Research in the causal graphical model tradition has rarely considered the cognitive processes involved in causal-based judgments. A limited sampling approach to building causal representations (a) is psychologically plausible, (b) accounts for the key discrepancy between graphical models and human judgments (Markov violations), and (c) explains why those discrepancies manifiest themselves in multiple causalbased tasks. Yet, it doesn't deny that people are sophisticated causal reasoners-they are, however, limited ones. As a process model, the causal sampler allows the causal graphical model framework to be extended to new phenomena, such as within- and between-subject variability and response times.

## Appendix

To calculate $\pi(q)$ (the probability of being in some state $q$ ), we simply use the normative calculation for each potential state. For example, when causal relations are generative, operate independently, and combine according to a noisy-or integration rule, $\pi(q)$ is defined as:

$$
1-\left(1-b_{j}\right) \prod_{q_{i} \in P a_{k}\left(q_{j}\right)}\left(1-m_{i j}\right)^{i n d\left(q_{i}\right)}
$$

where $b_{j}$ is the strength of causes exogenous to the model on the node, $\operatorname{Pa} k\left(q_{j}\right)$ denotes the parents of $q_{j}$ in the causal model, $m_{i j}$ denotes the causal strength between node $j$ and parent $i$, and $\operatorname{ind}\left(q_{i}\right)$ is an indicator function that yields 1 if feature $q_{i}$ is present, 0 otherwise.

# Understanding the Role of Perception in the Evolution of Human Language 

Isaac Davis (isaacd@andrew.cmu.edu)<br>Department of Philosophy, Carnegie Mellon University

#### Abstract

In this paper, we propose a flexible modeling framework for studying the role of perception in language learning and language evolution. This is achieved by augmenting some novel and some existing evolutionary signaling game models with existing techniques in machine learning and cognitive science. The result is a "grounded" signaling game in which agents must extract relevant information from their environment via a cognitive processing mechanism, then learn to communicate that information with each other. The choice of cognitive processing mechanism is left as a free parameter, allowing the model to be tailored to a wide variety of problems and tasks. We present results from simulations using both a Bayesian perception model and a neural network based perception model, which demonstrate how perception can "preprocess" environmental data in a way that is well suited for communication. Lastly, we discuss how the model can be extended to study other roles that perception may play in language learning. Keywords: Evolutionary Signaling Games, Perception, Language Evolution, Reinforcement Learning

## Introduction

In this paper, we are interested in studying three broadly defined types of interaction between perception and language learning. The first, and perhaps most obvious, is how our perceptions of the world constrain and affect our ability to learn language. The second type of interaction is the reverse of the first- how does learning a language shape our perceptions of the world? The third interaction, with a long history of philosophical inquiry, is how differing cognitive representations between agents affects their ability to communicate with each other. We propose a flexible modeling framework that can be used to represent and study all three types of interactions between perception and language learning.

This framework has two core components. The first are evolutionary signaling games which have been used extensively to explain a wide variety of communication phenomena in animals, from mating calls and warning calls in mammals and birds, to pheromone signaling in insect communities. More recent work has applied these models to the evolution of human language and human linguistic phenomena, such as compositionality (Franke 2015) and convex perceptual categories (Jager 2007, O'Connor 2014). These models typically represent a situation in which two agents must coordinate their behavior in such a way as to achieve some common goal, but without any pre-defined common language with which to communicate.

We shall see, however, that the standard signaling game model is not well suited for studying interactions between cognition and language learning. In order to represent perception and language in the same model, we derive a "grounded" signaling game, in which agents respond to raw sensory inputs, rather than cleanly-defined information states. We
achieve this using unsupervised learning techniques from Machine Learning and Cognitive Science.

In the following section, we present the relevant background in signaling games and reinforcement learning, and briefly discuss why the standard model is not yet equipped for studying interactions between perception and language learning. We then present our grounded signaling game model, and draw on literature in Deep Reinforcement Learning to derive an effective learning rule. In order to avoid introducing too much complexity at once, we first present the model with a "trivial" perception mechanism, consisting of the identity map on sensory inputs. After deriving the learning rule for this model, we then outline how to incorporate a non-trivial perception mechanism, and briefly discuss the two perception mechanisms we will test. We then present results from a battery of experiments in which the agents must learn to communicate structured visual information from a synthetic image environment. These results provide insights into the role of perception as a "pre-processing" step for communication, and reveal some interesting interactions between the type of environment and perception mechanism. Lastly, we discuss how the current model can be extended to study all three types of interaction addressed in the introduction.

## Background and Related Material

## Signaling Games

In a two-player signaling game, the sender observes an information state $d \in \mathcal{D}$, drawn from some probability distribution $P(\mathcal{D})$. The sender then chooses a signal $x \in X$ according to some decision rule, and transmits the signal to the receiver. The receiver then observes the signal, and chooses some act $a \in \mathcal{A}$ according to the receiver's decision rule. Both players then receive a payout $R(d, a)$, which is a function of the state, and act, but not the signal. The game is fully cooperative, in that both players receive the same payout every round.

The sender's decision rule can be represented by a function assigning each state $d$ to a probability distribution $P_{s}(x \mid d)$ over signals, and likewise for the receiver's rule $P_{r}(a \mid x)$. With this notation, the expected reward for both players is given by

$$
\begin{equation*}
E\left[R \mid P_{s}, P_{r}\right]=\sum_{d \in \mathcal{D}, x \in X, a \in \mathcal{A}} P(d) P_{s}(x \mid d) P_{r}(a \mid x) R(d, a) \tag{1}
\end{equation*}
$$

An evolutionary signaling game is played for many rounds, and after each round, players update their strategies according to some learning rule. The most well-studied and often used form of reinforcement learning in signaling games is Roth-Erev reinforcement learning. A Roth-Erev learning agent (the sender, for this example) is represented by a set of decision parameters $W^{s}$, one parameter for each state-signal
pair. Each weight $w_{i, j}^{s}$ represents the sender's unnormalized probability of choosing signal $x_{i}$ given state $d_{j}$, and the RothErev update rule is very simple. If in one round of play the sender observes state $d_{j}$, chooses signal $x_{i}$, and receives reward $R$, then the sender updates weight $w_{i, j}^{s}$ by some fixed proportion of the reward, $\Delta w_{i, j}^{s}=\alpha R$, and leaves all other weights unchanged.

In a signaling game with two equiprobable states, RothErev reinforcement learning will always converge to a signaling system equilibrium, in which the correct act is always chosen. In games with more than two states, or with nonuniformly distributed states, Roth-Erev learning will sometimes converge to a partial pooling equilibrium, in which some states are communicated accurately, and others are "pooled" into a single signal. Such outcomes are Nash Equilibria, meaning that neither player can improve the outcome by unilaterally changing their own strategy. The probability of converging to such partial pooling equilibria increases with the number of states (Huttegger, Skyrms, Smead, \& Zollman 2010).

While our general framework is compatible with any signaling game model, the experiments for this paper will be based on the Sim-Max game (Jager 2007), a variation of the standard signaling game. In a Sim-Max game, the receiver's goal is to guess which state the sender observed, and the reward function is a distance metric representing "similarity" between states. Such models are used when the state space is much richer than the signal space, and one-to-one state-signal mappings are no longer possible. An example of this is coloreven though colors vary continuously, we employ a relatively small number of words for describing them.

## Limitations of the Standard Model

The Roth-Erev reinforcement learning model is favored in signaling games for its simplicity and minimality of cognitive assumptions. However, there are two factors that prevent us from using the standard model for our purposes. The first factor is entirely practical. In particular, Roth-Erev reinforcement learning, while simple and well studied, does not scale well to larger problems, as it requires a single decision parameter for each state-signal pair. This makes Roth-Erev learning prohibitively slow to converge on large problems, and restricts us to relatively small simulations.

The second problem with the standard model is more conceptual. In the standard treatment of signaling games, states are represented as uniform, discrete "labels," or in the usual Sim-Max game as a uniformly distributed compact subset of Euclidean space. The key feature in these models is that there is no internal structure to the states themselves. That is, the players cannot discriminate between two states except through the reward function- two different states are either identical or not, but any further delineation between states can only be inferred from their effect on the payout. This, however, is often regarded as an advantage of the standard representation, rather than a limitation. The agents need not be
endowed with an inner mental language (Skyrms 2010), they need not know what the game is "about," or even that they are playing a game at all. It is certainly important, if we wish to study interactions between perception and language-learning, that we not make any restrictive cognitive assumptions which would "screen off" the cognitive details of interest. However, outside of very simple or tightly controlled experimental settings, the standard representation actually imposes some very strict assumptions about the agents' perceptions, albeit implicitly.

To illustrate this, consider the following two very similar, but not identical signaling games: in Game 1 , the sender observes one of ten cards $C_{1}, \ldots, C_{10}$, each of which depicts a digit $0-9$, and sends one of ten signals. The receiver must pull on one of ten levers, each of which bears a digit $0-9$. If the card and chosen lever show the same number, both players receive a reward of 1 , otherwise they receive no payout. This game fits exactly into the signaling game framework described above.

Now consider Game 2: in Game 2, the signals and the receiver's actions are the same as Game 1. However, instead of observing one of ten cards, the sender now observes a card depicting a handwritten digit $0-9$. How would we represent the state space for Game 2? A first guess might be to represent it as having the same state space as Game 1 , since each observation depicts one of 10 digits. But unlike Game 1, we cannot guarantee uniformity across separate instances of the same digit. Not all instances of 0 will look the same, and so they are distinct information states. To assume that they are not distinct information states is to assume that the sender perceives them as the same, or recognizes that they are of the same category. But these are acts of cognition. Seeing a digit handwritten on a card is not the same an recognizing which digit it depicts, or even recognizing that it is a digit at all. In this sense, the standard approach of representing states and acts as finite sets of distinct labels implicitly imposes presupposes a fixed way in which agents perceive, recognize, and process their environments.

This brings us to the two underlying principles of our framework. First, in order to represent all of the information available to agents, without explicitly assuming how they perceive or represent that information, we must represent states as raw sensory inputs, rather than discrete information states. Second, because sensory inputs tend to be high-dimensional, it is no longer the case, as with the standard signaling game, that states cannot be distinguished except through the reward function. In particular, Unsupervised Learning algorithms can infer informational structure from high-dimensional sensory inputs without any feedback or supervision. Thus, by integrating an unsupervised perception model into a "grounded" signaling game, we can represent the evolution of both the external signaling language and the agents' internal representations in the same framework.

## The Model

In this section, we present the model used in the experiments for this paper. We first present the model with a "trivial" perception mechanism, which performs no significant cognitive processing. Once we derive the learning rule for this model, we then outline how a non-trivial perception mechanism can be incorporated. The framework is designed to place no restrictions on what perception model we use, and so we will test two mechanisms, representing two schools of thought on modeling cognitive processing.

## The Grounded Signaling Game

In the experiments we present here, the state space $\mathcal{D}$ will be a synthetic image environment, presented to the sender as a vector of raw pixel values, and the signal space $X=\{0,1\}^{k}$ will consist of binary vectors of length $k$. As with the SimMax game, the receiver's action will be produce a guess dout as to which state $d^{\text {in }}$, the sender initially observes, based on the sender's signal $x$. The reward function will be a distance metric representing similarity between images.

Recall that a Roth-Erev learning agent requires one parameter for each state-signal pair. In these experiments, however, we will use 36 -pixel binary images, and signals between 4 and 36 bits in length. Even though only a small number of possible images $d \in\{0,1\}^{36}$ will ever appear with non-zero probability, the players do not know ahead of time which images are present, or how many appear with positive probability. This is an important distinction, as the receiver must reconstruct the original image pixel-by-pixel, rather than simply guessing from a list of potential images. Therefore, defining a Roth-Erev reinforcement learning agent for this game would require up to $2^{72}$ separate decision parameters for each player. Clearly this is intractable even for small images, and we must look elsewhere to derive a tractable learning rule. To this end, we draw on the representational flexibility of Artificial Neural Networks (ANNs).

Figure 1: Information flow for one round of the signaling game

Figure 1 depicts a single round of the signaling game. Rather than defining the sender with one decision parameter per state-signal pair, we define a decision rule $P_{s}\left(x \mid d^{\text {in }}, W^{s}\right)$ with one parameter per state-signal coordinate pair. Given a state $d$, we define, for each signal-coordinate $x_{i}$ :

$$
\begin{equation*}
P_{s}\left(x_{i}=1 \mid d\right)=\sigma\left(\sum_{j=1}^{n} W_{i, j}^{s} d_{j}\right) \tag{2}
\end{equation*}
$$

where $\sigma$ is the standard sigmoid activation function $\sigma(x)=$ $1 /\left(1+e^{-x}\right)$. Those familiar with ANNs will note that this is the standard expression for the activation value of a unit with sigmoid activation function. In the stochastic network corresponding to this game, the activation value is treated as a probability, and the output of unit $x_{i}$ is sampled from the Bernoulli distribution $x_{i} \sim \operatorname{Bernoulli}\left(P_{s}\left(x_{i}=1 \mid d\right)\right.$ ). Each weight $W_{i j}^{s}$ determines, in some sense, the "importance" of coordinate $j$ in determining the value of signal component $x_{i}$. The sender then generates the signal $x$ by first computing the activation probability for each signal coordinate, then independently sampling each coordinate from the computed Bernoulli distribution. Thus, the sender's probability of sending signal $x$ given object $d$ factors as:

$$
\begin{equation*}
P_{s}(x \mid d)=\prod_{i=1}^{k}\left(P_{s}\left(x_{i}=1 \mid d\right)\right)^{x_{i}}\left(1-P_{s}\left(x_{i}=1 \mid d\right)\right)^{1-x_{i}} \tag{3}
\end{equation*}
$$

The receiver's distribution is defined similarly, with the roles of $d$ and $x$ being reversed. With $P_{s}$ and $P_{r}$ defined as above, the expected reward function in equation (1) can be interpreted as an objective function $J\left(W_{s}, W_{r}\right)=E\left[R \mid P_{s}, P_{r}\right]$ to a multi-agent optimization problem, where both players wish to maximize $J\left(W_{s}, W_{r}\right)$, but each player directly controls only one set of parameters. For this experiment in particular, the cooperative objective is to output an image that is most similar to the input image, which is the same objective used in training certain types of auto-encoders (a type of unsupervised ANN, trained to accurately reconstruct its own inputs). Thus, we can efficiently represent a single round of this signaling game as a single forward pass through the three-layer stochastic-sigmoid auto-encoder network shown in figure 1.

## The Learning Rule

An auto-encoder, like most feed-forward neural networks, is generally trained using some variation of gradient descent via back-propagation of errors ${ }^{1}$. In each step of the backpropagation algorithm, an input vector is passed through the network, generating a hidden representation (in this case signal) from which the latter half of the network attempts to reconstruct the original input. The error signal (difference between input and output) at each unit is "propagated" backwards, and each weight is adjusted according to its "effect" on the resulting error. Back-propagation algorithms have been extremely successful in training neural networks to perform highly complex tasks, so it is tempting to co-opt the backpropagation algorithm as a "learning rule" for our two agents. However, even though we can represent our signaling game with a three-layer feed-forward network, a key assumption of the model prevents us from using back-propagation directly. In particular, the back-propagation algorithm computes the update to layer $l$ as a function of the parameter and activation

[^317]values of layer $l+1$. In this scenario, however, each layer represents a separate human agent, who cannot share parameter information with each other, thus preventing the requisite gradient information from flowing across agents.

Because of this, we instead use a REINFORCE learning rule, first named in Williams (1992). Consider a single round of the signaling game in which sender observes state $d=\left(d_{1}, \ldots, d_{n}\right)$, sends signal $x=\left(x_{1}, \ldots, x_{k}\right)$, receiver guesses state $d^{\prime}=\left(d_{1}^{\prime}, \ldots, d_{n}^{\prime}\right)$, and both players receive reward $R\left(d, d^{\prime}\right)$. We define $\Delta W_{i, j}^{s}$ and $\Delta W_{i, j}^{r}$, the weight updates for sender and receiver, as

$$
\begin{align*}
\Delta W_{i, j}^{s} & =\varepsilon\left(R\left(d, d^{\prime}\right)-b_{i j}\right)\left(x_{i}-P_{s}\left(x_{i}=1 \mid d\right)\right) d_{j}  \tag{4}\\
\Delta W_{i, j}^{r} & =\varepsilon\left(R\left(d, d^{\prime}\right)-b_{i j}\right)\left(d_{i}^{\prime}-P_{r}\left(d_{i}^{\prime}=1 \mid x\right)\right) x_{j} \tag{5}
\end{align*}
$$

where $\varepsilon$ is a learning rate and $b_{i j}$ is a reinforcement baseline. The main property of REINFORCE rules, as shown in (Williams 1992), is that the weight updates shown in equations (4) and (5) are unbiased estimates of the true gradient of $J\left(W_{s}, W_{r}\right)$, the expected reward function. That is, $\left(R\left(d, d^{\prime}\right)-b_{i j}\right)\left(x_{i}-P_{s}\left(x_{i}=1 \mid d\right)\right) d_{j}$ is an unbiased estimate of $\partial J / \partial W_{i j}^{s}$, and $\left(R\left(d, d^{\prime}\right)-b_{i j}\right)\left(d_{i}^{\prime}-P_{r}\left(d_{i}^{\prime}=1 \mid x\right)\right) x_{j}$ is an unbiased estimate of $\partial J / \partial W_{i j}^{r}$. This allows the two players to cooperatively implement an approximate gradient descent algorithm, despite the fact that neither player is explicitly computing any gradients. This rule is both computationally inexpensive and avoids the information-sharing problem of backpropagation, so it is well suited to our task.

Even though equations (4) and (5) are unbiased estimates of the true gradient, they can be very high variance estimates, so outside of very simple tasks, the "pure vanilla" REINFORCE rule (i.e. $b_{i j}=0$ ) can be hopelessly slow to converge. We therefore use a minimum variance, unit-specific baseline derived in Bengio (2013), given by the expression.

$$
\begin{equation*}
b_{i j}=\frac{E\left[\left(h_{i}-\sigma\left(a_{i}\right)\right)^{2} R\right]}{E\left[\left(h_{i}-\sigma\left(a_{i}\right)\right)^{2}\right]} \tag{6}
\end{equation*}
$$

where $h_{i}$ is the output value and $\sigma\left(a_{i}\right)$ the activation value of unit $i$. This can be easily computed on the fly by maintaining moving averages of weight updates and rewards over time.

## Adding Perception to the Model

The signaling game model we just introduced is "grounded," in the sense that states are represented as sensory inputs, but we have yet to incorporate a perception mechanism. While perception is a broadly defined and widely studied subject, we will adopt a very general stance on what constitutes "perception." We will take perception to be any map $F: \mathcal{D} \rightarrow \mathcal{Z}$ from states (represented as sensory inputs) to lower-dimensional internal representations $Z$. These internal representations can be interpreted as the features, categories, concepts, patterns, rules, etc. from which our higher-level decisions are made. For these particular experiments, we shall use perception models that learn both a recognition map and a generative map. The recognition map $F: \mathcal{D} \rightarrow Z$ infers a latent
representation $z$ from an object $d$, while the generative map $F^{-1}: Z \rightarrow \mathcal{D}$ generates an object $d$ from an internal representation $z$ (this is a slight abuse of notation, as the generative map will not in general be the inverse of the recognition map).

Figure 2: Perception as a pre-processing step prior to signaling game

In the experiments we present here, perception will take the form of a pre-processing step (figure 2). Prior to playing the signaling game, each player will independently sample images from their environment, engaging in unsupervised learning, training their recognition maps $F_{s}, F_{r}$ as well as generative maps $F_{s}^{-1}, F_{r}^{-1}$. Once the perception mechanisms have been trained, the signaling game proceeds as usual, except that the sender now makes their signaling decision $P_{s}\left(x \mid z_{s}^{i n}, W^{s}\right)$ as a function of the sender's internal representation $F_{s}\left(d^{i n}\right)=z_{s}^{i n}$ of the state $d^{i n}$. The receiver then observes the signal, and first generates an internal representation $z_{r}^{\text {out }}$, which is then mapped to output image $d_{r}^{\text {out }}$. The reward value is then computed as usual, and we apply the same REINFORCE updates in (4)-(5) to the player's decision parameters.

## Representing Perception

There has been surge of interest in computational models of perception, from both Machine Learning and Cognitive Science. We will test two different models, representing two main approaches that have been taken in studying perception.

The first are Bayesian models, which represent perception as a rational inference problem. Given object $d$, we infer a latent representation $z$ by maximizing the posterior probability $P(z \mid d) \propto P(d \mid z) P(z)$ using Bayes' rule. This requires an object model $P(d \mid z)$, as well as a prior distribution $P(z)$ over all possible latent representations. We shall use an Infinite Latent Feature Model, which learns a binary feature representation of visual data, without having to pre-define a fixed number of latent features. This is achieved using an Indian Buffet Process (IBP) prior, which defines a probability distribution over binary vectors with an unbounded number of features (Griffiths \& Ghahramani 2005). While exact inference over this distribution is intractable, MCMC sampling methods can be used to perform tractable inference.

The second perception mechanism we shall test a Helmholtz Machine (Dayan et al 1995), representing a neurocomputing model of perception. A Helmholtz Machine is a type of variational auto-encoder, which learns a lowdimensional representation of sensory inputs by iteratively inferring latent representations from data, then reconstructing simulated data from internal representations. These two steps are iterated in an alternating "wake-sleep" cycle, with the objective of minimizing the Kullback-Liebler divergence between the true distribution and the generative distribution. The result is a low-dimensional binary representation of the data, encoded on the hidden units of the network. While the Helmholtz Machine in its original form has been rendered largely obsolete by more powerful methods, we use this architecture for its relative simplicity and pedagogical value in the context of our goals.

## Experiments and Results

In this section we describe the environments and experimental conditions we tested, present the results of these experiments, and discuss their implications.

## Experimental Conditions

We tested three different 36 -pixel synthetic image environments, each intended to represent a different kind of informational structure. For the first environment (PICTURE), we defined 8 specific 36-pixel images, each equally likely to appear, and assign 0 probability to all other images. These 8 images were chosen so as to avoid recurring components or features across images. This serves as a baseline evaluation for the perception mechanisms- we can think of the PICTURE environment as representing a "traditional" signaling game setup, in which the "true" state space consists of 8 discrete states that share no common internal structure. In the context of our project, "there are only 8 things here" represents prior knowledge or recognition, and so the players must learn that their environment contains only these 8 images directly through their sensory inputs.

The second environment (FEATURE) consists of compositionally distributed images. We define four $3 \times 3$ pixel patterns (features), and generate each $6 \times 6$ pixel image by randomly selecting any number of the four features and compos-
ing them into a single image. This construction is based on an experiment in Griffiths \& Ghahramani (2005). The third environment (HIERARCHY) is hierarchically distributed over two categories: there are 12 images with non-zero probability, depicting either horizontal or vertical bars. Images are divided into category $A$ (vertical) and category $B$ (horizontal). Within each category, each image is equally likely to appear, but images from category $A$ are twice as likely to appear as images from category $B$. The FEATURE and HIERARCHY environment test the agents' abilities to learn non-trivial informational structure from the environment.

For each environment, we test a noiseless version, in which images are presented to the sender with binary pixel values, as well as two levels of corrupting noise, in which each pixel is independently perturbed before being shown to the sender. For a reward function, we test three different distance metricsHamming $\left(L_{1}\right)$, Euclidean $\left(L_{2}\right)$, and a patch-specific function that depends only on certain regions of the image.

## Results

Figure 3 shows a summary of results across our experiments, using the Hamming metric reward function (we observed no significant differences across reward functions). Convergence rates indicate the number of iterations required to achieve a threshold $90 \%$ of optimal performance, averaged over 5 runs for each condition. The Bayesian and Helmholtz columns correspond to the two perception models, while the Identify column indicates the trivial perception mechanism that performs no cognitive processing.

| Conditions |  | Bayesian |  | Helmholtz |  | Identity |  |

${ }^{1}$ Value indicates SD of mean-zero Gaussian noise
${ }^{2}$ Smallest bit-size that converged to optimum (best pooling outcome if optimum not achieved) across all runs *Indicates partial pooling outcome

Figure 3: Results
In the PICTURE environment, both perception mechanisms drastically improved convergence speed, by effectively reducing the scale of the problem from $2^{36}$ to 8 states. This pre-processing also smoothed over irregularities that would occur under the trivial perception mechanism, where the receiver would fix the value of certain pixels across all images. Introducing the perception mechanism allows the receiver to reconstruct the image based on their own internal representations of the environment, rather than by individually choosing the value of each output pixel.

