choices for nearly 200 common household containers from French-Dutch simultaneous bilinguals of 6 different age groups, along with monolingual control groups. Multidimensional scaling analysis on a group level suggests that convergence is present in bilinguals at all ages. On the individual level, pairwise between-subject correlations show that monolingual naming patterns in different languages show a remarkable correspondence at younger ages. Between age 5 and adulthood, the naming patterns of monolingual children demonstrate increasing divergence as they learn the language specificities of their L1. Bilingual children, however, maintain a fully converged naming pattern up till age 10 . They start learning some language-specific idiosyncrasies from age 12 onwards, but never to the extent of monolinguals. We propose a gradual divergence perspective for bilingual lexical development.

# An immersive binaural horizon for sonic data analytics 

Richard Windeyer<br>The Centre for Drama, Theatre and Performance Studies, University of Toronto and the Perceptual Artifacts Lab, OCAD University<br>Dan MacDonald<br>Biomedical Simulation Lab, Department of Mechanical and Industrial Engineering, University of Toronto<br>\section*{David Steinman}<br>Biomedical Simulation Lab, Department of Mechanical and Industrial Engineering, University of Toronto<br>Ambrose Li<br>Perceptual Artifacts Lab, OCAD University<br>Peter Coppin<br>Perceptual Artifacts Lab, Faculty of Design, OCAD University and The Department of Mechancial and Industrial Engineering, University of Toronto

#### Abstract

Accessible data analytics-that can be experienced through vision, hearing, and touch-poses a challenge to interaction design. It is also a human rights requirement because many societies mandate that all individuals have the right to experience products and services, yet not every individual accesses media visually. As more data is presented through visualization, accessibility for populations who do not access data through vision decreases.

Guidelines that claim to make visual media accessible through text fail to translate the iconic properties of visual shapes, thus subtracting affordances for pattern recognition. Non-linguistic sonication can be a means for non-visual pattern recognition.

Hearing is optimized for detecting locations on a horizontal plane, and our approach for presenting data analytics recruits this optimization by using an immersive binaural horizontal plane. We will demonstrate our approach via two case studies: A sonic translation of a map and a sonic translation of a computational fluid dynamics simulation.

# A model of cultural co-evolution of language and mindreading 

Marieke Woensdregt<br>University of Edinburgh, Edinburgh, United Kingdom<br>Simon Kirby<br>University of Edinburgh<br>\section*{Chris Cummins}<br>University of Edinburgh<br>\section*{Kenny Smith}<br>University of Edinburgh

#### Abstract

Language requires mindreading for entertaining communicative intentions, and mindreading in turn profits from language as a means for sharing mental states. Hence it has been hypothesised that the two skills have co-evolved.

We present a Bayesian agent-based model to formalise this hypothesis. This model combines referential signalling with mental states, such that a speaker's topic choice is probabilistically dependent on their perspective on the world. In order to learn the language, a learner has to simultaneously infer the speaker's lexicon and perspective. Learners can solve this task by bootstrapping one with the other, but only if the speaker uses an informative language.

We will present results of an iterated learning version of this model, showing that selection on communication results in the emergence of a fully informative lexicon from scratch. However, selection on perspective-taking alone also results in the emergence of partially-informative lexicons, which is sufficient for inferring others' perspectives.

# Language as a process: An exploration among pre-adolescent Chinese EFLs 

Hing Yi Wong<br>The Education University of Hong Kong, Hong Kong, Canton, China<br>Susanna Yeung<br>The Education University of Hong Kong<br>Wen Chung Wang<br>The Education University of Hong Kong<br>Chi Wing Yip<br>The Education University of Hong Kong

#### Abstract

This paper reports a reading intervention programme, the LMVS (Linguistically Mediated Visual Search) among pre-adolescent Chinese EFLs. It sets out to test whether managing the process of silent reading might modify text complexity as perceived. The paper is a combination of two studies. The first study was the development and assessment of a reading comprehension test. The second study piloted an intervention for pre-adolescents. Item-by-item analysis of students' performance in the post-test show changes in the perception of item difficulty after the intervention. Chinese EFL struggling readers were found to be weaker in lexical analysis. They also faced difficulties in decoding main ideas in compound/complex sentences. In response to the analysis, strategies were developed for automatic syntactic processing. The paper proposes seeing language as a process, rather than a product so that learner management skills might be prepared for reading intervention.

# Influences of the Matching Effects of Cognitive and Emotional Factors on Attitude Change 

Tung-Cheng Wu<br>National Cheng Kung Univeristy, Tainan, Taiwan, ROC<br>Jon-Fan Hu<br>National Cheng Kung Univeristy, Tainan, Taiwan, ROC<br>Shu-Ling Peng<br>National Cheng Kung Univeristy, Tainan, Taiwan, ROC

#### Abstract

This research is aimed to study whether we will have the same attitude change when we have the same intensity of cognitive or emotional level for attitude. People who have higher involvement will be persuaded by central route and low involvement will be persuaded by peripheral route: the matching effect in attitude change. The present study controlled the intensity of both cognitive and emotional factor and instructed participants to express their initial attitude as well as attitude change under four experimental manipulations. Results showed that only matching effect of emotional factor was found but not cognitive factor. A connectionist model was therefore built to simulate the processes and found that there would have different thresholds for cognitive and emotional routes and the threshold of cognitive route should be higher than emotional route. Implications are proposed based on the behavioral and simulation investigations.

# Is infants' mutual exclusivity response based on preference to novelty or non-name of an object? 

Qinmei Xu<br>Center for Learning and Cognitive Science, College of Education, Zhejiang University, Hangzhou, China<br>Ye Tao<br>Department of Special Education, Zhejiang Normal University, Hangzhou, China<br>Yuyan Wang<br>Department of Psychology and Behavioral Sciences, Zhejiang University, Hangzhou, China<br>\section*{Jon-Fan Hu}<br>National Cheng Kung University, Tainan, Taiwan, ROC

#### Abstract

Although "mutual exclusivity (ME)" is the term to refer to the behavior that infants map a novel label onto a novel object rather than a familiar object, two studies, using preferential looking paradigm, aimed to investigate whether infants' ME is based on preference to novelty or non-name of an object. In Study 1, 18-month-olds were tested on 2 conditions: familiar-object/novel-object trials with known label and familiar-object/novel-object trials with unknown label. The infants preferred to novel objects before naming but no naming effect found for both conditions. In Study 2, 18-month-olds in the same two conditions as Study 1 were pre-familiarized to both of novel and familiar objects. The results showed that the naming effects were found for both conditions, indicating that ME occurred. The findings of the present studies suggest that pre-familiarization could be used to validate if 18 -month-olds' ME response is based on non-name preference of an object.

# Children's Attention to Semantic Content versus Emotional Tone: Differences between Two Cultural Groups 

Yang Yang<br>Cornell University, Ithaca, NY, United States

Li Wang
Peking University, Beijing, China
Qi Wang
Cornell University, Ithaca, NY, United States

#### Abstract

People from varied cultural backgrounds differ in their attention to particular aspects of emotional cues. Whereas semantic content explicitly expresses feelings, vocal tone conveys implicit information regarding emotions. This study examined the attention to different emotional cues in European-American and Chinese children. Participants were 121 EuropeanAmerican and 120 Chinese children (4-9 years old). They played two games in which they listened to spoken words and judged the pleasantness of the word meaning while ignoring the vocal tone (meaning game) or judged the pleasantness of the vocal tone while ignoring the word meaning (tone game). Preliminary results showed that European-American children paid more attention to word meaning than did Chinese children. Additionally, older (8-9 years old) Chinese children attended more to vocal tone than did their European-American counterparts. The results suggest that children acquire culturally specific attention bias by 8-9 years old.

# Knowledge partitioning in forecasting 

Lee-Xieng Yang<br>National Chengchi University<br>\section*{Tzu-Hsi Lee}<br>National Chengchi University

#### Abstract

In this study, we would like to examine whether the learned forecasting function can be separated for use by context. The participants were asked to learn to forecast the position of a target, defined as a sine function of trial number. A context cue was paired with the moving of the target systematically and randomly in two conditions. The learning performance was quite good in both conditions. In the transfer phases, in the systematic-context condition, some participants learned to rely on context to direct their prediction (i.e., knowledge partitioning), whereas some others and those in the randomized-context condition learned to rely on the concept about the function for forecasting. However, contrary to the precedent knowledge partitioning studies, the variety of using context or not was found within participants across transfer phases. The modeling results favored the associative account over the rule account on accommodating the training and transfer response patterns.

# Working Memory and lexical ambiguity resolution in Chinese 

Michael Yip<br>The Education University of Hong Kong

#### Abstract

Two cross-modal priming experiments were conducted to examine the underlying mechanism of lexical disambiguation process was in activational nature or in inhibitory approach. In experiment one, forty native Cantonese listeners were recruited to participate in two tasks (1) a Chinese version reading span task (Daneman \& Carpenter, 1980) to measure their WM capacity and (2) a cross-modal priming task (Yip, 2015). In experiment two, another group of native Mandarin listeners were recruited to participate in the same two tasks in Mandarin. The results revealed that sentence context had an early effect on the disambiguation processes for both high- and low-WM span groups and the underlying mechanism of the disambiguation process for the high-WM span group seemed to be in an inhibitory nature.

# Impact of Polarity, Rationality, and Math Ability on Numerical Magnitude Knowledge 

Laura Young<br>Temple University, Philadelphia, PA , United States<br>Julie Booth<br>Temple University, Philadelphia, PA , United States<br>Kelly McGinn<br>Temple University, Philadelphia, PA , United States

#### Abstract

Previous research has shown that numerical magnitude knowledge is related to current mathematic abilities and predictive of future mathematics performance. Much of this early research examined magnitude knowledge of positive whole numbers, more recently this has been extended to positive rational numbers. However, research about negative number magnitude knowledge is less abundant. The present study aims to understand how different types of magnitude knowledge relate to one another and whether performance differs according to the type of number line scale. Thirteen number line scales were used to assess 7th grade students' $(\mathrm{N}=180)$ magnitude knowledge of positive and negative, whole and rational numbers. Correlational analyses illustrate that performance on most scales are significantly related. Further analyses reveal that students' performance differed depending on the scale's polarity and the number type of the scale. Moreover, performance differences were found to vary according to students' mathematics classroom ability level. Educational implications are discussed.

# Global consequences of local complexity: evidence from recall of visually presented nonwords 

Mackenzie Young<br>Johns Hopkins University

Colin Wilson<br>Johns Hopkins University

#### Abstract

There is extensive evidence that structural regularities affect the processing of visually-presented words. However, it is not known whether the processing consequences of an orthographic violation are limited to the offending subpart (e.g., an unattested onset cluster) or apply more globally (e.g., to the entire word). We provide evidence of global disruption from the recall of briefly-presented nonwords that were manipulated for degree of orthographic markedness and length. Error rates were higher for both the initial and final portions of nonwords beginning with more marked onsets; symmetrically, report of marked onsets was degraded in words with longer endings. These effects suggest that, as in other visual tasks, the fidelity with which one element can be represented depends on the overall stimulus complexity. We present a modified version of rational models of visual word perception in which global effects result from the distribution of a limited processing resource over letter positions.

# Children's Reasoning about Geometric Footprints 

Christopher Young<br>University of Chicago, Chicago, Illinois, United States

Alana Foley<br>University of Chicago

## Susan Levine

University of Chicago

#### Abstract

We explored preschool's children's understanding of the correspondence of 3-D objects and 2-D faces in a novel task. In the "footprints" task children were shown a geometric solid, such as a pyramid or a prism, and asked to select which shape the solid would make if it were dipped in ink and stamped on a piece of paper. Through a latent class analysis of children's errors we found children differed significantly in their misconceptions about object structure. Three distinct classes of children emerged: children who could only match visible faces, children who believed solids have an 'essential' face irrespective of rotation, and children who differentiated faces based on a solid's rotation. We examined the characteristics of children in each of these classes using a battery of spatial tasks and numeric tasks. Our results suggest errors found in older children's and adults' reasoning about geometric concepts develop prior to formal schooling.

# Relevance Theory, Pragmatic Inference and Cognitive Architecture 

Wen Yuan<br>Beihang University, Beijing, China<br>Richard Cooper<br>Birkbeck, University of London

#### Abstract

Relevance Theory (RT: Sperber\&Wilson, 1986) argues that human interpretative processes maximize relevance and postulates that there is a relevance-based procedure that a listener follows when trying to understand utterances. However, Mazzone (2013) points out that RT fails to explain how speaker-related information, such as the speaker's abilities or preferences, is incorporated into pragmatic processes. He proposes that situational or goal schemata, with the speaker represented as a component, are sufficient to activate the hearer's speaker-related knowledge and further asserts that human communication is driven by goal management and action rather than relevance maximization. Yet Mazzone cannot fully explain how linguistic meaning and speaker-related knowledge are integrated within a modular system. Based on RT's cognitive requirements and contemporary cognitive theory, we argue that this integration is realized within working memory via production-like conversational rules with which the constructed utterance interpretation should be consistent, and present a simple model of this process.

# Do you forgive past mistakes of virtual assistant? A study on changing impressions of virtual character when using its assistance multiple times 

Masahide Yuasa<br>Shonan Institute of Technology

#### Abstract

We investigated the gain-loss effect of virtual/personal assistant character, which provides intelligent assistance to humans, and focused on not only the first impression of using the assistance but also changing impression about the character when used multiple times for assistance. The experiment used a fictive retrieval system (searching onomatopoeia), and the virtual assistant character looked up for suitable words for the user (success), or failed to find the words (mistake). There were three sessions, differing by the task of character's mistake; two tasks were successes and one was a failure in each session. The results showed that the group of people who had low expectation from its first appearance, formed negative impressions after the final mistake, significantly. Consequently, final mistake influenced the formation of negative impression more than other mistakes, thus showing that the final mistake in multiple times of assistance was associated with loss effect.

# Knowledge acquiring on event chronology in Russian-language texts 

Vera Zabotkina<br>Russian State University for the Humanities<br>Mikhail Epifanov<br>Russian State University for the Humanities<br>Elena Pozdnyakova<br>Moscow State Institute of Foreign Relations (University),

#### Abstract

Chaining the sequence of events through awareness of their temporal relations is an important aspect of text understanding. As a rule, text provides only partial knowledge of event unfolding however various types of additional sources (documents, personal diaries, etc.) provide an added knowledge to make chronology more precise. The paper argues the novel approach to automated retrieval of information on temporal relations between events marked in the text. The data retrieved will provide additions to computer ontology which formally represents the actual events chronology.

A system of linguistic algorithms for analyzing the contexts with specific verbal (or linguistic situations) inputs is suggested within the present approach. We use syntactic graphs of the sentences and some grammatical characteristics of the words produced by the system for the automatic syntactic analysis of Russian texts.

# The Impact of Presentation Order on Category Learning Strategies: Behavioral Data and Self-Reports 

Christina Zeller<br>University of Bamberg, Germany

## Ute Schmid

University of Bamberg, Germany

#### Abstract

The presentation order in supervised categorization learning can influence the category representation. For example, the order can bias a rule-based approach focusing the identification of relevant features or an exemplar-based approach focusing the similarity of category members. In a blocked design stimuli can either be presented in a way that relevant features over stimuli become obvious or that two succeeding stimuli share as many common features as possible (cf. Mathy \& Feldman, 2016). In an empirical study with 21 participants we investigated both orders for the 5-4 category structure (Medin \& Schaffer, 1978) and assessed categorization behavior and self-reports in the first trials. Results suggest that the answer behavior and selfreports during the first trials can be influenced by the presentation order. However, in both groups feature-based and similaritybased explanations were reported. Additionally, the similarity-based group named more feature-based rules including irrelevant features.

# Walking dynamics of intertemporal choice 

Arkady Zgonnikov<br>School of Psychology, National University of Ireland, Galway<br>Iñaki Rañó<br>Intelligent Systems Research Centre, University of Ulster, Derry/Londonderry, UK<br>Denis O’Hora<br>School of Psychology, National University of Ireland, Galway<br>\section*{Kongfatt Wong-Lin}<br>Intelligent Systems Research Centre, University of Ulster, Derry/Londonderry, UK

#### Abstract

The notion that cognitive processes 'leak" into motor output of decisions inspired much recent process-tracing research. In mouse-tracking, an increasingly popular decision-making paradigm, difficult choices lead to increased curvature of the mouse trajectories towards the unchosen option. Here we explore whether traces of a decision process can be found in its motor output in a more naturalistic setting. Our subjects performed a series of choices between a smaller reward now and a larger reward at some delay. Using Kinect camera, we recorded subjects' walking trajectories when they moved towards their preferred option displayed in one of the corners across the room. We found that deviation of subjects' trajectories from the ideal trajectory increased with delay when they preferred the "later" option, and decreased with delay in trials where the "now" option was chosen. Our results suggest that walking trajectory of a person can provide information about their ongoing thought processes.

# A Spatial-Temporal Analysis of a Visual Working Memory Task with EEG and ECoG 

Qiong Zhang<br>Carnegie Mellon University, Pittsburgh, Pennsylvania, United States<br>Marieke van Vugt<br>University of Groningen, Groningen, Groningen, Netherlands<br>Jelmer Borst<br>University of Groningen, Groningen, Groningen, Netherlands<br>John Anderson<br>Carnegie Mellon University, Pittsburgh, Pennsylvania, United States

#### Abstract

In this study, we investigated the neural correlates of a visual working memory task. Two experiments were carried out using scalp electroencephalography (EEG) and Electrocorticography (ECoG), respectively. In each trial, participants judged whether a test face had been among a small set of recently studied faces. We used a combination of hidden semi-Markov models (HSMMs) and multi-variate pattern analysis (MVPA) to decompose the neural signal into a sequence of latent stages. Analyzed separately, EEG and ECoG data yielded converging results on the durations of recovered stages. Combining these stages with the high spatial resolution of ECoG suggested that activity in the temporal cortex reflected item familiarity in the retrieval stage; and that once retrieval is complete, there is active maintenance of the studied face set in the medial temporal lobe (MTL). During this same period, the frontal lobe guides the decision by means of theta coupling with the MTL.

# To organize or not to organize? Examining biases in search strategies using Lego building blocks 

Mona Zhu<br>University of Waterloo, Waterloo, Ontario, Canada<br>Kimberley Yuen<br>University of Waterloo, Waterloo, Ontario, Canada<br>Evan Risko<br>University of Waterloo, Waterloo, Ontario, Canada

#### Abstract

A widely-accepted notion is that organization can improve task performance and generally allow us to better function within a given task environment (Kirsh, 1995; 1996). However, it remains unclear the extent to which individuals believe that organization will help to improve task performance when they are asked to carry out mundane tasks in the real world. To examine this, individuals were asked to search through a pile of Lego building blocks for specific pieces. Prior to the search task, they were asked their preferred strategy for this task (e.g., organizing vs. not organizing the Lego pile prior to search) and to estimate how much time and effort each strategy would take for task completion. While both strategies were comparable in terms of objective task completion time and subjective time and effort estimations, participants were overwhelmingly biased against choosing the organization strategy. Implications for the current study will be discussed.