In the FEATURE environment, convergence to the optimum was fast and reliable through all levels of noise, even
with the trivial model. The fact that communication is easier to learn in the FEATURE environment than the PICTURE environment, even though the former contains twice as many states as the latter, shows that it is not just the number of distinct states that affects learning, but the content of the states themselves. However, the trivial model was only able to converge to the optimum using a 6-bit signal, which is not minimal. The Bayesian perception mechanism, however, allowed the agents to correctly identify 4 latent features in their environment, which enabled them to learn to communicate using a minimal 4-bit signal. The Helmholtz model did not lead to any reduction in signal size. This is because the Bayesian model learns the number of latent features from the data, while the Helmholtz Machine uses a fixed number of hidden units. Thus the Bayesian model was able to learn a more efficient 4-feature representation than the network-based model, enabling more efficient communication.

In the HIERARCHY environment, convergence was fast and reliable under all 3 models, using a minimal 4-bit signal. The Helmholtz model is able to learn the more efficient representation in this environment, using one hidden unit to code for the category, and 6 more for each image within a category. This reduced convergence time by up to half. The Bayesian model, however, learns a less efficient representation, identifying 1 binary feature for each of the 12 images in the environment, and does not significantly improve convergence speed.

## Discussion and Future Work

The results from the previous section demonstrate how a perception mechanism can be incorporated into a signaling game model, and shed some light on the first interaction we raised in the introduction. In particular, we saw that a perception pre-processing step can enable faster and more robust cooperative learning from high-dimensional sensory inputs. We also saw that certain perception models can learn more efficient representations in certain environments. In this section, we discuss how the existing model can be extended to address the other types of interactions we wish to study.

## Other Roles of Perception

In the experiments presented here, perception was used strictly as a pre-processing step, but in order to better understand how language-learning can affect perception, we must allow the perception mechanisms to be trained in parallel with the signaling game. While the REINFORCE rule we present here does not scale well to very deep models with multiple hidden layers, recent advances in Deep Reinforcement Learning and Deep Q-learning allow us to scale the basic architecture up to very large tasks. Additionally, we may be interested in fixing the behavior of one agent, so that the non-fixed player learns the language of the fixed player. This would allow us to observe any influence that the fixed player's language has on the non-fixed player's learned representations.

## Perceptual Similarity in Communication

The model we present here already has most of what we need to address the third type of interaction, relating to perceptual similarity across agents. That is, we already represent the evolution of both the external language and the internal representations, so all we need is a means of quantifying "perceptual similarity" across multiple agents. To this end, we can use cross-systems analysis techniques like Representational Similarity Analysis (Kriegeskorte, N., Mur, M., \& Bandettini, P. A. 2008), a method for quantifying "representational similarity" between two different representation systems, regardless of the underlying topologies of the systems themselves. This would allow us to study inter-agent learning performance as a function of the similarity between their internal representations, and perhaps identify a "communicability threshold" of perceptual similarity below which no communication is possible.

#### Abstract

The present study provides evidence for far analogical retrieval, i.e., analogical retrieval across disparate task domains, as a result of analogical comparison. Participants read source stories, which were then retrieved after a filled delay through abstract letter-string cues that matched the relational form of key parts of stories. They then generated responses to an ambiguous letter-string analogy problem. Evidence was found for far analogical retrieval of higherorder relations because 1. comparison of letter-string analogies cued source stories specific to the relations showed in the letter-strings, and then 2. those same relations formed the basis for how subjects solved novel letter-string problems. The experiment offers support for the schema induction account of analogical retrieval, and suggests that people are more sensitive to relational structures than was previously thought.

Keywords: analogy; memory; reasoning; analogical retrieval; letter-string analogies

## Introduction

Analogical retrieval leads to many important insights in science and design. It appears that these insights often emerge as a result of analogical retrieval from vastly different domains to one's present situation. Despite this, studies of schema induction in analogical thinking have primarily focused on the relatively narrow domain of semantic differences between stimuli, and cross-domain effects have been rare. The schema induction account of analogical retrieval (Gentner et al., 2009) suggests that cross-domain analogical retrieval should be facilitated by a comparison of analogues, by promoting a structural alignment of common relations. A more general principle, or schema, is then assumed to be available as a memory probe for future mapping in analogous situations. Evidence for the schema induction account was established through a comparison of target analogues, i.e., late analogical abstraction. This effect has been demonstrated in both studies of cued-retrieval (Gentner et al., 2009) and problem solving (Kurtz \& Loewenstein, 2007).

The effect was demonstrated in the domain of negotiation with a controlled memory set (Experiment 4; Gentner et al.,
2009). Undergraduates read seven negotiation scenarios, with only one containing the target negotiation principle. After 30 minutes of a filled delay, half of the participants were given two example cases of a certain negotiation principle and were explicitly asked to compare them, noting the key parallels. The other half were given the two cases to read separately. They were subsequently asked to recall a source case that best matched the two target comparison cases. Participants that explicitly compared target cases were significantly more likely to retrieve the source cases than participants that read the target cases separately. It appeared the explicit comparison made the abstract schema directly available as a retrieval cue to the original story.

The main limitation to this literature is that most studies have only varied what Barnett and Ceci (2002) call the knowledge domain of the analogues, despite the possibility for retrieval across different task domains. Inherent to the schema induction account is the assumption that analogical comparison highlights relational structure regardless of surface features. That is, it allows a cross-domain mapping. However, as information is often relevant across different tasks, it is important to understand whether and how crosstask retrieval can occur. This is an important hole to fill in the literature.

In addition to investigating whether we can elicit remindings across task domains, we can further investigate whether the cross-task commonalities that can serve as the basis for analogical remindings are limited to specific levels of abstraction. That is, the present study investigated retrieval rooted in common surface features, first-order relations, and higher-order relations (respectively). Including these different levels of abstraction as controls for each other in the analyses ensured a more adequate test of analogical retrieval. That is, a retrieval based in surface features across task domains without relational controls is not very surprising, given people's sensitivity for retrieval of surface features (Gentner, Rattermann, \& Forbus, 1993). Further, retrieval of relational content across task domains is more valid when controlled for by the possibility of a surface feature retrieval. That is, it is more likely that a source story was retrieved because of a relational match to
the letter-string cue when a surface feature alternative was also possible.

The schema induction account assumes that analogical comparison abstracts one's stimulus representation, i.e., relational commonalities are highlighted, and mismatches of features are ignored. To further test this account it is important to examine the representation formed from the comparison independently from the test of retrieval. Gentner et al. (Experiment 1; 2009) used a post-retrieval transfer task to confirm participant representations, but scoring was based on how well participants' descriptions matched a target schema, not directly analyzing the schema used by the participants. Hofstadter's (1995) letter-string proportional analogies could be used as a clearer way of determining the type and level of representation a person currently has. For instance, if asked "Suppose the letter-string abc were changed to abd; how would you change the letter-string mrrjjj in 'the same way'?" (Hofstadter, p. 238), one answer could be mrrkkk, if succession relation is used because $k$ follows $j$, just as $d$ follows $c$. A higher-order response represents $a b c$ as 1-2-3 and $a b d$ as 1-2-4, as per their order in the alphabet. The quantity of different letters in the string $m r r i j j$ can also be represented numerically as 1-2-3. This higher-order relational mapping leads to the inference that the fourth term in the analogy should be a quantity successor of $m r r i j j$ that can be numerically represented as 1 -2-4, i.e., mrrijjj.

## Present study

The present study extends the late analogical abstraction effect (Gentner et al., 2009) to investigate far analogical retrieval, i.e., retrieval across disparate task domains. Letterstring analogies were used as cues to retrieve story narratives (see Figure 1). This will be referred to as far analogical retrieval, as analogues are retrieved across task domains, a significantly more disparate - and conceptually far - retrieval than in previous studies. Each comparison cue had one analogous initial source story that matches the underlying schema. A pilot study (Dekel, 2016) showed that these source stories could be retrieved by analogous stories, replicating the late analogical abstraction effect (Gentner et al.). In the present study, correct source story retrieval after the letter-string comparison provided evidence for far analogical retrieval. A subsequent transfer task with a novel letter-string analogy determined participant schema representation for each level of abstraction (surface features, first-order relations, and higher-order relations).

The main hypothesis was that participants that compare two target letter-string analogies that share a particular schema would retrieve the source story that emphasizes the same schema, significantly more than participants comparing target stories that do not share this schema. For the transfer task, it was hypothesized that participants will respond to the transfer task according to their schema condition (see Figure 4).

Figure 1: Comparison of simplified designs in Gentner et al. (2009) and the present study. While participants in Gentner et al. retrieved source stories from a comparison of story cues, participants in the present study retrieved source stories from a comparison of letter-string cues.

## Method

## Participants

One hundred and eighty-one first-year undergraduates from the University of Sydney subject pool were recruited online, and were given course credit for their participation. Participants were randomly allocated to one of three schema conditions: surface schema, first-order relational schema, higher-order relational schema. One participant did not complete the first filler task and another did not complete the analogy example page (both due to computer error), so their data was excluded from the analysis of retrieval rates.

## Materials

The experiment was completed online and all materials were webpages coded with HTML and JavaScript.

Source stories The three source stories, shown in Table 1 , were designed to differ in semantic content, but be equivalent in structure and length. Each story presented an initial conflict, and a subsequent resolution. Critically, the resolution of each story also provided the information that made up the target schema for that story, which would then either match or mismatch with the later letter-string analogies. The first story schema is simply changing an E to an $F$. It is considered a surface story because its similarity to the later cues is based on an identical change. The second story schema is succession (of Valerie by Sylvia), considered to be a first-order relational story because it is related to the later cues by virtue of one relation (succession) and no surface features. The third story schema is the correspondence of quantity to an order (number of staff to a day's order in the week), considered to be a higher-order story because it relies on a mapping of firstorder relations. That is, numerical representation connects the first-order relational structure of two types of succession: ordinal succession, as in the order of days in the week, and quantity succession, as in the number of staff allocated.

Table 1: Source Stories and Explicit Principles.

| Schema condition | Story text | Explanation text |
| :---: | :---: | :---: |
| Surface | John is an owner of a small-town computer company and wanted to advertise his company to the town. He printed out some flyers with large font size to put up. However, there was a typographical error in the flyers, with the title printing out as 'Elash Computers' instead of 'Flash Computers', which John knew would confuse potential customers if put up around town. As such, he had to rewrite the company name for the posters, changing the ' $E$ ' to an ' $F$ ', and printing them again. There was only a typo in the word 'Elash', so only the letter ' $E$ ' was changed from the letter ' $E$ ', to the letter ' $F$ ', correcting the word 'Elash' to 'Flash'. | Both pairs rely on the same rule: Change E to F. |
| First-order relation | Jerome is an advisor to the King of a large nation and wanted to confirm the successor to the throne. He thought of Valerie, who was the king's eldest daughter. However, the advisor found out that despite being the next in line to the throne, Valerie had run away to a mountain town because she did not want to take on the responsibilities associated with being a Queen. As such, he worked out that Sylvia should be the next in line to the throne as she is the second-oldest sibling. The order of succession in the kingdom is found by birth order, so if the first born child is not able to uphold the throne, then the second born is next in line. | Both pairs rely on the same rule: Succession. For example: <br> Triangle changes to square because of the number of sides, and G to H because of alphabetic order. |
| Higher-order relation | Julia is a manager at a local information centre and wanted to staff her centre efficiently. She usually has about three people working every day. However, the number of visitors to the centre increases consistently each day, with almost no visitors on Mondays and peak number of visitors on Sundays, so most days the centre is either overstaffed, or understaffed. As such, she decided that she will roster on an amount of staff that corresponds with the order of that day in the week. The centre will have one staff member on Monday, being the first day of the working week, two on Tuesday, and so on, with seven people working on Sundays. | Both pairs rely on the same rule: Order corresponds to quantity. For example: E (fifth in the alphabet) changing to F (sixth in the alphabet) = five symbols (letters or shapes) changing to six symbols. |

Letter-string analogue comparison Participants received one of three pairs of proportional letter-string analogies to compare, as shown in Figure 2. In the figure, all three pairs are presented together to facilitate comparison of the differences between each pair. The first pair was designed to induce the surface schema, the second the firstorder schema, and the third the higher-order schema. The same basic structure and symbols (letters and shapes) were used for all three of the comparisons. Below this comparison, participants read a short explanation of the target principle, shown in Table 1 and then completed a short test of the principle.

Procedure. The experiment was run as an online study through a series of webpages. Participants read three oneparagraph narratives and typed how each story was resolved. They then completed two minutes of an unusual uses task (Diamond, 2013) and a page designed to inform and train participants about the structure and function of proportional analogies.

Participants then completed the comparison task, as per their schema condition, and on the subsequent page were asked to retrieve the source story that matched the comparison they just did. They then completed two minutes of a new unusual uses task. Participants then responded to the letter-string proportional analogy Suppose that the letterstring $A B C$ was changed to $A B D$; how would you change the letter-string C S SNNN in the same way? Following this, participants rated some prototypical responses to the analogy, and then a subsequent follow-up page asking participants to indicate the extent to which they used any of the letter-strings or stories when generating the letter-string analogies. Figure 3 shows this procedure.

Figure 2: The three pairs of comparison cues. The surface comparison (a) makes it apparent that the critical change is that from $E$ to $F$, regardless of position in the string or presence of shapes. In the first-order relational schema comparison (b) the increase in the letters' alphabetic order and shape's number of sides, expresses the concept of succession. The higher-order relational schema comparison (c) connects the alphabetic succession of the initial strings to the ordinal succession of the latter shape or letter strings. The higher-order relationship numerical representation connects these two forms of succession.

## Results

## Far analogical retrieval

A chi-square test was conducted for the cross-tabulation of retrieval by schema condition (Table 2). The retrieval variable had four levels: null retrieval, surface story, firstorder story, and higher-order story. Schema condition had three levels: surface schema, first-order schema condition, and higher-order schema condition. The overall effect was significant, $\chi^{2}(6, N=179)=46.55, p<.001$, suggesting an association between people's schema condition and story retrieval rates. To investigate the specific effects, the conditions were collapsed into 2 x 2 tables for each predicted effect. For each effect, schema condition was recoded into a dichotomous variable of those in the target schema condition and those that are not. Retrieval condition
was recoded into a dichotomous variable of those that retrieved the target schema story and those that did not.

Figure 3: Experimental procedure.
Participants in the surface schema condition retrieved the surface schema story ( $86.4 \%$ ) significantly more than those not in the surface schema condition $(40 \%), \chi^{2}(1, N=179)=$ $34.51, p<.001$. Those in the first-order schema condition retrieved the first-order schema story ( $31.1 \%$ ) significantly more than those not in the first-order schema condition $(13.6 \%), \chi^{2}(1, N=179)=7.91, p<.001$. Those in the higher-order schema condition retrieved the higher-order schema story ( $37.3 \%$ ) significantly more than those not in the higher-order schema condition (10.8\%), $\chi^{2}(1, N=179)$ $=17.6, p<.001$. The main hypothesis was thus supported by these results as a comparison of letter-string analogies facilitated correct retrieval of source stories with the same underlying schema.

Table 2: Frequency of Story Retrievals by Schema Condition.

|  | Schema Condition |  |  |  |
| :--- | :--- | :--- | :--- | :--- |
| Story <br> retrieval | Surface | First- <br> order | Higher- <br> order | Total |
| Surface | 51 | 28 | 20 | 99 |
| First-order | 5 | 19 | 11 | 35 |
| Higher-order | 1 | 12 | 22 | 35 |
| Null | 2 | 2 | 6 | 10 |
| Total | 59 | 61 | 59 | 179 |

## Transfer response

Responses were coded through the schema they presumably expressed. As in Burns (1996), letter-string responses generated by two or fewer participants were collapsed into the category Other. Figure 4 shows the structural hierarchy of the three prototypical responses to the letter-string analogy task. Participant response of DSSNNN was considered a Surface response, since it only takes into account the $C$ changing into $D$. Participant responses of CSSOOO, CSSNNO, CSTNNO were collapsed into category First-order, since they all use the first-order principle of succession. Participant response of CSSNNNN was considered Higher-order, since it takes into the higherorder correspondence of numerical representation. Table 3 shows the frequencies of these responses for each schema condition.

A chi-square test was conducted of letter-string response by schema condition. Letter-string response had four levels: surface, first-order, higher-order, and other. Schema condition had three levels: surface schema, first-order schema condition, and higher-order schema condition. The overall effect was significant, $\chi^{2}(6, N=176.04)=176.04, p$ $<.001$, suggesting an association between people's schema condition and letter-string response rates. To probe the specific effects, the conditions were collapsed into $2 \times 2$ tables for each predicted effect. For each effect, schema condition was recoded into a dichotomous variable of those in the target schema condition and those that are not. Letterstring response condition was recoded into a dichotomous variable of those in that generated the target letter-string response and those that did not.

The surface schema response was generated significantly more by those in the surface schema condition (70\%) than those not in the surface schema condition $(0.03 \%), \chi^{2}(1, N$ $=181)=94.12, p<.001$. First-order schema responses were generated significantly more by those in the first-order schema condition ( $82 \%$ ) than those not in the first-order schema condition (26.7\%), $\chi^{2}(1, N=181)=49.91, p<$ .001. The higher-order schema solution was generated significantly more by those in the higher-order schema condition (60\%) than those not in the higher-order schema condition $(0.006 \%), \chi^{2}(1, N=181)=108.16, p<.001$. As per the initial hypothesis, the selective generation of letter-
string responses were congruent with one's schema condition.

Figure 4: A representation of three responses to the analogy $\mathrm{ABC}: A B D:: \mathrm{CSSNNN}:$ ?. The surface response (a) considers the change from $C$ to $D$, per se, so merely changes the $C$ in CSSNNN to a D. The first-order relational response (b)
considers the change from C to D as one of ordinal succession, as per their order in the alphabet. Since $C$ is the last term in the string, NNN, as the last string of CSSNNN, is also changed to its successor in the alphabet: OOO. The higher-order response (c), on the other hand, considers the entire string and each letter's position in the alphabet, representing ABC as $1-2-3$ and ABD as 1-2-4. The change is still an ordinal succession, as C and D are successors in the alphabet, but the letters have been represented numerically. The quantity of different letters in the string CSSNNN can also be represented numerically as 1-2-3. This numerical representation allows this first-order relation to map to the ordinal succession relation of ABC. This higherorder relational mapping leads to the inference that the fourth term in the analogy should be a quantity successor of CSSNNN that can be numerically represented as 1-2-4, i.e.,

CSSNNNN.

Table 3: Frequency of Letter-string Responses by Schema Condition.

|  | Schema Condition |  |  |  |
| :--- | :---: | :---: | :---: | :---: |
| Letter-string <br> response | Surface | First- <br> order | Higher- <br> order | Total |
| Surface | 42 | 4 | 0 | 48 |
| First-order | 11 | 50 | 21 | 77 |
| Higher-order | 0 | 1 | 36 | 35 |
| Other | 7 | 6 | 3 | 21 |
| Total | 60 | 61 | 60 | 181 |

## Discussion

Successful cross-domain analogical retrieval is rare. Despite this, the results of the present study provide evidence that schema induction can facilitate far analogical retrieval, i.e., analogical retrieval across disparate task domains. The effect was found for surface, first-order relational, and higher-order relational schemas. As well as providing support for a schema induction account of analogical retrieval, the results of the present study also address the three limitations in this literature were identified above. First, there is now evidence that analogue comparison can facilitate analogical retrieval across stimuli that share no surface features, except for the presence of alphabetic characters. Second, while prior research usually neglects to consider different levels of abstraction in analogical retrieval, the present study investigated retrieval of surface features, first-order relations, and higher-order relations. Third, the present study used a transfer task to probe the way participants were representing their schema.

The main limitation of the present study is that the apparent retrieval effects, might actually be mapping effects. The combination of a relatively small number of source stories and short delay might mean that participants were considering each source story as a potential match to their comparison cue and then actively deciding on the best perceived mapping. Future replications of the present study should therefore include a larger set of source stories and a longer delay between source story encoding and the retrieval phase. Further, it is not clear what exact role the explicit principle played in cuing the source stories. In general, it seems that explicit principles are not sufficient to induce a schema, but do seem to facilitate induction. Thus, future replications should systematically manipulate the explicit principle and its inclusion with comparison to determine its role as a retrieval cue for the far analogical retrieval.

Relational priming is sometimes used to explain analogical retrieval effects (Holyoak, 2012). It is unlikely to explain all of the present retrieval results because most relational priming effects are demonstrated using individual word pairs of highly familiar relations. There is little evidence to suggest that a higher-order relation can be primed in the same way, and the participants in our study had little to no previous experience with the specific
relations presented to them. Further, pilot data (Dekel, 2016) shows that changing the explicit principle in the higherorder condition to a more specific form does not significantly impact retrieval rates. This suggests a lesser role of explicit principle wording in any potential priming.

# Conversational topic connectedness predicted by Simplicity Theory 

Jean-Louis Dessalles (dessalles@telecom-paristech.fr)<br>LTCI, Telecom ParisTech, Université Paris-Saclay Paris, France

#### Abstract

People avoid changing subject abruptly during conversation. There are reasons to think that this constraint is more than a social convention and is deeply rooted in our cognition. We show here that the phenomenon of topic connectedness is an expected consequence of the maximization of unexpectedness and that it is predicted by Simplicity Theory.

Keywords: Conversation, topic change, simplicity, unexpectedness, interestingness.

## Introduction

A few decades ago, attempts were made to understand how and why conversational topics are almost systematically connected to each other, while abrupt topic shifts are avoided or even socially repressed. Jerry Hobbs (1990), for instance, describes several connection patterns that topics must respect to come next to each other in conversation and he wonders whether these mechanisms are due to cognitive constraints or are mere social conventions. The constraint of topic connectedness is so strong that abrupt topic change is classically considered characteristic of pathological conversation. The inability to respect topic connectedness during conversation has been for instance described in autism (Hale \& Tager-Flusberg, 2005; Volden et al., 1997) and in schizophrenia (Harrow et al., 1983). Even in these conditions, it is not clear whether patients merely ignore the constraint or still respect it covertly. The latter possibility would result from the patients' inability to realize that some elements needed for connecting topics lie only in their mind and have not been made public (Harrow et al., 1983).

Though authors had an intuition about what a conversational topic is and about how an utterance can be appropriate, the lack of proper definitions made the problem of topic connectedness difficult to address formally. When commenting on his maxim 'be relevant', Grice wonders

> "what different kinds and focuses of relevance there may be, how these shift in the course of a talk exchange, how to allow for the fact that subjects of conversation are legitimately changed, and so on. I find the treatment of such questions exceedingly difficult" (Grice, 1975).

Conversation has often been described either at the surface level, with notions like repairs and adjacency pairs, or at the sociological level, with notions like involvement, face preservation or gender talk. The present study adopts a rather different perspective, a cognitive one. The point is to show that the problem of topic connectedness can be derived as a natural consequence of conversational mechanisms operating at the cognitive level.

The remainder of the text starts by making a distinction between two fundamentally different conversational modes:
narratives and argumentative discussions. The way narratives connect to each other is particularly intriguing. We will observe patterns of topic connection using data taken from a corpus of spontaneous conversations. I will then introduce the Simplicity Theory (ST) framework and show how it can be used to explain the topic connectedness phenomenon.

## Conversational Topics

For long, it was hardly possible to study spontaneous conversations by making any hypotheses beyond what could be objectively observed. No assumptions were made about the participants' beliefs or desires. As a consequence, the existence of two sharply contrasted conversation modes, narratives and argumentative discussions, was considered unimportant. Though these two modes may be observed in pure form during conversations, they are sometimes intertwined, making the distinction less apparent at the surface level. If one takes a cognitive perspective, however, the distinction cannot be overlooked. The first explicit description of the narrative/argumentation dichotomy was apparently given by Jerome Bruner (1986), though many authors (e.g. Sacks, 1992; Tannen, 1984; Eggins \& Slade, 1997) implicitly distinguished between stories and other forms of verbal interaction.

## Conversational stories

People tell stories during conversations, i.e. they mention past events that are supposed to have occurred. Despite early studies (Sacks, 1992; Labov \& Fanshel, 1977:105; Polanyi, 1979; Tannen, 1984), the importance of the phenomenon has rarely been acknowledged until more recently (Norrick, 2000), as it only occurs among people who are already acquainted and is absent from most corpora recorded in the lab. Typical conversational narratives are easy to recognize. They are most often about past events (the past tense is used in English) for which the four w's (when, where, what, who) get instantiated. Consider the following conversation from my corpus. It involves two French women who had some trouble buying butter ('beurre' in French) during their stay in Spain [translated from French].

D:[...] she was with her cousin in Spain. And so... they wanted to buy butter. And then [laugh] her cousin said to her, she didn't speak one word of Spanish, but she said to her: "I can speak Italian; Italian and Spanish, that's the same", and then
O : Oh là là! Oh là là!
D: So she enters the store, and she says 'Burro'. And then [laugh] then everyone was staring at her, and so 'burro' means 'donkey'.
$\mathrm{O}:$ Oh! [laugh]. It means 'donkey'! She wanted to say 'Butter'! Burro. [laugh] It plays tricks, isn't it?

This story is definitely reporting a situated event: the 'when', 'where', 'what', 'who' are supposed to be constants and not variables. However, being situated is not sufficient for an event to be worth telling.

> "if you come home and report what the grass looked like along the way, that there were four noticeable shades of green some of which appeared just yesterday because of the rain, then there may well some tightening up on the part a your recipient. And if you were to do it routinely, then people might figure that there's something odd about you" (Sacks 1992:219)
> "We would intuitively reject such introductions as 'Let me tell you something ordinary that happened yesterday...' A narrative that is in fact judged to be ordinary may be rejected after it is told by expressions equivalent to 'So what!"" (Labov \& Fanshel 1977:105)

The missing ingredient that is required to turn an event into a story has been informally described by several authors in similar terms: narratable events should be 'problematic' (Ochs et al., 1992), 'different from ordinary experience' (Labov \& Fanshel 1977:105), 'unexpected, deviant, extraordinary, or unpredictable' (van Dijk, 1993), 'abnormal' (Schank, 1979), 'odd or unexpected',' rare', 'impossible or unheard of', be 'the violation of a norm' (Polanyi, 1979), 'depart from expectations', be a low probability event (Agar, 2005). The 'burro' story above definitely matches many of these criteria. We will subsume all these properties by saying that an event must be unexpected to be storyworthy. This notion will be refined below.

Languages offer means to emphasize unexpectedness, ranging from adjectives like odd, funny to specific markers like the wo particle in Cantonese (Luke 1990). Unexpectedness is the key element that controls storyworthiness. Emotional events are of course interesting, but happy or tragic situations do not arouse emotion unless they are unexpected (Saillenfest \& Dessalles, 2012). We will see that the unexpectedness requirement is also the very reason why narrative topics are connected.

## Argumentative discussion

A significant amount of conversational time is devoted to an activity that radically differs from story telling, namely argumentative discussion. The argumentative mode seems to be the prevalent one, at least in my corpus of family conversations. During an argumentative discussion, people deal with problems, i.e. incompatibilities between beliefs and/or desires ${ }^{1}$. The following conversation deals with TV and radio power consumption (translated from French).

P - When you put it into standby mode using the remote control with the small red dot on.
L-mmm
P- Does the TV remain switched on?
L-Yes.

[^318]P- So it is to be avoided,
L-No.
P- leaving it that way permanently?
L-No. People would say yes, but, it is quite irritating; you don't take advantage of having a remote control, and, uh, I mean, you will save six month or one year on the TV's life expectancy. Pff.
D-[to P] Not at all. And anyway, it sets..., it damages tubes a lot to set them on and off.
L-No but anyway, the tube is switched off when you put in standby mode.
D-I don't think so.
L-No, one should not compare consumer electronics and professional tubes.
D-Because, still, when you [really] switch it on, you can hear quite a discharge.
L-Yes, well, the tube warms up. When you put it..., No, no, the tube is switched off, but because it is consumer electronics, uh, otherwise you burn the tube, if it is consumer electronics.
O-A totally unrelated issue: when I put, I leave my radio plugged in, knowing that it is also a cassette recorder,
L-Yes.
O-I can hear something. [...] Should I switch... should I pull off the plug each time or it cannot damage the engine.

The problem here is the apparent incompatibility between the standby mode and the wish to keep the TV undamaged (the last utterances show the transition to the next topic). Discussions function as consistency maintaining devices: participants point to an incompatibility (like standby mode vs. no damage) or try to resolve a previously mentioned incompatibility.

## What counts as a topic?

Based on the argumentative/narrative dichotomy, the notion of topic can receive a proper definition.

- The topic of a narrative is the unexpected event it refers to.
- The topic of an argumentative discussion is the logical inconsistency that motivates it.

One could be tempted to consider that stories and argumentation are just two extremes in a continuum. An utterance like (talking about a toddler) "She is going down the stairs by herself!" might seem hard to classify either as narrative or as argumentative, as the event is both unexpected and potentially problematic (the child may fall down). And how would this injunction to a child: "Don't touch it!" or an exclamation like "Oh, that's wonderful!" be classified? There are reasons, though, to stick to the narrative $v s$. argumentation dichotomy. The most important one comes from the conviction that human conversational behaviour cannot be based on a wide gamut of unrelated cognitive devices. The narrative competence, as described by Simplicity Theory (see below), and the argumentative competence, as described in a minimal way in (Dessalles, 2016) can account for the relevance of most conversational utterances.

The crucial element that helps decide in which mode we are is negation. If the speaker has the negation of the state of affairs in mind (the child [should] not go down the stairs by herself; the child should not touch the object), then the
move is argumentative; if the event is regarded as unexpected, it is a narrative move ${ }^{2}$.

## Topic shift and topic drift

Respecting transitions between conversational topics seems almost as important as making appropriate moves.

> Not only are there socially sanctioned rules for appropriate topics of conversation, but also, in the course of a conversation, it is impolite to make an abrupt change of topic even to another socially sanctioned topic. To make a change of topic one must usually create some link to the previous topic, or one must drift to another topic in a stepwise fashion. (Shiller 1995:184)

Hobbs (1990) identified several patterns through which successive topics connect to each other. One of them is 'semantic parallelism'. Two topics may share a common predicate $p$ applied to different (but similar) arguments $a_{1}$ and $a_{2}: p\left(a_{1}\right)$ and $p\left(a_{2}\right)$. For instance, two stories about an accident share this common feature, though the different roles (driver, victim...) would differ. Conversely, two stories may be connected by an argument instead of by the predicate: $p_{1}(a)$ and $p_{2}(a)$, e.g. if successive stories involve a same protagonist.

Hobbs then considers connections that apply to argumentative discussions. It is often artificial to talk about topic change in argumentative discussion. Hobbs prefers to talk about topic drift. Since argumentative discussions go around problems (i.e. logical inconsistencies between beliefs and/or desires), a solution to a previous problematic issue may be regarded itself as problematic. This may lead to topic drift: People stack problematic topics on top on each other, and may or may not revert to a previous one. When there is a 'main issue', the topic can be clearly identified. For instance, in my main corpus of French conversation, one discussion about preparing a meal that would suit North American visitors consists of 255 utterances and lasts for twenty minutes. In many cases, however, discussions drift with no intent to reconsider the initial issue.

## Observing topic shifts

Stories tend to cling to each other, forming what Deborah Tannen (1984:100) calls story rounds. During a conversation among friends, she counted 48 narratives, 21 of which where told in five rounds: two stories about sex differences for language learning, five stories about adopted children, five about summer camps, five about strange accidents and four about child discovery of sexuality. The 'burro' story (see above) is part of a story round as well. This story round in detailed in Table 1. Transitions between topics (here, association or analogy) are shown.

As mentioned above, argumentative discussions tend to drift through logical connections. However, in some cases, discussions can be connected to each other in much the

[^319]same way as narratives. Table 2 shows an example of what we may call argumentation rounds. The above discussion about the TV in standby mode is included in this round. Note that a story is embedded in this sequence, as it is used as an argument (independently from its unexpected character that makes it a story in its own right).

Table 1: Example of story round

It is interesting to observe the different categories of topic transition, as they are described for instance in (Hobbs, 1990), at work in real conversations. The point is not to make precise quantitative assessments, as we expect significant variance depending on the kind of corpus we observe (number and age of participants, degree of acquaintance, situation and so on). Rather, we would like to get just some rough idea of the relative importance of the different forms of topic connections.
The corpus chosen here is a set of conversations recorded during family gatherings during three years. The total duration is 17 h 50 min . Participants are mostly the same
across recordings. In order to avoid selection bias, a sampling method has been used. Two-minute long slices were selected around 139 randomly defined time locations. 8 of these slices were ignored as no one was talking at the central time. 18 more were discarded as unintelligible. Reasons for unintelligibility are multiple and include noises, simultaneous loud conversations and child screams. The 113 remaining excerpts can be classified as shown in Table 3.

Table 2: Example of argumentation round

Several comments have to be made about these results. The main observation is that very few topics are introduced out of the blue in this kind of corpus. This may suggest that the number of abrupt topic change observed in other corpora (e.g. Nordenstam, 1992) might be overestimated, either because some crucial connecting piece of knowledge might be unknown to the external observers, or because conversations elicited in the lab might lack the spontaneous aspect of normal conversation.

Almost any connection seems possible between narratives (the term 'signal' refers to mentions of unexpected events that are 'here and now'3 ${ }^{3}$. The most represented topic connection in this corpus is analogy, which means that these narratives occurred in typical story rounds. The connection might be less tight, as when only one element is common with the parent topic.

[^320]Another observation is that the most basic pattern: problem-solution or solution-problem, is the majority argumentative connection but is not the only one. Problems may also refer to the current situation (e.g. I am missing a fork) or to an element from a preceding narrative. Surprisingly, a problem may also refer to another problem. This occurs in a problem-solution-problem-problem pattern, in which the last problem suggests that not adopting the solution is a problem as well (see (Dessalles, 2016) for a minimal model of relevant argument generation).

Table 3: Topic shift counts

|  | Topic type | Link with parent topic | \# / 113 |
| :---: | :---: | :---: | :---: |
|  | Problem | None | 1 |
|  | Problem | Situation | 12 |
|  | Problem | solution, refutation | 13 |
|  | Problem | Problem | 6 |
|  | Problem | Narrative | 3 |
|  | Solution | Problem | 33 |
|  | Signal | Situation | 14 |
|  | Narrative | None | 3 |
|  | Narrative | Situation | 2 |
|  | Narrative | Temporal | 1 |
|  | Narrative | Common item | 4 |
|  | Narrative | Close association | 3 |
|  | Narrative | Analogy | 13 |
|  | Narrative | Problem | 1 |
|  | Narrative | Explanation, refutation, solution | 4 |

## Explaining topic connectedness

In this section, we go beyond description and ask why conversation topics are so systematically connected. The suggestion will be that topic connectedness is the expected outcome of the quest for unexpectedness and that it is predicted by Simplicity Theory.

## Simplicity Theory

Simplicity Theory (ST) has been developed to explain event narratability. As discussed above, the core notion is unexpectedness: events must be unexpected to be tellable, and conversely unexpected events are systematically tellable. The notion of unexpectedness is not intrinsic to the event. It depends on the observer and on the current context. Previous attempts to define unexpectedness as 'low probability' failed to incorporate this necessary relation to the context.

ST is based on the notion of abnormal simplicity. Imagine that the numbers $1,2,3,4,5$ and 6 are drawn in the National Lottery. Tough the probability of this outcome is exactly the same as for any other draw, the news would be considerably more thrilling. Intuitively, the consecutive draw is interesting because it is abnormally simple. Simplicity is
obvious here as the sequence $1,2,3,4,5,6$ is compressible. The underlying theoretical notion is a cognitive (i.e. resource-bounded) version of Kolmogorov complexity ${ }^{4}$. Complexity here means 'minimal description length'. 1, 2, $3,4,5,6$ can be described using a much shorter code than a 'normal' draw like 3, 17, 27, 28, 33, 45. The consecutive draw can be described using the 'increment' operation, which is one of the simplest operations in the context of numbers, whereas the 'normal' draw cannot be 'compressed' down to a shorted description than itself.

Unexpectedness (or abnormal simplicity) $U$ results from a contrast between causal complexity $C_{w}$ (the circumstances or choice points that brought the event to happen) and description complexity C. Formally:

$$
\begin{equation*}
U=C_{w}-C . \tag{1}
\end{equation*}
$$

Though ST was initially developed to account for specific situations such as lottery draws or coincidences, we were surprised to find that the complexity drop between causality and description generalizes to all narratable situations (Dessalles, 2008). For instance, a fortuitous encounter is all the more narratable as the place of the encounter is complex (or hard to reach) and the encountered person is simple (a close acquaintance or a celebrity). The former parameter (location remoteness) controls the causal complexity, while the latter (minimal description of the person) controls the description complexity (see www.simplicitytheory.science for further examples). ST also accounts for problems underlying argumentative topics: the intensity of the problem corresponds to a high value of causal complexity $C_{w}$ (Dessalles, 2013).

Simplicity Theory accounts for many aspects of interestingness that are left otherwise unexplained. It explains why recent events are more interesting if they are closer in time and space, why 'round' anniversaries (after exactly 1,10 or 100 years) make past events worth talking about, why mishaps concerning celebrities might be as interesting for certain audiences as if they concerned own family, why people are fond of exceptions, norm-breaking behaviour and record-breaking performances, why collectors value items that are remarkable due to a simple feature (e.g. an inverted image on a stamp), and so on. All these predictions are derived from the equation $U=C_{w}-C$ (Dessalles, 2008; 2013; Saillenfest \& Dessalles, 2015; see www.simplicitytheory.science).

## Context and simplicity

Context plays a prominent role in the phenomenon of topic connectedness. ST not only defines this role, but also defines what the context is. In ST's framework, the context is defined as the set of properties that contribute to making the event unexpected. Formally, such properties can be written as:

$$
f\left(s, c_{1}, c_{2}, \ldots\right)
$$

[^321]where $s$ is the event, $f$ is a predicate and $c_{i}$ are constants. Note that a property may represent a conjunction of properties: $f\left(s, c_{1}, c_{2}, \ldots\right)=\wedge f_{i}\left(s, c_{i 1}, c_{i 2}, \ldots\right)$. For instance, a property of the event might be takes_place(s, Spain). The unexpectedness of $s$ is:
\[

$$
\begin{equation*}
U(s)=C_{w}\left(f\left(s, c_{1}, c_{2}, \ldots\right)\right)-C\left(f\left(s, c_{1}, c_{2}, \ldots\right)\right) \tag{2}
\end{equation*}
$$

\]

It is easy to define context based on (2):

$$
\begin{aligned}
& \qquad \text { Context }= \\
& \text { properties and constants involved in complexity drop. }
\end{aligned}
$$

Using complexity chain rule, we can write:

$$
\begin{equation*}
C\left(f\left(s, c_{1}, c_{2}, \ldots\right)\right) \leq C(f)+C\left(c_{1} \mid f\right)+\ldots+C\left(s \mid f, c_{1}, \ldots\right) \tag{3}
\end{equation*}
$$

Conditional complexity $C(x \mid y)$ means the minimal description length of $x$ when the description of $y$ is available. (3) generalizes easily to conjunctions $\wedge f_{i}$.

We see from (2) and (3) that when telling a story or pointing to a problematic situation, the mention of contextual elements such as $f$ or $c_{i}$ encroaches on unexpectedness, as it diminishes the gap between causal complexity and description complexity.

## Topic connectedness explained

Topic connectedness offers an opportunity for conversational narrators to save on the description side under the following hypothesis:

## Hypothesis: Elements of the previous context are available for free for further descriptions.

For instance, if $T_{-1}$ represents the preceding context and if $f$ and $c_{1}$ are part of it, then $C\left(f \mid T_{-1}\right)=0$ and $C\left(c_{1} \mid f, \mathrm{~T}_{-1}\right)=0$. They disappear from (3). Since $T_{-1}$ has no reason to have a causal effect on $s, C_{w}\left(s \mid T_{-1}\right)=C_{w}(s)$, and (2) becomes:

$$
\begin{equation*}
U\left(s \mid T_{-1}\right)=C_{w}(s)-C\left(s \mid f, c_{1}, T_{-1}\right) \tag{4}
\end{equation*}
$$

We can see that if $f$ and $c_{1}$ are part of the current context (i.e. contribute to the complexity drop in (1) and are thus relevant):

$$
\begin{equation*}
U\left(s \mid T_{-1}\right)>U(s) \tag{5}
\end{equation*}
$$

We can conclude that the situation is more unexpected after $T_{-1}$ than in the absence of any context, and that the presence of $f$ in $T_{-1}$ makes it (more) relevant. As a consequence, an event that would be impossible to introduce out of the blue may get enough unexpectedness to be worth telling.

For instance, in the 'burro' story, elements like 'trip', 'foreign country' or 'communication failure' are available for free from the previous story about attempts to ask for milk at breakfast in Italy (see Table 1). Moreover, 'butter' appears simple as 'milk' was previously mentioned, and 'Spain' would appear simpler than most other countries (seen from France) as 'Italy' was mentioned. The second story would have been less unexpectedness without these elements already available. Similarly, in the argumentation round of Table 2, the close analogy between the TV and the radio getting possibly damaged in standby mode makes the second discussion much easier to introduce. The analogy
spares the complexity of describing some elements of the second discussion (consumer electronics, standby mode, getting damaged), making the problem worth discussing about. In the excerpt, note that despite the close analogy, the speaker still feels the additional precaution 'A totally unrelated issue' (original: "une question tout à fait à côté") to be necessary when introducing her topic.

## Discussion

Hobbs (1990) wonders "to what extent topic drift [is] a matter of cognition and to what extent a matter of convention". The above development suggests that social conventions play hardly any role, beyond the mere control of the unexpectedness threshold (as a result, switching topic might be easier in relaxed or intimate situations).

Could it be that the reuse of contextual elements from one context to the next would just be due to some sort of cognitive laziness or inertia on the speaker's side? We can exclude this possibility: as we saw, topic connectedness is not only a fact, but also a requirement. A same topic that would be interesting during a story round or an argumentation round may appear inappropriate or even pathological when introduced out of the blue (Sacks, 1992). The present paper suggests that a cognitive determinism is involved.

When introducing a topic abruptly, bringing concepts and names into the new context adds to descriptive complexity and, as a result, diminishes unexpectedness, up to a point that the new topic is at risk of loosing all relevance. Already mentioned concepts or names are, by contrast, descriptively costless. The very existence of 'story rounds' or 'argumentation rounds' seems to be entirely due to the temptation of using elements of the previous context to enhance the unexpectedness of the next one. The demand for unexpectedness appears to be a universal property of human spontaneous conversation. Topic coherence through conversation seems to be a side-effect of this requirement.

# The Cognitive Architecture of Recursion: Behavioral and fMRI Evidence from the Visual, Musical and Motor Domains 

Mauricio de Jesus Dias Martins (diasmarm@hu-berlin.de)<br>Berlin School of Mind and Brain, Humboldt Universität zu Berlin, Luisenstrasse 56<br>10117 Berlin, Germany<br>Max Planck Institute for Human Cognitive and Brain Sciences, Stephanstrasse 1a 04103 Leipzig, Germany

#### Abstract

In this manuscript, we summarize the results of our research program aiming at describing the cognitive architecture underlying the representation of recursive hierarchical embedding. After conducting a series of behavioral and fMRI experiments in the visual, musical and motor domains, we found that, behaviorally, the acquisition of recursive rules seems supported by cognitive resources that are general across domains. However, when we test well-trained participants in the fMRI, their representation of recursion seems supported by activating schemas stored in (visual, musical and motor) domain-specific repositories. This suggests that the resources necessary to acquire recursive rules are different from those necessary to utilize these rules after extensive training.

Keywords: recursion; hierarchy; embedding; visual; motor; music

Recursion is a fascinating concept that has inspired researchers from many disciplines because of its associations with language, music and mathematics, which are uniquely available to the cognitive repertoire of humans (Hauser, Chomsky, \& Fitch, 2002).

The definition of recursion is much discussed, and the term is currently used with many different possible meanings (Fitch, 2010). In the original mathematical terminology, recursive functions are those that take their own output as input for the next iteration, such as the function generating the natural numbers:

$$
\begin{aligned}
& \mathrm{N}_{0}=1 \\
& \mathrm{~N}_{\mathrm{i}}=\mathrm{N}_{\mathrm{i}-1}+1, \text { for } \mathrm{i}>0
\end{aligned}
$$

One of the properties of these functions is the capacity to generate an infinite set of outputs.

Empirically, this property of infinity is impossible to verify (Lobina, 2011). However, there are other properties of recursion that make it interesting for empirical cognitive sciences. For instance, when we combine recursion with hierarchical embedding, we can generate complex hierarchies using simple rules (Martins, 2012). In fact, recursion has been discussed as a necessary condition to generate hierarchical structures of unbounded depth, and the most efficient procedure to generate multiple hierarchical levels (Berwick \& Chomsky, 2016). For instance, in language, even though the use of recursive computations cannot be directly verified, it is inferred from the ability to generate hierarchical structures, as it is thought to be the only plausible mechanism to generate sets of sets (Berwick \& Chomsky, 2016), without which there
can be no multiple levels of embedding. The same standard has been proposed for the visual-spatial domain (Martins, 2012).

Complex hierarchical structures occur in language, music and action planning (Fitch \& Martins, 2014). In these domains, it is difficult to establish the empirical boundaries of the generative capacity. This is especially true when external memory and recording devices are available, as for example, in written language or in large scale engineering projects, such as those involved in building a particle accelerator. Independently of how complex a base structure is, it is always possible to embed it within a higher-order hierarchy.

The investigation of these properties of human cognition pose several challenges, which we tried to address in a systematic 6-year long research program. The first challenge was the definition of a clear theoretical framework to make recursion empirically tractable and consistent with a number of different domains (Martins, 2012; Martins \& Fitch, 2014). Crucially, the availability of recursion must be tested experimentally and neither simply assumed nor deduced from pure analytical methods (Martins \& Fitch, 2015). The crucial behavioral signature of a computational capacity of recursion is the ability to generate muliple new hierarchical levels (Martins, 2014; Berwick \& Chomsky, 2016). This relation is independent of particular algorithmic and biological implementations (Berwick \& Chomsky, 2016).

Thus, the second challenge was the development of experimental techniques that could be used to test the ability to represent recursive hierarchical embedding in different domains. Once these two challenges were met, we could start answering two central questions: (1) in which domains of cognition recursion is available, and (2) if recursion were available in more than one domain, would it be instantiated by a domain-general capacity, or by multiple domain- specific abilities?

## Recursion in the visuo-spatial domain

In our previous work, we were able to establish that in addition to language (Roeper, 2011), the ability to represent recursive hierarchical embedding is available in the visual domain (Martins, Martins, \& Fitch, 2015) (Figure 1). We have shown that both human adults and children (Martins, Martins, \& Fitch, 2015; Martins, Laaha, Freiberger, Choi, \& Fitch, 2014) are able spontaneously acquire a hierarchical selfsimilarity rule of the kind $\mathrm{A} \rightarrow \mathrm{A}[\mathrm{A}]$ and to use it to make judgments about well-formed visual fractals and violations
(Figure 2A). Crucially, this ability differed cognitively from a control, iteration task (Martins, Martins, \& Fitch, 2015), in which participants made judgments about similar fractals which were not generated via a hierarchical embedding rule (Figure 2B). In particular, while visual iteration correlated strongly with visuo-spatial working memory and non-verbal intelligence, recursion correlated weakly with these measures, correlating instead with performance in the Tower of Hanoi, a recursive planning task (Martins, Martins, \& Fitch, 2015).

Figure 1: Examples of both 'recursive' and 'iterative' processes generating a visual fractal. While recursive hierarchical embedding steps generate new hierarchical levels, embedded iteration adds elements to fixed hierarchical levels, without generating new.

A. Visual Recursion Task

B. Visual Iteration Task

Figure 2: In both tasks participants are exposed to the first three steps generating a fractal (top row) and asked which image from the bottom row is the correct continuation. Despite using the same pairs of test images, the visual recursion and iteration tasks correlated with different abilities (Martins, Martins, \& Fitch, 2015).

As in language (Roeper, 2011), the development path towards the acquisition of visual recursion requires the induction of simpler iterative (conjunctive) representations first, before recursive embedding becomes available (Martins, Laaha, Freiberger, Choi, \& Fitch, 2014). However, we also found that the representation of visual recursion is independent of verbal resources (Martins, Mursic, Oh, \& Fitch, 2015) and that it is not instantiated by the classical brain networks supporting language (Martins, Fischmeister, et al., 2014). Using fMRI, we found that the capacity to represent recursion in the visual domain is supported by the visual ventral stream and by structures (e.g. Medial Temporal Lobe) associated with the episodic memory system (Figure 3). Interestingly, we found that in comparison with non-recursive iterative procedures, recursion hinges mostly on top-down, internal representations (Fischmeister, Martins, Beisteiner, \& Fitch, 2016), associated with the Default Mode Network and Semantic Memory. These findings provide some cues concerning the basic mechanisms underlying recursive hierarchical embedding and its usefulness for human cognition: by providing strong top-down priors, recursion can facilitate the processing of complex hierarchical structures.

Figure 3: Brain networks supporting the representations of Recursion $>$ Iteration (red) and Iteration>Recursion (blue) in the visiuo-spatial domain (thresholded at a voxel-wise $F D R$-adjusted $p<.05$ with a 10 -voxel extent threshold).