# Emotion in Deceptive Language 

Iraide Zipitria

University of the Basque Country (UPV/EHU)

## Basilio Sierra

University of the Basque Country (UPV/EHU)

## Imanol Sopena-Garaikoetxea

University of the Basque Country (UPV/EHU)

#### Abstract

Deception involves emotions of fear and guilt. These negative emotions are expressed in language in terms of psychological distance from the deception object. The psychological distance and emotional experience reflect an attempt to control the negative mental representation. More especifically emotional distance is represented in deceptive language by means of cues of reference, verb tense and detail avoidance. Then, hints of emotions of fear and guilt should be displayed in language.The present work analyses emotional language cues for deception detection by means of Machine Learning(ML) techniques and Linguistic Inquiry and Word Count (LIWC). Results show that Support Vector Machines (SVM) best represents the discrimination between true and false information (up to $74.15 \%$ of accuracy rates) based only on the effect of emotion in deceptive speech.

[^2]:    Organized by Wayne D. Gray. Address all correspondence to Wayne Gray [wayne.gray.cogsci@gmail.com](mailto:wayne.gray.cogsci@gmail.com).

[^3]:    ${ }^{1}$ For an accessible introduction to enactivism see (McGee, 2005).

[^4]:    ${ }^{2}$ This interpretation is suggested by a version of the task by (Froese, Iizuka, \& Ikegami, 2014) in which participants' experience of the other's presence is one of the dependent variables.
    ${ }^{3}$ The reader should be aware that this is a necessary oversimplification of the variety of positions held within philosophy of science overall and that even within cognitive science there are heated debates on the precise understanding of deductivenomological, probabilistic, rational, mechanistic and other explanations. We merely focus on the distinction that has been most widely used in discussions between traditional cognitive science and REC.

[^5]:    ${ }^{4}$ This view composed of several statements can of course be translated into a continuum of positions. Arguing against the explanatory primacy of components might mean rejecting explanations that (a) ignore interactions, (b) assume only linear interactions, (c) assume only static interactions ignoring dynamics, (d) ignore the effect of parameters external to the system. We thank anonymous reviewer for pointing this out.

[^6]:    ${ }^{5} \mathrm{We}$ should note here that it might be that the mechanistic approach and enactivism rely on different notions of causality that make them incompatible. Addressing this possibility would require not merely examining the respective commitments but also the plausibility of particular models of causality assumed, e.g. whether circular causality typically adopted by enactivists is a helpful notion.

[^7]:    ${ }^{1}$ The integration of information across fixation is a local update for each cell.

[^8]:    ${ }^{1}$ In this paper, we use the term text to refer generally to any coherent or self-contained piece of spoken or written language.

[^9]:    ${ }^{2}$ According to a bag-of-words model, a language corpus is a set of texts, where each text is an unordered set, or bag, of words.

[^10]:    ${ }^{3}$ Full details about how the corpus was created, including all the code used to create it, is available at https://github.com/lawsofthought/tantalum
    ${ }^{4}$ Full details about the Gibbs sampler for the HDPMM, including the code implementing it, can be found at https://lawsofthought.github.io/gustavproject.
    ${ }^{5}$ Full details about how we sampled the texts, including the code implementing the sampling and the sampled texts themselves, can be found at https://github.com/lawsofthought/berkelium.
    ${ }^{6}$ Full details about how we sampled from the posterior predictive distribution, including the code implementing the sampling, can be found at https://github.com/lawsofthought/gallium.

[^11]:    ${ }^{7}$ Here, as above, we use the term text to denote any coherent and

[^12]:    self-contained piece of language.

[^13]:    ${ }^{8}$ Full details about how these two associative models were created, including the code implementing them, can be found at https://github.com/lawsofthought/gallium.

[^14]:    ${ }^{9}$ Full details about the recognition test word lists were created, including the code implementing this, can be found at https://github.com/lawsofthought/berkelium.

[^15]:    ${ }^{10}$ This is open-source software and is available at https://github.com/lawsofthought/wilhelmproject
    ${ }^{11}$ All raw data, and code for all analyses, can be found at https://github.com/lawsofthought/gallium.

[^16]:    ${ }^{1}$ Across all three experiments, we find no evidence of spatialnumerical associations in the vertical dimension.
    ${ }^{2}$ Consistent with previous research on pseudoneglect (Lourenco \& Longo, 2007; for review, see Jewel \& McCourt, 2000), there is an overall leftward bias in all three experiments.

[^17]:    ${ }^{3}$ Mean accuracy was not significantly different across the three experiments as determined by a one-way analysis of variance (ANOVA).

[^18]:    ${ }^{1}$ Note that we will be using the label "normative", "correct", or "logical" response as a handy shortcut to refer to "the response that has traditionally been considered as correct or normative according to standard logic or probability theory". The appropriateness of these traditional norms has sometimes been questioned in the reasoning field (e.g.,see Stanovich \& West, 2000, for a review). Under this interpretation, the heuristic response should not be labeled as "incorrect" or "biased". For the sake of

[^19]:    ${ }^{1}$ To help children understand the hypotheses under consideration, the confederate announced the full set of hypotheses before the child began teaching (e.g., "I see, Dax could mean fork, or Dax could mean white, or it could mean white fork.").

[^20]:    ${ }^{1}$ In an ongoing replication with adults, we are finding the same pattern of results as we did with children: Adults' ratings are influenced by the informant's knowledge state and the degree of information omission, but not by the value of the functions taught.

[^21]:    ${ }^{1}$ The set of languages is (per language family, in ISO 639-2): (Semitic) ar, he; (Indo-European) bg, bs, cs, da, de, el, en, es, fr, hr, it, nl, no, pl, pt, ro, ru, sl, sr, sv; (Finno-Ugric) et, fi, hu; (Austronesian) id; (isolate) ja; (Turkic) tr; (Vietic) vi; (Sino-Tibetan) zh.
    ${ }^{2}$ We used $k$-clique percolation (Palla et al., 2005) with $k=9$.
    ${ }^{3}$ We used a manually compiled stemming dictionary to lemmatize the words and correct spelling and alphabetic variation.

[^22]:    ${ }^{4}$ Annotation was done for English only. It is possible that Haspelmath's functions are not always translated: a conditional may be translated as an declarative. Being relatively infrequent, we consider these cases noise.
    ${ }^{5}$ Evaluating the method on a parallel Bible corpus against a gold standard of Strong number annotations gives a cluster purity of .89 and a cluster recall of . 90 .

[^23]:    ${ }^{6}$ We use sets of translated terms, because an indefinite pronoun in English may be translated to multiple terms in other languages.

[^24]:    ${ }^{7}$ These clusters do not completely coincide with the further analysis of Haspelmath (1997, par. 5.6), but we leave that comparison for future research.

[^25]:    ${ }^{8}$ Here and elsewhere, we observe evidence of a finer-grained semantic space for PEOPLE than for THINGS, in line with typological observations such as Silverstein (1976): The distribution of functions given each ontological category is more spread out for PEOPLE than for THINGS (Tab. 2), and decreasing the number of clusters to 3 or 2 deteriorates the Rand score less for THINGS than for PEOPLE (Tab. 3). We note that usage data reveals distinctions that remain obscured when glossing over ontological categories.

[^26]:    ${ }^{1}$ Inspecting the oriented items with inanimate objects versus living beings indicated no differences in how often the intrinsic FoR was applied. The two types of items were therefore pooled.

[^27]:    ${ }^{1}$ A conceptual replication was defined as a study that did not introduce an additional, non TP-based cue, and did not differ from the original study protocol in a significant way. For example, studies that included a priming phase pre-familiarization, or a test phase involving carrier phrases were not included. See Github repository for a full list of included papers and the subset of conceptual replications.
    ${ }^{2}$ https://github.com/christinabergmann/StatLearnDB
    ${ }^{3}$ Given that infant looking-time studies generally accept either familiarity or novelty preferences, one might argue that we should instead use the absolute value of looking-time difference as dependent measure. Indeed, in the studies reported here that pit statistical learning against other cues, a switch in looking-time

[^28]:    preference is explicitly predicted. We address these cues and their impact in the Complete Literature section of the paper. We would also like to address the general idea of absolute values in metaanalysis, and point to why this method may not be appropriate: 1) Theories of infant cognition and language acquisition have long sought to motivate the direction of looking-time preference; metaanalysis offers the potential power to test those theories and generate new possibilities when the theory is found to be inadequate. 2) Two opposing outcomes should reflect two underlying effects. Using raw effect sizes and testing the value of proposed moderators is a much more powerful use of metaanalytic techniques. Furthermore, it is important to recognize that allowing for two opposing outcomes, without the ability to predict those outcomes, increases the risk for false positives and might violate basic assumptions of sampling and null hypothesis significance testing.
    ${ }^{4}$ To assess the impact of this imputation, we re-ran our analysis with imputations based on varying means and verified that our conclusions about key findings do not change.

[^29]:    ${ }^{1}$ We use the SpaCy python library, available at https://spacy.io

[^30]:    ${ }^{2}$ We use the PyEnchant python library, available at http://pythonhosted.org/pyenchant/.

[^31]:    ${ }^{3}$ Note that all of the sentence pairs in SNLI were generated by providing subjects with a caption for an unseen image and asking them to produce a further caption that is either true, false, or maybe true of the image. So all of the sentences in SNLI can be described as image captions. The point of using this caption-based strategy in the construction of the dataset is to eliminate co-reference ambiguities that make it difficult to determine the appropriate inferential relationship between two sentences. See Bowman et al. (2015) for more details.
    ${ }^{4}$ Two of the main captions had no associated contradictions in SNLI, so subjects in the contradiction condition only rated 18 captions.

[^32]:    ${ }^{1}$ In this specific case, we assume the parameters (i.e., causal strength $w_{S}$, expected length of delays $\mu$, and delay variability $\alpha$ ) to be known which is consistent with the setup of the experiment.

[^33]:    ${ }^{2}$ Where necessary, we ruled out paths that implied an implausibly high number of failed connections, or extreme cause-effect delays, until the number of possible paths fell below 100,000 .

[^34]:    ${ }^{3}$ Try the task https://www.ucl.ac.uk/lagnado-lab/el/it or watch a trial https://www.ucl.ac.uk/lagnado-lab/el/itv.

[^35]:    ${ }^{1}$ For a more complete discussion of the flexibility of adjective ordering in French, including features which predict whether an adjective can be pre-nominal, see Fox and Thuilier (2012).

[^36]:    ${ }^{2}$ Note that the standard error on estimates for coefficients encoding contrasts between the French-like condition and the postnominal harmonic condition is very high. This is likely due to individual variation in the French-like condition, where some participants strongly regularized the input order (similar to behavior in the post-nominal harmonic condition), while others shifted away from the input dramatically. This is illustrated in Figure 4.

[^37]:    ${ }^{3}$ The numeral 'one' in French, un(e), corresponds to the indefinite article ' $a$ ', and therefore may be acquired differently or much earlier than other numerals.

[^38]:    ${ }^{1}$ Another common name for the Valence dimension is Pleasure (PAD). Our choice of terminology (VAD) follows the more recent stimulus sets we use here (Warriner, Kuperman, \& Brysbært, 2013; Ferré, Guasch, Martínez-García, Fraga, \& Hinojosa, 2016).

[^39]:    ${ }^{2}$ http://topepo.github.io/caret/index.html

[^40]:    ${ }^{3}$ https://github.com/JULIELab/EmoBank

[^41]:    ${ }^{1}$ We note that analyses in VOT space do not tell us about the context effect on the basis of individual participants' subjective perceptual ambiguity, however.

[^42]:    ${ }^{2}$ This perceptual ambiguity measure can also be computed on a by-subject basis and does not change the results.

[^43]:    ${ }^{1}$ Source code for the simulation, including a complete list of parameters and their values, is available from the first author on request.

[^44]:    ${ }^{2}$ That is, those cortical units that represent cognitive schemas.

[^45]:    ${ }^{3}$ Note also that the dopamine system is vulnerable to change in normal ageing (Cham et al., 2008).

[^46]:    ${ }^{1}$ Results from Mintz (2003) show that merging pronouns with nouns, and auxiliaries, copulas, and non-finite forms with verbs does not bias categorization results.
    ${ }^{2} X_{-} d o g \sim n$ and $X_{\_} d o g s \sim n$ are different contexts, just as light $\sim n-X$, light $\sim v_{-}$, and light $\sim a d j-X$

[^47]:    ${ }^{3}$ The bias towards nouns and verbs in categorization does not result from an imbalance in the set of target words, consisting of 40 adjectives, 47 adverbs, 76 function words, 145 nouns, and 148 verbs.

[^48]:    ${ }^{1}\left(\left(A^{2} B\right)^{N}\right)$ and $\left(\left(A^{3} B\right)^{N}\right)$ are, in full, N repetitions of AAB and AAAB , respectively. In general $X^{N}$ means the symbol or sequence X repeated N times.

[^49]:    ${ }^{1}$ Since both local and non-local antecedents are acceptable for the LD reflexive, there were no mismatch trials for this anaphor in the embedded clause sentence types discussed here.

[^50]:    ${ }^{2}$ However, the main model shows that overall participants in the Local condition were more likely to accept the LD reflexive with the local antecedent ( $\beta=0.517, \mathrm{z}=3.444, \mathrm{p}=.001$ ).

[^51]:    ${ }^{1}$ For a given model with $n$ blocks, we define the set of possible correct states as the set of unique states traversed along any path which begins at the null state, ends at the goal state, and contains $n$ states. These states can be enumerated computationally.

[^52]:    ${ }^{1}$ The model performance results (reported in a later section) were virtually the same or worse when the standard deviation instead of variance of the relative distribution was set to be proportional to the mean and/or the tradeoff parameter $\kappa$ in the static model was incorporated into $w(t)$ as a multiplicative constant to put subjective value and time weight on the same scale.
    ${ }^{2}$ Mathematical proof on the necessity of this assumption for accommodating the relevant phenomena is available upon request.

[^53]:    ${ }^{3}$ Overall BICs across participants showed the same pattern.

[^54]:    ${ }^{1}$ The amplitude of the sine waves was $.5, .5$, and a third amplitude sampled from a normal distribution with a mean of zero and a standard deviation .1(low), 2 (medium), or 3 (high).

[^55]:    ${ }^{2}$ Brightness and saturation were adjusted by a similar adjustment with a standard deviation of 15 （low）， 25 （medium），or 35 （high）．

[^56]:    ${ }^{1}$ In general, the most efficient place to move the eyes next in a rational model depends not just on visual information already obtained but also contextual information. For the present paper, we ignore contextual information for simplicity.

[^57]:    ${ }^{2}$ Note that motor error in a rational model has only random error (variance), but not systematic error (bias).

[^58]:    ${ }^{1}$ Our results may seem to invite comparison with those reported in associative priming, where the facilitation provided by forwards and backwards priming is frequently indistinguishable (Koriat, 1981; Thompson-Schill et al., 1998). However, the association norms employed in such studies are distinct from the type of association built through temporal co-occurrence patterns (Jones et al., 2006; Lund, Burgess, \& Audet, 1996), and are thus not directly comparable to our findings.

[^59]:    ${ }^{1}$ To better understand adjective-noun relations in English, we retrieved the top 50k most frequency nouns from the ukWaC, along with information about the adjectives preceding them, including: their number, average frequency, and entropy (i.e., the uncertainty over the noun's prior distribution). These results were log-transformed to approximate normality. For convenience, a base-two logarithmic transform was used for adjective-number, yielding adjective maximum entropy in bits.

[^61]:    ${ }^{1}$ This conclusion fits well with the finding that word frequency effects in recognition are closely related to list composition. Systematically varying the frequency of targets and foils in pure list conditions neatly illustrates this point. While a list of LF targets is similarly well-discriminated when paired with a set of HF or LF foils, foil-frequency dramatically affects discrimination of HF targets. When paired with LF foils, the error rate is close to zero; when paired with other HF foils, the error rate far exceeds that of LF targets (Underwood \& Freund, 1970). In line with this, raising the proportion of HF items on a list increases the magnitude of the WFE (Dorfman \& Glanzer, 1988; Malmberg \& Murnane, 2002).

[^62]:    ${ }^{1}$ Items that are represented in terms of the same description and configuration of variables in Table 1 differed from one another in terms of 1) the use of an instrument by the Causee, 2) for unintentional Causees, the medium of interaction between the Causer and the Causee (physical (e.g., pushing) vs non-physical (e.g., yelling loudly to startle) manipulation). The impact of these further variables has not yet been analyzed.

[^63]:    1 Intriguingly, recent data from fMRI experiments indicate that the left vOT area is also significantly associated with writing and its acquisition (Ludersdorfer, Kronbichler, \& Wimmer, 2015; Purcell, Jiang, \& Eden, 2017; Purcell, Napoliello, \& Eden, 2011; Rapp \&

[^64]:    ${ }^{1} \mathrm{We}$ interpreted the disappearance of the stimulus as a response deadline in each task. In the discussion, we note that this assumption

[^65]:    does not change core findings.

[^66]:    ${ }^{1}$ We created the composite outcome measures using two separate PCAs because we wanted the outcome measures to clearly reflect participants' responses to the original questions. For example, as shown in Table 2, pcl primarily reflects variability in judgments of urgency, risk perception, and willingness to change one's behavior, but it also loads onto the other three judgments; $p c 2$ loads positively on the first two questions (goal and solvable) and negatively on the remaining four (inevitable, urgent, risk, behavioral intentions). These patterns of weighting the original questions present some difficulty in interpreting what each factor actually reflects (e.g., $p c 2$ mostly reflects an optimistic outlook regarding our capacity to address climate change, but also, to a lesser degree, reflects the inverse of judgments of urgency, risk perception, and willingness to change one's behavior). In contrast, conducting separate principal components analyses-one on the first three questions, one on the last three questions-yields two outcome variables that clearly correspond to the original questions: tractable is tightly correlated with the three questions used to create it (goal, $r=.73$; solvable, $r=.80$; inevitable, $r=-.64$ ) and only slightly correlated with the other three questions (urgency, $r=$ .10 ; risk perception, $r=.09$; behavior, $r=.10$ ); serious is tightly correlated with the three questions used to create it (urgency, $r=$ .83; risk perception, $r=.82$; behavior, $r=.85$ ), and only slightly correlated with the other three questions (goal, $r=.18$; solvable, $r$ $=-.02$; inevitable, $r=-.11$ ).

[^67]:    ${ }^{1}$ In the general case, language can of course be visual as well as auditory, and object identification can be done through many modalities. For simplicity, we focus on audio-visual matching here.

[^68]:    ${ }^{2}$ Note that we are considering environmental noise, which is different from the noise inherent to perception.

[^69]:    ${ }^{1}$ We included plain exemplars of the critical object kinds after most children during piloting for Exp. 3 cited the pimwit's spots to explain why the speaker who had denied it was pretty was wrong.

[^70]:    ${ }^{1}$ If both the current and previous word's semantic distance had been included as factors in a single regression model, this would have greatly reduced the amount of usable data because both adjacent words would have to be content words.
    ${ }^{2}$ The displayed coefficients for current (previous) surprisal come from the regression model that includes current (previous) semantic distance. Consequently, exactly the same set of words was involved in estimating the coefficients for the surprisal and semantic distance measures, even though surprisal (unlike semantic distance) is also defined for function words.

[^71]:    ${ }^{1}$ Given these fairly fundamental disagreements, it should come as no surprise that what counts as a normative response in any number of contexts is hotly debated. For the sake of simplicity, terms like "normative," "correct," and "logical" will be used to indicate conclusions that are considered correct in classical logic and probability.

[^72]:    ${ }^{2}$ This analysis was meant to assess whether there was a rather diffuse and non-specific conflict detection signal that predicted an individual's detection on a given task by a composite of their relative effects on other tasks. Were the data not binary, a factor analysis would perhaps be appropriate here. Essentially, this was the most liberal test we could devise to check for generality of conflict detection effects. However, it is worth noting that a more conventional test, using multiple regressions with all tasks as predictors except the one being predicted, generated the exact same pattern of results, with all models being uninformative except where BR \& CON items were concerned.