## Recursion in the music and motor domains

Recently, we have extended this research to the musical and motor domains, where the availability of recursion has been previously suggested (Corballis, 2014; Jackendoff \& Lerdahl, 2006). We found that both musicians and non-musicians can acquire rules governing recursive embedding in tonal hierarchies (Figure 4A) (Martins, Gingras, Puig-Waldmueller, \& Fitch, 2017), and that this capacity shares resources with visual recursion and with recursive action planning (Tower of Hanoi). This suggests some degree of domain-generality. However, when we measured the brain activity underlying this
musical capacity in well-trained participants (using fMRI), we found little overlap between the musical and visual domains.

Here, we exposed 15 non-musicians to the first three steps forming a tonal fractal, either using recursive or iterative rules (Figure 4B and 4C), then gave them 4 seconds to try to imagine how the correct continuation ( $4^{\text {th }}$ step) would sound like. This 4 -second period was the 'generation phase'. After the 4 seconds, they were exposed to a test stimulus ('test phase') and asked to judge whether this was a correct continuation or a foil. Overall, participants performed 4 sessions of 18 trials each (6 trials of Fractal, 6 of Iteration and 6 of Repetition)

Figure 4: (A) Example of music fractal with tonal relations between levels, which were identical across all levels. (B) Cross-level fractal (recursive) rule, (C) Withinlevel (iterative) rule.

By contrasting Recursion>Iteration in the "generation phase" (while controlling for the activations in steps I, II and III) we found that recursive hierarchical embedding in music is supported by the primary and secondary Auditory Cortices in the left hemisphere and by the right Superior Temporal Gyrus, an area known to encode complex tonal relations (Figure 5) (Martins, Fischmeister, et al., in prep.). Interestingly, despite differences in the specific pattern of activation, we found again evidence that the representation of recursive embedding is supported by top-down processing: These activations occur in anticipation to a certain tonal sequence before it is played ("generation phase"), but only when the sequence was generated recursively (vs. iteratively). There were no task differences in the "test phase", only a main effect of correctness (i.e. violation>well-formed structures).

Figure 5: Brain network supporting the representation of recursive hierarchical embedding in tonal sequences during the "generation phase" (FWE-adjusted $p_{\text {cluster }}<.05, p_{\text {voxel }}<$ .001). The Repetition task was a working memory task, in which participants simply had to buffer step 3 (a complete and well-formed fractal) and then determine whether step 4 was a repetition of step 3. The opposite contrasts (Iteration $>$ Recursion and Repetition>Recursion) yielded no activations.

Finally, we tested participants in the motor domain (Figure 6). Here we asked 20 (non-musician) participants to execute motor sequences on a 16-keys keyboard as depicted on a computer screen. Similar to the music domain, we exposed participants to the first two steps of a process generating motor fractals, then asked them to plan the next correct step (the "planning phase") for 6 seconds. After the planning phase they were asked to execute the correct sequence on the keyboard without visual assistance ('execution phase'). Iteration and Repetition baseline tasks were devised, similar to the music domain. Each participant performed 4 sessions of 20 trials each ( 8 Fractal, 8 Iteration and 4 Repetition trials).

Figure 6: A) Example of a recursive process generating sequences of (silent) finger movements. Red, Green and Blue denote key presses with the thumb, index and middle fingers, respectively. On each step N, each key press is substituted by a sequence of 3 key presses with less than one third of the duration $d_{n}$. B) Example of an Iterative process generating the same motor fractal.

We found that during the planning of hierarchical motor sequences using recursive rules, participants activated a network known to instantiate motor planning and imagining, comprising the Somato-Motor and Premotor cortices bilaterally, Cerebellum and Basal Ganglia (Figure 7) (Martins, Bianco, Sammler, \& Villringer, in prep.). Furthermore, we found that the underlying generating rule (Recursive>Iterative) changed how the execution of identical motor sequences were neurally represented: During the execution of a sequence formed using iterative rules, we found a strong activation in the primary motor hand area ( $x=-52$, $y$ $=-18, \mathrm{z}=50, \mathrm{Z}=6.06$, FWE $\mathrm{p}_{\text {cluster }}<.05, \mathrm{p}_{\text {voxel }}<.001$ ). In contrast, when the sequence was formed recursively, we did not find a direct activation in the motor cortex, but a modulation of this area from a fronto-striatal cluster (PPI: Recursion>Iteration: $x=-36, y=-24, z=48$, cluster extent $=$ 182 voxels, $Z=3.96, p_{\text {voxel }}=.016$ ).

Figure 6: Brain network supporting the representation of recursive hierarchical embedding in the motor domain (FWE-adjusted $p_{\text {cluster }}<.05, p_{\text {voxel }}<.001$ ).

## Discussion

Taken together, these results suggest several things: (1) The acquisition of recursive rules is probably supported by cognitive resources that are general across domains; (2) However, when we test participants that are well-trained and at ceiling performance in the fMRI, their representation of recursion is instantiated by domain-specific neural systems; (3) In contrast with other (iterative) rules applied to hierarchies, recursion seems to allow a controlled top-down processing, in both discrimination (visual and tonal) and production (motor) of well-formed hierarchical structures. This result is consistent across several domains.

The apparent contradiction between points (1) and (2) can be solved if we surmise that the resources necessary to acquire recursive rules are different from those necessary to utilize these rules after extensive training. We hypothesize that acquisition requires domain-general resources, which are perhaps slow and effortful, while expert use is instantiated by activating schemas stored in domain-specific repositories, which are formed after a process of automatization. The answer to this question requires novel research investigating the neural networks supporting the acquisition of recursive rules.

# The Temporal Cheerleader Effect: Attractiveness Judgments Depend on Surrounding Faces Through Time 

Alexia Toskos Dils (alexia.toskos@purchase.edu)<br>Scott Niedopytalski (scott.niedopytalski@purchase.edu) Jeffrey Arroyo (jeffrey.arroyo@purchase.edu) Stephen J. #### Abstract

Previous research has found that people are seen as more attractive when they appear in a group rather than in isolation. The present study asks whether faces that surround us in time also affect how attractive we appear to be. Participants rated the attractiveness of famous female faces presented in a sequence of three and in isolation. We found that people do integrate information about attractiveness over time, but that temporal context has the opposite effect of static context. People perceived faces as less attractive in a series than in isolation. We also varied the attractiveness of surrounding faces in order to examine how the serial position of contextual information might figure into people's judgments. We found that faces presented earlier in the sequence figured more heavily into people's judgment than did faces presented later in the sequence. These findings highlight the role of temporal context in perceptions of attractiveness.

Keywords: face perception, attractiveness, serial position effects, ensemble coding, cheerleader effect

## Introduction

In a $5^{\text {th }}$ season episode of the American comedy television series The Office, the employees of Dunder Mifflin paper company spend an entire day debating whether actress Hilary Swank is "hot" or not. The office workers are torn on the issue, battle lines are drawn, and emotions get heated. Though in part a satirical referendum on the public's dark obsession with - and objectification of - celebrity, the plotline of this episode raises an important question: What factors influence perceptions of attractiveness?

The intrinsic features of individual faces certainly contribute to the perception of attractiveness, for both evolutionary and cultural reasons. Female faces, for example, are rated as more attractive the more sexually dimorphic and prototypically "female" they are (Valenzano, Mennucci, Tartarelli, \& Cellerino, 2006), and the more symmetrical they are (Perret et al., 1999). However, certain situational factors such as amount of exposure to a face (Rashidi, Pazhoohi \& Hosseinchari, 2012) as well as the perceived market value of the person making the judgment (Morgan \& Kisley, 2014) can also impact attractiveness judgments.

Researchers have also examined whether contextual factors can influence attractiveness ratings. Recent work, for example, has uncovered a so-called "cheerleader effect" in which people are rated as more attractive when they
appear in a group than when they appear in isolation (Walker \& Vul, 2013). Walker and Vul explain these findings as a sort of perceptual averaging phenomenon. The idea is that people spontaneously extract an ensemble code when viewing a group of faces, and because average faces are seen as highly attractive (Langlois, Musseman, \& Roggman, 1994), attractiveness ratings for the faces that contributed to the ensemble receive a boost. This suggests that perceptions of attractiveness are in part constructed online, in the moments we experience another person's face.

Often the faces we encounter in a crowded place are processed serially, rather than all at once. For example, faces come in and out of sight as we walk down the street, scan a room, or swipe through profile pictures on social media websites. Interestingly, evidence from studies of object perception suggests that the visual system is capable of constructing average representations over time in addition to space. Albrecht and Scholl (2010) found that people's estimates of the average diameter of a growing or shrinking disc depended on which part of the disc received the most screen time. Participants overestimated the average when frames on the larger end of the spectrum hung on the screen longer than did frames on the smaller end of the spectrum, and vice versa.

Is information from faces spontaneously integrated over time in a similar way? The present study asks whether the cheerleader effect extends to faces that appear near one another in time in addition to space. Importantly, the study was also designed to address whether serial position influences how information about attractiveness is integrated over time. Do all faces in a sequence figure equally into the ensemble code, or is the average representation that people extract weighted more heavily by faces appearing early or late in the series?

Though research suggests the visual system computes ensemble codes of information presented close in space and time, the data is often inconsistent with a simple averaging account. For example, studies of the perception of serially presented lines have reported a recency effect in people's judgments: Estimates of line length were biased toward lines that appeared toward the end of the sequence (Weiss \& Anderson, 1969). And while Walker and Vul (2013) concluded that an averaging effect best captured the data they observed in their work on the cheerleader effect, not all of their findings are consistent with this interpretation. For
example, if the cheerleader effect results from simple averaging, then the more faces that contribute to the ensemble code, the more attractive the resulting average should be (i.e., increasing the number of faces in a group photograph should strengthen the cheerleader effect). Walker and Vul (2013, Experiment 4) tested this hypothesis with set sizes ranging from two to 16 . Although they found a cheerleader effect within each set size, the magnitude of the effect did not increase with the number of faces in the set.

In light of these findings, the present study was designed to differentiate between different possible accounts of the temporal cheerleader effect we investigated. On the one hand, it is possible that faces appearing at the end of a sequence bias the perceived attractiveness of faces earlier in the sequence (i.e., a recency effect). This would be consistent with the work of Weiss and Anderson (1969) on line perception. However, it is also possible that the first face might influence the perceived attractiveness of faces appearing later in the sequence. There are at least two reasons we might expect such a primacy effect. First, there might be a contrast effect (Kenrick \& Gutierres, 1980; Pegors, Mattar, Bryan, \& Epstein, 2015), such that seeing a highly attractive face may make subsequent faces seem less attractive by contrast, and vice versa. Second, there might be an anchoring effect, such that subsequent faces appear to have a similar attractiveness level as a previously presented face (Pegors, Mattar, Bryan, \& Epstein, 2015; Taubert, Van Der Burg, Alais, 2016; Tversky \& Kahneman, 1974).

Both contrast and anchoring effects have been observed in recent studies examining the effects of the attractiveness of the previous face on online judgments of serially presented faces (Pegors et al. 2015; Taubert et al., 2016). Pegors and colleagues suggest that the contrast effect derives from perceptual components of the judgment, whereas the anchoring effect derives from a bias to respond in the same way as in the previous trial. The present study extends this work to offline judgments of facial attractiveness. Does the temporal context in which a face appears affect later memory of how attractive that face was? Offline judgments further allow us to examine any serial position effects more fully. Specifically, this design element allows us to test whether faces that follow us in time can retroactively meddle with how attractive we are judged to be.

In order to (a) determine whether or not an offline, temporal cheerleader effect exists, and (b) understand the mechanisms underlying such an effect, participants in the present study rated the attractiveness of a variety of famous female faces. On each trial, faces were presented either in isolation or in a series of three faces. Afterward, participants were cued by the name of each celebrity they saw and asked to rate how attractive the person looked in the photograph. Celebrity faces were used (as opposed to non-famous faces) to allow for offline attractiveness ratings to be collected after all faces disappeared from view. The celebrity's name uniquely picked out which face participants were being asked to rate.

The stimulus set included two versions of each celebrity: an "attractive" version where the celebrity was photographed favorably, and an "unattractive" version where the celebrity was photographed uncharitably (see Figure 1 for example stimuli). On trials where faces were presented in a series, the middle face was always an attractive face and was either preceded by or followed by an unattractive face. Therefore, in the unattractive first condition, participants first saw an unattractive face followed by two attractive faces. In the unattractive last condition, participants saw two attractive faces followed by an unattractive face.

To the extent that people do integrate information about attractiveness over time, offline judgments of a given face should depend on whether the face was presented in isolation or in the middle position of a series of three faces. If the mechanism by which information is integrated is a contrast effect, then viewing an unattractive face in the first position of the sequence should cause the middle face to seem more attractive than it does in isolation, and vice versa. Alternatively, if the mechanism is anchoring, then seeing an unattractive face in the first position of the sequence should make subsequent faces seem less attractive than they do in isolation, and vice versa. Finally, if the mechanism is simple averaging, then all faces should appear more attractive when they are presented in a sequence, since research suggests that averaged faces appear more attractive (Langlois, Musseman, \& Roggman, 1994). However, since there are only three faces being averaged together here and one was specifically chosen to appear highly unattractive, it could be the case that the average of this small set would actually appear less attractive. What's more, these effects may depend on where the unattractive face appears in the sequence. If the averaging effect is subject to primacy effects, then the first face in the sequence will figure more heavily into the average. However, if the averaging effect is subject to recency effects, then later faces in the sequence will figure more heavily into the average. This study will help to rule out some of these possibilities.

## Experiment

## Methods

Participants 50 "master-level" participants were requested from Amazon's Mechanical Turk worker pool for this study. 68 people actually followed the link to the experiment and began the study, but 17 of those people did not complete the task. The remaining 51 participants were included in the study. There were 27 males and 23 females in the sample, with a mean age of $41.20(S D=12.67)$. One participant declined to provide demographic information. Each participant received $\$ 1.50$ for their time spent on the study.

Stimuli and Procedure Participants rated the attractiveness of faces in three within-subjects conditions: isolation (a face shown by itself), unattractive first (an unattractive face followed by two attractive faces in sequence), unattractive
last (two attractive faces followed by an unattractive face in sequence).

Figure 1. Example stimuli used in this study. On the left is the "unattractive" photograph of Debra Messing that participants saw, and on the right is the "attractive" photograph of the same celebrity.

Photographs of 75 unique female celebrities made up the stimulus set for this study. Two photographs were collected for each celebrity: an "attractive" version in which the person was made up for an event, and an "unattractive" version in which the celebrity was captured poorly (i.e., photographs found in tabloids claiming to have "shocking" pictures of the person; see Figure 1 for example stimuli). Therefore, the final stimulus set consisted of 150 celebrity photographs. Each participant saw a subset of 75 faces sampled from this full stimulus set ( 50 attractive faces and 25 unattractive faces). Participants saw either the attractive version or the unattractive version of each unique celebrity, and never both. Whether a celebrity was presented as attractive or unattractive was counterbalanced across participants.

The study was conducted using Qualtrics survey building software. On each trial, participants saw female celebrity faces presented either in isolation or in a series of three faces. Each face was presented along with the celebrity's name and remained on the screen for one second. Afterward, participants were instructed to rate the attractiveness of each face they had just seen, cued only by the celebrity's name. Participants entered their responses using a continuous sliding scale without numbers on it. This was designed to prevent participants from tracking the specific ratings they assigned to faces throughout the study. The scale ranged from "very unattractive" to "very attractive". Participants were allowed to take as much time as they needed to enter their ratings. The order in which participants were prompted to rate each celebrity was randomized on each trial. See Figure 2 for a schematic representation of the trial structure in this task.

Each participant completed 125 trials. 75 trials consisted of faces presented in isolation, and 50 trials consisted of faces presented in a series. Of the 50 trials in which the faces were presented in a group, 25 were unattractive first trials, and 25 were unattractive last trials. The middle face in the sequence was always attractive. Which face appeared in which position in the sequence was counterbalanced
across participants. All trial types were interleaved, and trials were presented to participants in random order.

## A.

B.

Figure 2. Trial structure for the conditions in which faces were presented in a sequence (A) and in isolation (B). Part A depicts an example unattractive first trial.

Participants rated each attractive photograph at two critical points in the study: once in isolation and once in the middle position of a series of three faces. We wanted to know whether attractiveness ratings for each photograph depended on this contextual manipulation, so we limited our analyses to the 50 attractive faces each person saw, as well as to ratings of the face presented only in the middle position on group trials.

At the end of the study, participants supplied information about their gender, race/ethnicity, and age. We also included a manipulation check designed by Oppenheimer, Meyvis, and Davidenko (2009) to ensure that all participants in our sample read task instructions carefully.

## Results

All 51 participants in this study correctly answered the instructions manipulation check, so data from all participants were analyzed. One participant declined to provide demographic information and therefore was not included in analyses that examined effects of gender.

To confirm that our participants found the "attractive" faces to be more attractive than the "unattractive faces," we compared participants' raw attractiveness ratings between
these two stimulus types. Indeed, participants rated the attractive faces more favorably on a scale from 1-100 ( $M=$ 70.91; $S D=13.12$ ) than they did the unattractive faces, $M=$ 34.46; $S D=16.46 ; t(50)=15.83, p<.001$.

For each participant, responses on analyzed trials were converted to $z$-scores. For each attractive face that a given subject saw, we subtracted the standardized rating of that face presented in isolation from the standardized rating of that same image shown in a group. Therefore, positive difference scores indicate that faces were rated as more attractive when presented in a group compared to isolation, and negative difference scores mean faces were rated as less attractive when presented in a group compared to isolation. Overall, participants rated celebrity faces as significantly less attractive when they were presented in a series than when they were presented in isolation ( $M_{\text {group-isolation }}=-$ $\left.0.098, S D_{\text {group-isolation }}=0.16\right), t(50)=-4.24, p<.05^{1}$.

Figure 3: Shift in standardized attractiveness ratings for faces presented in a sequence from those same faces presented in isolation. Error bars represent 1 SEM.

The differences in z-scores were submitted to an ANOVA with one within-subjects factor (order of attractiveness: unattractive first vs. unattractive last) and one betweensubjects factor (gender of participant: male vs. female). The ANOVA revealed a significant main effect of order of attractiveness on the attractiveness deficit for faces presented in a group relative to isolation. Specifically, the effect was stronger when participants saw an unattractive face first in the sequence ( $M=-0.16, \mathrm{~S} D=0.23$ ) than it was when participants saw an unattractive face last in the sequence $(M=-0.03, S D=0.23), F(1,48)=9.78, p<.005$ (see Figure 3). These effects were similar in men and women: The attractiveness deficit did not depend on the

[^322]gender of the participant $(F(1,48)=0.04, p>.50)$, and there was also no interaction between gender and order of attractiveness, $F(1,48)=1.97, p>.05$.

Post-hoc analyses revealed that seeing an unattractive face at the beginning of the sequence caused the middle face to appear less attractive than it did in isolation ( $M_{\text {group-isolation }}$ $\left.=-0.16, S D_{\text {group-isolation }}=0.23\right), t(50)=-5.07, p<.001$. While the presence of an unattractive face at the end of a sequence produced a numerical reduction in attractiveness of the middle face relative to isolation, this shift did not reach statistical significance $\left(M_{\text {group-isolation }}=-0.03, S D_{\text {group-isolation }}=\right.$ $0.23), t(50)=-1.03, p>.05$.

## Discussion

The purpose of this study was to determine whether and how people integrate information from faces over time when judging the attractiveness of others. In our experiment, participants viewed a series of attractive and unattractive female celebrity faces in isolation and in a series of three images. They were then asked to rate the attractiveness of each face (cued only by their name) on a sliding scale from very unattractive to very attractive. The results indicate that people do integrate information over time when judging the attractiveness of faces. Contrary to the "cheerleader effect," which suggests that faces are perceived as more attractive when they are presented in a group, the results from this experiment suggest that faces are perceived as less attractive when presented in a series than when they are presented in isolation. The results further show that this effect is stronger when an unattractive face is presented first in the series compared to when it is presented last.

There are a number of reasons why attractiveness ratings might be different for faces presented in a series compared to isolation. For example, seeing faces in a sequence may lead to a contrast effect, where seeing an attractive face causes a subsequent face to appear less attractive (and vice versa). Or there could be an anchoring effect where people rate subsequent faces to be similarly attractive to the initial face. Finally, there could be an averaging effect where all faces in the sequence contribute to an ensemble code that figures into attractiveness judgments for each face in the sequence. The results from the present study help to rule out one of these three possibilities: the contrast effect. Had our manipulation produced a contrast effect, then seeing an unattractive face first would have caused the middle face in the series to seem more attractive. Instead, our results showed the opposite pattern: viewing an unattractive face made the subsequent face appear to be less attractive than when it was viewed in isolation.

The data are partially consistent with an anchoring effect. An attractive anchor face should cause subsequent faces to seem more attractive than usual, and an unattractive anchor should cause subsequent faces to seem less attractive than usual. Indeed, unattractive faces at the beginning of the sequence caused subsequent faces to appear less attractive than usual, but the opposite pattern did not obtain for
attractive faces presented early in the sequence. Therefore these data are only partly in line with the findings of Taubert et al. (2016).

Pegors and colleagues (2015) concluded from their study examining sequential attractiveness judgments that contrast effects result from stimulus (perceptual) bias, whereas anchoring effects result from response bias. The present findings are not consistent with this explanation as the study design itself rules out response bias as a possible contributor. On trials in which faces were presented in a group, participants saw all three faces before responding to any one of them. They then entered their responses in a different order than the one in which the faces were presented. We analyzed the data based on the stimulus order and not the response order, so the partial anchoring effect should not necessarily be interpreted as a result of response bias. Furthermore, the lack of a contrast effect is a departure from the findings of Pegors and colleagues, suggesting there may be a qualitative processing difference between online and offline judgments of serially presented faces that persists well beyond the presentation of the face.

The findings presented in this paper are perhaps most consistent with an averaging effect. By including an unattractive face in the sequence of three, we may have reduced the attractiveness of the ensemble code participants extracted from the series, which then biased subsequent ratings of individual faces in the sequence. Furthermore, it appears that the serial position of the unattractive face influenced how the average representation was constructed. Contrary to the findings of Weiss and Anderson (1969), our results revealed a primacy effect on perceptual averaging. Namely, unattractive faces presented at the beginning of the series figured more heavily into the average than did unattractive faces presented at the end of the series. However, because averaging faces together generally increases perceived attractiveness, this account depends on the possibility that averaging only a small number of faces together (three), one of which is especially unattractive, can sometimes reduce rating attractiveness (perhaps, for example, when the faces are of familiar people, as in the present study). Indeed, morphs containing familiar (celebrity) faces are rated as less attractive than are the component faces used to generate the morph (Halberstadt, Pecher, Zeelenberg, Ip Wai, \& Winkielman, 2013). Therefore, using celebrity face may itself have lowered the attractiveness of the average face people constructed over time in the present study. Future work is required to confirm this possibility, however.

In order to preserve the design element in this study that no participant saw both the attractive and unattractive versions of the same celebrity, we did not include trials in which all faces in a sequence were attractive, nor did we include trials in which all faces were unattractive. Future work will examine these trial types so as to build a more complete picture of the way in which attractiveness in faces is integrated over time.

One ongoing study attempts to further differentiate between an anchoring and averaging account of our findings by replicating the present study with unattractive faces in the target (middle) position on group trials. If our findings reflect a cheerleader effect, then the results from this new study should mirror the results in the present study. Specifically, the middle face in the sequence would be rated as less attractive than a face presented in isolation, but this effect would only appear in the unattractive first condition. However, if our current findings reflect an anchoring effect, we should predict that the unattractive last condition in this ongoing study would produce the strongest anchoring effect - the condition in which an attractive face appears in the first position of the sequence. After all, this is the condition where the difference in attractiveness is largest between the first and middle faces. Therefore, an anchoring effect in this new version of the task predicts that the middle face would be rated as more attractive in a series than it is in isolation.

Our judgments about the attractiveness of others factor into a variety of important decisions we make every day. For example, whether a candidate would make a good fit for a job (Dipboye, Fromkin, \& Wilback, 1975), or whether to ask a person out on a date can be influenced by how we perceive the attractiveness of that individual. This study highlights one way in which such important decisions might be influenced by the faces that happen to surround us in the moments leading up to them.

#### Abstract

We present the project aimed at creating a database of detailed architectural process models of memory-based decision models. Those models are implemented in the cognitive architecture ACT-R. In creating this database, we have identified commonalities and differences of various decision models in the literature. The model database can provide insights into the interrelation among decision models and can be used in future research to address debates on inferences from memory, which are hard to resolve without specifying the processing steps at the level of precision that a cognitive architecture provides.

Keywords: inference from memory; process model; ACT-R; decision making; model database

## Introduction

How do we infer which of two cars will be more durable? Which company will be more successful in the coming year? To address such questions, in a typical two-alternative forced-choice task of inference from memory (Gigerenzer \& Goldstein, 1996), two objects (e.g., two companies) are presented on a computer screen. A subject has to infer which of the two objects scores higher on a criterion of interest (e.g., the company growth in the next year) by relying on knowledge stored in memory.