[^73]:    ${ }^{1}$ Note that in RT this is the opposite: a positive sign means going with the pattern, and negative against it.

[^74]:    ${ }^{1}$ Data, materials, figures, and code are available here: https: / / github.com/tobiasgerstenberg/tower_counterfactual
    An interface to view the stimuli and play around with the different noise models may be accessed here: http://web.mit.edu/tger/ www/demos/towers/physics_interface.html

[^75]:    ${ }^{1}$ A running record was included in the test battery to obtain an online measure of decoding accuracy and was included after the experiment commenced. Thus, 13/24 participants have running record data available.

[^76]:    ${ }^{1}$ We vary the dimensionality of the memory and word embedding, the number of computational hops (accesses to the memory cache to answer a single question), the number of training and testing examples ( 1000 vs. 10000), and the size of the world from which the dataset of stories is generated ( 5 vs. 10 vs. 30 entities per entity type, which correspond to the objects, container, etc. in the story).

[^77]:    ${ }^{1}$ The code for running our experiments is available online: https://github.com/RobGrimm/CogSci2017-MultiWordUnits

[^78]:    ${ }^{2}$ The same argument can be made for adults, who are faster to recognize and produce frequent four-word MWUs in similar experiments (Arnon \& Snider, 2010). Such results also support theories of adult linguistic competence which include MWU-like constituents (O’Donnell, 2015).

[^79]:    ${ }^{3}$ Note that we do not claim that the acquisition of MWUs always precedes the acquisition of single words, but merely that this happens often enough to have a measurable impact on word learning.

[^80]:    ${ }^{4}$ Corpora names (see http://childes.talkbank.org/access/ for references): Bates, Bernstein, Bliss, Bloom70, Bloom73, Bohannon, Braunwald, Brent, Brown, Carterette, Clark, Cornell, Demetras1, Demetras2, ErvinTripp, Evans, Feldman, Garvey, Gathercole, Gleason, HSLLD, Hall, Higginson, Kuczaj,MacWhinney, McCune, McMillan, Morisset, Nelson, NewEngland, Peters, Post,Providence, Rollins, Sachs, Snow, Soderstrom, Sprott, Suppes, Tardif, Valian, VanHouten, VanKleeck, Warren, Weist

[^83]:    ${ }^{1}$ When a calculation error resulted in a difference of +1 or -1 compared to the correct value, problems were still considered correctly solved.

[^84]:    ${ }^{1}$ Participants did Study 2 first，followed by the clock question （Study 1）that was inserted in the middle of a questionnaire．As participants were not given any feedback，no significant influence was expected from the first task on the second one．

[^85]:    ${ }^{1}$ "Moreover, it must be confessed that perception and that which depends upon it are inexplicable on mechanical grounds, that is to say, by means of figures and motions. And supposing there were a machine, so constructed as to think, feel, and have perception, it might be conceived as

[^86]:    increased in size, while keeping the same proportions, so that one might go into it as into a mill. That being so, (we should, on examining its interior, find only parts which work one upon another, and never anything by which to explain a perception. Thus it is in a simple substance, and not in a compound or in a machine, that perception must be sought for. Further, nothing but this (namely, perceptions and their changes) can be found in a simple substance. It is also in this alone that all the internal activities of simple substances can consist" (Leibniz 1714, section 17).

[^87]:    ${ }^{1}$ Data are available at https://cocolab.stanford.edu/ datasets/tangrams.html

[^88]:    ${ }^{2}$ Specifically, we used the Universal Dependencies tags csubj, ccomp, xcomp, and advcl for subordinate clauses and acl for adjectival clauses (Schuster \& Manning, 2016)

[^89]:    ${ }^{3}$ There is a broader debate over the timescales at which lexicons and lexicon learning mechanisms operate; here, we assume a discourse-level structure to the lexicon, where there is uncertainty over how words are used in the given conversation. See Frank, Goodman, \& Tenenbaum (2009) for a related approach at the scale of cross-situational word learning.
    ${ }^{4}$ All results can be reproduced running our code in the browser at http://forestdb.org/models/conventions.html
    ${ }^{5}$ In our implementation, we enumerate over coarse-grained bins; preliminary experiments using variational inference on the full continuous distribution give similar results.

[^90]:    ${ }^{6}$ In our simulations, we used $\alpha=10$ and found the basic reduction effect over a range of different biases

[^91]:    ${ }^{1}$ Planned sample size, exclusion criteria, and analysis plan preregistered at https://osf.io/y7mvt

[^92]:    ${ }^{2}$ https://github.com/emilyfae/socref_uncert

[^93]:    ${ }^{3}$ Planned sample size, exclusion criteria, and analysis plan preregistered at https://osf.io/y7mvt/.

[^94]:    ${ }^{1}$ A recent exception is (Moss, 2015).

[^95]:    ${ }^{2}$ For convenience, the prior distribution over states is assumed to be a symmetric betabinomial distribution between 0 and 10 with shape parameters $\alpha=\beta$ free in the model.

[^96]:    ${ }^{3} \mathrm{We}$ assume $\theta_{\text {probably }}=\theta_{\text {likely }}$ and $\theta_{\text {might }}=\theta_{\text {possible }}$. The threshold of the remaining modifier $\theta_{\text {certainly }}$ is free in the model.
    ${ }^{4}$ The delta function $\delta_{s \in \llbracket m \rrbracket}$ gives 1 as output if the state $s$ belongs to the meaning of $s, 0$ otherwise. The expression rat.bel $(. \mid o, a)$ refers to the belief distribution over states induced in a rational agent by the observation of $o$ red balls out of $a$.

[^97]:    ${ }^{5}$ Goodman and Stuhlmüller (2013) use Kullback-Leibler divergence as a measure of discrepancy between speaker and listener beliefs. We found Hellinger distance a more adequate measure in the present setting because utilities in terms of KL-divergence lead to speakers who will never use messages that are semantically false, whereas HD allows messages to be send if they are "true enough." The Hellinger distance between two discrete distributions $P$ and $Q$ is defined as $\operatorname{HD}(P, Q)=\frac{1}{\sqrt{2}} \sqrt{\sum_{i}\left(\sqrt{P_{i}}-\sqrt{Q_{i}}\right)^{2}}$.
    ${ }^{6}$ As $\lambda \rightarrow \infty$, the choice approaches perfect rationality.

[^98]:    ${ }^{7}$ The possible choices included not only likely but also probable in embedded position. However, having not found interesting differences in the behavior of these two expressions, the results reported in this paper, the visualization in Figure 5 and the model evaluation are all based on data in which the counts of participants' choices of messages containing probable and likely have been aggregated.

[^99]:    ${ }^{8}$ The other parameters of interest are $\alpha$ : mean $=6.373$, HDI: $5.546-7.178$; and $\lambda:$ mean $=5.429$, HDI: 5.192-5.659.

[^100]:    ${ }^{1}$ While other variations of this category structure were used to counterbalance features and category locations, they preserved this same main category structure and so we discuss the experiment in terms of this one. We do this for the other experiments, as well.

[^101]:    ${ }^{1}$ The encoding duration of the distractor is an arbitrary value, as we did not know the exact duration of the attentional capture of the reading task of non-words, but we were interested on the relative effect of an additional free time and not on the absolute effect of the free time in this study.

[^102]:    ${ }^{2}$ All the results discussed below are represented by the solid lines in all panels B, which correspond to the simulation of the model with the default value $(r=1.5)$ of the removal strength parameter. The dashed lines will be discussed latter.

[^103]:    ${ }^{1}$ The constraint that words always have four CVCV segments is a simplification for convenience. In principle, our model should be applicable to any set of phonemes and syllable structures. See Pajak et al. (2016) for the complete list of phonemes and stimuli used.

[^104]:    ${ }^{2}$ In particular, the distance between dissimilar phonemes in feature space is large because their means differ in multiple units across multiple dimensions. The distance between highly-similar phonemes on the other hand is small since they are only one unit apart along a single dimension.

[^105]:    ${ }^{3}$ Depending on how model fits are quantified it may also be possible to fit the discrimination results very well but overestimate accuracy on the word learning task. Critically, however, discrimination accuracy will always be lower than word learning accuracy in the $M_{-} A_{-}$model.

[^106]:    1 Hereafter, we call verbal probability phrases verbal probabilities.

[^107]:    *(the treatment will be helpful in that case.)

[^108]:    ${ }^{2}$ In the following analyses, the ratings were mapped onto 0-1 scale.

[^109]:    ${ }^{3}$ In this analysis, we used density values for 99 probabilities ( $1 \%, 2 \%, 3 \%, \ldots, 97 \%, 98 \%$, and $99 \%$ ).

[^110]:    1/https://github.com/jasbi/cogsci2017

[^111]:    ${ }^{2}$ For the data, full results including non-critical trials, and statistical analyses visit the paper's online repository.

[^112]:    ${ }^{3}$ We used a tight prior in this case to decrease posterior correlations between cutpoints and intercept.

[^113]:    ${ }^{1}$ Although many students in this age range have poor spelling, coders did not have trouble determining what a given child had written, even when words were misspelled (e.g., "the toltal", "write the anser next"). Inter-rater agreement between coders on whether a given definition was relational ranged from 95-100\%.

[^114]:    ${ }^{1}$ The model and data analysis source code are available at https://github.com/ctn-archive/kajic-cogsci2017.

[^115]:    ${ }^{2}$ We use italics to refer to the name of a population of neurons or the vector that is represented by that population, which is to be inferred from the context. The bold font is used to refer to labels assigned to vectors representing a word. For example, cue $\cdot$ animal refers to the dot product between the vector represented by the population of neurons labeled "cue" and the vector corresponding to the word "animal".

[^116]:    ${ }^{3}$ See Troyer et al. (1997) for more detailed description of the categorization procedure.

[^117]:    ${ }^{1}$ Which object (the blue fruit or the red stalk) appeared more frequently with which frame, as well as which object was paired with which long name, were both counterbalanced between participants, giving a total of 4 possible object-frame-name pairings which a participant might be trained on. This ensured that potential factors such as sound symbolism, or higher saliency or learnability of any specific object-word pairing, could not systematically bias our results.

[^118]:    ${ }^{1}$ Children also participated in a homogeneous condition, in which all distractors are identical (but distinct from the target). This condition is designed to require less SSA because target tracking is supported exogenously by increased salience of the target. We did not analyze this condition as distinguishing exogenous vs. endogenous effects was not of interest for this study.

[^119]:    ${ }^{2}$ We omitted difficulty level 3 , as only one age group (7 year olds) completed it.

[^120]:    Alex and Josh are both employees at a large company. Their coworker Max has been asked to decide how to assign bonuses to Alex and Josh. Due to company policy, Max can either: give $\$ 1,000$ to one employee and $\$ 100$ to the other or give [ $\$ 0$ / \$100 / \$500 / \$1000 / \$1,100] to both. Alex and Josh currently make the same amount each year, do the same job, [and have received identical work evaluations / but Alex has received a better work evaluation].
    Participant group 1: What would you do? (Give Alex the \$1,000 bonus and Josh the $\$ 100$ bonus / Give Josh the \$1,000

[^121]:    ${ }^{1}$ Without exclusion criteria, $\left(\chi^{2}=1.87, p=0.17\right)$

[^122]:    ${ }^{1}$ This is because the variance estimator we used is statistically unbiased, see eq. 2 .

[^123]:    ${ }^{2}$ Similar results hold if the mean is unknown, but the formulas are much more complicated.
    ${ }^{3}$ The prior hyperparameters were chosen to match the setup of the example discussed above $(N(0,1)$ payoff distribution and $t=$

[^124]:    15). The interpretation of the parameters is that the prior is based on a sample of size $2 \alpha=15$ with variance $\beta / \alpha=1$.

[^125]:    ${ }^{1}$ This analysis is equivalent to a chi-squared test of independence, but it accounts for individual heterogeneity in the data (see Willemsen \& Johnson, 2011).

[^126]:    ${ }^{2}$ All pairwise contrasts were significant, $p<.05$, apart from the contrast between probability and delay regarding the last item, and the contrast between amount and probability regarding intermediate items.

[^127]:    ${ }^{3}$ This is the case in our experiment. In fact, it is twice as likely for an alternative-wise transition to occur (6 transitions) compared to a dimension-wise ( 3 transitions).

[^128]:    1A third condition with misleading descriptions called the conflicting descriptions experience condition has not been included here as it was not relevant to our current investigation.

[^129]:    2 In cases where the sphericity assumption has been violated, the Greenhouse-Geisser correction to $d f$ has been used.

[^130]:    ${ }^{1}$ A programming error meant that all participants in Experiment 1 completed the brightness-relevant task.

[^131]:    ${ }^{2}$ For the correlated condition, this provides an index of the bypass strategy (Dyson \& Quinlan, 2010). The bypass strategy describes a strategy whereby participants monitor only the trial-by-trial sequences making the same response as on the previous trial when the stimulus is the same as the previous trial and switching responses when the stimulus changes.

[^132]:    ${ }^{1}$ We report the mean and the $95 \%$ highest density interval (HDI) of the posterior distributions for each parameter. The HDI represents the range of credible values given the model specification and the data. We chose not to interpret the DDM fits for the Bullseye/Face tasks since there was no suggestion of any non-guessing signal.

[^133]:    ${ }^{1}$ It might seem surprising that any children failed to remember whether the Other child was older or younger. However, recall that the photos of the Other child used in the study reflected a range of ethnicities. Anecdotally (given the small number of excluded children) children who missed this question tended to miscategorize the age of a photo of a child of another race than themselves, possibly reflecting an own-race bias in processing faces (Anastasi \& Rhodes, 2005).

[^134]:    ${ }^{1}$ All family trees, feature matrices (and code) can be found at https://github.com/MollicaF/LogicalWordLearning

[^135]:    ${ }^{2}$ This may be due to data sparsity for UnCLE in the trees. As UNCLE is the most complex concept learned here, it may be that UNCLE requires more unique data points to be learned. Under our Zipfian data sampling, the model receives data for less than half of the unique uncles in the trees. When you relax the sampling assumption to uniform, the model does learn UNCLE and having the correct hypothesis in the space alters the time scale of the shift (to around 30 data points).

[^136]:    ${ }^{3}$ This pattern holds if the data distribution is uniform or becomes more peaked-i.e., a Zipfian exponent of 0,1 or 2.

[^137]:    ${ }^{1}$ We assumed each word conveys on average 10 bits, which is

[^138]:    true of our stimuli, and an average sentence length of 10 words.

[^139]:    ${ }^{2}$ All code and data are available at:

[^140]:    ${ }^{3}$ We set our presentation rate at $147 \mathrm{~ms} /$ word even though previous tasks have gone as fast as $84 \mathrm{~ms} /$ word because we were concerned about enervating participants after one story.

[^141]:    ${ }^{4}$ Analyses excluding their data do not significantly alter the results we present here.
    ${ }^{5}$ We did not have an exclusionary cut-off for participant accuracy because we designed our questions to be difficult and inspire engagement with the text.

[^142]:    ${ }^{6}$ Although, it is clear that there are several alternative proposals to be explored in the future including parallel processing and retrieval accounts (e.g., Lewis \& Vasishth, 2005).

[^143]:    ${ }^{7}$ Average reading time $516 \mathrm{~ms}(\mathrm{SEM}=2.25)$ and average bits per five word chunk 50 bits ( $\mathrm{SEM}=0.5$ ) give an information processing rate around $100 \mathrm{bits} / \mathrm{sec}$.

[^144]:    ${ }^{8}$ The optimal preparation model (Smith \& Levy, 2008) also suggests this decoupling, although the predictions are less clear.

[^145]:    ${ }^{1}$ Multitasking can, in some situations, be achieved by rapid sequential processing (e.g., switching between asynchronous serial processes, as is common in computers), rather than through true synchronous processing. Here, our focus is on forms of multitasking that reflect truly concurrent processing, sometimes referred to as perfect timesharing or pure parallelism.

[^146]:    ${ }^{2}$ Note that it is ensured that, for the uniform distribution $U[0,1]$ of stimulus unit activations in the task-relevant set of input units, every relevant output unit is equally likely to be required for execution.

[^147]:    ${ }^{3}$ All reported results were obtained using gradient decent to minimize the MSE of each training pattern. However, we observed the same qualitative effects using the cross-entropy loss function.

[^148]:    ${ }^{1}$ Holyoak and colleagues (Holyoak et al., 2010; Lee \& Holyoak, 2008) at points extend this claim even further, suggesting that SMT establishes analogical inferences "solely on the logical form of representations and not on their meaning" (Lee \& Holyoak, 2008 p 1120). This however would suggest that SMT is insensitive to the content of the higher-order relations that bind predicates. This is incorrect. SMT distinguishes higher-order constraining relations that confer systematicity (such as cause and prevent) from nonconstraining relations (such as and), which do not. (Falkenhainer, Forbus, \& Gentner, 1989; Gentner, 1983). Here we focus on the aspects of their argument that would prove challenging for the theory.

[^149]:    ${ }^{2}$ One alternative way participants could implement a global strategy would be to generate a posterior probability for the system of base relations, and either increase or decrease their estimate contingent upon which cause is absent in the target. For example, if participants are given $G_{1} P_{1} P_{2}$ as a base and $G_{1} P_{1}$ as a target, dropping a preventative relation (e.g., $P_{2}$ ) may lead them to boost their probability estimate. However, while this is certainly possible, we

[^150]:    believe that such an explanation is far less parsimonious than an account based on higher-order relational mapping (i.e., $G_{1}>P_{1} P_{2}$ ).

[^151]:    ${ }^{1}$ CRT is correlated with cognitive ability (Frederick, 2005; Toplak, West, \& Stanovich, 2011), but can still predict rational thinking and performance on heuristics and biases tasks after controlling for the variance associated with assessments of intelligence, thinking dispositions, executive functions and cognitive skills. Thus, people who score highly on the CRT can be categorized as being more likely to engage in rational, analytic thinking (Shah, Michal, Ibrahim, Rhodes, \& Rodriguez, 2017).

[^152]:    ${ }^{2}$ See https://www.youtube.com/watch?v=n2gRewFVssY
    ${ }^{3}$ See https://www.youtube.com/watch?v=d56jnzPwBOU
    ${ }^{4}$ See https://www.youtube.com/watch?v=ALris6B4yj4

[^153]:    ${ }^{5}$ A possible drawback of normalized scores (such as the NSPM) is that they are prone to overestimations. An extreme example can illustrate this situation: If a participant assigned a preference of 2 to the mirror-alternative and 1 to the shift-alternative, her NSPM score would be $66.6 \%$, thus having a strong additive effect in computing averages, even though the mirror-alternative was ranked as negligible. This can be controlled by using geometric means: when a score is a ratio such as $X_{i} / Y_{i}$, the geometric mean is the only mean with the property $\mathrm{GM}\left(\mathrm{X}_{\mathrm{i}} / \mathrm{Y}_{\mathrm{i}}\right)=\mathrm{GM}\left(\mathrm{X}_{\mathrm{i}}\right) / \mathrm{GM}\left(\mathrm{Y}_{\mathrm{i}}\right)$ i.e. it "normalizes" the ranges being averaged in such a way that no range dominates the weighting (Fleming \& Wallace, 1986).