Models of inference describe how subjects make inferences by using attributes of objects (e.g., who is the company's CEO) as cues. Many inferential models have focused on describing not just what the outcome of the inference would be, but also which processing steps a decision maker would take to reach a decision. These models include, among others, the various fast-and-frugal heuristics from the adaptive toolbox of heuristics (Gigerenzer, Todd, \& the ABC Research Group, 1999), parallel constraint satisfaction (PCS; Glöckner \& Betsch, 2008) and sequential sampling models (e.g., Lee \& Cummins, 2004).

Such process models have increased substantially our understanding of how people make inferences (e.g., Bröder, 2012) and why the inferential process is successful (Gigerenzer \& Brighton, 2009), but perhaps more importantly they have raised other questions and fueled important debates: Do people rely on a repertoire of strategies or on a single strategy (e.g., Lee \& Cummins, 2004; Marewski, Schooler, \& Gigerenzer, 2010; Newell, 2005; Glöckner \& Betsch, 2008)? Which types of models
(e.g., heuristics vs. more complex models) describe better people's decision processes (e.g., Goldstein \& Gigerenzer, 2002; Newell \& Bröder, 2008) and under what circumstances? When do people rely on non-compensatory as opposed to compensatory strategies (Glöckner \& Bröder, 2011)?

One major barrier to addressing those and related questions is that many models are almost always underspecified compared to the data that they are tested against. Specifically, process models of decision making often remain silent about components of cognition that are the foundation of decision making, such as perception, motor action, or memory. We argue that specifying relevant cognitive-behavioral processes will help those models make more precise predictions about, for example, response time and other process data. The increased precision, in turn, will not only allow researchers to more easily tell potentially competing models apart, but also aid in addressing ongoing debates and open research questions.

In fact, a significant amount of research has already started to embed existing decision models into detailed cognitive theories (Dimov, Marewski, \& Schooler, 2013; Fechner, Pachur, Schooler, Mehlhorn, Battal, Volz, \& Borst, 2016; Marewski \& Mehlhorn, 2011; Marewski \& Schooler, 2011; Nellen, 2003; Thomas, Dougherty, Sprenger, \& Harbison, 2008; Schooler \& Hertwig, 2005). The aim of the current line of work is to expand upon these efforts by systematically implementing existing models of inference in the cognitive architecture ACT-R (Anderson, 2007).

In what follows, we will briefly introduce ACT-R and present a summary of the model database that we are in the process of constructing. We will then explain in detail what knowledge each of the decision strategies requires for its functioning. We will conclude by discussing the advantages and shortcomings of our models. Once finalized, we plan to make the database of architectural process models of decision making available to the public.

## ACT-R

ACT-R is arguably the most advanced integrated theory of cognition. It has been used to construct models of very diverse tasks and phenomena, which include, among others, associative recognition (Schneider \& Anderson, 2012), analogy making (Salvucci \& Anderson, 2001) and multitasking (Salvucci \& Taatgen, 2008).

Table 1: Outline of the database of architectural process models of decision making, together with summaries of hypothesized procedural and declarative, symbolic and subsymbolic knowledge.

| Model | Source | Declarative <br> knowledge | Procedural knowledge |  |
| :--- | :--- | :--- | :--- | :--- |
| Recognition <br> Heuristic |  <br> Gigerenzer <br> $(2002)$ | Alternatives | Try to retrieve chunks representing alternatives. <br> Select alternative corresponding to successfully <br> retrieved chunk. | Information at the subsymbolic <br> lever |
| Fluency Heuristic |  <br> Hertwig $(2005)$ | Alternatives | Retrieve chunks representing alternatives and time <br> retrieval using timing module <br> Select alternative with faster retrieval time. | environment) |

ACT-R describes cognition as a set of modules that communicate through a procedural module realized as a central production system. The production system consists of production rules (i.e., if-then rules) whose conditions (the "if"-parts) are matched against the modules. If a rule's conditions are met, then the rule can fire and the specified action can be carried out. Modules model different cognitive processes, such as vision (visual module), motor action (motor module), declarative memory (declarative module), short-term information storage (imaginal module) and time tracking (timing module; Taatgen, van Rijn, \& Anderson, 2007). Productions send commands to modules to perform an action or change their state, or to access content placed in modules' buffers. In fact, because productions can only access content placed in the buffers, these can be thought of as processing bottlenecks. For instance, a production rule cannot access all information stored in the declarative module, but only the information placed in its associated retrieval buffer.

Productions are the representation of choice for procedural knowledge, while declarative knowledge, such as factual and episodic knowledge, is represented as chunks. Perceptual and memory modules, respectively, perceive and retrieve information in the form of chunks. A chunk consists of a set of slots, where each slot is (a pointer to) another chunk. For example, a chunk containing information about a company's annual revenue will have a slot with the company's name and another slot with its revenue.

ACT-R distinguishes a symbolic and a subsymbolic system. Productions, modules and buffers constitute the symbolic system, whose dynamics are governed by a set of equations, describing ACT-R's subsymbolic system. At the subsymbolic level, chunks' activations determine, for example, retrieval time or recall probability; productions' utilities reflect which productions were more successful in the past and therefore more likely to fire; visual parameters determine the time needed to shift visual attention to an object in the visual field, while motor parameters determine the time to generate a motor response.

Each ACT-R model is essentially composed of specifications of how declarative and procedural knowledge interact, both at the symbolic and subsymbolic levels. We will now focus on describing the declarative and procedural knowledge used in defining the models in the database. We refer those interested in a detailed exposition of ACT-R to Anderson (2007).

## Model building blocks

The models of inference that we will consider are presented in Table 1. In implementing these models in ACT-R, we relied on the building blocks that this cognitive architecture provides.

## Perceptual and motor processes

All models have equivalent perceptual and motor processes, involving visual perception from a screen and manual action on a keyboard. The models first perceive
each of the alternatives presented on a computer screen and, after executing a sequence of cognitive steps, they make a response by pressing the appropriate key on a keyboard. The primary contribution to behavioral predictions of the perceptual and motor processes in our models is to add a realistic estimate of perceptual-motor latency.

## Declarative chunks

The factual knowledge (e.g., "Berlin is a capital") that a model relies upon to make a decision is stored in declarative memory. Ten types of chunks are needed to construct the models in the database. Table 2 provides a summary of those chunk types and examples in Lisp code for each. Note that the examples are given for the city-size task, in which cities act as alternatives and subjects need to infer which of two cities is larger.

The simplest chunk type contains just the name of the alternatives. For example, if the alternatives are cities, whose relative sizes need to be inferred, such a chunk contains the city name (e.g., "Berlin"). These chunks are all that is required for inferential models, which rely on accessibility information, such as the recognition and fluency heuristics.

The second chunk type contains an entire cue profile of an alternative (i.e., the set of cues associated with an alternative). Such chunks are used, among others, by exemplar and prototype models. Some exemplar models also require chunks with direct criterion knowledge in addition to the cue profile. Moreover, prototype models require not only cue profiles, but also a stored prototype of an object with a high criterion value.

Table 2: Declarative knowledge categories.

| Chunk type label | Chunk examples in Lisp code |
| :--- | :--- |
| Alternative | (berlin name Berlin) <br> (berlin name Berlin airport yes capital <br> yes ...) |
| Cue profile | (berlin name Berlin population <br> Cue profile with <br> direct criterion <br> knowledge |
| High criterion value <br> prototype | (big-city name prototype airport yes <br> capital yes ...) |
| Cue profile pair | (pair1 airportl yes airport2 no <br> capitall yes capital2 no ...) |
| Cue profile pair <br> prototype | (prototype-left airportl yes airport2 <br> no capitall yes capital2 no ...) |
| Cue | (cue1 type airport) |
| Cue value | (berlin-airport city Berlin cue airport <br> value yes) |
| Cue validity | (airport-validity cue airport validity <br> 90) <br> (cue-pair first airport second capital) |
| Cue validity pair |  |
| Note. In these examples, chunk names, used for convenience, are <br> presented in bold; slot names, indicating a specific attribute, are in <br> italics, while slot values, representing the attribute values, are in <br> normal font. |  |

Resembling exemplar and prototype models, instancebased learning theory and parallel constraint satisfaction consider cue configurations to make inferences. However, they differ from the former in that they require chunks, which contain pairs of cue profiles. For example, the model "Instance-based learning theory individual" retrieves the cue profiles of both alternatives and then retrieves a cue profile pair from a successful previous trial. It then makes an inference based on the decision outcome of the retrieved cue profile pair. Similarly, our implementation of the parallel constraint satisfaction model requires a prototype of a successful cue profile pair.

Unlike configural models, like exemplar models, cueabstraction models (Newell \& Bröder, 2008) operate on individual cues. Such models, like take-the-last, retrieve cues one by one. Take-the-last requires separate chunk types for a cue and for the values of the alternatives on that cue. In addition to these chunks, other models, like take-the-best, require information about cue validities (i.e., the probability of making a correct inference using only this cue if the cue discriminates; see, Gigerenzer, Hoffrage, \& Kleinbölting, 1991), which, if taught in the experiment (e.g., Bröder, \& Schiffer, 2003), are stored numerical values. Finally, in some experiments one is provided only with the validity hierarchy, which can be represented as validity pairs of subsequent cues.

## Procedural knowledge: The sequence of processing steps

The procedural knowledge of a model consists of a finegrained sequence of processing steps (i.e., productions) that the model relies upon to make a decision. In all models, the sequence of processing steps includes commands to the visual module to encode the information presented on the screen and to the motor module to press a key to respond in a computerized experiment. As for the rest, the exact sequence of processing steps follows the original model definitions.

For example, fast-and-frugal heuristics usually rely on separate cues, on which detailed search, stopping and decision rules operate. Those models often theorize about the order, in which cues are considered. This ordering can be modeled through productions. In addition, productions can also determine if the model weighs cues equally, as in tallying, or differently, as in the weighted additive model, and execute this process. If cues are weighted equally, productions are required to send a request to declarative memory to retrieve the cue values. Productions then increment by 1 the number, which tracks the count of cues with a positive cue value of the alternative of interest. Other models, such as exemplar models, rely on all available cue information stored in a single chunk to make a decision. In such models, procedural knowledge is more peripheral to the decision process and mostly focuses on retrieval attempts.

Productions not only initiate retrieval, but are also dependent on what is retrieved, because a key determinant of which productions can fire is the available declarative
knowledge. Specifically, at each point in time only those productions, whose condition match the buffer states, will be considered to fire. Ultimately, which chunks are retrieved from memory will determine what could be placed in the buffers and therefore which productions will match.

## Information at the subsymbolic level

At the subsymbolic level, there is continuously valued information, which is necessary for the execution of some inferential strategies. However, productions cannot directly read out subsymbolic values. Instead, the model needs to let subsymbolic values guide symbolic knowledge. Thus far, we have identified four ways in which subsymbolic values play a key role in the execution of strategies.

First, the activation of chunks representing alternatives contains information about the alternatives' occurrence frequency in the environment. Specifically, base-level activation is a function of prior history of a chunk, which partially depends on environmental occurrence frequency, which, in turn, is related to many criteria of interest (Hertwig, Herzog, Schooler, \& Reimer, 2008). Accessibility-based strategies, such as the fluency heuristic, track the retrieval speed of alternatives as determined by their activation and choose the alternative, which was retrieved noticeably faster.

Second, activation can order cues, because cues which have a higher occurrence in the environment likely will have a higher activation. Thus, these cues may be more likely to be considered first in lexicographic strategies, such as take-the-first-cue or a sequential sampling model.

A third way in which information at the subsymbolic level can be used is as an implicit cue weighting mechanism. This weighting can take place through spreading activation, which is determined by the degree of association between the chunks placed in buffers and the chunks in declarative memory. If the cue profile of one of the alternatives is currently placed in the imaginal buffer, then it will activate cue profiles in memory through spreading activation. Those cue profiles will then have precedence in retrieval. Exemplar models rely on this process to make an inference about the alternative's criterion value.

Finally, production utility contains information about prior success. Production utility determines which production is more likely to fire when two or more productions are competing. If such a competition takes place between productions, which select which cue will be considered next, the utility of these productions can act as a cue's importance (e.g., as its validity, see Gigerenzer, Hoffrage, \& Goldstein, 2008, for the hypothesis that such a reinforcement learning process can teach cue validities) in lexicographic cue-abstraction models. This is the mechanism used in the model "Take-the-best reinforcement", which encodes the selection of each cue with a separate production and then learns the success of those cues through trial and error.

## Discussion and conclusion

We aim to provide a database of ACT-R implementations of decision models used in the literature on inferences from memory. We have divided these models into their key components. The models can serve as a basis for model tests and further model developments. Specifically, this database can be used, first, in model comparison simulations on the outcome and process level, whereby one identifies regions in the parameter space where these models diverge. Second, this database can be used in future studies to identify decision processes using both behavioral and neural data. This is an important advantage of ACT-R, because any ACT-R model can generate fMRI predictions on top of behavioral process predictions, such as response time, because of the established module-to-brain mappings (for an introduction, see Borst \& Anderson, 2015).

In addition, we think that the systematic examination of the building blocks of existing decision models will help us gain insights into how the models are related to each other. For example, through these implementations, we see that the parallel constraint satisfaction model can be conceived as functionally similar to an instance-based learning model, which stores and retrieves prototypical cue profile pairs.

It is important to note that in creating our ACT-R models we were forced to work with the mechanisms that ACT-R provides. For example, the original parallel constraint satisfaction model is cast as a connectionist network, in which connection weights are iteratively updated after each decision. This leads to cues effectively changing their validities as trials progress. As currently conceived, our model does not reproduce this behavior. Nevertheless, the model "Instance-based learning theory average", which in our database is very similar, effectively provides such a mechanism and can be thought as functionally analogous to the original parallel constraint satisfaction.

Such redefinitions and novel distinctions introduced in our modeling endeavor were due to the partial overlap between the various decision models in the literature. Another such distinction that we decided to introduce was in the declarative representation, which cue-abstraction models, like take-the-best and the sequential sampling model introduced by Lee and Cummins (2004), rely on. Originally, both models were conceived as, first, considering a cue, and only then examining the values of that cue for both alternatives. We have kept this definition for take-the-best and other heuristics. However, we have decided to label those models, which retrieve cue values directly, in a manner purely determined by declarative principles, sequential sampling models. These models can, for example, consider the value of cue 2 for alternative A, followed by the value of cue 4 for alternative $B$, and so on.

Another remark concerns the high degree of detail, which ACT-R introduces when decision models are implemented in it. The fine-grained way in which ACT-R models are specified has forced us, in many cases, to make assumptions about processes, about which the original models remained silent. For example, we had to rely on assumptions about
how cues are ordered in take-the-best. We have considered two ways to order cues in this work. Our first implementation relies on declarative retrieval to order cues, while the second one relies on procedural knowledge and utility learning. These assumptions reflect, so we hope, realistic ways of learning. On the one hand, in many experiments on take-the-best, one is explicitly taught the cue hierarchy, which is then stored as declarative knowledge. On the other hand, in natural settings, ordering cues according to validity is likely to occur through reinforcement learning, whereby one has had significant experience with considering several cues in the same setting.

To conclude, we would like to stress that Table 1 does, naturally, not include all possible tweaks and modifications that one can introduce when constructing models in ACT-R. It will be left to input from the different researchers working on inference from memory to determine which of our current ideas will survive, and which ones will be replaced or extended by others.

# Talking to Ourselves to Engage Control? Testing Developmental Relations Between Self-directed Speech, Cognitive Control and Talkativeness 

Sabine Doebel (sabine.doebel@colorado.edu), Cleo Andersen-Green (cleo.andersengreen@colorado.edu)<br>and Yuko Munakata (munakata@colorado.edu)<br>Department of Psychology and Neuroscience, University of Colorado Boulder, Muenzinger Psychology 345 UCB<br>Boulder, CO 80309 USA

#### Abstract

Is self-directed speech critical to cognitive processes supporting complex, goal-directed behavior? If so, how? An influential developmental hypothesis is that children talk to themselves to support cognitive control processes, and that with age this speech becomes increasingly covert and strategic. However, while many studies suggest language supports cognitive control, evidence that self-directed speech gradually internalizes has been mixed. Moreover, extraneous factors that could co-vary with self-directed speech, age, and cognitive control, such as talkativeness, have not been systematically tested. In this cross-sectional study of 865 - to 7 -year-old children we measured overt, partially covert, inner, and strategic speech on four cognitive tasks, along with task performance and child talkativeness. We did not find consistent evidence that self-directed speech changes with age; however, we did find consistent associations between self-directed speech and talkativeness. Partially covert and strategic speech predicted performance on one task, and inner speech was implicated on another. Self-directed speech tended to correlate across tasks, and these correlations held controlling for talkativeness. Taken together, these findings suggest 5- to 7 -year-old children may use different forms of self-directed speech to support cognitive control, and that the form this speech takes depends in part on factors beyond age, such as the cognitive demands of a task and child characteristics like talkativeness.

Keywords: cognitive control; executive functions; selfdirected speech; language and thought

## Introduction

What role does language play in our ability to flexibly override impulses and achieve goals? An influential developmental hypothesis is that language is key to the emergence and exercise of cognitive processes supporting goal-directed behavior (Luria, 1961; Vygotsky 1934/2012; Winsler, Fernyhough, \& Montero, 2009). On this view, children's control processes are initially supported by the speech of others (e.g., parents and teachers), and later by children's own external speech, which is gradually internalized as inner speech (i.e., verbal thought) during childhood. Self-directed speech is thought to change qualitatively with internalization (e.g., becoming more condensed), allowing it to more effectively support cognitive control (Alderson-Day \& Fernyhough, 2015; Vygotsky 1934/2012).

This hypothesis fits with a large body of research indicating that language supports cognitive control across development. Children use their own speech to support many aspects of cognitive control, including planning (Al-

Namlah, Fernyhough, \& Meins, 2006; Fernyhough \& Fradley, 2005;), working memory (Al-Namlah et al., 2006; Flavell, Beach, \& Chinsky, 1966), and task switching (Karbach \& Kray, 2007). Moreover, linguistic interventions in which labels or other kinds of linguistic input are provided to children have been found to support cognitive control performance both in the moment (e.g., Kray, Eber, \& Karbach, 2008) and in the longer-term (Doebel, Dickerson, Hoover, \& Munakata, 2017; Doebel \& Zelazo, 2016). Experiments using articulatory suppression during cognitive tasks suggest older children and adults use inner speech when engaging cognitive control (e.g., Emerson \& Miyake, 2003; Kray, et al., 2008).

Key questions remain concerning the extent to which selfdirected speech changes with age, and the kinds of speech children use to support cognitive control. Evidence for the hypothesis that self-directed speech gradually internalizes has been mixed. For example, while some studies have found that overt, task-relevant speech decreases with age (Winsler \& Naglieri, 2003), others have not (Al-Namlah, et al., 2006; Flavell et al., 1966). And external forms of selfdirected speech do not always predict performance (e.g., Doebel, et al., 2017; Winsler \& Naglieri, 2003). Moreover, key variables that might account for the presence or absence of different forms of self-directed speech have not been systematically examined. For example, how talkative a child is may co-vary with age, performance, and self-directed speech, and thus could explain any relations found among these variables. Consistent with this idea, previous work has found correlations between self-directed speech and social speech/talkativeness (Al-Namlah et al., 2006; Fernyhough \& Fradley, 2005).

Gaining further insight into factors that predict selfdirected speech in childhood is critical both to understanding the role of language in cognitive control and how it can be improved in those who struggle with it. For example, if self-directed speech does generally internalize with age across a particular age window, this could suggest that training children to internalize their speech might help them better engage control.

The current study aimed to clarify relations between selfdirected speech, age, performance, and talkativeness in children 5 to 7 years of age, a developmental period posited to reflect key transitions in self-directed speech (Gathercole, 1998; Winsler \& Naglieri, 2003; Winsler et al., 2009). We assessed children's use of task-relevant overt, partially covert, inner, and strategic speech during four
cognitive tasks tapping control processes. The study evaluated two contrasting hypotheses. If self-directed speech becomes more internalized and strategic with age, then age-related changes in speech should be found across tasks, and self-directed speech should be associated with cognitive performance. However, if self-directed speech does not generally change across childhood and manifests differently depending on task demands and child characteristics, then inter-task correlations among selfdirected speech indices may be present, and possibly correlated with talkativeness, but relations with age should be less consistent.

## Method

## Participants

Eight-six 5- to 7-year-old children $\left(M_{\text {age }}=5.99\right.$ years $S D_{\text {age }}$ $=.61$, range $=5.0-7.1$; females $=47$ ) were recruited from a database of families who had previously indicated interest in participating in research. Four additional children were excluded from the study due to uncooperativeness $(n=3)$ and developmental delay $(n=1)$. Some children did not complete all tasks due to failure to demonstrate understanding during practice or uncooperativeness. In total, $84,83,72$, and 76 children completed the delayed serial recall task, selective attention task, Tower of London, and the immediate serial recall task, respectively. Most participants ( $>90 \%$ ) had at least one parent with a four-year college degree and were Caucasian and non-Hispanic.

## Measures

Children completed four cognitive measures across two test sessions. The tasks were completed in the following order: delayed serial recall, selective attention, Tower of London, and immediate serial recall. A fixed order was used to minimize variation between subjects in task performance due to differences in order (Friedman, et al., 2008). The first three measures were used to assess external self-directed speech in addition to cognitive performance. The last measure was used to index inner speech.

Delayed Serial Recall Task (adapted from Flavell, Beach, \& Chinsky, 1966; Fig. 1) Children were presented with pictures of objects serially on a computer screen, and, after an eight second delay, were asked to recall the order in which they were presented. At test, the three items were presented together in a new order, and children had to point to the pictures in the order that they saw them. Following three practice trials, children completed 10 test trials.

Selective Attention Task (adapted from Manfra \& Winsler, 2006; Fig. 2) Children were shown a page of three pictures that matched on one of three dimensions (shape, color, number), and were asked to search a box for a picture card that reflected the matching dimension. The box contained 18 picture cards depicting a single dimensional value (e.g., a purple splotch or a silhouette of a star).

Following three practice trials, children completed 12 test trials.

Figure 1: Delayed serial recall task.

Tower of London planning task (adapted from Fernyhough \& Fradley, 2005; Fig. 3) Children were presented with two apparatuses, each of which had three wooden pegs of different lengths and three colored wooden spheres on the pegs. The spheres were configured in a different arrangement on each apparatus, and children were instructed to make one apparatus look like the other in as few moves as possible. They were also instructed that they could only move one sphere at a time and had to keep all spheres on the pegs (i.e., not holding a sphere in their hand while making moves with another sphere). Children completed six trials in total, half of which could be completed in three moves, and the other half of which could be completed in four moves. Performance was indexed by the total number of moves children made in excess of the minimum number required, divided by the total number of trials completed. If children broke rules or asked to start over, the trial was restarted. Only the final attempt at a trial and trials that were successfully completed were included in our analyses.

Immediate Serial Recall (adapted from Al-Namlah et al., 2006; Tam, Jarrold, Baddeley, \& Sabatos-DeVito, 2010) This task was identical to the delayed serial recall task except that 1) there was no delay between the stimuli presentation and the test phase; 2) children were instructed not to label the pictures overtly while they were being initially presented (Al-Namlah et al., 2006); and 3) children completed two ten-trial blocks instead of one: a phonologically similar block and a phonologically dissimilar block. The phonologically dissimilar block involved the same items presented in the delayed serial recall task. The phonologically similar block involved items that had similar-sounding names (e.g., clock, clown, cat). Inner speech was indexed as the accuracy rate on the phonologically similar block subtracted from the accuracy rate on the phonologically dissimilar block, with the
expectation that children who used inner speech (i.e., verbal coding of the to-be-remembered objects) would perform worse on the phonologically similar block because verbal coding would make the items more confusable.

Figure 2: Selective attention task.

Figure 3: Tower of London planning task.

Talkativeness Parents were asked to rate their child's level of talkativeness with people he or she does not know on a 5point scale, with 1 indicating that the child is not at all talkative, and 5 indicating that the child is very talkative. This approach was adapted from prior work in which teachers were asked to rate children's general talkativeness (Fernyhough \& Fradley, 2005). We opted to ask more specifically about talkativeness with unfamiliar people in order to reduce the likelihood that parents' evaluations would reflect how talkative their child is at home, which we expected would result in a less sensitive measure.

## Self-directed Speech Coding

Our coding scheme was based on prior work in this area (Winsler \& Naglieri, 2003; Flavell et al., 1966). Speech during each trial of each cognitive task was coded from videos by a research assistant who was blind to the experimental hypotheses. Ten percent of the videos were coded by a second blinded research assistant and inter-rater agreement was high, $r \mathrm{~s}>.85$. Each task was coded for nonsocial overt speech, defined as normal volume speech not directed at another person that could support task performance (rather than meta-comments about the task or stimuli, or comments unrelated to the task) and partially covert speech, such as whispering, muttering, and lip movement.

In addition, task-specific speech strategies were coded. On the delayed serial recall task, labeling at the onset of a trial (when the stimuli were being presented) and rehearsal
(during the presentation and test interval) were coded. On the selective attention task, labeling the matching dimension (e.g., "They're all purple") at the onset of or during the test trial was coded. On the Tower of London task, labeling the sphere and the location the child was placing or planning to place it was coded (e.g., "This one goes here for now"). For analyses, the number of trials on which a child used each coded form of speech was scaled by the number of trials the child completed.

## Results

## Self-directed Speech Variability and Frequency

As expected, all cognitive tasks elicited some self-directed speech (Table 1), and there was variability across tasks in the kinds of speech children used. However, numerous children did not use overt or partially covert self-directed speech on the tasks: 20 of 84 on the delayed serial recall task; 21 of 84 on the selective attention task; and 29 of 77 on the Tower of London task. This is comparable to rates of self-directed speech found in prior work (Fernyhough \& Fradley, 2005; Flavell et al., 1966; Manfra \& Winsler, 2006; Winsler \& Naglieri, 2003). Children showed evidence of inner speech on the immediate recall task, performing significantly worse on the phonologically similar block ( $M_{\text {accuracy }}=65 \%, S D=22 \%$ ) than on the phonologically dissimilar block ( $M_{\text {accuracy }}=72 \%, \mathrm{SD}=24 \%$ ), $M_{\text {diff }}=.07$ $S D_{\text {diff }}=.17, t(76)=3.74, p<.001$, consistent with previous findings (Al-Namlah et al., 2006; Tam, et al., 2010).

Table 1: Prevalence of Different Forms of External Self-directed Speech Across Measures

| Self-directed Speech <br> Task and Index | Mean \% of <br> trials on which <br> speech used | $N$ <br> children <br> using <br> speech |
| :--- | :---: | :---: |
| Delayed serial recall | $.30(.42)$ | 35 |
| Overt speech | $.31(.35)$ | 52 |
| Partially covert speech | $.27(.35)$ | 42 |
| Rehearsal | $.44(.44)$ | 48 |
| Labeling | $.24(.35)$ | 38 |
| Selective attention | $.28(28)$ | 58 |
| Overt speech | $.28(.34)$ | 47 |
| Partially covert speech |  |  |
| Labeling | $.16(.27)$ | 28 |
| Tower of London | $.22(.26)$ | 44 |
| Overt speech | $.15(.24)$ | 28 |
| Partially covert speech |  |  |
| Labeling |  |  |

## Relations Between Self-directed Speech and Age

We found minimal support for the hypothesis that selfdirected speech changes with age (Table 2). Zero-order correlations indicated that only partially covert speech on the selective attention task was related to age, such that as children got older they used less partially covert speech

Table 2: Correlations Between Self-directed Speech Indices and Age, Talkativeness, and Task Performance

| Self-directed <br> Speech Measure <br> and Index | Age | Talkativeness | Task <br> Score |
| :--- | :--- | :--- | :--- |
| Delayed recall | -.17 | $.19^{\wedge}$ | .04 |
| Overt | .13 | .14 | $.33^{* *}$ |
| Partially covert | .03 | $-.32^{* *}$ | $-.28^{*}$ |
| No speech | .18 | .09 | $.31^{* *}$ |
| Rehearsal | -.13 | $.28^{*}$ | $.19^{\wedge}$ |
| Labeling |  |  |  |
| Selective attention | -.03 | $.32^{* *}$ | .01 |
| $\quad$ Overt | $-.28^{*}$ | .16 | -.06 |
| Partially covert | .18 | $-.32^{* *}$ | .06 |
| No speech | -.08 | $.31^{* *}$ | .02 |
| Labeling |  | .17 | .14 |
| Tower of London | .08 | .17 |  |
| $\quad$ Overt | . .03 | $.28^{*}$ | .05 |
| Partially covert | -.10 | $-.20^{\wedge}$ | -.10 |
| No speech | .05 | $.26^{*}$ | -.07 |
| Labeling | .00 | .02 | - |
| Immediate recall |  |  |  |

(Table 2). All other age/self-directed speech correlations were not significant.

These analyses were followed up with linear regressions predicting age from self-directed speech, with related speech indices simultaneously included in models to control for one another's effects, and the results were unchanged. On the selective attention task, partially covert speech remained a significant predictor, $B=-7.36, S E=2.82, t=$ $2.60, p=.01$, whereas overt speech was not, $t<1, p>.25$. On the delayed serial recall task and Tower of London, neither overt nor partially covert speech were associated with age, $t \mathrm{~s}<1.38, p \mathrm{~s}>.17$. Similarly, neither rehearsal nor labeling changed with age on the delayed serial recall task, $t \mathrm{~s}>1.5, p \mathrm{~s}>.13$.

## Relations Between Self-directed Speech and Talkativeness

Across tasks, children who tended to use external forms of self-directed speech also tended to be more talkative (Table 2). Talkativeness was correlated with overt speech on all tasks, partially covert speech on the Tower of London (but not the delayed serial recall or selective attention tasks), and labeling (but not rehearsal) on the delayed serial recall and selective attention tasks. Inner speech on the immediate recall task was not associated with talkativeness. Talkativeness was not associated with age, $r=-.06, p>.25$, nor was it associated with performance on any of the tasks, $r \mathrm{~s}<.16, p \mathrm{~s}>.14$. As such, it was not included as a control variable in any models involving these factors.

## Relations Between Self-directed Speech and Performance

Children performed well on the four tasks (Table 3) and examination of histograms did not reveal floor or ceiling effects. Self-directed speech predicted performance on the delayed serial recall task. Zero-order correlations indicate partially covert speech and rehearsal were associated with performance on the delayed serial recall task, and also indicated a marginally significant association between labeling and performance on that task (Table 2). These findings were confirmed with linear models. Partially covert speech was a significant predictor of performance on delayed serial recall, controlling for overt speech, $B=.22$, $S E=.07, t=3.2, p=.002$, whereas overt speech was not predictive when controlling for partially covert speech, $t<1$, $p>.25$. Similarly, rehearsal was a significant predictor of performance on the delayed serial recall task, controlling for labeling, $B=.18, S E=.07, t=2.62, \mathrm{p}=.02$, consistent with prior work (Flavell et al., 1966). There was also a nonsignificant trend such that labeling tended to predict performance on the delayed serial recall task, controlling for rehearsal, $B=.09, t=1.59, p=.11$. However, self-directed speech on the selective attention task and Tower of London was not predictive of performance on those tasks, $t \mathrm{~s}<1, p \mathrm{~s}$ $>.25$.

Table 3: Performance on Cognitive Measures

| Measure | $M$ | $S D$ | Range |
| :--- | :--- | :--- | :--- |
| Delayed recall | .75 | .22 | $0-1$ |
| Selective attention | .94 | .13 | $.33-1$ |
| Tower of London | .65 | 1.48 | $0-11$ |
| Immediate recall - <br> phonologically similar block <br> Immediate recall - <br> $\quad .65$ | .22 | $0-1$ |  |
| $\quad$ phonologically dissimilar block | .72 | .24 | $0-1$ |

## Correlations Between Self-directed Speech Indices Within and Across Tasks

Many self-directed speech indices were correlated across tasks (Table 3). For example, children who used partially covert speech on the delayed serial recall task also tended to use it on the selective attention and Tower of London tasks, and children who used rehearsal on the delayed serial recall task tended to label on the selective attention task. These findings generally held when controlling for talkativeness, with the exception that some of the correlations between partially covert speech on Tower of London and other indices (partially covert speech and labeling on delayed serial recall, and labeling on selective attention) were no longer statistically significant, $r \mathrm{~s}<.18, p \mathrm{~s}>.10$.

We also found many correlations between self-directed speech indices within tasks. Some correlations were very strong, suggesting that certain strategies tend to be expressed more or less covertly.

Table 3: Correlations Between Self-directed Speech Indices Within and Across Cognitive Tasks

| Task and Speech Index | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9 | 10 |
| :--- | :--- | :--- | :--- | :--- | :--- | :--- | :--- | :--- | :--- | :--- |
| 1. DR overt |  |  |  |  |  |  |  |  |  |  |
| 2. DR partially covert | -.17 |  |  |  |  |  |  |  |  |  |
| 3. DR rehearsal | .06 | $.74^{* * *}$ |  |  |  |  |  |  |  |  |
| 4. DR labeling | $.82^{* * *}$ | $.26^{*}$ | $.27^{*}$ |  |  |  |  |  |  |  |

## Discussion

The current study provides several new findings related to the role of self-directed speech in developing cognitive control. We did not find evidence that self-directed speech undergoes a general internalization process with age. Instead, our findings suggest that the format of self-directed speech may depend in part on other factors like child talkativeness and the specific cognitive demands of a task. We found that 5- to 7-year-old children used inner, partially covert, and strategic speech while engaging cognitive control on different tasks, and that more overt forms of speech tended to be related to talkativeness. The finding that external forms of self-directed speech predicted performance on the delayed serial recall task but not the selective attention and Tower of London tasks suggests that children may have been supporting cognitive performance on the latter tasks with internalized speech. The delayed serial recall task likely had the highest working memory demands of all the tasks (given the need to maintain three items in mind in a particular order across time) and as such, external speech may have been necessary to support performance. Conversely, the working memory demands of the selective attention and Tower of London tasks may have been lower, and thus inner speech may have been sufficient to support performance on those tasks. For example, on the selective attention task children needed to identify a common dimension among three objects on a page and keep that dimension in mind to guide their searching, but they could always look back at the objects on the page to recall the dimension, and they only had to maintain one dimension in mind.

These findings are consistent with an alternative view of how linguistic input influences developing cognitive control, and highlight the possibility that inner speech may play a role in cognitive control from early in development. For example, teaching 5-year-old children labels that can be used to support cognitive control helps children later engage control; however, children's tendency to vocalize the labels
when engaging control does not predict performance (Doebel, et al., 2017), consistent with the possibility that children can rapidly internalize speech used to support control. Foundational cognitive control processes begin to develop very early in life (Munakata, 1998), and continue to develop rapidly in early childhood, between 3 and 5 years of age (Diamond, 2013). Internalized forms of self-directed speech could be critical to the emergence of these processes.

An alternative interpretation of our findings is that there are indeed robust age-related changes in self-directed speech, but that our age range and sample size were too constrained to detect them. For example, prior work has found age differences in the use of rehearsal to support serial recall when the age groups being compared were 5,7 and 10 years (Flavell et al., 1966), and that overt selfdirected speech decreases with age in a large sample aged 5 to 17 years (Winsler \& Naglieri, 2003). However, given the frequency and variability in speech use in the current study, and that our sample spanned an age range identified as a transition period in the use of self-directed speech (e.g., Winsler \& Naglieri, 2003; Winsler, et al., 2009), it was surprising that age was not a significant predictor of speech on most tasks. Another possibility is that age-related patterns only manifest when cognitive demands are high and inner speech is insufficient to maintain the goal representations guiding performance. Future experiments can test this by manipulating the maintenance demands in a task and testing associations between age and self-directed speech.

Our findings are correlational, leaving open alternative explanations for the relation between self-directed speech and cognitive control. For example, it is possible that developmental increases in cognitive control lead to changes in self-directed speech (and that self-directed speech is epiphenomenal). Or a third, unmeasured variable may explain the relation between self-directed speech and cognitive control. Experiments manipulating cognitive control and testing influences on self-directed speech, and vice versa, could address this causal issue.

Self-directed speech may be a good target for interventions to improve cognitive control. Given that cognitive control develops dramatically in early childhood and predicts success in life across a range of outcomes (e.g., academics, health, and wealth; Moffitt, et al., 2011), there has been great interest in developing effective interventions to improve it. However, results of interventions to date have been mixed (e.g., Melby-Lervag \& Hulme, 2013). One potential reason is that approaches to date have not optimally targeted the processes that support developing cognitive control. Training children to use different forms of self-directed speech to support cognitive performance, such as labeling, rehearsal, and partially covert speech, may be a fruitful approach to improving control in children. ${ }^{1}$

The current study advances knowledge on the role of selfdirected speech in cognitive control by suggesting that the kinds of speech children use to support cognitive performance in childhood may depend on a range of factors beyond age, such as child talkativeness and the cognitive demands of a task. Future work can further test how selfdirected speech relates to cognitive control and how it can be targeted in cognitive control interventions.

# The Interplay Between Self-evaluation, Goal Orientation, and Self-efficacy on Performance and Learning 

Kit S. Double (kit.double@sydney.edu.au)<br>Department of Psychology, University of Sydney<br>Sydney, NSW, Australia<br>Damian P. Birney (damian.birney@sydney.edu.au)<br>Department of Psychology, University of Sydney<br>Sydney, NSW, Australia

#### Abstract

Objective Self-awareness Theory (Duval \& Wicklund, 1972) proposes that self-evaluation increases an individual's awareness of any discrepancy between their current performance and an internal goal. In the current study we prompted self-evaluation throughout an intelligence test (Analysis-Synthesis Test - AST) using confidence ratings (CR). AST performance, the extent to which participants incidentally learnt task-relevant rules (learning rules was unnecessary because they were provided), self-efficacy, and goals, were assessed. The results indicated an effect of performing CR on both performance and rule learning, but the effect depended on self-efficacy. Compared to matched controls ( $n=45$ ), participants who performed CR ( $n=41$ ) and had high self-efficacy performed better on the AST but learnt fewer rules. Performing $C R$ had no effect on participants low in self-efficacy. This suggests that selfevaluation interacts with self-efficacy to modify participants' goals, specifically CR appear to shift individuals high in self-efficacy from a mastery goal to a performance goal.

Keywords: reasoning, intelligence, reactivity, goal orientation, self-efficacy

## The Interplay Between Self-evaluation, Goal Orientation, and Self-efficacy on Performance and Learning

Accurate self-knowledge is a highly valued attribute and important to everyday functioning. Awareness of our own abilities and past performance facilitates realistic goal selection and allows us to better direct our future behavior. There is some evidence that self-evaluation occurs almost continuously when we perform a demanding cognitive activity, and this self-evaluation may occur both spontaneously and unconsciously. Self-evaluation in this context is often referred to as performance monitoring or alternatively error detection. Performance monitoring is vital to learning outcomes as it allows the learner to identify errors so that they can avoid repeating them in the future (Yeung \& Summerfield, 2012). Performance monitoring is also important for the effective allocation of cognitive
resources (Carter et al., 1998). Accurate performance monitoring is central to an individual's ability to regulate their own cognitive behavior (Nelson \& Dunlosky, 1991) and, in particular, effectively make decisions about study time (e.g. Metcalfe \& Finn, 2008; Son \& Metcalfe, 2000). Furthermore, learners need to continually evaluate the effectiveness of different study activities on their learning in order to select the best possible study behaviors (Flavell, 1979).

Given the importance of accurate self-knowledge, individuals such as students and employees are often encouraged to self-reflect and self-evaluate their performance so that they can better identify their strengths weaknesses and detect issues or errors (Carver \& Scheier, 2001). However, there is little direct evidence that selfevaluation leads to more accurate self-knowledge (Silvia \& Gendolla, 2001). Indeed, self-assessment is often systematically inaccurate and flawed, which can often lead to negative outcomes and ineffective decision making (Dunning, Heath, \& Suls, 2004). Objective self-awareness theory (OST; Duval \& Wicklund, 1972, 1973) contends that self-focused attention does not necessarily lead to accurate self-knowledge, instead it directs individuals' attention to discrepancies between their current performance or behavior and their internal standards or goals (Silvia \& Duval, 2001), referred to here as goal discrepancies. OST theory argues that when an individual becomes aware of a goal discrepancy, they either modify their behavior to bring it in line with their goal, modify their goal, or disengage from the activity, which reduces their awareness of the goal discrepancy (Silvia \& Duval, 2001). For example, upon reflecting on their studying, a student may determine that they have not been working hard enough to prepare for an upcoming exam, which may lead them to study more or set a more modest goal for the exam, alternatively they may try to distract themselves to avoid thinking about studying for the exam.

Which of these three strategies an individual adopts is largely determined by their self-efficacy, if an individual has high self-efficacy they will believe that they can improve their performance to match their goal and will act accordingly, whereas individuals low in self-efficacy may lower their goals or disengage from the task because they do not believe they can implement the necessary improvements
in their performance. We can conceptualize these expected changes in terms of the goals we expect participants to adopt. We hypothesize that self-evaluation will lead high self-efficacy participants to focus on improving their performance, whereas low self-efficacy participants will either disengage from the task or lower their goal, both of which are likely to impair their performance on the task. These hypotheses therefore relate to changes in a participants goal orientation.

Goal orientation is a well-studied concept that broadly concerns the distinction between mastery goals that concern development, improvement, and learning compared with performance goals which prioritize performing well and demonstrating ability (VandeWalle, 1997). Generally speaking mastery goals are considered advantageous for a range of outcomes including academic engagement (Ames \& Archer, 1988; Pintrich, 2000; Wolters, 2004), job performance (Janssen \& Van Yperen, 2004; VandeWalle, Brown, Cron, \& Slocum Jr, 1999), and cognitive ability (Eison, 1981). Although some have conceptualized goal orientation as a trait or at least a quasi-trait like concept (DeShon \& Gillespie, 2005), goal orientation is domain specific and can equally be considered as state-like (VandeWalle, Cron, \& Slocum Jr, 2001). The goal orientation that an individual selects for a particular situation is somewhat determined by an individual's selfefficacy (Diseth, 2011). Individuals with high self-efficacy tent to pursue their goals with more effort and endeavor to develop from the experience of goal pursuit (DeGeest \& Brown, 2011). Given this, a number of studies have expectedly shown a positive relationship between high selfefficacy and mastery goal orientation (Bell \& Kozlowski, 2002; Diseth, 2011).

H1: In the control group (without self-evaluation), high self-efficacy participants will display mastery goal orientated behavior, whereas low self-efficacy participants will show performance goal orientated behavior.

The rationale behind encouraging self-evaluation in schools and workplaces has often been that they will elicit greater effort and goal driven behavior. However, as previously mentioned, when an individual becomes aware of a goal discrepancy they can either change their behavior or alternatively they can modify their standard/goal. With regards to modifying a goal, this may occur quantitatively (e.g. changing from a goal of a 75 on an exam to a 65) or qualitatively changing the nature of the goal (e.g. changing from try to master the material in a class to focusing on passing the exam). Based on this OST framework we expect that self-evaluation will lead participants with high selfefficacy to shift to a performance orientation in order to improve their performance and reduce the goal discrepancy. As previously stated, participants with low self-efficacy are likely to naturally adopt a performance goal-orientation and therefore self-evaluation should have little effect on the goal-orientation they adopt.

There is some previous evidence that self-evaluative prompts lead to such changes in goal orientation. A recent study by Mitchum, Kelley, and Fox (2016) using a wordpair learning paradigm found that, if the list of word-pairs participants were learning contained both difficult and easy items, then performing judgments of learning (i.e. rating how likely it is that they will recall a word-pair on a later test) resulted in participants spending more of their study time on the easier items rather than the difficult items. This resulted in participants who performed judgments of learning recalling fewer word-pairs on a subsequent test. The authors suggested that in the presence of both easy and hard items, judgments of learning make participants aware of the fact that they will inevitably fail to remember all of the words on the list, so they adopt a performance orientation rather than a mastery orientation and over study the easier items.

H2: Self-evaluation will result in participants adopting a performance goal orientation, regardless of their level of self-efficacy

In the current study we induce self-focused attention by asking participants to self-evaluate their performance after each item on an intelligence test, by providing confidence ratings (CR). CR direct participants' attention to their current subjective belief in their performance by require participants to reflect on, evaluate, and quantify their performance. A previous study which examined the effects of eliciting confidence ratings from participants while they completed an intelligence test found that participants who provided CR, performed better than participants who performed the task without providing ratings (Double \& Birney, 2017). Crucially, a subsequent experiment showed that this effect depended on the confidence/self-efficacy of participants, with CR facilitating the performance of high self-confidence participants but hindering the performance of low self-confidence participants.

H3: Performing CR will facilitate performance in high-self-efficacy participants and impair performance in low self-efficacy participants

In the current experiment participants completed a deliberately difficult task so that they would be likely to experience a performance discrepancy when they selfevaluated their performance. Of primary interest is whether this self-evaluation causes participants to improve their performance and/or change their goal orientation.

## Method

## Participants

A community sample of 85 participants ( $80 \%$ female) was recruited using an advertisement placed in a newsletter of the Australian Broadcasting Corporation as part of a research partnership with the University of Sydney $\left(M_{\text {age }}=\right.$
63.75, $\mathrm{SD}=9.83$ ). Participants received no remuneration for participating in the study. Participants were randomly allocated to the confidence ratings group (CR group; $n=42$ ) or a control group that did not provide confidence ratings (No-CR group; $n=43$ ).

## Materials and procedure

Participants completed the following measures online from their own personal computers using Qualtrics (Qualtrics, 2015) and Inquisit (Inquisit, 2016). All materials were programmed to display in a standardized fashion.

Analysis Synthesis Task (AST; Woodcock, McGrew, Mather, \& Schrank, 2001): A modified computerized version of the AST tasks was performed by participants. The AST task requires participants to solve problems by combining a series of tiles using a set of simple rules (e.g. a red triangle and purple square make blue circle). The rules are displayed continuously in the form of a key at the top of the screen. Figure 1 presents a typical question. One tile is blank and participants must decide which tile correctly fills the blank. Participants could combine any two tiles that are next to each other either horizontally or vertically.

As the task was expected to be difficult for a community sample, participants were given a series of practice items and were allowed to continue to practice until they felt they were ready to progress to the test phase (minimum of 12 practice items, maximum 36). The test block consisted of 20 items that were approximately ordered according to their difficulty. There were 5 rules in each of the practice and test blocks (different rules/stimuli were used in the practice and test phases).

Participants in the CR group were asked to rate their confidence that they answered the previous item correctly using a scale from $0-100 \%$. In order to reduce any response time effect on performance, participants in the control group were shown a blank screen for 2000 ms after each trial.

Figure 1: A typical question drawn from the AST task. that were used in the test block.

Self-efficacy: As self-efficacy is domain specific we used a particularly proximal measure of self-efficacy by having participants predict their score on the test block as a percentage after completing the practice block.

Rule Recall Test: After finishing the test block participants unexpectedly performed a recall test of the rules Participants had been given no prior warning that they would need to recall the rules on the later task and it was not necessary that participants memorize them as they had been displayed on the screen continuously during the AST task. The recall test asked participants questions such as "what color is the combination of the red triangle and blue circle?".

## Results

All data analysis was performed using $R$ version 3.2.3 ( R Core Team, 2015). Table 1 presents summary statistics for key study variables. The number of practice trials performed did not differ significantly between the CR group and the No-CR group, $F(1,83)=.17, p=.683$. Participants' initial predictions of their performance did not differ significantly between the CR group and the No-CR group, $F(1,83)=$ $.002, p=.967$.

Table 1: Descriptive statistics for key study variables.

| Variable | N | $M$ | SD |
| :--- | :---: | :---: | :---: |
| Predicted performance | 85 | 31.5 | 21.7 |
| Number of practice trials | 85 | 23.1 | 9.7 |
| AST practice score | 85 | 10.6 | 4.9 |
| AST test score | 85 | 10.3 | 2.7 |
| Rules recalled | 74 | 2.2 | 1.7 |

## AST Performance

Performance was analyzed using a linear regression model with number of correct items as the criterion variable. Experimental group and self-efficacy were entered as predictors along with the relevant interaction. In addition, as we were primarily interested in the moderating effect of self-efficacy, over and above ability, we included participants' practice scores and number of practice trails as covariates. Overall there was no main effect of experimental group, $\beta=.08, t(79)=.89, p=.378$. Self-efficacy was a significant negative predictor of performance, $\beta=-.27, t(79)$ $=2.02, p=.047$. Practice score and practice trial count were both positive predictors of test performance; $\beta=.68, t(79)=$ $7.19, p<.001$ and $\beta=.35, t(79)=4.03, p<.001$ respectively. Crucially, the group X predicted performance interaction was a significant predictor of test performance, $\beta$ $=.27, t(79)=2.07, p=.042$, see Figure 2 .
A simple slopes analysis indicated that self-efficacy was a significant negative predictor for the No-CR group, $\beta=-.18$, $t(79)=2.02, p=.047$, but not a significant predictor of performance for the CR group, $\beta=.06, t(79)=.74, p=.464$.

As shown in Figure 2, participants with high self-efficacy performed better in the CR group than the NO-CR group, whereas there was no group difference for participants with low self-efficacy.

Figure 2: Average number of correct items on the analysis synthesis task as a function of experimental group and predicted performance. The values used for high and low predicted performance are 1 standard deviation above and below the mean respectively. Error bars represent $\pm 1$ standard error of the mean.