[^154]:    ${ }^{1}$ We use the term referent to denote anything referred to by a word - an object or event, or set of semantic properties (e.g., $\{$ INDEFINITE, SINGULAR $\}$ for $a n$ ).

[^155]:    ${ }^{1}$ The pre-trained Word2Vec model is available at https://code.google.com/archive/p/word2vec/; The pre-trained GloVe model is available at http:// nlp.stanford.edu/projects/glove/

[^156]:    ${ }^{1}$ The authors are mentioned in alphabetical order.
    ${ }^{2} \mathrm{We}$ are using the classical abbreviations.

[^157]:    ${ }^{3}$ http://mentalmodels.princeton.edu/models/mreasoner/

[^158]:    ${ }^{4} A \leftarrow \perp$ is called an assumption because it can be overwritten under the Weak Completion Semantics, as we will discuss later.

[^159]:    ${ }^{5}$ If $\mathcal{P}=\{A \leftarrow \perp, A \leftarrow \top\}$ then $w c \mathcal{P}=\{A \leftrightarrow \perp \vee \top\}$. This is semantically equivalent to $w c \mathcal{P}=\{A \leftrightarrow \top\} . A \leftarrow \perp$ is overwritten.

[^160]:    ${ }^{6}$ The wheels of a lawnmower are wet if the gras is wet; the wheels are wet if the sprinkler is on; the gras is wet if it is raining.

[^161]:    ${ }^{7}$ We remove the fact from the program that generated the observation, because otherwise the explanation would be empty.

[^162]:    ${ }^{1}$ In Dutch, verb/noun distinctions are differentiated through affixes to the root. For example, telefoneren (to phone) is a verb and telefoon (telephone) is a noun. The English translations do not reflect that participants responded with a single word.

[^163]:    ${ }^{1}$ A task/process/input-output mapping is defined as a unique mapping from all possible vectors in the input subspace to corresponding vectors in the output subspace, that is independent of the mappings for all other combinations of input and output components in the network.

[^164]:    ${ }^{2}$ Although we are restricting ourselves to logistic functions with unit steepness, in a more general setting one can use the steepness as another design parameter.

[^165]:    ${ }^{3}$ Simulation details are omitted due to space constraints.

[^166]:    ${ }^{1}$ All the results follow straightforwardly for structured messages as long as there is a deterministic linearization, such as reverse Polish notation for tree-structured messages.

[^167]:    ${ }^{2}$ I here consider only discrete signals and messages. The continuous case requires either a limit on the power of the signal or for source and channel coding to be considered simultaneously.

[^168]:    ${ }^{3}$ Composition operations that involve copying, such as Suffixaufnahme in Old Georgian (Michaelis \& Kracht, 1996), present an interesting wrinkle. If they can be handled by introducing an integer coefficient for each $l_{m_{i}}$, the ultimate independence result of this section still holds. In any case, they make the signal longer, so they should not present a more efficient bound than Equation 7 .

[^169]:    ${ }^{4}$ I obtained similar results when using $b=6,780$, the number of distinct characters.

[^170]:    ${ }^{5}$ As the CEDict pronouncing dictionary has an average length of about 3.1 non-tone pinyin letters, or 2.8 phonemes, per character type, the optimization rate of Mandarin is similar to the others.

[^171]:    ${ }^{1}$ We thank Kevin T. Kelly for pointing us to the Ellsberg paradox.

[^172]:    ${ }^{1}$ In 2016 a PewResearch poll found the majority ( $62 \%$ ) of US adults get their news through social media. Source: http://www.journalism.org/2016/05/26/news-use-across-social-media-platforms-2016/

[^173]:    ${ }^{2}$ Further simulations in which total network size has been varied, but density has been kept constant at $1 \%$ (i.e. 10 agent-links for 1000 agents, 50 links for 5000 agents) have shown clustering effects remain constant (i.e. depend on relational, not absolute links / network size).
    ${ }^{3}$ Mathematically, P(Declaration) starts to have an impact when it effectively reduces the average number of "functional" links to a point below the absolute threshold for a singular cohesive network (i.e. if it reduces the average number of active links below 4 in the present model; left-hand panel of Fig. 3).
    ${ }^{4}$ The present model demonstrates this with fixed, neutral (0.5) priors for all agents. If variance in priors is included, such that $S D$

[^174]:    ${ }^{1}$ this problem is similar, but not identical, to the problem of reverse inference (Poldrack, 2006)
    ${ }^{2}$ Whereas a minor degree of systematicity does seem to exist

[^175]:    ${ }^{3}$ What makes representational codes different is a surprisingly difficult question to answer. Due to space

[^176]:    ${ }^{4}$ in fact, because of that linear one-to-one relationship, replicating our simulation with these two examples leads to

[^177]:    ${ }^{1}$ We thank Xiaonan Liu for pointing us to these representations

[^178]:    ${ }^{2}$ i.e., trials with the same target regardless of distractors

[^179]:    ${ }^{1}$ Because each of the models we examined is parameter-free, metrics that take into account model complexity such as the Bayesian Information Criterion would give identical results to those only taking into account likelihood.

[^180]:    ${ }^{1}$ Admittedly, this could well be considered a bald-faced lie.

[^181]:    ${ }^{2}$ These exclusions were of participants who failed to select the Helpful message in a Control condition (where the goal was to help) on at least $40 \%$ of trials. We also excluded those who selected the Helpful message in the Low Suspicion condition on $40 \%$ or more trials (where the goal was to hinder, and double bluffing was unreasonable). There was no difference in the significance of our findings if these people were included..

[^182]:    ${ }^{1}$ Unless speech is assumed to be a normally distributed IID process without temporal contiguity, a larger F0 range does not guarantee lower temporal predictability (c.f., e.g., a sine wave).

[^183]:    ${ }^{1}$ The model may also account for other asymmetries in speech production. We plan to pursue this in future work.

[^184]:    ${ }^{1}$ Other experimental manipulations in the original corpus were not the focus of our analysis.
    ${ }^{2}$ To address the within-subjects nature of the data, we removed variance due to teams in a secondary analysis (summarized below)

[^185]:    and found a similar pattern of results. We did not test for order effects or learning, but if learning has occurred it would increase the performance variability in the dataset.
    ${ }^{3}$ Fusaroli \& Tylén's lexical choices

[^186]:    ${ }^{1}$ In counterfactual terms: Had a human seen a green-striped elephant, s/he would have yet recognized it as an elephant. Geoffrey Hinton once told a similar story about a pink elephant!

[^187]:    ${ }^{2}$ Fahlman and Lebiere (1989) also suggest linear, Gaussian, and asymmetric sigmoidal (with range 0 to +1 ) activation functions as alternatives. Our proposed framework can be straightforwardly adapted to handle all such activation functions.

[^188]:    ${ }^{3}$ More precisely, it has been shown how the continuous-time version of MAL, Langevin dynamics, can be implemented in a neurally-plausible manner. But note that MAL amounts to sampling from the underlying Langevin dynamics.
    ${ }^{4}$ Formally, $f\left(\cdot ; W^{*}\right): \prod_{i=1}^{n} D_{i} \rightarrow \prod_{j=1}^{m} R_{j}$ where $D_{i}$ and $R_{j}$ denote the set of values that input unit $i$ and output unit $j$ can take on, respectively.
    ${ }^{5}$ In counterfactual terms, this is equivalent to saying: Had input instance $X$ been presented to the network, it would have classified $X$ in class $j$.

[^189]:    ${ }^{6}$ More specifically, $Z$ renders the computation of the gradient of the log-likelihood for those models intractable.
    ${ }^{7}$ The MAL algorithm inherits this property from the MetropolisHasting algorithm, which it uses as a subroutine.

[^190]:    ${ }^{8}$ Due to the inherent randomness in CCNN construction, training could lead to networks with different structures. However, since in this work we are solely concerned with generating examples using

[^191]:    CCNNs rather than how well CCNNs could learn a given discriminitive task, we arbitrarily pick a learned network. Note that our proposed framework can handle CCNNs with arbitrary structures; in that light, the choice of network is without loss of generality.
    ${ }^{9}$ Yet, too large a $\beta$ is not good either, leading to a sparse and coarse-grained exploration of the input space. Some measures have been proposed in computational statistics for properly choosing $\tau$; cf. (Roberts \& Rosenthal, 1998).

[^192]:    ${ }^{1}$ The use of deontic logic for normative reasoning is the subject of active debate. Although further discussion of this debate is outside the scope of this paper, we note that our proposed approach does not require using deontic operators. We can still reason about norms and learn them using the schema described in Definitions 2 and 3. We would simply need to replace the deontic operators and modify the predicates slightly. Norm $\mathcal{N}_{5}$ in example 1 would become: $\mathcal{N}_{5}:=[0.3,0.6]::$ in (library, $\left.X\right) \Longrightarrow$ forbidden $(X$, talking $)$

[^193]:    ${ }^{2}$ We ensured that the imported actions were physically plausible in the given scene/context.
    ${ }^{3}$ We focus here on permissions. Prescriptions and prohibitions show very similar patterns overall, but prohibitions differ from the other two norm types in interesting ways (e.g., less consensus, slower activation) that will be treated in a separate investigation.

[^194]:    ${ }^{1}$ For instance, a subject's indifference point at interval 1 is 0.8 (see Figure 4). Given a manipulation point of -0.3 , the respective manipulated trial must yield a subjective value ratio (SS/LL) of 0.5 at an interval of 1 . The same logic applies over all manipulation points and intervals.

[^195]:    2 The fitting of the logistic regression model was performed using the StixBox mathematical toolbox by Anders Holtsberg (http://www.maths.lth.se/matstat/stixbox/). The fit was based on the model $\log \left[\frac{p}{1-p}\right]=X b$, where $p$ is the probability that the choice is 1 (SS) and not $0(\mathrm{LL}), X$ represents value differences, and $b$ represents the point estimates for the logistic function.

[^196]:    ${ }^{3}$ The fit of the hyperbolic function was based on minimizing the summed squared errors (SSE). $R^{2}$ is defined as the ratio of the sum of squares of the regression ( $S S R$ ) and the total sum of squares (SST). Since $S S T$ is defined as $S S R+S S E, R^{2}$ is defines by $1-$ SSE/SST.

[^197]:    ${ }^{1}$ We scored the top 30 male and top 30 female first names between 1911 and 2010 in Germany (Bielefeld, 2016) on a scale from 30 (for the most popular male/female name in a year) to zero (for names not listed during a year). These scores were then weighted, for each gender separately, by the proportion of people in the German population who belong to the cohort (Statistisches Bundesamt, 2014). We selected the most popular male and female name in each decade based on the summed raw scores each name received across these ten-year periods. In addition to these 20 most popular names from each decade, we selected the most frequent male and female name in the population (that was not already in the list) based on the total sum of the weighted scores across all years. Finally, the 22 selected names were ranked based on the sum of their weighted scores across all years.

[^198]:    ${ }^{2}$ For few participants, this resulted in the mixture collapsing on the SCM. For these participants, we used a prior that assigned low initial weight to the SCM (e.g., .001) and equal weight to the other two strategies. To ensure unbiased estimation of latent groupmembership, these unequal priors were taken into account in the calculation of membership probabilities.
    ${ }^{3}$ Yet children's inferences were well calibrated to their cohort's instances. Evaluating inferences based on a ranking derived from children's reported number of instances, flips the accuracy pattern such that children significantly outperform adults, $t(78)=-2.40$, $p=.019, d=-.536, B F_{10}=2.70$.

[^199]:    ${ }^{1}$ English does have pronominal gender, but not a full-fledged grammatical gender system.

[^200]:    *These two authors contributed equally.

[^201]:    ${ }^{1}$ Since no comparisons were produced before session 4 (26 months), graphs \& analyses focus on sessions 5-12 (26-58 months).

[^202]:    ${ }^{2}$ Utterances using the word 'favorite' were not coded, since it was not clear that children understood its meaning as comparative.

[^203]:    1 To make the saturated model identifiable, we constrained $\sigma^{2}$ to be the same for both latent classes.

[^204]:    ${ }^{\dagger}$ These authors contributed equally.

[^205]:    a. Masha didn't run $[\mathrm{QUICKLY}]_{\mathrm{F}}$.
    b. $[\mathrm{MASHA}]_{\mathrm{F}}$ didn't run quickly.

[^206]:    ${ }^{1}$ Model-generated probabilities are mapped onto a 7-point scale with the following formula: RATING $=1+6 * P(\phi \mid M)$.
    ${ }^{2}$ The Python code used to implement the model can be downloaded at https://github.com/jonscottstevens/Prosody-Projection.

[^207]:    ${ }^{1}$ Theoretical work in semantics has instead focused on how in-

[^208]:    formation from a comparison class is used and what representations might be preferred (Bale, 2011; Solt, 2009).

[^209]:    ${ }^{2}$ Corpus accessed via https://corpora.linguistik. uni-erlangen.de/cgi-bin/demos/Web1T5/Web1T5_freq. perl. Due to potential polysemy and idiosyncracies of our expermental materials (Table 1), we made the following substitutions when querying the database for emprical frequency: produce $\rightarrow$ "fruits and vegetables"; things you watch online $\rightarrow$ "online videos"; days in $\{$ season $\} \rightarrow$ " $\{$ season $\}$ days"; dishwashers $\rightarrow$ "dishwashing machines"; videos of cute animals $\rightarrow$ "animal videos".

[^210]:    ${ }^{3}$ This was the maximal mixed-effects structure that converged.

[^211]:    ${ }^{1}$ The addition of random intercepts and slopes involving Items (Egg, Rose, etc) did not improve the fit of these models.

[^212]:    ${ }^{2}$ While we did not assess children's emergent literacy skills here, ongoing studies are employing parent surveys to do so.

[^213]:    ${ }^{1}$ Due to limited space, we do not report main effects of or interactions with Channel. Main effects of and interactions with

[^214]:    ${ }^{2}$ More fine-grained analyses of HP sentences, however, do suggest a relationship between knowledge and late positivities that is mediated by offline, knowledge-based Cloze measures. For lower-

[^215]:    Cloze (and, by inference, less-frequently-accessed) compared to higher-Cloze items, post-N400 activity was more positive-going, but only for high-knowledge individuals.

[^216]:    ${ }^{1} \rho^{*}=$ Spearman-Brown adjusted correlation, a measure of splithalf reliability

[^217]:    ${ }^{1}$ It is suggested that the simultaneous processing of two competing samples emulates deliberation over two multiattribute options. This analogy works under the assumtpion that, in real-life multiattribute choices and on each moment, one attribute is considered and the corresponding attribute values serve as inputs into a preference formation process (Tsetsos et al., 2012)

[^218]:    ${ }^{1}$ The corpus in this work is about 25 times larger.

[^219]:    ${ }^{2}$ In fact, the number of possible syntactic derivations is constrained by a very large beam.

[^220]:    ${ }^{3} 5$-gram surprisal predicts conditional frequency effects based on $n$-gram co-occurrence counts. Previous work has shown that 5 -gram frequency controls are sufficiently able to control for frequency effects that syntactic frequency controls are sometimes unable to predict reading times over them (van Schijndel \& Schuler, 2016), so 5 -grams create a strong baseline with which to test other frequency influences.

[^221]:    ${ }^{4} \mathrm{An}$ alternative to the approach taken in this paper would be to maintain a constant vocabulary size but to train the conditional probabilities of that vocabulary over a much larger training set. Such an approach would only help if the weakness of lexical entropy is due to poor probability estimates rather than to unknown words.

[^222]:    ${ }^{1}$ Translating research on norms into predictions about structural reasoning is not straightforward. First, moral norms carry deontic content, which distinguishes them from other kinds of structural constraints (such as a wage gap) that do not. Second, categoryspecific norms can be interpreted in either essentialist or structural terms (e.g., if girls are not allowed to go out after 9 pm , this could stem from inherent characteristics of girls, or structural forces). Existing studies about norms have not made these distinctions, complicating their interpretation with regard to structural reasoning.

[^223]:    ${ }^{1}$ In order to compute power, we need to have an estimate of the true effect, the sample size, and an estimate of the standard deviation.

[^224]:    ${ }^{2}$ The presentation below generalizes to the two-sided test.

[^225]:    ${ }^{3}$ This can be confirmed by running the following command using R ( R Core Team, 2014): power.t.test(delta=0.1,sd=1, $n=36$, alternative $=$ "one.sided", type="one.sample").
    ${ }^{4}$ Treating lower p-values as furnishing more evidence against the null hypothesis reflects a misunderstanding about the meaning of the p-value; given a continuous dependent measure, when the null hypothesis that $\mu=0$ is true, under repeated sampling the p -value has a uniform distribution (see proof in the Appendix). This has the consequence that, when the null is true, a p-value near 0 is no more surprising than a p-value near 0.05 .

[^226]:    ${ }^{5}$ Note that this range is an error; power cannot be less than $5 \%$ if Type I error is set at $5 \%$.

[^227]:    ${ }^{1}$ The dependency could be equally well be between the relative clause verb and the head noun; nothing hinges on assuming a gaphead noun dependency.

[^228]:    ${ }^{2}$ In the published paper, Gibson and Wu (2013) did not delete any data, leading to the results shown in Table 1.

[^229]:    ${ }^{3}$ We also used a simpler method than k -fold cross-validation to compare the models; this method is described in Vehtari et al. (2016). The results are the same regardless of the model comparison method used.

[^230]:    ${ }^{4}$ A reviewer suggests that the direct-access model may simply be an elaboration of the distance model. This is by definition not the case: direct access (i.e., distance-independent access) is incompatible with the distance account.

[^231]:    ${ }^{1} \mathrm{CoV}$ is the standard deviation of a data set divided by its mean. Studies of magnitude estimation in animals and humans have found that response variability correlates with target magnitude, producing a CoV of 0.15 (see Whalen, Gallistel, \& Gelman, 1999).

[^232]:    ${ }^{1}$ Radical enactivism is just one position in the greater antirepresentationalist movement in the philosophy of cognitive science. Less ambitious positions within this movement will not be discussed in this paper.
    ${ }^{2}$ This understanding does not presuppose that cognition must be explained by appealing to representation.

[^233]:    ${ }^{3}$ There is another class of alternatives to the representational explanation as I characterize it in $\S 2$, which I call cognitiveneuroscience explanations. REC does not offer these explanations so they won't be considered here. Relating the representational explanation to these alternatives will be left for future work.
    ${ }^{4}$ CCTC can be made more rigorous with any number of formal theories of computation. Here, I follow Gallistel and King's and assume a functioning homomorphism view of computation and the Turing machine mathematical formalism because these apply to the desert ant example in section 4.1 (see Gallistel \& King 2009: 196-206).

[^234]:    ${ }^{5}$ This is a minimal conception of CCTC. Many classical computationalists, such as Jerry Fodor (1975), endorse a language of thought, but CCTC is compatible with the absence of a language of thought. Furthermore, CCTC need not (and I think should not) posit anything like that found in our folk psychological theories (Stich 1983).
    ${ }^{6}$ This is not the only reason RECers have for rejecting representations. For example, another reason, which I deal with below, concerns the causal efficacy of semantic properties. For brevity's sake I can present no more reasons here.

[^235]:    ${ }^{7}$ This is only a sketch of Wittgenstein's view, but a sketch will do here.

[^236]:    8 As Kaplan (2015) argues, dynamical models can be explanatory when construed as representing the dynamics of the mechanism responsible for the phenomena to be explained, but not when they are merely phenomenological. In these cases, the mechanism and not just its dynamic behaviour constitute the explanation.

[^237]:    ${ }^{9}$ Some might want to resist this claim and argue that detection systems do involve information-bearing structures. For good reasons to not to resist see (Ramsey 2007).

[^238]:    ${ }^{1}$ Motion tracking ( $\sim 5.32 \mathrm{~ms}$ ) and data transfer ( $\sim 5$ to 8 ms ) time, plus screen refresh rate $(\sim 13.33 \mathrm{~ms})$ resulted in a minimal delay between a participant's movement and rendering of 26.67 ms .
    ${ }^{2}$ Individuals creating similar chaotic movement sequences produced behavior with the average frequency for a given trial between .14 and .57 Hz , and an overall average frequency of .32 Hz (Washburn et al., 2015).
    ${ }^{3}$ Washburn et al. (2015) used these sequences to train individuals to act as master systems during interpersonal anticipatory synchronization and demonstrated that the training consistently led to individuals producing chaotic movement behavior.
    ${ }^{4}$ Harmonic spring systems are flexible with relatively few intrinsic dynamics. For slave systems with inherently chaotic dynamics it will be harder to evaluate whether anticipatory behavior of another chaotic system is primarily a product of coordination.

[^239]:    ${ }^{1}$ Belief states (Kaelbling et al., 1998) or predictive state representations (Littman et al., 2001) are sufficient for planning, but can be computed internally in each module and do not need to be communicated.

[^240]:    ${ }^{1}$ Compared to adults, children credited robots with slightly greater physiological capabilities. This is particularly obvious in examining modal responses for items like feel safe (adults: no, $n=82$; children: yes, $n=40$ ), feel tired (adults: no, $n=88$; children: no, $n=38$, yes, $n=36$ ), and feel scared (both age groups: no, $n=93$ adults, 50 children), which each have emotional and cognitive connotations in addition to their relevance for biological life.

[^241]:    ${ }^{2}$ Note, however, that have goals loaded more strongly on the social-emotional factor, and two potentially "moral" items (have self-control; communicate with somebody else), loaded equally on the social-emotional and perceptual-cognitive factors.

[^242]:    ${ }^{1}$ An alternative definition of complexity, perimeter squared over ink area, has been used successfully by Pelli, Burns, Farell, \& Moore-page (2006) to account for human efficiency in letter identification. However, it was found that this measure of complexity was a significantly weaker predictor of RT in the same/different judgment, as originally reported in Wiley, Wilson, \& Rapp (2016).

[^243]:    ${ }^{2}$ Only the "same" pairs are used here because they are used to measure the effects of visual complexity. The "different" pairs are discussed in detail in Wiley, Wilson, \& Rapp (2016), where they were used to determine the relative importance of various visual features (e.g. lines, curves) for letter perception and how that relative importance differed between naïve and expert observers.

[^244]:    ${ }^{3}$ The monoscriptal participants had varying degrees of knowledge of languages written in the Roman alphabet other than English, primarily Spanish or French.

[^245]:    ${ }^{1}$ We also considered Probability of Improvement and Probability of Maximum Utility (Speekenbrink \& Konstantinidis, 2015) as alternate decision strategies, but have omitted them because they failed to reach performance comparable to UCB.

[^246]:    ${ }^{2}$ Note that the peak in average reward for the GP-UCB is due to the use of human parameter estimates, whereas a GP-UCB model with optimized hyper-parameters and a dynamic $\beta$ is known to achieve sublinear regret bounds (i.e., monotonically increasing average reward; Srinivas et al., 2010)

[^247]:    ${ }^{3}$ Because horizon length varied within subjects, we compare the aggregate mean of the cross-validated parameter estimates for $\beta$.

[^248]:    ${ }^{1}$ These two questions, although indirect assays of the agents' desires, were selected as being more natural to the context. To

[^249]:    answer these two questions, however, children have to infer the two agents' desires.

[^250]:    ${ }^{1}$ This and subsequent numbers represent statistically significant results, as described above.

[^251]:    ${ }^{1}$ Multiple imputation is the recommended tool to predict missing data when missingness depended on other observed variables, but not the missing variable itself (Sinharay, Stern, \& Russell, 2001). In our case, because missingness was a result of the parent's decision, it was associated with patterns observed in parent-child interactions (as shown in the logistic regression), but was not directly associated with children's behavior in the test. Therefore, multiple imputation is suitable to simulate behavior for the notconsented children.
    ${ }^{2}$ The two test measurements regarding activation of target function were imputed as binary variables, whereas all other test measurements were imputed as continuous variables. For each test measurement, a logistic regression model (for binary variables) or a linear regression model (for continuous variables) was first fitted on the data from the consented group. From the fitted model, posterior distributions were computed for the 8 parameters in the logistic regression model or the 9 parameters in the linear regression model (intercept, coefficients for the 7 observational measurements, and the residual variance for linear regression only). Then the values for the not-consented group were imputed for $m=$ 100 runs. For each run, a new set of parameters were randomly drawn from their respective posterior distributions, and were used to compute the expected values plus random errors for each child in the not-consented group. The means and standard deviations of the not-consented group and of the whole population were then calculated for this test measurement. The procedure is then repeated for the remaining runs of simulations, and applied to the other test measurements.

[^252]:    ${ }^{1}$ In a recent book chapter (Zawidzki, forthcoming), Zawidzki takes a stronger stance on mindshaping. Although Zawidzki seemingly proposes mindshaping as a separate alternative to inferential mindreading, in doing so one may throw out the baby with the

[^253]:    ${ }^{2}$ Blokpoel et al. proved that Bayesian inverse planning can encode and 'solve' computational problems that are amongst some of the hardest problems known in computer science. For details (and a full tutorial) see Blokpoel et al. (2013).

[^254]:    ${ }^{3}$ No results are known for 1-p by itself. It is, however, prudent to assume that restricting $1-p$ by itself also does not lead to tractability of Bayesian inverse planning.

[^255]:    ${ }^{1}$ Due to space limit, these results were not reported here.

[^256]:    ${ }^{2}$ The log-likelihood of participants' eye movement patterns being classified as the eye-mouth pattern was also correlated with the percentages of "fearful" responses, but with a smaller Pearson's r, $r=.394, p=.007$. This effect may be due to the similarities between the two representative patterns. Note that the two patterns were significantly different: eye movements classified as the eye-mouth pattern had higher likelihoods of being generated by the eye-mouth model, and vice versa (Chuk et al., 2014).

[^257]:    ${ }_{1}$ Publication-based author.

[^258]:    ${ }^{1} \mathrm{http}: / /$ www.freeciv.org/

[^259]:    ${ }^{1}$ The coefficients $(\beta)$ are interpretable as log-odds, but can also be transformed to an odds ratio $\left(O R=e^{\beta}\right)$.

[^260]:    ${ }^{1}$ Due to the difference, the Google graphic was not included in the analysis since it was designed differently compared to the other questions.

[^261]:    ${ }^{2}$ The 6 Google logo related questions tested participants on correctly recalling the colors of each of the letters in 'google.'

[^262]:    ${ }^{1}$ An earlier version of R\&R (Alhama, Scha, and Zuidema (2016), Alhama and Zuidema (2016)) features a different probability for retention, with a binary switch over an attenuation parameter. This design was inspired by experimental studies in which the stimuli eventually contained 25 ms pauses, a duration that is supposed to be perceived by humans only subliminally. The stimuli we plan to use for our simulations, based on Frank et al. (2010), differ significantly in the use of pauses, which have a duration of 500 ms (and therefore should be clearly perceived). The retention probability we present here is more general, since the effect of pause length could be accounted for with different values of $\mu$.

[^263]:    ${ }^{2}$ The only parameter that we keep fixed in our search is $\mu_{n p}=$ 1.0 , since the interpretation of the relative importance of pauses is clearer if only one of the $\mu$ parameter is varied.
    ${ }^{3}$ We optimize our parameters on the same data we evaluate the model on, as seems to have been the case for the models we compare with. This brings the risk of overfitting, so in the discussion section we briefly discuss better ways of evaluating models.

[^264]:    ${ }^{4}$ Even though the values that parameter $D$ can take range from 0.0 to 1.0 , the number of types stored by $\mathrm{R} \& \mathrm{R}$ grow very rapidly in our model due to the memorization segments of any length. For this reason, small values are impracticable, since the probability of recognizing a segment quickly drops close to zero.

[^265]:    ${ }^{1}$ Graphs with high clustering coefficients and low average path lengths, as in small-world networks, are efficient to search and relay information through, while scale invariance allows a single algorithm to operate across seemingly disparate representational frames.

[^266]:    ${ }^{2}$ SEEDLingS networks contain many more nouns than the WordBank network (resulting in different connectivity patterns), but AoA data is only available for the 369 CDI nouns for all networks
    ${ }^{3}$ http://nlp.stanford.edu/projects/glove/

[^267]:    ${ }^{4}$ We omit these due to space, but thank an anonymous reviewer for this suggestion; they will be presented at CogSci.
    ${ }^{5}$ https://github.com/andreiamatuni/wordgraph
    ${ }^{6}$ https://github.com/BergelsonLab/semspace

[^268]:    ${ }^{7}$ Scale free networks are inherently ultrasmall (Cohen \& Havlin, 2003)
    ${ }^{8}$ Phonological neighborhood effects are saved for future work

[^269]:    ${ }^{9}$ Node degrees are from the SEEDLings-All network at peak similarity threshold of $\varepsilon=0.13$

[^270]:    ${ }^{1}$ The p-curve app conducts three different statistical tests to detect whether there is right skew. All of these tests were statistically significant ( $\mathrm{p}<0.001$ for all), indicating that the curve is very unlikely to be not right skewed.

[^271]:    ${ }^{2}$ This study was not included in the preliminary meta-analysis reported here because it did not provide the relevant standard statistical information.
    ${ }^{3}$ Another difficulty with sorting out the different potential effects of learned CP is that nearly all the published work is not designed to address this question. This makes it impossible in most cases to distinguish between, as an example, acquired distinctiveness of a dimension plus compression versus just expansion. These two cases have the same behavioral outcome, and thus must be distinguished through experimental controls, such as different kinds of training.

[^272]:    ${ }^{1}$ One research tradition which arguably falls outside these debates is the distributed cognition research programme (e.g., Hutchins, 1995a). While distributed cognition is explicitly cognitivist, it succeeds in avoiding the group actor assumption by analysing individual actions as part of a larger system encompassing physical artefacts as well as actors within a space (Hutchins, 1995b).

[^273]:    ${ }^{2}$ It might be argued that this is not really a joint action phenomenon at all. Just as Tomasello argued that the individual chimpanzees were all merely hunting in parallel, all in their own self-

[^274]:    interest, so one might argue that the pedestrian's activity and the driver's activity are merely two individual action phenomena that happen to overlap in space. But this sort of argument again commits us to dividing the world up a priori into individual and joint actions. The argument is only valid, in other words, if we already accept the group actor assumption.

[^275]:    ${ }^{1}$ The facial recognition algorithm was adapted from the Open Source Computer Vision Library (OpenCV v2.4.13; Bradski, 2000) and programmed in Python 2.7. OpenCV is an open source library that provides a common infrastructure to machine vision applications in academia and industry.

[^276]:    ${ }^{1}$ In the Smartphone condition participants could do the experiment with the following devices: iPhone, Android, Windows Mobile Phone and BlackBerry. In the PC condition participants could use a desktop or a laptop computer. No tablets were allowed.

[^277]:    ${ }^{2}$ In the Smartphone condition, $39 \%$ of participants used an iPhone during the experiment, $58.5 \%$ an Android, $2.2 \%$ a Windows Mobile Phone and $0.2 \%$ a BlackBerry.

[^278]:    ${ }^{1}$ Each set of items also included some non-temporal items, which are not discussed here.

[^279]:    ${ }^{2}$ That references using complementary prepositions (such as "in front of" vs. "behind") need not result in perfectly complementary response patterns was also observed for the spatial domain (e.g., Grabowski \& Weiß, 1996).

[^280]:    ${ }^{1}$ Olfactory and gustatory words were not used because there were too few in our candidate stimuli, and were not required.

[^281]:    ${ }^{2}$ Segment selection (partly based on the Brian Vision Analyzer tutorials at http://www.erpinfo.org/the-erp-bootcamp.html). The critical period spanned from 300 ms before target onset to 800 ms after target onset (the period before onset is 100 ms longer than the general baseline of the ERPs because that improved the selection of segments). Gradient: $75 \mu \mathrm{~V} / \mathrm{ms}$. Threshold for difference between maximum and minimum voltage in segment: $\pm 150 \mu \mathrm{~V}$ (this was increased or decreased by up to $40 \mu \mathrm{~V}$ in a minority of cases where the automatic selection yielded too noisy waveforms), interval length 200 ms . Amplitude: $-100 \mu \mathrm{~V}$, $+100 \mu \mathrm{~V}$. Low activity: $0.5 \mu \mathrm{~V}$, interval length 50 ms .

[^282]:    ${ }^{3}$ Quick group: Auditory-to-visual: $62 \%$ (SD=48 pp.). Haptic-tovisual: $61 \%$ ( $S D=49 \mathrm{pp}$.). Visual-to-visual: $63 \%$ ( $S D=48 \mathrm{pp}$.). Slow group: Auditory-to-visual: $64 \%$ ( $S D=48$ pp.). Haptic-tovisual: $64 \%$ ( $S D=48 \mathrm{pp}$.). Visual-to-visual: $64 \%$ ( $S D=48 \mathrm{pp}$.).

[^283]:    ${ }^{1}$ In all analyses in the present paper including the three-level factor DISCOURSE CONDITION the degrees of freedom were corrected by applying the Greenhouse-Geisser correction. In the text the uncorrected degrees of freedom are reported.

[^284]:    ${ }^{1}$ One exception is the work of Carruthers, Masson, and Stege (2012) which found that the planarity of graphs has no effect on human performance in the Vertex Cover problem.

[^285]:    ${ }^{2}$ Here we will only consider undirected graphs.
    ${ }^{3}$ We included the spectral gap as it admits an efficient polynomial algorithm as opposed to the other three predictors which are NPhard. As such, it may prove as a practical predictor of performance.

[^286]:    ${ }^{1}$ Specifically, the previous model possessed six components used to achieve the primary cross-dimension comparison task: the object height reporter and object length reporter; the length comparator, which compared the results from the object height/length reporters; comparison recorder; and the center highlighter and orientation inhibitor, which generated a fixation on the center proto-object and inhibition on peripheral proto-objects, respectively.

[^287]:    ${ }^{2}$ When there are three dots, only one dot goes uncounted, which is approximated with high accuracy.

[^288]:    ${ }^{3}$ Our usage of the terms serial and parallel in this paper align with this strong and weak sense of attentional dependency, respectively.

[^289]:    ${ }^{1}$ To do so, agents would have to infer or come equipped with knowledge about $P_{N}\left(\cdot \mid s_{a}\right)$, which could itself be subject to updates. We stick to the simpler case of noise-free inference here, but as long as the actual state is not always recoverable our general results also hold for agents that reason about noise.

[^290]:    ${ }^{2}$ Knowing $k$ allows learners to compute the likelihood of a type not reporting $k-\left|d_{l}\right|$ state observations. A better but more complex alternative is to specify a prior over $k$ with learners performing a joint inference on $k$ and the teacher's type. For simplicity, we opt for the former, albeit admittedly artificial, assumption.

[^291]:    ${ }^{3}$ Concretely, results are obtained for probabilistic speaker behavior following the definitions of Brochhagen et al. (2016). Nothing essential to our main argument and simulation results hinges on these details, so we background them here for ease of exposition.

[^292]:    ${ }^{1}$ We collapsed congruent RTs (Yellow prime/Yellow target and Green prime/Green target) and we did the same for the incongruent RTs (Yellow prime/Green target and Green prime/Yellow target.

[^293]:    ${ }^{1}$ This vector is computed by calculating the dot product between the situation-state matrix and the original $25 k$-dimensional situation vector, and then normalizing each dimension of the resulting vector by the sum over the dimensions of the original $25 k$-dimensional situation vector.

[^294]:    ${ }^{1}$ For the case of $\alpha_{k}$, the conditional posterior cannot be computed analytically and the parameter is sampled with the MetropolisHastings rule (Yildirim, 2012).

[^295]:    ${ }^{2}$ Taken from Salakhutdinov et al. (2012)

[^296]:    ${ }^{3}$ Averages across 10 random repetitions and all categories are reported.
    ${ }^{4}$ Each category contains a varying number of examples

[^297]:    ${ }^{1}$ One-tailed binomial tests reflect the directional nature of our hypothesis, but the outcome is comparable with two-tailed tests (same: $p=.052$; different: $p=.020$ ).

[^298]:    ${ }^{2}$ We compared performance of Mandarin-speaking preschoolers in the current study with English-speaking preschoolers in Walker et al. (2016). Considering each condition separately, we find a significant difference between Mandarin- and English-speaking preschoolers in the different condition (one-tailed $p=.022$, Fisher's exact) and a marginal difference in the same condition (one-tailed $p=.068$, Fisher's exact). Combining across different and same conditions, we find that Mandarin-speaking preschoolers significantly outperform English speakers (one-tailed $p=.004$, Fisher's exact).

[^299]:    ${ }^{1}$ Precision and recall scores consider the "high" class as positive label.

[^300]:    ${ }^{1}$ I also experimented with a procedure that excluded any TENS/DIGITS pairs from the proposal distribution for a given form that were assigned to any previous forms within a window of arbitrarily chosen size. However, this exacerbated the label-switching problem (a trivial issue); less trivially, it was difficult to motivate a window size which plausibly paralleled working memory.

[^301]:    ${ }^{2}$ It is well known that South Asia is home to rigid societal hierarchies, and historically, exact number systems may have been the preserve of elite groups, while marginal groups relied on an alternative system (prior to language standardization). While this theory is blatant speculation, it is worth briefly noting that Sinhala, an Indic language whose speakers chiefly practice Buddhism (which preaches a doctrine of egalitarianism), developed a transparent number system.

[^302]:    ${ }^{1}$ In order to avoid biasing the results with children who were responding with nonsensical numbers, we excluded responses on which PAE scores were over $500 \%(n=2)$ for this analysis.

[^303]:    ${ }^{2}$ Because Overall PAE and Work Expended PAE were highly collinear and conceptually and empirically confounded, we ran separate models using each PAE type (see Table 2).

[^304]:    Such a result would advance our understanding of both the mechanisms controlling perceptual learning and the face inversion effect in a number of ways. We would have found an experimental procedure (anodal tDCS at Fp 3 brain site) able to selectively affect perceptual learning and its expression, and this would help in discriminating between competing theories. Furthermore, we would have additional evidence that perceptual learning is a contributor (at least in part) to the face inversion effect. Finally, this would be the first demonstration in the literature of how relatively brief

[^305]:    ${ }^{1}$ The precise details of the strategy classification had to be omitted from this paper for space reasons, but will appear in a longer version of this manuscript that is currently under review.

[^306]:    ${ }^{1}$ Note that Jern and Kemp (2013)'s model is slightly different, as they used a non-conjugate model. Their model acts very similar to our version of it and receives comparable fits.

[^307]:    ${ }^{1}$ The experiment took place in an open plan office and there were other colleagues working quietly in the room. Participants were made aware of this before the experiment started, so that they were not distracted by this.
    ${ }^{2}$ The full list of words and phrases used for each category, are as follows:- Certainty adverbials: absolutely, actually, certainly, clearly, plainly, definitely, evidently, indeed, obviously, really, surely, undoubtedly, unquestionably, for certain, for sure, of course; Uncertainty adverbials: allegedly, apparently, arguably, conceivably, inexplicably, likely, maybe, perhaps, possibly, potentially, presumably, probably, reportedly, seemingly, supposedly; Uncertainty modals: may, might, can, could and Hedges: quite, sort of, kind of , might, a bit, a little bit, just, at least, approximately, about, around, something like, almost, pretty, sometimes.