## Rule Recall

11 participants did not complete the rule recall test and were therefore excluded from the analysis. Rule recall was analyzed using a second linear regression with number of correctly recalled rules as the criterion variable.

Experimental group, self-efficacy, and the interaction between the two were entered as predictor variables. In addition, to control for performance on the analysis synthesis task, AST test performance was entered as a covariate. Again there was no significant main effect of experimental group, $\beta=-.16, t(69)=1.54, p=.128$. Selfefficacy and AST performance were both significant positive predictors of rule recall performance, $\beta=.47, t(69)$ $=2.94, p=.004$ and $\beta=.33, t(69)=3.03, p=.003$ respectively. Again the hypothesized group X self-efficacy interaction was significant, $\beta=-.36, t(69)=2.25, p=.028$, see Figure 3. Simple slopes analysis indicated that selfefficacy was a significant positive predictor of recall performance for the No-CR group, $\beta=.31, t(69)=2.94, p=$ .004 , but not for the CR group, $\beta=-.01, t(69)=.11, p=$ .911. As shown in Figure 3, participants with high selfefficacy in the No-CR group outperformed all other groups in terms of rule recall.

Figure 3: Average number of rules recalled as a function of experimental group and predicted performance. The values used for high and low predicted performance are 1 standard deviation above and below the mean respectively. Error bars represent $\pm 1$ standard error of the mean.

## Discussion

Self-evaluation is often assumed to be an effective method to obtain accurate self-knowledge about one's abilities and performance. Organizations and educators often pursue formal and informal opportunities for feedback and evaluation, such as performance reviews, testing etc. These procedures may have many benefits such as improving communication, identifying ongoing issues, and providing feedback. However, in terms of the effect of self-evaluation on performance the current results reveal two important caveats in determining whether there is a benefit to performance/learning outcomes as a result of selfevaluation. The first is the importance of self-efficacy, our results show that self-evaluation improved the performance of participants with high self-efficacy but had no effect on participants with low self-efficacy. The second finding of note is that the effect of self-evaluation may depend on the nature of the outcome you are assessing. For participants high in self-efficacy, self-evaluation improved performance but impaired incidental learning, whereas there was no effect on either outcome for low self-efficacy participants.

According to OST, self-efficacy moderates the way in which we behave when confronted with goal discrepancies. The theory suggests that when high self-efficacy participants are confronted with goal discrepancies they work to improve their performance, whereas low selfefficacy participants may disengage from the task (thereby reducing awareness of the goal discrepancy). Our results conform to this general pattern with high self-efficacy participants improving their performance in response to CR
and low self-efficacy participants obtaining no benefit. This is in keeping with the previous finding by Double and Birney (2017), who demonstrated that performing CR during Raven's Progressive Matrices improved the task performance of high-confidence participants and impaired the performance of low-confidence participants. Our results have similarly found an asymmetry in the effect of CR on performance as a function of self-efficacy. Although we found no evidence of impaired performance in low selfefficacy participants, our results demonstrated that CR were beneficial only to participants high in self-efficacy. The difference in findings between this and Double and Birney (2017) in terms of low self-efficacy participants needs further exploration but may be a result of differences in how self-efficacy/self-confidence was assessed or the nature /difficulty of the task.

The current results suggest that high self-efficacy participants ordinarily adopt a mastery goal orientation, but shifted to a performance orientation when asked to perform CR. The finding that high self-efficacy participants tend to adopt a mastery goal is in keeping with the established relationship between goals and self-efficacy (Bell \& Kozlowski, 2002; DeGeest \& Brown, 2011; Diseth, 2011). Importantly, to our knowledge the results of the current study are the first to show that self-evaluation prompts high self-efficacy participants to adopt a performance orientation, which benefits performance but hinders incidental learning. When individuals high in self-efficacy are made aware of goal discrepancies they are likely to be motivated to reduce that discrepancy by attempting to improve their performance (Silvia \& Duval, 2001). The current results indicate that this focus on performance may come at the cost of a shift away from learning in line with the classic goal orientations paradigm (VandeWalle, 1997). It may be that, as a result of the evaluative nature of CR , they prompt high self-efficacy participants to direct attention to task relevant information and ignore task-irrelevant (rule) information. This suggests that appropriateness of using self-evaluation may depend on the outcomes of interest. In classrooms and workplaces self-evaluation has often become commonplace, but this may be problematic given the current body of evidence suggesting that a mastery orientation has many relative advantages in such settings (Janssen \& Van Yperen, 2004; Pintrich, 2000; Wolters, 2004). Although selfevaluation may be beneficial, the current results indicate that both self-efficacy and whether the valued outcomes are learning or performance based need to be considered before advocating self-evaluation.

Metacognitive interventions are often encouraged in the education literature and have obtained some positive results (Berardi-Coletta, Buyer, Dominowski, \& Rellinger, 1995; Desoete \& Roeyers, 2006). The current results, however, raise the possibility that such interventions are selectively benefiting students with high self-efficacy. Metacognitive prompts encourage individuals to monitor and evaluate their performance. Although the metacognitive literature has argued that such behaviors are important for error
monitoring, strategy selection and allocating cognitive resources, such behaviors also induce self-focused attention and may have an interactive effect with self-efficacy. Metacognitive prompts encourage individuals to monitor and evaluate their performance but do not necessarily provide a framework for doing so accurately. Although individuals are generally able to monitor their performance effectively, there are significant individual differences in the accuracy of such monitoring. It may be that in the current study, participants' evaluations of their own performance were shaped by their self-efficacy (i.e. high self-efficacy participants were likely to evaluate their performance positively and vice versa) and as such self-evaluation may reinforce existing beliefs in ability and thereby benefit only those who have a positive view of their own ability.

The current study has provided evidence that selfevaluative practice interact with self-efficacy to affect performance and incidental learning in an intelligence test. Given that self-evaluation is widely encouraged in both schools and workplaces, these results provide much needed research into the factors that affect the benefits of selfevaluation. The current results suggest that self-evaluation is beneficial to the performance of high self-efficacy individuals, but impairs incidental learning, most likely as a result of encouraging such individuals to adopt a performance goal orientation. For individuals low in selfefficacy, however, self-evaluation appears to have no effect on either their performance or learning outcomes.

#### Abstract

The current study incorporates concepts from dynamical systems theory (DST) and embodied cognition to propose a novel method of answering traditional questions in social psychology. Namely, we were interested in understanding postural sway complexity during the important interpersonal task of disclosing a hidden stigmatized identity (e.g., mental health disorder, history of sexual abuse). Using detrended fluctuation analysis and multifractal detrended fluctuation analysis, we captured postural activity while people shared their personal secrets to an imagined other. Results suggest that disclosure context, defined by both disclosure confidant and antecedent goals, is indeed embodied in our complex postural activity.

Keywords: Postural Sway; Concealable Stigmatized Identities; Detrended Fluctuation Analysis; Multifractal Detrended Fluctuation Analysis

## Introduction

The current project applied concepts from dynamical systems theory (DST) to common social-psychological phenomenon through the analysis of complex postural activity. Postural sway refers to subtle, unintentional movements that all people exhibit even when standing still. These nearly imperceptible fluctuations have demonstrated a functional role in maintaining balance and even efficiently exploring the environment (i.e., detecting depth) (Era \& Heikkinen, 1985). Generally, healthy adults tend to sway approximately 1 cm in the anterior-posterior (AP) direction and .5 cm in the mediolateral (ML) direction during quiet stance leading to great variability in postural activity within individuals (Baldan et. al., 2014). Research has found that there is meaningful structure to this movement variability in both
the AP and ML planes that exhibits fractal scaling, or self similarity across different timescales (Delignières, Torre, \& Bernard, 2011). This complex structure of postural sway allows us to adapt to different types of constraints-either personal, task relevant, or environmental-that exist across different time scales. The current project utilized two nonlinear data analytic techniques well suited to postural sway time series including detrended fluctuation analysis (DFA), and multifractal detrended fluctuation analysis (MFDFA) to characterize the spatio-temporal structure of postural activity during a social psychological event.

The complex (i.e., fractal) structure of postural variability can be influenced by a number of factors including schizophrenia (Kent et al., 2002), age, and movement disorders such as Parkinson's disease and Huntington's disease (lipsitz, 2004). A change in complexity is characterized by shifts from persistent pink noise to either anti-persistent white noise, or deterministic Brownian motion. As such, fractal, or pink noise, in postural sway has been consistently found in healthy adult populations, and a decline in complexity towards either white or Brownian noise is associated with a decline in health (Lipsitz, 2004).

While a change in the complex structure of postural variability is typically associated with poor health, recent research has found that cognitive activity can also impact postural behavior. For example, Riley, Baker, and Schmit (2003) found that postural sway standard deviation was reduced when participants were asked to complete a difficult digit rehearsal task. This change in postural sway as a function of a cognitive tasks, paired with the fractal nature of sway suggests a functional link between the brain and the body whereby the dynamics of human perceptual, motor, and cognitive processes are interaction-dominant (Riley, Shockley, van Orden,
2012). Interaction dominant-dynamics further suggest that each component system are coupled and therefore are reciprocally linked. This means that the behavior of each component, in this case the brain, the motor system, and the environment, depends on the activity of the other components (van Orden, Hollis, \& Wallot, 2012). To examine this phenomenon in a social psychological context, we will determine how postural activity changes while people disclose a concealable stigmatized identity (CSI) to an imagined other.

## Concealable Stigmatized Identity Disclosure

A CSI is any identity that is not immediately available to others, but could be socially devaluing if revealed, for example a mental health disorder, LGBT status, or a history of sexual abuse. While avoiding discrimination through concealment seems like an ideal solution, the extant literature has noted the numerous positive outcomes to disclosing (e.g., building trust, greater quality of life, etc.) as well as the negative impact of concealing (e.g., social isolation, anxiety, etc.) (Chaudoir \& Quinn, 2010).

Disclosure of a CSI, or the interpersonal process of sharing personal information, is a complicated process. The discloser must first decide how and when they want to share their identity with someone. Further, the discloser should be constantly evaluating their confidant's reaction to determine if they can expect a positive reaction with the desired social support, or a negative reaction and little or no support. Research suggests that, when disclosing a CSI to a confidant people will have specific goals for disclosing such as to build intimacy in a relationship, or to explain certain behaviors. Research suggests that the numerous goals for disclosure are either approach oriented-focused on achieving positive outcomes-or avoidance orientedfocused on avoiding negative outcomes (Chaudoir \& Fisher, 2010).

Approach and Avoidance Goal Motivation Research on goal motivation suggests that approach and avoidance systems result in differential exploration of the environment such that those who possess approach goals are interested in "reducing the discrepancy between themselves and their goal" (e.g., closing the gap between the discloser and the confidant; Chaudoir \& Fisher, 2010). Further, individuals who utilize approach goals in their disclosure may attend to positive stimuli in the environment. Conversely, when utilizing avoidance goals, individuals are interested increasing the distance between themselves and potential negative outcomes (e.g., increasing distance between the discloser and the confidant; Carver \& White, 1994). As research from embodied cognition suggests, changes in emotional or motivational systems would be reflected in behavioral
outcomes. Therefore, postural sway behavior provides a unique look into the embodiment of goal during the disclosure of a CSI. Further, as research has found a loss of complexity in postural sway as a function of increased cognitive load, it is likely the case that avoidance motivation, which is associated with attuning to negative environmental cues and less relaxed behaviors, would also lead to a loss of complexity. Further, there are many people in our lives with whom we can disclose such as with our friends and family (close others) and with our coworkers and bosses (professional others).

Disclosure Confidant Disclosure of a CSI can occur across all life domains and within different types of relationships. Our relationships with others can vary greatly as a function of domain context (e.g., workplace, family life, and social setting, etc.). Often, our relationships with family members will be different from our relationships with a boss or a coworker due to social norms associated with these contexts. Therefore, the level of detailed disclosure of a CSI is likely less for those we have a professional relationships with compared to our close friends or family members. In fact, many people may feel motivated to keep a CSI hidden completely from their coworkers as revealing such information could have a detrimental impact on their career path and job outcomes (Jones \& King, 2014).

Despite the potential for negative outcomes due to CSI disclosure, disclosure in the workplace should not be discounted. Research suggests potential negative workplace consequences of concealing including less job satisfaction and attention (Day \& Scheonrade, 1997). With a large portion of the workforce continuously making decisions about the information they reveal and conceal in a workplace setting, it is becoming increasingly apparent that a better understanding of workplace disclosure is necessary. However, the increased tension and threat involved with disclosing across different life domains might also impact the behavioral expression via postural sway behavior.

Postural Activity While the current literature has noted the importance of positive interpersonal disclosure outcomes across multiple life domains (i.e., home life, work life) utilizing different goals, little is known about how these different contexts impact the embedded nature of our cognitive and behavioral systems within the world. The present study is the first of its kind to examine the disclosure experience through the lens of embodied cognition in order to understand how the disclosure context is differentially manifested in measurable behavioral outcomes (i.e., postural activity).

Despite attempts to understand the impact of nonverbal behaviors on personal self-disclosure (see Derlega \& Berg, 2013), the existent literature has
focused on general self-disclosure, not disclosure of a CSI specifically. Further, nonverbal behaviors have typically been characterized by discrete, observable behaviors (e.g., facial expression, nods, and openness). The current project examines time dependent postural sway by utilizing dynamic data analytic tools that can capture the disclosure process as it occurs. By examining postural sway behavior during the disclosure of a CSI we can gain a better understanding of how our mental processes are manifested in our bodies relationship with the environment. Further, support for this claim would suggest that shifting motivation systems might lead to more positive behaviors, both verbal and nonverbal, during a disclosure event, and therefore more positive disclosure outcomes.

## Current Project

This project hopes to be the first to bridge the gap between the three discussed areas of research: disclosure context (i.e., close other and professional other disclosure), antecedent goals for disclosure events, and embodied cognition during the disclosure of a CSI. With this project, we hope to integrate theory from stigma, embodied cognition, and interaction-dominant dynamics to capture a holistic understanding of the cognitive and movement processes at play during CSI disclosure. As such, this project will utilize theory unique to postural sway literature, and measurement and data analytic techniques novel to disclosure. Finally, our results and discussion will be presented in such a way that both social and ecological psychologists might be able to utilize theory and methods from each other in future research endeavors. Based on previous postural sway research, we expect disclosures utilizing approach goals to close others would exhibit pink noise compared to avoidance disclosures to professional targets.

## Method

## Design

This study employed a 2 (goal motivation: approach/avoidance) $\times 2$ (target: close other/professional other) mixed design with goal motivation is the between subjects variable and disclosure target the within subjects variable. The primary dependent variables are postural sway dynamics measured at the head and waist (via mono-fractal and multi-fractal scaling) and responses on the Behavioral Approach System/Behavioral Avoidance System (BIS/BAS) scale.

## Participants

43 undergraduates were recruited from a large Midwestern University to participate in this study. Prior
to recruitment, participants were prescreened to determine their eligibility. In order to participate in this study, participants had to self-identify as living with a CSI. One participant was excluded from data analysis due to technical errors resulting in a sample of 42 participants. The majority of participants were female (36) and identified as white (35). The mean age was $20.21(S D=3.09)$. See table 1 for a breakdown of each CSI represented in this study.

Table 1. Table 1 shows the number of participants with each CSI type

| CSI Type | $N$ |
| :--- | :---: |
| Mental Health Disorder | 16 |
| Sexual Assault | 7 |
| Gender/Sexual Minority | 10 |
| Eating Disorder | 4 |
| Multiple CSI's | 2 |
| Other | 3 |

## Procedure

In the first portion of the study participants were seated at a computer equipped with Media Lab software (Empirisoft, 2014) where they completed the majority of the experiment. They were first asked to think about and describe a secret that they often keep hidden. Each participant was then instructed to write two disclosure letters sharing this secret to a close friend/family member and the other to someone with whom they have a professional relationship. Specifically, they were asked to think about a person in their life that they have not told this secret, but would like to. Prior to writing each letter, participants were told to write $3-5$ goals they have for their disclosure. To manipulate approach and avoidance goals, participants were simply told to either "think about achieving positive outcomes with their letter" or "think about avoiding negative outcomes with their letter" respectively.
After writing both disclosure letters, participants acted out their disclosure as if the person they wrote the letter to was standing in the room. During the disclosure event, two Polhemus sensors (one attached to a headband on the back of the head, the other attached to a belt just bellow the belly button) recorded postural activity at 60 Hz (FASTRAK, Polhemus, VT, USA). The experimenter explained that they should act as though they were talking to the person that they chose, using their letter as a guide. After completing the disclosure for both written letters, participants completed a number of self-report measures including the BIS/BAS scale (Carver \& White, 1994).

## Data Analysis

To capture the time dependent structure of postural variability as a function of both goal priming and disclosure confidant during the disclosure of a CSI, both DFA and MFDFA were used. Because postural data exhibits non-stationary, time-dependent variation, these data are characterized by fractional Brownian motion (fBm) making it particularly well suited to DFA (et al., 2000; Delignières, Torre, \& Bernard, 2011).

DFA provides the scaling exponent, $\alpha$, which describes the fractal scaling of a time series whereby: $\alpha$ $\approx .5$ indicates random, white noise scaling; $\alpha \approx 1$ suggests persistent pink noise scaling; and $\alpha \approx 1.5$ indicates Brownian motion.

MFDFA is an extension of the DFA and examines differences in the scaling exponents between small and large fluctuations. The relevant outcome parameter of interest in MFDFA is a characterization of the width of the multifractal spectrum $\mathrm{h}_{\text {MAX-MIN. }}$. Because MFDFA tells us whether there are different scaling exponents that exist at fast and slow fluctuations, if $\mathrm{h}_{\text {MAX-MIN }}$ is greater than 0 , we can assume the time series exhibits multifractality. See Ihlen (2012) for a detailed description of both DFA and MFDFA procedures.

Finally, Prior to analyzing each postural sway time series in the AP plane at the head ( $\mathrm{AP}_{\mathrm{HEAD}}$ ) and waist ( $\mathrm{AP}_{\text {WAIST }}$ ) and the ML plane at the head ( $\mathrm{ML}_{\text {HEAD }}$ ) and waist ( $\mathrm{ML}_{\text {WAIST }}$ ), the data were downsampled from 60 Hz to 30 Hz , linearly detrended, and, low-pass filtered at 20 Hz using a $2^{\text {nd }}$ order Butterworth filter. A surrogate analysis (detailed below) was also performed for DFA and MDFA for validation purposes.

## Results

A series of separate mixed method ANOVA's were performed on all relevant outcome parameters for DFA, and MFDFA to test our hypotheses that approach and avoidance goal motivation and target confidant would impact the dynamical structure of postural activity during a disclosure event. Four separate 2 (goal: approach/avoidance) $\times 2$ (target: close other/professional other) ANOVA's were performed on all outcome parameters, one each for $\mathrm{AP}_{\text {HEAD }}, \mathrm{ML}_{\text {HEAD }}, \mathrm{AP}_{\text {WAIST }}$, and $\mathrm{ML}_{\text {WAIST }}$ sway. Prior to statistical analysis, outliers 3 SD above and below the mean were identified and replaced with the mean value.

## Detrended Fluctuation Analysis

A series of ANOVAs were performed to capture differences in sway as a function of $\alpha$. To verify that there was a difference between the original time series and the randomly reshuffled, surrogate time series, a third 2 level term in the ANOVA (data: original/randomly reshuffled) was included making the analysis a $2 \times 2 \times 2$ design. There was a main effect of
data type for all $\mathrm{AP}_{\text {HEAD }}, \mathrm{AP}_{\text {WAIST }}, \mathrm{ML}_{\text {HEAD }}$, and $\mathrm{ML}_{\text {WAIST }}$, (for all $F(1,40)>2097, p<.0001$ ) such that the original data results were significantly larger from the randomly reshuffled, surrogate time series. That is, the original time series produced an average $\alpha$ around 1.3 for all directions of sway and the reshuffled time series produced $\alpha$ of .5 for all directions of sway. There were 2-way interactions of goal and data type for $\mathrm{ML}_{\text {HEAD }}$, and $\mathrm{ML}_{\text {WAIST }}(F(1,40)=5.52, p=.024$, and $F(1,40)=4.74, p=.035$, respectively), however, these results simply reflect a main effect of goal priming for the original data; no differences emerged in the reshuffled time series as a function of goal priming. As such, below is the planned $2 \times 2$ ANOVAs on the analysis of real (non-shuffled) data.
The ANOVA comparing the $\alpha$ exponent for $\mathrm{AP}_{\text {HEAD }}$ revealed a significant target by group interaction, $F(1,40)=4.32, p=.04, \eta_{\mathrm{p}}^{2}=.098$. Bonferroni post hoc comparisons were used to examine differences between $\alpha$ for close other and professional other disclosures for each approach and avoidance primed disclosures separately. Results indicate a marginally significant difference in the $\alpha$ exponent between close other and professional other target disclosures in the avoidance primed condition, whereby close other disclosures exhibited less persistent fractal scaling in their postural sway $(M=1.36, S D=.11)$ compared to professional other disclosures; which were more persistent and closer to pink noise $(M=1.3, S D=.1)$. There was no difference between close other and professional other disclosures during approach primed disclosures $(T(21)=$ $.49, p>.05)$. There were no other main effects for $\mathrm{AP}_{\text {HEAD }}$ sway (all $\left.F(1,40)<1.8, p>.05\right)$.

Next, an ANOVA comparing the alpha exponent from $\mathrm{ML}_{\text {HEAD }}$ revealed a significant main effect of goal priming $\left(F(1,40)=5.81, p=.02, \eta_{\mathrm{p}}^{2}=.13\right)$ such that approach primed disclosures exhibited more persistent fractal scaling in their postural sway $(M=1.28, S D=$ .13) compared to avoidance primed disclosures; which were less persistent and closer to Brown noise ( $M=1.35$, $S D=.13$ ). There were no other main or interaction effects for $\mathrm{ML}_{\text {HEAD }}$ (all $F(1,40)<2.1, p>.05$ ). Similar to the results found in $M L_{\text {HEAD }}$ sway, a significant main effect of goal priming emerged in $\mathrm{ML}_{\text {WAIST }}$ sway $\left(F(1,40)=4.56, p=.04, \eta_{\mathrm{p}}^{2}=.1\right)$, whereby those in the avoidance condition exhibited a loss of complexity compared to those in the approach primed condition ( $M$ $=1.34, S D=.14$ and $M=1.28, S D=.14$ respectively). No other main effects or interactions were significant for $\mathrm{ML}_{\text {WAIST }}$ (all $F(1,40)<1.9, p>.05$ ). Finally, there were no significant effects of $\alpha$ on $\mathrm{AP}_{\text {WAIST }}$ sway (all $F(1,40)$ $<2.47, p>.05$ ) (see Figure 1).

Figure 1: This figure represents mean $\alpha$.

$$
* p<.05, * * p<.01
$$

## Multifractal Detrended Fluctuation Analysis

The final series of ANOVA's compared the $h_{\text {MAX-MIN }}$ value for each independent variable. To check that there is a difference between the original time series and the surrogate time series, a third 2 level term (data: original/surrogate) was included in the initial analysis. The surrogate time series was developed by shuffling the time series using an inverse amplitude-adjusted Fourier transform to maintain the same scaling relation $\alpha$ (see Ihlen \& Vereijken, 2010 for detailed description) There was a significant main effect of data type for all $\mathrm{ML}_{\text {HEAD }}$, $\mathrm{ML}_{\text {WAIST, }}, \mathrm{AP}_{\text {HEAD }}$, and $\mathrm{AP}_{\text {WAIST }}$ (all $F(1,40)>54.7, p<$ $.0001)$ whereby the $\mathrm{h}_{\text {MAX-MIN }}$ was greater in the original data compared to the phase reshuffled time series. There were no 2-way interactions including data type suggesting there was no impact of goal priming or target confidant on results of the surrogate analysis (all $F(1,40)$ $<3.9, p>.05$ ). Therefore, results of the planned 2-way ANOVA examining goal priming and target confidant are reported below.

The analysis of $\mathrm{h}_{\text {MAX-MIN }}$ for $\mathrm{AP}_{\text {HEAD }}$ revealed a main effect of goal priming $\left(F(1,40)=4.95, p=.03, \eta_{\mathrm{p}}{ }^{2}=.11\right)$ such that the width was larger for approach primed disclosures ( $M=.97, S D=.04$ ) compared to avoidance primed disclosures ( $M=.85, S D=.04$ ). There were no other significant results for $\mathrm{AP}_{\text {HEAD }}$ (all $F(1,40)<3.01, p$ $>.05$ ). The same pattern of significant results emerged for $\mathrm{ML}_{\text {HEAD }}$ and $\mathrm{ML}_{\text {WAIST }}$, such that a main effect of goal motivation was revealed for both $(F(1,40)=8.57, p=$ $.006, \eta_{\mathrm{p}}^{2}=.18$ and $F(1,40)=7.62, p=.009, \eta_{\mathrm{p}}^{2}=.16$ respectively). The width for $\mathrm{ML}_{\text {HEAD }}$ was larger for
approach-primed disclosures $(M=1.04, S D=.22)$ than avoidance primed disclosures $(M=.89, S D=.22)$. Similarly, the ML ${ }_{\text {WAIST }}$ width was larger for approachprimed disclosures $(M=1.02, S D=.18)$ than avoidance primed disclosures $(M=.9, S D=.18)$ (Figure 2).