[^308]:    ${ }^{1}$ In this context the term 'false information' refers to incorrect or inaccurate information that is initially presented as true.

[^309]:    ${ }^{2}$ Planned contrasts are reported for predicted differences. Tukey's posthoc tests are reported when no difference between conditions was predicted.

[^310]:    ${ }^{1}$ It is important to note that there are numerous domains within cognitive science that formalize representation in various ways. In the present paper, we work within the framework of structuremapping theory.

[^311]:    ${ }^{1}$ Software available at gitlab.bucknell.edu/AI-CogSci-Group/IGT-Open/

[^312]:    ${ }^{1}$ Although more sophisticated amortization schemes have been developed in the machine learning literature (e.g., Stuhlmüller et al., 2013; Rezende et al., 2014; Paige \& Wood, 2016), they are difficult to test experimentally in humans.

[^313]:    ${ }^{1}$ Fits were carried out per subject and identified parameters that minimized squared error. The parameters were $w_{Y}$ (the marginal probabilities of $Y_{A}$ and $Y_{B}$ ), $w_{Y X}$ (the strength, or causal power, of the links between the $Y \mathrm{~s}$ and $X$ ), and $w_{X}$ (the strength of alternative causes of $X$ ). Predicted conditional probabilities [0-1] were multiplied by a scaling parameter $s$ to bring them into the range of subjects' ratings [0-100]. The best fitting parameters averaged over subjects were $w_{Y}=.401, w_{Y X}=.483, w_{X}=.178$, and $s=158.6$.
    ${ }^{2}$ Rather than explicit sampling, the causal samplers predictions for a given chain length has an analytic solution involving repeated multiplication of the matrix of transition probabilities between graph states defined by the Metropolis-Hastings rule. Fractional values of chain length involve computing the weighted average of the joint probability distributions that obtain when chain length is rounded up and down. The best fitting parameters averaged over subjects

[^314]:    were $w_{Y}=.440, w_{Y X}=.469, w_{X}=.233, s=137.7$, and chain length $=17.9$.

[^315]:    ${ }^{3}$ Our lab has subsequently extended these finding to a more traditional hypothesis testing task in which subjects rate the posterior probability of the graph in Figure 1A relative to alternative hypotheses (those formed by removing one or both of the causal links).

[^316]:    ${ }^{4}$ The best fitting parameters $\left(w_{Y}=.519, w_{Y X}=0.440, w_{X}=.243\right.$ averaged over subjects), were those that maximized the likelihood of the distribution of pennies.
    ${ }^{5} w_{Y}=.534, w_{Y X}=0.410, w_{X}=.328$, chain length $=10.1$.

[^317]:    ${ }^{1}$ Technically, exact back-propagation cannot be applied to a stochastic network, though there are several versions of "approximate" back-propagation for stochastic networks, e.g. (Gu, Levine, Sutskever, \& Mnih 2015)

[^318]:    ${ }^{1}$ The word 'argumentation' in English sometimes conveys an idea of dispute or may refer to situations in which some individual tries to convince another. We do not consider such restrictions.

[^319]:    ${ }^{2}$ Note that speaker and hearer may adopt different attitudes, e.g. if the latter proposes a solution (go and grab the child) to what was a 'look at this!' utterance.

[^320]:    ${ }^{3}$ One such signalled event is a news about the near future. It is listed as 'narrative', though narratives are typically about past events.

[^321]:    ${ }^{4}$ Note that the 'resource-bounded' restriction makes the notions of complexity and of unexpectedness computable (Saillenfest \& Dessalles, 2015).

[^322]:    ${ }^{1}$ Due to an error in setting up the study, one trial was lost in the unattractive last condition in one third of participants. Therefore, only 24 trials instead of 25 went into data analysis for those participants in that condition.

[^323]:    ${ }^{1}$ Children have been successfully trained to use rehearsal to support delayed serial recall, but they stopped using the strategy when told they did not have to use it (Keeney, Canizzo, \& Flavell, 1967). Whether children stopped because they could not sustain the strategy or because the experimenter's instructions influenced motivation to use it is not clear.

[^324]:    ${ }^{1}$ For the time being we leave the question of realism of the acoustic part to future work.

[^325]:    ${ }^{2}$ https://github.com/tensorflow/models/tree/master/ inception

[^326]:    ${ }^{3}$ http://scikit-learn.org/stable/modules/clustering

[^327]:    ${ }^{4} \mathrm{An}$ area in the map is associated to a word if the activation of the neurons within it are at their peak when they respond to a stimulus of that particular word.

[^328]:    ${ }^{1}$ Source code and notebooks available as a Github repository at https://github.com/sebastien-forestier/CogSci2017

[^329]:    ${ }^{1}$ Because participants were on average enthusiastic to learn new topics in math ( $M=4.29, S D=0.94$ ), more so even than other topics, we did not further analyze the results of this measure.

[^330]:    ${ }^{1}$ This article is an abridged, modified version of Mareschal, D. \& French, R. M. (2017) TRACX2: a connectionist autoencoder using graded chunks to model infant visual statistical learning. Phil. Trans. R. Soc. B 2017372 20160057; DOI: 10.1098/rstb.2016.0057.

[^331]:    ${ }^{1}$ In this paper, a $95 \%$ confidence interval was calculated by bootstrapping, based on 1000 sampling, with replacement.

[^332]:    ${ }^{2}$ Two participants in self-others, two in dialectical, and one in selftwice conditions were excluded from analysis, as confidence data was not collected.

[^333]:    ${ }^{1}$ In reality, compound words (especially very frequent ones) might be planned as a single phonological sequence (Jacobs \& Dell, 2014). This does not affect the interpretation of our results, as we did not ask our participants to produce compounds, but rather sequences of two unrelated words.
    ${ }^{2}$ While Griffin (2003) found a reversed word-length effect on speech latencies (i.e., longer latencies when $\operatorname{word}_{l}$ was shorter) as well as on gaze-speech lags, Meyer et al. (2007) only found this effect on gaze-speech lags.

[^334]:    ${ }^{3}$ Although Griffin (2003) varied word2 frequency and length, between-items differences were very small.

[^335]:    ${ }^{4}$ Variation in the Long condition was not sufficient to allow treating this variable as a continuous predictor in the analyses. Instead, Length was treated as a categorical predictor (Short vs. Long) throughout.

[^336]:    ${ }^{5}$ Perhaps parafoveal information was sufficient for speakers to identify intact right pictures more often than degraded ones.

[^337]:    ${ }^{6}$ Alternatively, retrieval difficulties with word $_{2}$ could have interfered with preparation of the articulatory code for the first syllable of word ${ }_{1}$, and slowed it down. However, note that articulatory retrieval does not appear to impose huge demands on central attention (Roelofs \& Piai, 2011). Also, this interference account would have also predicted a smaller effect of degradation on the gaze-speech lag when word $_{l}$ was long, because with long words the temporal overlap between articulatory encoding for the first syllable of word $_{1}$ and word $_{2}$ retrieval should have been shorter.

[^338]:    ${ }^{1}$ We have the original raw data file from the norming study, but, alas, have lost the handwritten surveys on paper. We therefore conducted a second norming study with the same materials. The results were similar and so we used the data from the original norming study. Interestingly, the few items were we found slight differences were the ones related to immigration - a topic that recently became highly controversial in Germany and many other countries.

[^339]:    ${ }^{1}$ e.g., JIBO: http://www.jibo.com

[^340]:    ${ }^{2}$ Ideally, an operationalization of brevity should obtain some metric from the surface realization of a potential utterance (e.g., phoneme count, simulated speech output time, etc.). This architectural integration is still a work in progress.
    ${ }^{3}$ While DIARC has the capacity to handle unconventional indirect requests (e.g., "My batteries are running low..."), for sake of clarity we focused on more conventional cases in our demonstration.

[^341]:    ${ }^{4}$ Scenario 1 involved an elder care setting in which a robot asked the nurse for a sick patient's medication ("Hand me the red pills."). Scenario 2 involved a household robot running low on battery that asked to be plugged in before important data was lost ("Plug me in."). Scenario 3 involved a service robot that requested to take a child's coat at a fancy reception ("Hand me your coat."). Finally, Scenario 4 involved a mine-sweeping robot that asked its superior officer to step aside as it searched a room in a training exercise ('Move out of the way.").

[^342]:    ${ }^{5}$ For example, what does it mean for utterance A to be equally less polite (e.g., 0.4) than utterance $B$ as utterance $B$ is less informative than utterance A?

[^343]:    1 There are two basic interpretations of the concept counterfactual in cognitive science: 'contrary to reality' (Pearl 2000; Hiddleston 2005; Rips \& Edwards 2013), and 'possible, but not implemented in some situation' (Roese \& Olson 1995; Roese 1997). For this paper only the first interpretation is actual.

[^344]:    ${ }^{1}$ Only 37 from 50 recordings were valid for the pause measuring.

[^345]:    ${ }^{1}$ Furthermore, in the princeps study that introduced the SSF framework, the small $b$ values, and the ones close to $a$ were equally present in the Si - and MA-versions of the problems.

[^346]:    ${ }^{1}$ This formula has been adapted across a range of studies, such as in political psychology research (Hardisty, Johnson \& Weber, 2010).

[^347]:    ${ }^{2}$ In each analysis 175 responses were analyzed (4 responses for each participant, one for each scenario, apart from one participant whose responses were not recorded for the final scenario due to an eye-tracking malfunction).
    ${ }^{3}$ GEE model was chosen as it represents a flexible approach to handling correlated data structures. A full discussion of this method can be found in Honish Edwards, Elden \& Leonard (2010).

[^348]:    ${ }^{4}$ Analysis conducted via a one-sample t-test with test value of 50.

[^349]:    ${ }^{5}$ Degrees of freedom for each study scenario:
    Study 1 df's: between (1, 101-104) Study 2 df's: $(1,39-40)$
    ${ }^{6}$ Indeed, in our study, as the one risk introduced four different side effects, we used information about three of the four of these as our three separate risks.

[^350]:    1 Three of the 62 students who initially participated were excluded from the analyses due to a technical error (one leading to a posttest log not being created, and the other to one of the topics between a pair not being discussed). There was a procedure error for two additional participants (i.e. they had kept their learningmaterial window open and used it for the posttest). Lastly, one student withdrew participation assent during the posttest. In addition, of the remaining 56 , due to an ID entry error one participant lacked a pretest log, and therefore was excluded from the multiple-choice question analysis, and for two participants we could not link their short-answer log IDs to their dialog screen IDs; they were excluded from the dialog metric analyses.

[^351]:    ${ }^{1}$ Gives the probability of $k$ successes in $n$ draws, from a population of size $N$ with exactly $K$ successes. Thus, similar to the binomial distribution, but drawing without replacement.

[^352]:    ${ }^{1}$ https://bitbucket.org/julianhough/stir

[^353]:    ${ }^{1}$ It is even possible for an a.s.-terminating program to have infinite expected run time. Consider a program defining a geometric distribution that repeatedly flips a fair coin until first flipping a heads after $n$ steps, then continutes for $2^{n}$ more steps thereafter.

[^354]:    ${ }^{1}$ For a concrete description of the removal see Section "Data Analysis" on the following page.

[^355]:    ${ }^{2}$ As every trial contained two gaze actions, one aligned to the first noun and one aligned to the second noun, the total number of gaze actions throughout the course of the experiment was 288 per list/participant.

[^356]:    "This diagram is intended to show a curved tube. In the diagram you are looking down on the tube from above. A metal ball is put into the end of the tube indicated by the arrow. The ball is then shot out of the other end. Your task is to draw the path the ball will follow after it comes out of the tube. Please flip the page and proceed."

[^357]:    ${ }^{1}$ As just one example, Bennett (1975, p. 71) defines in and on using the notions of location at the interior of an object (for in), and location at the surface of an object (for on).
    ${ }^{2}$ We examined the 7 items for which the rate of expression use

[^358]:    ${ }^{2}$ We examined the 7 items for which the rate of expression use exceeded the truth-value acceptance rate and found that, for all but one item, the absolute difference between use and acceptance was less than 0.3.

[^359]:    1 For the document pairs used in Lee et al. (2005), the highest reported correlation between a model and humans was .77 (Yeh, Ramage, Manning, Agirre, \& Soroa, 2009).

[^360]:    3 We considered the approach of transforming scores into a 0-1 scale, as in Lee et al. (2005). However, this approach is overly sensitive to the minimum and maximum values. On the other hand,

[^361]:    ${ }^{1}$ Data of native signers were collected as part of a bigger project conducted between 2010 and 2015 (Sümer, 2015).
    ${ }^{2}$ Pictures used in the study were originally developed by Dr Jennie Pyers and were adapted further for the purposes of this present study.

[^362]:    ${ }^{1}$ In total, the data of 2079 and 583 participants went towards the joint Simon ( $M=21.88 /$ group, $S D=9.02$ ) and $\operatorname{IGNG}(M=$ 16.66/group, $S D=5.79$ ) random-effects meta-analyses, respectively.
    ${ }^{2}$ When the number of participants per group was not specified, the total number of participants reported was assumed to be distributed evenly amongst groups. Standard errors (SE) were converted into standard deviations (SD) for future computations.
    ${ }^{3}$ Control condition criteria included a physically present, human co-actor, actively responding to an alternative stimulus.

[^363]:    ${ }^{4}$ In cases where authors provided alternative hypotheses regarding whether the JSE would manifest itself, or not, we could not definitively code the condition as a 'wipeout' or 'non-wipeout,' and the dataset was excluded from the analysis ( $n=10$ ).
    ${ }^{5}$ Large samples were defined as $n>24$, reflecting the $75^{\text {th }}$ percentile of sample size.

[^364]:    ${ }^{6}$ The summary effect size of wipeout conditions was also significantly smaller than that of control conditions, but we have omitted this additional analysis for brevity, given that the reported difference between wipeout and non-wipeout conditions is stronger evidence of the former's impact on the size of the JSE.

[^365]:    ${ }^{7}$ A supplementary analysis of the control versus non-control task conditions, with the wipeout data removed from the latter to diminish potential cancellation effects, also yielded no significant difference between the summary effect sizes. This supports the notion that there is some flexibility in the task conditions that can be applied and still elicit the JSE.

[^366]:    ${ }^{1}$ Although it would be more appropriate to speak about entities including humans, in the following we refer to spatial objects.

[^367]:    ${ }^{2}$ This was due to a better readability. For the purpose of calculating Odds Ratio and the further meta-analysis, absolute frequency of accuracy based on the number of participants and the percentage of the correctness of the given responses are used.

[^368]:    Together with two former classmates from university, Agent 1 and Agent 2, you have founded a small startup company of which you are the CEO. You are in charge of the management and finances, while Agent 1 and Agent 2 manage the creative direction part. Your team works from Mondays to Thursdays. The printer in your office works fine, only when it receives two printing orders at the same time it crashes.

[^369]:    ${ }^{1}$ Each of these two single-mental state conditions involves more specific tests of integration capacity. For example, in explicit desire (alone) condition, the participant's ability to produce a false belief indicates that she can recognize the relevance of the provided desire to an action that produces an unforeseen outcome.

[^370]:    ${ }^{1}$ The compensation-consistency parameter is scaled so that the the maximum compensation is twice the number of steps in the accumulation process, because due to the scaling of $\rho$ to $[-1,1]$ the maximum evidence is $S$ and the minimum evidence is $-S$. Thus, the maximum compensation can not be bigger than twice the number of accumulation steps

[^371]:    ${ }^{2}$ The Bayes factors were calculated with ttestBF function of the R-package "BayesFactor"

[^372]:    *This equation assumes a constant branching factor and an upper bound on the complexity of planning. People's planning time likely increases less than exponentially fast with the planning horizon but our approximation may be sufficient for small problems.

[^373]:    ${ }^{1}$ Throughout this paper, we will use the term "conditionals" to refer specifically to indicatives.

[^374]:    ${ }^{2}$ cf. Strong Ramsey test, proposed by Rott (1986), according to which "If $p$, then $q$ " is acceptable if and only if $q$ is acceptable under the supposition of $p$ but not acceptable under the supposition of $\neg p$.

[^375]:    ${ }^{3}$ In the "sensibleness" data, this effect was also significant, $t(61.65)=2.86, p=.006, r=.35$.

[^376]:    ${ }^{4}$ Note that, in the context of our experiment, the differences in people's assertability judgments could have only resulted from the semantics of the evaluated sentences, since the conversational contexts remain constant.

[^377]:    ${ }^{1}$ There was a marginal effect of order; Forced Choice (FC) Retention before Free Recall (FR) led to higher Retention (FC: $\mathrm{t}(46)=2.38, p=.021$, and $\mathrm{FR}: \mathrm{t}(44)=1.88, p=.067$ ). However, main effects and interactions in the overall ANOVA remain the same with and without order included.

[^378]:    ${ }^{1}$ Our implementation adapts source code from https://github.com/devsisters/DQN-tensorflow

[^379]:    ${ }^{1}$ http://www.hera-project.com

[^380]:    ${ }^{1}$ For each side of the table, subtask trajectories examined include: rest-to-pickup, pickup-to-target, pickup-to-pass, rest-to-receive, receive-to-target, pass-to-rest, and target-to-pickup.

[^381]:    ${ }^{1}$ Where there are duplicated singular values, the SVD is not unique, so more precisely we mean there exists a basis which makes the SVD is block diagonal.

[^382]:    ${ }^{2}$ In the general case representations will be distributed across the hidden units, and so there will not be a unit which responds to the analogy and nothing else, but this is simply a rotation of the representation space, and because of the linearity of derivatives the same general pattern will emerge.

[^383]:    ${ }^{1}$ Development of the MacBrain Face Stimulus Set was overseen by Nim Tottenham and supported by the John D. and Catherine T. MacArthur Foundation Research Network on Early Experience and Brain Development. Please contact Nim Tottenham at tott0006@tc.umn.edu for more information concerning the stimulus set.

[^384]:    ${ }^{1}$ The linear nature of this relation was confirmed using a Generalized Additive Model with penalized spline-based smoothers.

[^385]:    ${ }^{1}$ The ACL Wiki lists the performance of some key approaches: https://www.aclweb.org/aclwiki/index.php?title=TOEFL_Synony m_Questions_(State_of_the_art)

[^386]:    ${ }^{1}$ Three children in the inaccurate condition did not provide answers to the "good or not good" question and one child in the accurate condition did not provide answers to the "ask for help" question.

[^387]:    _—_ Musicians - English non-words preceded by musical segments
    Musicians - English non-words preceded by Tibetan letter strings
    Non-musicians - English non-words preceded by musical segments
    _ Non-musicians - English non-words preceded by Tibetan letter strings

    ${ }^{2}$ Based on the inertial data from the IGS suit, it is possible to calculate a kinematic chain with the hips as root. Hence, the position of the hip joint in the virtual scene is the reference point for all body

[^395]:    movements.
    ${ }^{3}$ While most participants remained unaware to the manipulation and attributed the variance in their grip aperture to inaccuracies of the tracking equipment, two participants reported to be aware of the manipulation after the experiment. Seeing that conscious awareness was not critical in this experiment, we did not perform a behavioral manipulation check in terms of a signal detection task to determine whether participants were able to consciously detect the manipulation of the visual grip aperture.

[^396]:    ${ }^{4}$ Please note that the data pattern remains nearly unaffected if the data is not filtered. Removing the size estimates from error trials only reduces the effect size of the three-way interaction.

[^397]:    ${ }^{5}$ Available at http://www.igroup.org/pq/ipq/index.php
    ${ }^{6}$ The considerable overestimation might be partially due to the initial slider position in the visual reproduction, starting at $90 \%$ of the sliding range for larger cubes.

[^398]:    ${ }^{1}$ Object locator constructs a priority map in three steps. First, following Bouma's law for visual crowding (Whitney \& Levi, 2011), object locator generates Marr wavelets centered at each tracked object's location, scaled so that the sizes of the suppressive fields increase as those objects enter the periphery. Second, since untracked stimuli produce visual crowding at a weaker rate than tracked stimuli (Whitney \& Levi, 2011), for each protoobject, we include the negative component of a wavelet whose amplitude is set to $20 \%$ of that for tracked objects. Third, Holcombe, Chen, and Howe (2014) report a general cost for having more tracked objects. We account for this effect with long-range suppression in the visual field, implemented as a constant value ( 0.04 in the model) subtracted from the entire visual field outside of each tracked object's enhanced region.

[^399]:    ${ }^{1}$ Thornton et al. had observed the largest effect size in the digit cancellation task, so we chose to include only this task to make room for additional measures testing the opportunity cost framework.
    ${ }^{2}$ Thornton et al. found no effects of gender in the original study, so we did not attempt to balance the gender representation in our sample of participants.

[^400]:    ${ }^{3}$ The distributions of cancellation scores were not normal, so we applied Wilcoxon's rank-sum test. ( $t$-test gave similar results)

[^401]:    ${ }^{4}$ The distribution of effort ratings was not normal for the simple cancellation task, but conformed to normality for the additive task.

[^402]:    ${ }^{1} \mathrm{P}(\mathrm{E})=$ perceived expertise $(0-1) ; \mathrm{P}(\mathrm{T})=$ perceived trust $(0-1)$; Rep is the represented statement (e.g., Hypothesis =1)

[^403]:    ${ }^{2} \mathrm{p}($ rep $\mid \mathrm{h})=\mathrm{p}($ rep $\mid \mathrm{h}, \exp$, trust $) * \mathrm{p}(\exp ) * \mathrm{p}($ trust $)+\mathrm{p}($ rep $\mid \mathrm{h}$, $\neg \exp$, trust $) * p(\neg \exp ) * p($ trust $)+p($ rep $\mid \mathrm{h}, \neg \exp , \neg$ trust $) * \mathrm{p}(\neg \exp )$ * $\mathrm{p}(\neg$ trust $)+\mathrm{p}($ rep $\mid \mathrm{h}, \exp , \neg$ trust $) * \mathrm{p}(\exp ) * \mathrm{p}(\neg$ trust $)$, mutatis mutandis for $\mathrm{p}($ rep $\mid \neg \mathrm{h})$

[^404]:    ${ }^{3}$ While it is not possible in the current model, this enables negative campaigning, as candidates could provide a negative representation (e.g., $\mathrm{p}($ candidate $\neg$ rep)) and attacks designed to undermine the trustworthiness or expertise of the opposing candidate. Intentionally, the model is built compartmentally to allow for increasingly complex persuasion campaigns.

[^405]:    ${ }^{1}$ For the sake of clarity, we provide the background story as an appendix after the bibliography.

[^406]:    ${ }^{2}$ Alongside the background story, full witness descriptions can be found in the appendix.

[^407]:    ${ }^{1} \mathrm{http}: / /$ semarch.linguistics.fas.nyu.edu/barker/Syllables/

[^408]:    ${ }^{2}$ We found that raw NWR performance scores resulted in weaker linear models and did not reach significance as a predictor. Therefore, we focus on the Phonological Chunk Sensitivity metric in the analyses (see Part 2).

[^409]:    ${ }^{1}$ Residual familiarity was derived by regressing out NoM, NoS, and NoM vs. NoS from raw familiarity.

[^410]:    ${ }^{1}$ Feldman and Tremoulet (2008) only briefly mentioned this hypothesis at the end of their paper, the bulk of which focused on detecting agency from observed motion patterns. The idea of using computational models (e.g., finite state automaton) to formalize agent detection is shared by our paper, but we dived into a very different domain-static visual sequences, where there is a substantial literature on the formalism of subjective randomness to draw on.

[^411]:    ${ }^{2}$ Griffiths and Tenenbaum (2003) only showed each participant half (128) of the stimuli-that is, one either saw a sequence (e.g., HTHHTHTT) or its complement (e.g., THTTHTHH).

[^412]:    ${ }^{3}$ This was suggested by two anonymous reviewers.

[^413]:    ${ }^{1}$ The structure-mapping theory and the multiconstraint theory postulate that the new hypothetical entities should be capable of filling the role played by their corresponding base objects, but they do not give further specifications about how to identify these entities in the target domain (see, e.g., Falkenhainter et al., 1989; Holyoak et al., 1994). With respect to the transferred relations, the structure-mapping theory (see, e.g., Falkenhainer et al., 1989) maintains that a generated relation in the target will be assumed to be identical to the corresponding source predicate. However, to the extent that this theory has always treated identicality as a "tiered" condition (Forbus, Ferguson, Lovett, \& Gentner, in press), we suppose the theory would admit inferences that include nonidentical relations as long as they can be regarded as identical at a higher level of abstraction. The multiconstraint theory adheres to the "copy of relations" postulate, but it treats it as a default rule that is adequate for initial explorations in the target (see, e.g., Holyoak et al., 1994). Under these considerations, we assume that CWSG involves either copying the base relations or replacing them by similar ones.

[^414]:    Note. ${ }^{*}$ Significant at $\alpha=.05 ;{ }^{* *}$ Significant at $\alpha=.01$

[^415]:    ${ }^{1}$ Two week test-retest reliabilities (from separate sample, $N=$ 215): $r=0.795$ ( 5 -item measure) and $r=0.923$ ( 10 -item measure).
    ${ }^{2}$ Conformity, for which ratings of both increases and decreases did not significantly differ from the scale midpoint of 50 , was excluded, though overall results do not change if it is included.

[^416]:    ${ }^{3}$ Only the 5 -item personality measure in Study 2, where participants on average experienced greater positive net change over the study period, substantially deviated from this pattern.

[^417]:    ${ }^{1}$ Although eye-tracking data were collected, they were not analyzed for this study.

[^418]:    ${ }^{1}$ In a roughly Bayesian sense
    ${ }^{2}$ Though the construction of a privileged and precise version of this concept is of considerable value, it is regrettably beyond the scope of the present article.

[^419]:    ${ }^{3}$ Such as in the earlier example involving misaligned concepts of justice.
    ${ }^{4}$ At least in this author's experience

[^420]:    ${ }^{5}$ Context is an incredibly complex topic, but for the purposes of this article, we will leave its nuances aside.
    ${ }^{6}$ Except possibly some component of the context, but the variance in context between participants in an interaction is beyond the scope of this article.

[^421]:    1 Wolf packs are only distributed cognitive systems in the context of the hunt. Outside of this context, they retain only a loose association and they do not otherwise share in joint tasks.

[^422]:    ${ }^{2}$ O'Donnell and colleagues (2015) describe wasp swarms as distributed cognitive systems, a usage inconsistent with the established definitions. This is an example of how the lack of an array of different concepts of nonreductive social cognition can leave some researchers forcing square pegs into round holes.

[^423]:    ${ }^{3}$ This may provide an alternate explanation for why individual vigilance against predators in Quelea quelea decreases with flock size (cf. Lazarus, 1979). Lazarus explains this effect in terms of an economy of energy, but it may simply arise from a situation in which only a local region of birds within the flock actively respond to predators.

[^424]:    ${ }^{4}$ The properties of the collective need not resemble the properties of its members (Hutchins, 1995a).

[^425]:    ${ }^{1}$ Slope estimates represent log transformed RT data.

[^426]:    ${ }^{1}$ Note that there are other appraisal variables proposed by the theory. Describing all the appraisal variables and their meanings is out of the scope of this paper.

[^427]:    ${ }^{2}$ Our computational model is inspired by the work of S. Marsella, Gratch, and Petta (2010) but implemented with completely different computation mechanism.

[^428]:    ${ }^{3}$ Currently, our model can generate and express eight different emotions described by (Ortony et al., 1990) namely Joy, Distress, Appreciation, Reproach, Gratitude, Anger, Liking and Disliking.

[^429]:    ${ }^{1}$ The materials were kindly provided by Stella Christie.

[^430]:    ${ }^{1}$ In fact, models of informativeness are often operationalized in terms of ruling out competing referential interpretations (Frank \& Goodman, 2012). The only way to apply such models to our experiment is with the trivial assumption that all true descriptions are equally informative.

[^431]:    ${ }^{2}$ Saturation and value were held constant to reduce the dimensionality of color space and to understand how people use color words to partition the range of hue values. This procedure is common practice when assessing expectations for basic color categories (Persaud \& Hemmer, 2016; Sims, Ma, Allred, Lerch, \& Flombaum, 2016)

[^432]:    It is not the case, that: If the toy block is not a cube, then the toy block is a cube.

[^433]:    If the figure on the upward facing side of the die is a circle, then the figure is black.

[^434]:    ${ }^{1}$ Analysis using a mixed logistic regression model-structuring outcomes as binary responses-did not change our findings

[^435]:    ${ }^{1}$ The authors wish to express their gratitude to both sets of authors for supplying the stimuli that allows for a direct test of the hypotheses.

[^436]:    ${ }^{2}$ Paolacci, Chandler \& Ipeirotis (2010) for validation of using Mechanical Turk. Note that Asian origin may also include Bangladeshi, Indian, and Pakistani participants. For the current experiment, however, participants were limited to people with Far Eastern origin.
    ${ }^{3}$ Further analysis using $2 \times 3$ two-way ANOVA with all three groups (Black, White, and Asian) revealed no significant interaction: $F(2,92)=1.76, p=.18$. This confirms that all three groups had the same pattern of response.

[^437]:    ${ }^{1}$ https://deepdreamgenerator.com/

[^438]:    ${ }^{2}$ This is known as the N170 event-related potential (ERP).

[^439]:    * Parameter was fit individually for each participant (Mean $\pm$ SD)

[^440]:    ${ }^{1}$ Enactive accounts may be disentangled from each other on the basis of their differing commitment to the necessary involvement of non-neural bodily states in mental imagery (see Foglia \& O'Regan, 2016; cf. Thomas, 1999). For the purposes of the present paper the commonalities rather than the differences between these approaches are highlighted.

[^441]:    ${ }^{2}$ We failed to obtain age for two participants.

[^442]:    ${ }^{3}$ Studies generally show low ambiguity detection rates across a range of more and less complex figures (detection rates are always less than $50 \%$; Brandimonte \& Gerbino, 1993; Hyman \& Neisser, 1991; Peterson, Kihlstrom, Rose, \& Glisky, 1992; Mast \& Kosslyn, 2002)

[^445]:    ${ }^{1} 4$ participants chose one of the two distractors or did not report any retrieval and were not included in the analyses

[^446]:    ${ }^{2} 2$ participants chose one of the two distractors or did not report any retrieval and were not included in the analyses

[^447]:    ${ }^{1}$ These are distributional semantic models that "frame the vector estimation problem directly as a supervised task, where the weights in a word vector are set to maximize the probability of the contexts in which the word is observed in the corpus" (Baroni et al., 2014, p. 238.)

[^448]:    ${ }^{2}$ Co-occurrences are generally viewed as symmetric relations, and we will keep with that tradition here: tiger co-occurs with bright twice in this sentence, and vice versa.
    ${ }^{3}$ This is the approach of Church \& Hanks (1989) and Islam \& Inkpen (2008), except that their contexts are defined as windows of text (i.e., strings containing $n$ words); the size of the window is an additional parameter for the model.

[^449]:    ${ }^{4}$ Pantel \& Lin (2002)
    ${ }^{5}$ Washtell \& Markert (2009)
    ${ }^{6}$ Evert (2005)
    ${ }^{7}$ Levy, Goldberg, \& Dagan (2015)

[^450]:    ${ }^{8}$ If computing a metric resulted in an undefined value $(\log 0)$, the value of the metric was replaced with zero.
    ${ }^{9}$ That is, a window size of 10 for SGNS and 5 for CBOW (as recommended at https://code.google.com/archive/p/word2vec/), and all other parameters left on their default settings.

[^451]:    ${ }^{10}$ Specifically, the frequency of the lowest-frequency word in each word pair.

[^452]:    ${ }^{1}$ We refer to implicit utterances made by the speaker as implications and inferences made by the listener as inferences.

[^453]:    ${ }^{1}$ To be clear, probabilistic models are also used for purposes other than explanation (e.g., prediction, hypothesis generation). This paper, however, only examines their explanatory import.

[^454]:    ${ }^{2}$ In Oaksford \& Chater 2007, P(q|p) was set to 0.9. See ibid. for the underlying account of conditional inference and for the mathematical details.

[^455]:    ${ }^{3}$ Uncertainty $I\left(M_{i}\right)$ given n mutually exclusive and exhaustive hypotheses, is $-\sum_{i=1}^{n} P\left(M_{i}\right) \log _{2} P\left(M_{i}\right)$.

[^456]:    ${ }_{5}^{4}$ See Goodman et al. (2015) for the modelers' response.
    ${ }^{5}$ See Griffiths \& Tenenbaum (2006) for an empirical study that attempts to directly test the optimality assumption.

[^457]:    ${ }^{6}$ As an anonymous referee pointed out, also the dynamical models used in ecological psychology are often understood as formalizations of affordances. This calls for a systematic comparison between the two modeling paradigms.

[^458]:    ${ }^{1}$ All procedures in the pilot study and experiments were approved by the Johns Hopkins University Institutional Review Board.

[^459]:    * COPD stands for Chronic Obstructive Pulmonary Disease

[^460]:    ${ }^{1}$ Given that the orientation of the two figures was never varied and that the two line figures were never identical, it is important to note that there was always at least one cell that would, on its own, allow the two line figures to be distinguished.

[^461]:    ${ }^{1}$ Our description generalizes across typical candidate inferences approaches (Falkenhainer, 1990; Gentner \& Colhoun, 2010; Gentner \& Markman, 1997) and other related approaches such as copy with substitution \& generation (Holyoak \& Hummel, 2000; Lee \& Holyoak, 2008). For our purposes, the distinctions matter less than the commonalities.

[^462]:    ${ }^{2}$ The current stimulus was designed with a near analogy rather than a distant analogy. We expected the homological nature of mammalian brains to make the analogy prima facie plausible. The rat brain to human brain analogy is often used in experimental study, although here we reverse source and target. Other stimuli (discussed later) have produced consistent, but less pronounced effects for analogies across more distant domains.

[^463]:    ${ }^{3}$ We intended the explanations in each domain to be interpreted by participants as mutually exclusive and exhaustive, but we did not assume this in their response structure. We allowed the model to account for the possibility that both explanations within a domain are correct or that both are incorrect. This compelled the use of the multivariate Dirichlet distribution rather than the Beta distribution.

[^464]:    ${ }^{1}$ This corpus was used because it was pre-analyzed and the ratings were successfully used in previous studies.

[^465]:    ${ }^{2}$ Since the hypothesized effect is due to mere exposure to the text, participants' agreement with the primes was not predicted to affect the results and it is therefore omitted from the analysis. Importantly,

[^466]:    ${ }^{1}$ It must be noticed that transfer of training to multivariate measures of a particular skill (e.g., spatial ability) does not necessarily mean that that skill has been successfully enhanced (Shipstead, Redick, \& Engle, 2012). In fact, the improvement in a

[^467]:    ${ }^{2}$ The item "striking a match" was considered inappropriate for primary school children and thus replaced with the item "dealing cards" (Groen, Whitehouse, Badcock, \& Bishop, 2013).

[^468]:    ${ }^{1}$ In an informative example on Hidden Markov Models (HMMs), Icard and Goodman (2015) present a setting wherein the relevant submodel is infinitely large-an example which highlights what is wrong with the sequential approach stated earlier.
    ${ }^{2}$ The terms "consult" and "retrieve" will be used interchangeably. We elaborate on the rationale behind that in Sec. 5, where we connect our work to Long Term Memory and Working Memory.

[^469]:    ${ }^{3}$ We elaborate more on this in the Discussion section.
    ${ }^{4}$ The term "nested" implies that the thus-far retrieved submodel is subsumed by every later submodel (provided that the reasoner proceeds with the retrieval process).

[^470]:    ${ }^{5}$ More precisely, PL induces a topological order on the nodes of a CBN, with temporal interpretations suggested in Def. 1.

[^471]:    ${ }^{6}$ There are cases, however, that, despite the precedence of cause to effect, quantifying the amount of time between their occurrences may bear no meaning, e.g., when dealing with hypothetical constructs. In such cases, PL should be simply construed as a topological ordering. From a purely computational perspective, PL is a generalization of topological sorting in computer science.

[^472]:    ${ }^{7}$ Taking one step backwards from variable $\boldsymbol{q}$ amounts to retrieving all the parents of $\boldsymbol{q}$.
    ${ }^{8} \mathrm{We}$ do not consider interventions in this work. However, with some modifications, the presented analysis/results can be extended to handle a generic causal query of the form $\mathbb{P}(\mathbf{O}=O \mid \mathbf{E}=$ $E, \operatorname{do}(\mathbf{Z}=Z)$ ) where $\mathbf{Z}$ denotes the set of intervened variables.

[^473]:    ${ }^{9}$ For a discussion on the special case (b), the reader is referred to: https://arxiv.org/pdf/1701.08100
    ${ }^{10}$ For a formal proof of Lemma 1, and the rationale behind Remark 1, the reader is referred to: https://arxiv.org/pdf/1701.08100

[^474]:    ${ }^{11}$ Note that the trend of the upper- and lower-bound curves as well as the size of the intervals shown in Fig. 3(right) are insensitive with regard to the choice of PLs for variables $\left\{\mathbf{x}_{t-i}\right\}_{i=-1}^{+\infty}$.

[^475]:    ${ }^{12}$ The very property that the submodel gets constructed incrementally in a nested fashion guarantees that the obtained lower and upper bounds get tighter as the reasoner adopts smaller ITs; see Fig. 3(left).

[^476]:    ${ }^{1}$ There is in fact converging evidence from formal semantics, syntax, and functional linguistics to support this analysis (Partee, 1987; Adger, 2003; Rijkhoff, 2004).

[^477]:    ${ }^{2}$ Note that we do not wish to make claims about the nature of the gestural elements produced by participants, and use the linguistic terms $\mathrm{N}, \mathrm{Adj}$, Num, and Dem for convenience.

[^478]:    ${ }^{3}$ Different t-tests have different degrees of freedom. This is due to the fact that not all data could be included for each test: some participants produced only incomplete gesture strings.
    ${ }^{4}$ Taken from: http://www.flaticon.com/packs/essential-set-2.

[^479]:    ${ }^{5}$ Adjectives can be incorporated in the noun in sign languages (Sutton-Spence \& Woll, 1999), and it is interesting that participants in Experiment 1 sometimes did this as well, but for the purposes of our experiment we wanted to discourage it.

[^480]:    ${ }^{6}$ Because in this experiment, some participants produced English orders, we ran a separate T-test on the orders that did not follow English structure, and found that subset of the data to be significantly more isomorphic than chance $(\mathrm{t}=3.3347, \mathrm{df}=10, \mathrm{p}<0.01)$.

[^481]:    ${ }^{7}$ Participants were as likely to produce structures like $\mathrm{N}-\mathrm{Num}-\mathrm{Adj}$ and Num-Adj-N as the isomorphic variants N -Adj-Num and Num-Adj-N.

[^482]:    ${ }^{1}$ The scale ranged from "very plausible" (1), to "not plausible,

[^483]:    difficult to imagine" (7).
    ${ }^{2}$ Images used (for both experiments) were taken from an open source database (www.openclipart.org) and pretested for naming.

[^484]:    ${ }^{3}$ This is the required setup for the subsequent extraction of the ICA events from EyeWorks Workload Module software (version 3.12).
    ${ }^{4}$ The middle of the referent noun was calculated by taking the audio duration of the whole word and using its half as the starting

[^485]:    point (for each word individually).
    ${ }^{5}$ NewInspections $\sim$ Constraint $+(1+$ Constraint | Subject) $+(1$ + Constraint | Item), family = "binomial"
    ${ }^{6}$ TargetInspections $\sim$ Gaze $+(1+$ Gaze | Subject $)+(1+$ Gaze | Item), family $=$ "binomial"

[^486]:    ${ }^{7}$ ICA $\sim$ Constraint*Plausibility + Half*Gaze $+(1+$ Constraint*Plausibility || Subject) + (1 + Constraint*Plausibility || Item), family $=$ poisson (link $=$ " $\log ^{\prime \prime}$ )

[^487]:    ${ }^{8}$ None of the students were familiar with Experiment 1.
    ${ }^{9}$ In order to counterbalance the referent nouns the experiment was run in two versions. Version a) included a verb fitting to one noun in the item (spill water vs. sausage), while the verb in version b) fit the other noun (grill sausage vs. water).

[^488]:    ${ }^{10}$ TargetInspections $\sim$ Gaze $+(1+$ Gaze | Subject $)+(1+$ Gaze | Item), family $=$ "binomial"
    ${ }^{1}$ IICA $\sim$ Gaze*Fit + Half*Gaze + ( $1+$ Gaze*Fit + Half*Gaze \| Subject $)+(1+$ Gaze*Fit || Item $)$, family $=$ poisson (link $=$ "log" $)$
    ${ }^{12}$ ICA $\sim$ Gaze*Fit $+(1+$ Gaze*Fit || Subject $)+(1+$ Fit | Item $)$, family $=$ poisson (link $=$ "log")

[^489]:    ${ }^{1}$ The two databases were "Kikuzo II Visual" (online database of Asahi Shimbun; date range: January 1, 1984 to May 23, 2016) and "Yomidasu Rekishikan" (online database of Yomiuri Shimbun; date range: January 1, 1986 to May 23, 2016).

[^490]:    ${ }^{1}$ Choices in linguistic encoding are known to be influenced by aspects of information structure, including contrastive focus,

[^491]:    ${ }^{2}$ Lowercased, replaced punctuation with space, replaced digits with NUM, removed empty lines, replaced tabs with spaces, removed multiple spaces, removed multiple NUMs, replaced umlauts by their conventional character bigrams, and added sentence begin and end markers.
    ${ }^{3}$ A threshold of 15 was selected since this was the highest possible while maintaining a less than $1 \%$ out of vocabulary rate on a different corpus (EUROPARL).

[^492]:    ${ }^{4}$ The sharp difference in perplexity scores between the test corpus and stimuli suggests that the German Wikipedia corpus is not an ideal match for our stimuli. We return to this point in the discussion.
    ${ }^{5}$ Foils were created in a two-stage process. First, a custom Python script randomly selected a foil candidate for each word in each experimental and filler item. Foil candidates were constrained such that they did not appear in bigrams with the correct word at the previous position in the sentence within a large German corpus. Second, each foil was then hand checked by at least two trained native-German linguists to ensure that it was not a grammatical continuation of the sentence. The same foil was used for identical words (or derivationally related words) across conditions.

[^493]:    ${ }^{6}$ Qualitatively identical results are obtained when raw RTs are used.

[^494]:    ${ }^{7}$ Note, however, that the cloze results validate both the stimuli and the RT findings.

[^495]:    ${ }^{1}$ Although there is some disagreement about the aspect of analytic thinking that the CRT measures (e.g. Stupple, Gale, \& Richmond, 2013; Toplak, West, \& Stanovich, 2011), it is a useful tool in measuring analytic ability and reflective processing.
    ${ }^{2}$ Six participants were excluded from the analysis due to incomplete pupil dilation data ( $\mathrm{N}=4$ ) or extreme outlier pupil dilation data ( $\mathrm{N}=2$ )
    ${ }^{3}$ We extended the original IGT to 140 trials to assess the learning effect (e.g. Bagneux, Font, \& Bollon, 2013).

[^496]:    ${ }^{1}$ see https://www.tekscan.com/

[^497]:    ${ }^{1}$ The Radiation problem is about a doctor who wishes to destroy a tumor in his patient's stomach using a ray. However, if he emits the rays at high intensity, the tumor will be destroyed, but so will be the healthy tissues of the patient. If a lower intensity is applied, the tissues will not be affected, but neither will be the tumor. In fact, the solution to this problem is analogous to the base AttackDispersion problem and requires the doctor to emit the rays at lower intensity from different directions simultaneously in order for the concentrated forces of the rays to destroy the tumor.

    2 The Attack-Desperation Problem was considered to be the superficially dissimilar analog of the Radiation Problem in Gick and Holyoak's study (1980). In that story a general wants to capture a fortress located in the center of the country. The problem arises when the general realizes he cannot send his troops all at once due to the mined roads, but if he divides his troops to small

[^498]:    units and attacks from many directions, they will not be affected and the combined forces will capture the fortress.

[^499]:    3 Algorithmic mind can be associated to fluid intelligence capacities. It is a Type 2 processing, which is typically linked to situations that require an optimal performance and a correct answer should be obtained (Stanovich, 2012).

[^500]:    ${ }^{4}$ Standard deviation in seconds.

[^501]:    ${ }^{5} 64$ out of the $67 ; 3$ participants had studied technical specialties

[^502]:    ${ }^{1}$ We also measured response time starting from when the stimuli came on the screen; results were qualitatively similar regardless of the choice of starting time.

[^503]:    ${ }^{2}$ We modeled log-RT using a linear mixed effects model with random effects for participant, trial, and a trial-by-motion direction interaction.

[^504]:    ${ }^{3}$ Because it was unclear how far the ball should travel in the "no motion" condition, we did not include those trials in this analysis.
    ${ }^{4}$ If we include the non-topological trials in this analysis, we still find a relationship between ball travel time and reaction time ( $r=$ $0.29, t(238)=4.6, p=7.2 * 10^{-6}$ ) but do not find statistical evidence that the slopes differ between non-topological, topological towards, and topological away conditions $(F(2,236)=1.01, p=0.37)$. Furthermore, if we remove topological trials that were not fully contained (Porous level 3 and Stopper levels $2 \& 3$ ), this relationship remains $(r=0.34, t(106)=3.7, p=0.00037)$ and we still do not find changes with motion condition $(F(1,105)=0.78, p=0.38)$.

[^505]:    ${ }^{5}$ This analysis considers all topological conditions, including the porousness and stopper trials in which simulation in theory could reach the incorrect goal. However, limiting this analysis to just the size and complexity trials (which were all fully contained) produces the same qualitative results.

[^506]:    ${ }^{1}$ This model did not detect a significant effect of age, which was treated as a continuous variable ( $\beta=0.03, S E=0.02, z=1.43, p$ $=.15$ )

[^507]:    ${ }^{1}$ The effect of $\lambda$ on model performance is gradual enough, and the differences between the different model variants large enough, that not much fine-tuning is required to make our point.

[^508]:    ${ }^{2}$ Franke and Degen (2016) also consider the combination $\mathcal{S}_{1} /$ $\mathcal{H}_{1}$, i.e., a non-iterative model. This would not do any better here, as we see in Table 3 that $\mathcal{H}_{1}$ never makes better predictions than $\mathcal{H}_{2}$.

[^509]:    ${ }^{3}$ Change in deviance between the two models, $\Delta D=59.26$, where deviance is -2 times log likelihood, follows a chi-square distribution with degrees of freedom equal to the number of parameters added to the more complex model. Six prior values must be specified to the labeling model-two each for color, shape and size itemsyielding $\chi^{2}=59.26, d f=6, p<0.001$.

[^510]:    ${ }^{1}$ Note that even the possibility of simultaneously performing multiple responses falls outside the scope of Niv et al.'s (2007) model, according to which all action-latency pairs are serially implemented (i.e., no alternative actions may be executed while the time indicated by the chosen latency passes).
    ${ }^{2}$ Indeed, Niv et al.'s (2007) model hard-codes into the definition of each state several variables that are needed to discover an optimal policy in the environments addressed by the model (e.g., the time elapsed since the last response when modeling interval schedules and the number of presses since the last reward when modeling ratio schedules).

[^511]:    ${ }^{1}$ Only participants who contributed to all trials were included in this analysis

[^512]:    ${ }^{1}$ The method of generating functions by Markov chains also applies to independent Bernoulli trials parameterized the probabilities of single elements (e.g., the probability of heads or tails), and it also generates higher-moment statistics such as variance (e.g., Sun \& Wang, 2015). Here we only present the main results and the exact generating functions are omitted.

[^513]:    ${ }^{1}$ We removed words such as 'excellent' from the task to reduce the likelihood that word valence in this task would influence future participant responses. This quiz block was followed by three more blocks.
    ${ }^{2}$ Due to an off-by-one error in our code, the first statement from the block after the word search task was erroneously displayed before the word search task. We excluded this error trial from the analysis.
    ${ }^{3}$ It should be noted that in this ANOVA, we are treating the block number as a factor variable rather than a numeric variable due to the non-linear relationship between block number and participant response; including the block number as a numeric variable yields qualitatively the same results.

[^514]:    ${ }^{1}$ Traditionally, general object similarity was manipulated as the membership of two objects to a same taxonomic category (e.g., Gentner \& Kurtz, 2006). However, general object similarities could also refer to other commonalities between objects taken in isolation, like, for example, intrinsic and functional properties.

[^515]:    ${ }^{1}$ In pilot testing we found no effect of subtle wording differences for these metaphorical phrases (i.e. "Working on a puzzle" versus "Solving a puzzle"; "Climbing a mountain" versus "Scaling a mountain"). In every case, about $90 \%$ of participants from the general public chose puzzle.
    ${ }^{2}$ Of note, the order of the metaphor preference judgment and the entailment ranking tasks was counterbalanced for the sample from the general public. Since there were no differences in how people responded on the two orderings, we did not counterbalance these tasks for the academics.

[^516]:    ${ }^{1}$ We do not view the boundary between the "literal" and the "metaphorical" as so sharp, "metaphoricity" is best thought of a continuous rather than categorical variable (cf., Rumelhart, 1979). That said, the distinction is still useful and informative in the context of understanding the nature of abstract thought (Lakoff \& Johnson, 1980).

[^517]:    1 MacLaury (1989) characterizes the application of Zapotec body part terms to parts of inanimate objects as analogical or metaphorical mappings from human body parts. An alternate view, taken by Levinson (1994) in his work on Tseltal, is that the terms are general abstractions and not metaphorical.

[^518]:    2 Since the instruction for the practice trial contained the meronyms 'head' and 'leg', a subvocal rehearsal effect on the test trials cannot be ruled out.

[^519]:    ${ }^{3}$ An anonymous reviewer points out that, since the instructions indicated there was a correct answer for each triad, the English speakers' responses may have been motivated by trying to find counterintuitive answers, as in an IQ test.
    ${ }^{4}$ A total of nine Novel Objects were originally designed by the third author and produced for the project Spatial language and cognition in Mesoamerica ('MesoSpace'; NSF Award \#BCS0723694) directed by the second author.

[^520]:    ${ }^{5}$ However, this result is also consistent with subvocal rehearsal being already at ceiling even in the non-primed condition.

[^521]:    ${ }^{1}$ Since in NR more entities bear the mentioned feature, and therefore attention is distributed across more objects, we do not take this difference to reflect any preference for a gricean/contrastive reading of the adjective.

[^522]:    ${ }^{1}$ The participant size was unbalanced because the original authors were concerned about unpredictability. For our purposes it should not impact our results.

[^523]:    ${ }^{2}$ Note that social influence also could have occurred at other places in the model (e.g., search). However, preliminary testing showed that the model actually fit worse when social influence occurred in a stage other than consideration.

[^524]:    ${ }^{1}$ Syllogisms are deductive reasoning problems in which one or more conclusions are derived from two premises. The two premises are categorical propositions which are assumed to be true. For example, the conclusion "All As are Cs" can be drawn from the two premises "All As are Bs" and "All Bs are Cs". The abstract terms, A, B and C can be substituted by concrete categorical terms like "apple" and "fruit".

[^525]:    ${ }^{2}$ The syllogism mentioned here is the MM4 syllogism in the study: Premise 1 as "Most As are Bs"; Premises 2 as "Most Bs are Cs "; and conclusion as "Most Cs are As".

[^526]:    ${ }^{3}$ Quantifiers with higher word frequencies are supposed be processed faster due to the availability heuristic or ease of retrieval, having a faster response time in a spontaneous timed task. A significant decrease of the recognition time for words with higher word frequency (e.g., O'Malley \& Besner, 2008) is generally found. The word frequency measures were taken from the British National Corpus: http://www.natcorp.ox.ac.uk.

[^527]:    ${ }^{4}$ The list can be retrieved from www.cc.uni-freiburg.de/data.

[^528]:    ${ }^{5}$ We performed the Levene's test for equality of variances and the results were not significant, i.e. equal variance can be assumed.

[^529]:    ${ }^{1}$ Left-side bias in face perception refers to the phenomenon that people often judge chimeric faces formed by two left halves of the original face to be more similar to the original face than those formed with two right halves (Brady, Campbell, \& Flaherty, 2005). This effect was also observed in Chinese literates viewing mirrorsymmetric Chinese characters (Hsiao \& Cottrell, 2009).

[^530]:    ${ }^{2}$ The part-whole paradigm (Tanaka \& Farah, 1993) can also demonstrate HP (Maurer et al., 2002). However, it involves memory performance heavily (Piepers \& Robbins, 2012). As the focus of this study is to examine perceptual effects, the complete composite paradigm was used to minimize memory demands and response biases (Richler, Cheung, \& Gauthier, 2011).

[^531]:    ${ }^{3}$ Hsiao and Cottrell (2009) showed that when character halves were misaligned, the HP effect of Chinese characters disappeared, suggesting that the effect reflected the inability to selectively attend to aligned character halves rather than inhibition control.

[^532]:    ${ }^{1}$ The percentages are calculated by Antón-Méndez (p. 129, Table 6 ) and they represent the frequency of the gender pronoun mistake (68 and 10 , respectively) with respect to the total number of pronouns produced where this particular mistake could have occurred.

[^533]:    ${ }^{1}$ Weight, mass, and density as physical notions have certainly been studied in development, across infancy (e.g. Baillargeon 2004), childhood (e.g. Carey 1999 2009), and adulthood (e.g. Hamrick et al. 2016. But there the concern is with questions such as 'When do infants realize big things move small things' and 'When do children understand weight and density are separate', and 'Can adults tell which block is heavy', not 'Do children think being weighed down relates to being sad'.

[^534]:    ${ }^{2}$ That is, with the intuition of the Western adult authors of this paper.
    ${ }^{3}$ Although, in contrast, consider the value and importance currently associated with slim technology products, or human figures. By the same logic, slim would imply less "stuff". Thus, this explanation is insufficient on its own.

[^535]:    ${ }^{4}$ At this age children possess a sufficiently large vocabulary and can correctly point to a heavier object when prompted, but have not received much formal education.
    ${ }^{5}$ One participant designated the heavy box 'The Hulk' and the light box 'Captain America'. Captain America was funny, and The Hulk was not smart.

[^536]:    1 "The text was a two-page, 1385 -word passage entitled Space Travel (see Appendix A) that described effects of space travel on the human body at an introductory level. It was adapted from several sources including two Web-pages from an educational Web

[^537]:    ${ }^{1}$ In this paper we will use the notation $\tilde{M}$ to denote a matrix having the same column vectors of another matrix $M$, but sorted in an inverse order.

[^538]:    ${ }^{1}$ Actually an analogous model of subjective belief update of the cell probabilities (using Dirichlet distributions) which is then compared to ideal patterns yields the same results (not elaborated here).

[^539]:    1 All data and analyses can be accessed on the Open Science Framework at osf.io/y6hqp.

[^540]:    ${ }^{1}$ http://www.brainmap.org/ale/

[^541]:    ${ }^{1}$ A separate, unrelated study comparing forms of scaffolding for essays was run concurrently in the same unit. The target essays did not involve the computer model or graphs, and condition assignment was independent for the two studies. Our results do not show condition effects of the unrelated study.
    ${ }^{2}$ The full unit is available at http://wise.berkeley.edu/ previewproject.html?projectId=18309
    ${ }^{3}$ The post-test is available at http://wise.berkeley.edu/ previewproject.html?projectId=18463

[^542]:    ${ }^{1}$ 'Verbal estimation' is a misnomer stemming from experiments where participants verbalized their estimates of duration, before the introduction of computers.

[^543]:    ${ }^{1}$ Based on $\mathrm{n}=55$ model runs and $\mathrm{n}=55$ human participants.

[^544]:    ${ }^{1}$ The formulation here appears different from (Shafto et al.,

[^545]:    2014) because the setup is different in two ways. First, the query and the label are kept distinct to match the setup of exploration. This gives rise the two likelihoods in Eq. 4, one for $y$ and one for $x$. It also gives rise to the expectation in Eq. 5 with respective to the predictive distribution over $y$. Second, in this setup, the teacher knows the concept from which the pattern is drawn from but not the pattern itself; thus, there is the marginalization over patterns in Eq. 5.
[^546]:    ${ }^{1}$ For the full set of problems as well as example videos for how the model described below solves the different trials please see: https://github.com/iyildirim/ stack-reconfiguration-problems
    ${ }^{2}$ Because several participants had trouble to successfully generate the trials 35-37, we will focus on the first 34 trials.

[^547]:    ${ }^{1}$ All mixed-effects models here and hereafter were implemented using the lmer4 package in R (Bates, Mächler, Bolker, \& Walker, 2015), and all effects were calculated by a likelihood-ratio test against the null-model that only had the random effect of subject (random intercept model).

[^548]:    ${ }^{1}$ A complete implementation of the model, raw data and analyses, and links to the experiments and pre-registration of hypotheses and method can be found at https://github.com/ejyoon/ cogsci2017

[^549]:    ${ }^{2}$ In addition, the model has a few parameters not of theoretical interest. For the purposes of generating model predictions a priori, we assign values to these parameters consistent with the previous literature with this class of models: the speaker optimality parameter ( $\lambda_{1}$ assigned to 2 ); the pragmatic speaker optimality parameter $\left(\lambda_{2}\right.$ to 2 ); the value scale parameter ( $\alpha$ to 1 ) in the utility function; and the parameter governing the cost of producing a negation $(C(u)$ to 2).

[^550]:    ${ }^{1} \mathrm{https}: / /$ code.google.com/archive/p/word2vec/
    ${ }^{2} \mathrm{http}: / /$ download.tensorflow.org/data/questions-words.txt
    ${ }^{3}$ Training with fewer data (e.g., 50\%) does not lead to qualitatively different results.