Figure 2: This figure demonstrates mean $\mathrm{h}_{\text {MAX-MIN }}$.

$$

## Discussion and Conclusion

Taken together, these results support our hypotheses that both goal motivation and disclosure confidant would impact unintentional postural activity. We sought to examine the disclosure event on a very small scale (i.e., postural behavior) in order to understand how context shapes the way people communicate through behavior. These results broadly support the idea that our cognition and emotional content are manifested and embodied in measureable behavioral outcomes (Marsh, Ambady, \& Kleck, 2005). Most notable in these results is the influence of antecedent goal priming on the structure of postural variability. By utilizing nonlinear data analytic techniques novel to disclosure research, we have provided support that our cognitive and motor systems are functionally linked as a complex dynamical system.

Specifically, the significant interaction of the scaling exponent $\alpha$, which revealed that close other disclosures exhibited more deterministic behavior than professional other disclosures at $\mathrm{AP}_{\text {HEAD }}$, is contrary to our hypothesis that professional other disclosures would be more deterministic. However, since this effect was only found in the avoidance condition, which is associated with negative outcomes, these results may indicate that participants expected greater threat to their intimate relationships during close other disclosures when they
were utilizing avoidance goals. Because this effect was only found in the AP direction, it is important that future work seek to replicate these results.

Finally, results of the MFDFA support the mounting evidence that postural sway behavior exhibits multiple scaling exponents, as well as our hypothesis that disclosure context would functionally impact movement variability. Importantly, a significant difference in the $\mathrm{h}_{\text {MAX-MIN }}$ parameter suggests that approach primed disclosures exhibit a wider range of scaling exponents than avoidance primed disclosures. This supports the theory that approach systems are associated with attuning to more positive stimuli in the environment. As theory of postural sway variability suggests, our postural system aids in efficiently exploring the environment. Because we see differences in the smallest and largest scaling exponents, this suggests participants are able to explore different stable states in the approach condition compared to the avoidance condition. This could make approach primed disclosures more adept at adjusting behaviors with new information.

The results of this project provide evidence that both disclosure confidant and antecedent goals can affect the disclosure event itself. Further, this research suggests that postural sway behavior is an emergent property of a complex system and serves a functional role in both attaining environmental information and embodying ones cognitive and emotional processes. This has implications for developing tools for people who want to disclose a CSI. For example, by simply shifting internal motivation from avoidant to approach a reciprocal distribution across behaviors at different time scales could cascade, from very fast processes including postural sway, to slower timescale behaviors such as gross body movement, language, and confidant reactions. Future research should examine this relationship as well as how number of disclosures or fear of disclosure impacts these effects.

#### Abstract

Responding to similarity, difference, and relative magnitude is ubiquitous in the animal kingdom. However, humans seem unique in the ability to represent relative magnitude and similarity as abstract relations that take arguments (e.g., greater-than $(x, y)$ ). While many models use structured relational representations of magnitude and similarity, little progress has been made on how these representations arise. Models that use these representations assume access to computations of similarity and magnitude a priori. We detail a mechanism for producing invariant responses to "same", "different", "more", and "less" which can be exploited to compute similarity and magnitude as an evaluation operator Using DORA (Doumas, Hummel, \& Sandhofer, 2008), these invariant responses can serve to learn structured relational representations of relative magnitude and similarity from pixel images of simple shapes.

## Introduction

Reacting to similarity, and magnitude ("same"/ "different", "more"/"less"; SDML) are hallmarks of complex organisms. For example, gerbils use the retinal size of a stimulus to estimate its distance (Goodale, Ellard, \& Booth, 1990), rats choose the larger of two food rewards (Kim et al., 2015), and pigeons learn to group pictures of 16 identical items in one set, and pictures of 16 different items in a different set (Young, Wasserman, \& Garner, 1997).
Humans, however, go beyond simple detection of relative magnitude and similarity. We make an analogies between a nucleus and the sun because they are both larger than their orbiting bodies (electrons and planets). We infer this relationship because we represent relative magnitude and similarity as abstract relations that take arguments (i.e., as predicates; see Holyoak, 2012).
Our ability to reason about abstract SDML manifests in a variety of domains such as analogy (e.g., Holyoak \& Thagard, 1995), categorisation (e.g., Medin, Goldstone, \& Gentner, 1993), and concept learning (e.g., Doumas \& Hummel, 2013). While models that use structured representations have had success in accounting for how humans use abstract SDML, these models say little about where the representations they use come from in the first place. For example, SME (Falkenhainer, Forbus, \& Gentner, 1989), STAR (Halford et al., 1998), and LISA (Hummel \& Holyoak, 1997, 2003) account for many phenomena from the analogy literature, but require the relations they use to make these analogies be hand-coded by the modeler. Similarly, Bayesian models of concept development and learning (e.g., Kemp, 2012; Kemp \& Tenenbaum, 2007, 2009; Lake et al., 2016) assume relational structures a priori, starting with a vocabulary
of objects and relations and learning new concepts by building new combinations of these innate elements.
Some models attempt to account for the origins of abstract concepts without assuming innate representations of relational concepts. For example, BART (Lu, Chen, \& Holyoak, 2012) uses feature lists generated by human subjects or corpora analysis to find properties associated with items in the world which instantiate particular relations. BART has difficulty with some edge cases of relational cognition (e.g., reasoning about something like an atom being bigger than something else when it has not experienced instances where an atom was bigger than anything), but the model makes a serious effort to account for development of analogy-making with minimal assumptions about the starting representations of the learning system.
In a similar vein, DORA (Doumas, Hummel, \& Sandhofer, 2008) explains how structured representations (i.e., predicates) can be acquired from unstructured representations (i.e., feature vectors). While DORA learns relational representations that can take any arguments (including edge cases and completely novel arguments; Doumas et al., 2008), DORA assumes a system to detect the invariant features that underlie the abstract concepts that it learns.
A complete account of how people acquire structured representations of abstract SDML relations must solve three problems. First, there must be some invariant features which remain constant across instances of the relation which the perceptual/cognitive system can learn to detect. Second, the system must isolate these invariants from other properties of the objects engaged in the relation to be learned. Third, the system must learn a predicate representation of the relational properties (i.e., an explicit entity that can be bound to arbitrary, novel arguments).
We solve the first problem with an extension to DORA which produces invariant responses to similarity and relative magnitude. We have previously shown how DORA can solve the second and third of these problems (Doumas et al., 2008). We begin with a brief overview of DORA, describe the process which produces invariant features for SDML, and provide simulations demonstrating how DORA solves all three problems to learn structured relational representations of SDML.

## Model

## DORA

DORA (Doumas, et al., 2008) is a symbolicconnectionist model, based on the LISA (Hummel \&

Holyoak, 1997, 2003) model of analogy. DORA learns structured relational representations from unstructured representations of objects (e.g. feature vectors).

LISAese Representations We begin by describing the end state of DORA's representations (i.e., its representations after it has gone through learning). Relational propositions are represented by a hierarchy of distributed and localist codes (see Figure 1). At the bottom, semantic units code the features of objects and roles in a distributed fashion. In the next layer, localist predicate-object (PO) units representing individual predicates (or roles) and objects, are connected to these distributed semantic representations. In the next layer, localist role-binding (RB) units link predicates and objects into specific role-filler pairs. At the top of the hierarchy, localist proposition ( P ) units link RB units into complete relational propositions. Importantly, while we use different names for the units in different layers, and different shapes to distinguish these units in diagrams, we do so only for the purposes of expositional brevity. These are just nodes in different layers of a network. RB units are just like PO units, except for the fact that they are in a different layer, and, therefore, take input from and pass input to different layers of units.

Figure 1. Complete relational proposition in DORA. Units in different layers are coded using different shapes for the purposes of exposition.

Propositions in DORA are divided into four mutuallyexclusive sets of layered networks: a driver, one or more recipients, long-term memory (LTM), and the emerging recipient (EM). Each set consists of a layered network of $\mathrm{PO}, \mathrm{RBs}$, and P units (i.e., there are specific layers coding for PO, RB, and $P$ units in the driver, and another set of layers coding for $\mathrm{PO}, \mathrm{RB}$, and P units in the recipient). Semantic units are shared across all networks (i.e., driver and recipient units are connected to the same pool of semantic units). The driver corresponds to the current focus of attention and controls the flow of activation. Units in the driver pass activation to the semantic units. Because the semantic units are shared by all sets, activation flows from the driver to the other three sets. DORA operations (e.g., mapping and relation learning, detailed below) proceed as a product of units in the driver activating their semantic units, which in turn activates units in the various other sets.
When a relational representation enters the driver the binding of roles to their fillers must be represented
dynamically without violating their independence (i.e., it is not sufficient to represent bindings using only conjunctive units; see, e.g., Doumas \& Hummel, 2005; von der Malsburg, 1999). DORA uses systematic asynchrony of firing to dynamically bind roles to their fillers (see Doumas et al., 2008). As a relational representation in the driver becomes active, bound objects and roles fire in direct sequence. Information about role-filler bindings is carried by proximity of firing (e.g., with roles firing directly before their fillers). This sequence-based binding keeps roles and their fillers distinct and thus independent. Using the example in Figure 1, in order to bind bigger to block and smaller to ball (and so represent larger (block, ball)), the units corresponding to bigger fire directly followed by the units corresponding to block, followed by the units for coding smaller followed by the units for ball.

Mapping DORA uses LISA's mapping algorithm (see Hummel \& Holyoak, 1997; Doumas et al., 2008). DORA learns mapping connections between units of the same type in the driver and recipient (e.g., between PO units in the driver and PO units in the recipient). These connections grow whenever corresponding units in the driver and recipient are active simultaneously. The connections act as mappings between corresponding structures in separate analogs. They also permit correspondences learned in mapping to influence correspondences learned later.

Relation Learning DORA uses comparison to isolate shared properties of objects and to represent them as explicit structures. DORA begins with simple featurevector representations of objects (i.e., a node connected to a set of semantic features describing that object). When DORA compares two objects, the two representations are activated simultaneously. For instance, if DORA compares a block that is larger than some object to a plate that is larger than some other object (e.g., when the block is larger than a ball and the plate is larger than a fork), then the nodes representing the block and plate fire together (Figure 2a). Semantic features shared by the compared objects (i.e., features common to the block and the plate) receive twice as much input and thus become roughly twice as active as features connected to one but not the other (Figure 2b). DORA then learns connections between a newly recruited PO unit and active semantic units via Hebbian learning (Figure 2c). In Hebbian learning the strength of a learned connection is a function of unit activation (i.e., stronger connections are learned to more active units). Consequently, the new PO unit becomes most strongly connected to the highly active semantic units. The new PO becomes an explicit representation of the feature overlap between the block and plate. In this example, DORA forms an explicit representation of the semantics of bigger things (i.e., the features common to both the block and plate). The new PO functions as a predicate representation of bigger because it can be dynamically bound to fillers via an RB unit (Figure 2d).

Figure 2. Comparison-based predication in DORA. DORA learns a representation of bigger by comparing a block that is bigger than some object to a plate that is bigger than some other object. (a) DORA compares a block and a plate. Units representing both become active. (b) Feature units shared by the block and the plate become more active than unshared features (darker grey). (c) A new PO unit learns connections to features in proportion to their activation (solid lines indicate stronger connection weights). The new unit codes the featural overlap of the block and plate (i.e., the role "bigger"). (d) This new PO unit functions as a predicate when dynamically bound to fillers.

DORA learns representations of multi-place relations by linking sets of co-occurring role-filler pairs into hierarchical relational structures. Continuing the example, when DORA compares a plate that is larger than a fork to a block that is larger than a ball, it will map larger (plate) to larger (block) and smaller (fork) to smaller (ball) (Figure 3a). When constituent sets of rolefiller pairs are mapped, a distinct pattern of firing emerges-namely, mapped RB units fire together and out of synchrony with any other RB units; Figure 3b-d). This pattern is a reliable signal that DORA exploits to combine sets of role-filler pairs into multi-place relations. In response to the pattern, DORA recruits a P unit that learns connections to any active RB units in the recipient (Figure $3 \mathrm{e}-\mathrm{g}$ ) via Hebbian learning. The result is a P unit linking the RB units in the recipient into a complete relational structure (larger (block, ball); Figure 3i).

## Producing invariant responses for basic SDML

A comparison-based solution to the problem of learning an invariant feature coding for "more", "less", and "same" requires the assumption that initially available magnitude information is coded by a direct neural proxy: All else being equal, higher magnitude items are coded (at least early in processing) by more neurons than comparatively lower magnitude items. For example, a larger item will be coded by more neurons
than a smaller item. There is a preponderance of evidence for this assumption. In visual processing, larger items take up more space on the retina (e.g., Wandell, 1995) and are coded by larger swaths of the visual cortex (e.g., Engel et al., 1994).

Figure 3. DORA learns a representation of the whole relation larger (block, ball) by mapping bigger(plate) to bigger(block) and smaller(fork) to smaller(ball). (a) The units coding bigger fire; (b) the units for plate and block fire; (c) the units for smaller fire; (d) the units for
fork and ball fire. (e) DORA recruits a P unit in the recipient. (f-g) DORA learns a connection between the new $P$ unit and the active RB unit (the unit coding for $\operatorname{bigger}(\mathrm{block})$ ). (h-i) The P unit learns connections to the active RB unit (coding for smaller(ball)). The result is a structure coding for larger(block, ball).

Basic magnitude calculation is accomplished by comparison. When the model attends to two representations with specific magnitude values (e.g., two POs attached to absolute size are present in the driver together; Figure 4a), the representations of the absolute magnitude semantics are co-activated and the PO units attached to these semantic units compete via lateral inhibition (Figure 4b). The POs will eventually settle, with either one PO becoming more active and inhibiting the other to inactivity, or, when both POs code for the same absolute magnitude, with both POs in a steady state of co-activation. More semantic units can then respond to the particular pattern of firing in the driver POs. Some units are excited by two active POs in the driver, others
are excited by a single highly active PO early in firing, or by a single highly active PO late in firing (these regions of excitement are easily learnable via simple neural threshold tuning). The active POs learn connections to the active semantic unit by Hebbian learning. If a single PO is active, that unit will learn connections to the semantics that are activated by a single highly active driver PO early in firing (which becomes the invariant signal for "more"; Figure 4c). When the active PO becomes inhibited (because of asynchronous binding), the second PO (the one inhibited by the winning PO) will become active (Figure 4d). That unit learns connections to the semantics that are activated by a single highly active driver PO late in firing (which becomes the invariant signal for "less"; Figure 4d). Otherwise, if two POs are co-active (i.e., they code the same magnitude), then they will learn connections to the semantics which are activated by two active driver POs (which becomes the invariant signal of "sameness".
(a)

(c)

(b)

(d)

Figure 4. The SDML detector working on POs coding different values on a dimension. For the purposes of clarity, only the predicate POs and their semantics are depicted in this figure. (a) Two POs coding for different heights are in the driver. (b) The semantics coding for absolute dimensional information become active and the two POs compete to become active. (c) The unit coding for the greater value on the dimension (here height-6) becomes active first, thus marking it as "more". The PO learns a connection to the semantic that responds to winning the SDML competition (i.e., the invariant of "more"). (d) The unit coding for the lesser value on the dimension (here height-3) will become active last, thus marking it as "less". The predicate is connected to the semantic unit coding for losing the SDML competition, or the invariant of "less".

In short, comparing different magnitudes in a network in which magnitude information is coded by an absolute
proxy (as in the human neural system) produces one of three patterns. (1) Both units settle into a state of similar co-activation-which occurs when two representations of the same magnitude are compared. (2) One unit becomes more active and forces the second unit to inactivity-which occurs when a unit codes for a greater magnitude. (3) One unit becomes active after it has been inhibited by a winning unit-which occurs when a unit codes for a lesser magnitude. Whatever units respond to these patterns naturally or through tuning become implicit invariant codes for the presence of "sameness", "moreness", and "lessness", respectively. Vitally, the same patterns will emerge and the same codes will become active when specific relative magnitudes are present even cross dimensionally. That is, the same patterns emerge and units become active during an instance of different absolute height, or width, or colour. What is left for the system is to learn explicit representations of these invariant semantics that are not tied to any specific magnitudes (e.g, a PO connected to semantics encoding 'more' \& 'height', without strong connections to any specific height) and can take other POs as arguments. In other words, exactly the learning that DORA does.

## Simulations

## Simulation 1

We tested whether DORA could learn structured representations of relative SDML relations starting with information about sets of shapes with features representing absolute values on dimensions. This simulation mirrored what happens during development when a child learns from experience without a teacher or guide.

The model began with pixel images of basic shapes (differing in shape, colour, size, width, and height). These images were pre-processed with a feedforward neural network that learned via back-propagation to deliver absolute shape, colour, size, width, and height information (akin to that information delivered by early visual processing). Each processed image was represented by a PO attached to the delivered features. In addition, each shape was also attached to a set of 10 extraneous features selected randomly from a set of 100 features, included as noise (as objects in the world contain several features extraneous to any particular learning goal). Each shape was then randomly paired with another to create pairs of shapes over which relations were learned. We created 100 pairs of objects in this manner and placed them in DORA's LTM.

We then allowed DORA to attempt to learn from these basic representations. On each learning trial, DORA selected one pair of objects from LTM at random and ran (or attempted to run) retrieval, mapping, SDML comparison, predication, and multi-place relation learning, and stored any representations that it learned in LTM. In short, we are testing whether unguided learning from simple shape objects is sufficient for DORA to
learn structured representations of relative SDML relations.

We defined a relational quality metric as the mean of connection weights to relevant features (i.e., those defining a relative magnitude on some specific dimension (e.g., 'more'+'height', or 'less'+'width')) divided by the mean of all other connection weights +1 (1 was added to the mean of all other connection weights to normalize the quality measure to between 0 and 1 ). A higher quality denoted stronger connections to the semantics defining a specific SDML relation relative to all other connections. We measured the relational quality of the last 100 items DORA had learned after each 100 learning trials for 1000 total learning trials. Importantly, we tested all representations that the model learned (not just those that instantiated the relevant relations) and included these in the relational selectivity calculation.
Figure 5 shows the quality of the representations that DORA learned. DORA learned representations of whole relational structures encoding relative magnitudes and similarity on all the encoded dimensions. DORA learned representations of bigger (one predicate PO connected most strongly to the semantics 'more' \& 'size', the other connected to 'less' \& 'size'), wider (predicate POs connected to 'more' \& 'width, and 'less' \& 'width'), taller (predicate POs connected to 'more' \& 'height, and 'less' \& 'height), same-size (predicate POs both connected most strongly to 'same' \& 'size;), same-width (predicate POs both connected most strongly to 'same' \& 'width'), same-height (predicate POs both connected most strongly to 'same' \& 'height'), same-colour (predicate POs both connected most strongly to 'same' \& 'colour'), and same-shape (predicate POs both connected most strongly to 'same' \& 'shape'). The results indicate that DORA can learn structured representations of relative SDML relations from objects that include only absolute values on dimensions even with the addition of extraneous noise.

Figure 5. Results of DORA's learning.

## Simulation 2

A crucial question remains: do the representations DORA learns meet the requirements of relational representations? Some hallmark of relational representations (see Holyoak, 2012) are that they, (i) form the basis of solving cross mappings; (ii) support
mapping similar, but non-identical predicates; and (iii) form the basis of overcoming the n -ary restriction.

During cross-mapping, an object (object1) is mapped to a featurally less similar object rather than a featurally more similar object because it (object1) plays the same role as the less similar object. Cross-mappings serve as a stringent test of the structure sensitivity of a representation as they require violating featural or statistical similarity.
We tested the relations that DORA had learned in the previous simulations for their ability to support finding cross-mappings. We selected two of the refined relations that DORA had learned during the previous simulation at random. We bound the relations to new objects, creating two new propositions, P1 and P2 such that the agent of P1 was semantically identical to the patient of P2 and patient of P1 was semantically identical to the agent of P2, and allowed DORA to attempt to map P1 and P 2 . We repeated this procedure 10 times, each time with a different randomly-chosen pair of relations. All 10 times DORA successfully mapped the agents and patients of P1 and P2. The relations DORA learned in the first simulation satisfy the requirement of crossmapping.

We also tested whether the relations that DORA has learned would support mapping to similar but nonidentical relations (such as mapping higher to greaterthan). Humans successfully map such relations (e.g., Bassok, Wu, \& Olseth, 1995; Gick \& Holyoak, 1983), an ability that Hummel and Holyoak $(1997,2003)$ have argued depends on the semantic-richness of relational representations. We selected one of the refined relations that DORA had learned during the previous simulation, R1, and constructed a new relation, R2, that shared $50 \%$ of its semantics (in each role) with the selected relation. So that mappings could not be based on object similarity, none of the objects that served as arguments of the relations had any semantic overlap. We repeated this process 10 times. Each time, DORA mapped the agent role of R1 to the agent role of R2 and the patient role of R1 to the patient role of R2, and, despite their lack of semantic overlap, corresponding objects always mapped to one another (because of their bindings to mapped roles).
Finally, we tested the model's ability to find mappings that violate the $n$-ary restriction: the restriction that an $n$ place predicate may not map to an $m$-place predicate when $n \neq m$. Almost all models of structured cognition follow the $n$-ary restriction (namely, those that represent propositions using traditional propositional notation and its isomorphs; see Doumas \& Hummel, 2005). However, the restriction does not appear to apply to human reasoning, as evidenced by our ability to easily find correspondences between bigger (Sam, Larry) on one hand, and small (Joyce), big (Susan), on the other (Hummel \& Holyoak, 1997).

To test DORA's ability to violate the n -ary restriction, we randomly selected a refined relation (R1) that DORA had learned in the previous simulation. We then created a single place predicate (r2) that shared $50 \%$ of its
semantics with the agent role of R1 and none of its semantics with the patient role. The objects bound to the agent and patient role of R1 each shared $50 \%$ of their semantics with the object bound to r2. DORA attempted to map R1 to r2. We repeated this process 10 times, and each time DORA successfully mapped the agent role of R1 to r2, along with their arguments. We repeated the simulation such that r 2 shared half its semantic content with the patient (rather than agent) role of R1. In 10 additional simulations, DORA successfully mapped the patient role of R1 to r2 (along with their arguments). In short, in all our simulations DORA overcame the $n$-ary restriction, mapping the single-place predicate r 2 onto the most similar relational role of R1.

## Conclusion

We have shown how structured relational representations of magnitude and similarity can be learned from objects with only absolute magnitude values. Our model exploits regularities that emerge in a connectionist network when distributed representations are compared or co-activated. These regularities serve as invariant signals that the model can learn to exploit to bootstrap the detection of relative magnitude differences and similarities. When linked with the DORA predicate learning algorithm, the system learns structured predicate representations of these relative magnitudes and similarities, and then can exploit the resulting representations to solve problems.
Our account provides a trajectory for similarity cognition that maps to cognitive complexity across species and maturational trajectories in humans. This trajectory reveals three distinct levels of abstraction in SDML computation; (i) implicit detection of SDML (responding based on the regular firing that occurs when absolute magnitudes are compared), (ii) implicit generalization of SDML (or learning based on the presence or absence of a particular feature; e.g., learning to respond based on the presence or absence of the 'more' feature), and (iii) predicate representations of SDML (or full-fledged relational representations that support complex cognitive capacities like analogy and reasoning).
This distinction may explain why humans solve some tasks involving similarity judgments without the extensive training that other animals require (e.g., Young, Wasserman, \& Garner, 1997). Humans may solve the task relationally rather than relying on generalized implicit similarity judgments.
Many cognitive architectures and task models rely on stimulus recognition. This theory explains how stimulus recognition might be computed. We believe that providing a computational account for a function existing models depend on represents a significant architectural contribution.

# Co-ordinating Non-mutual Realities: The Asymmetric Impact of Delay on Video-Mediated Music Lessons 

Sam Duffy (s.duffy@qmul.ac.uk)<br>Patrick G. T. Healey (p.healey@qmul.ac.uk)<br>Cognitive Science Group<br>School of Electronic Engineering and Computer Science<br>Queen Mary University of London<br>London, E1 4NS, United Kingdom

#### Abstract

During a music lesson, participants need to co-ordinate both their turns at talk and their turns at playing. Verbal and musical contributions are shaped by their organisation within the turntaking system. When lessons are conducted remotely by video conference, these mechanisms are disrupted by the asymmetric effects of delay on the interaction; in effect a "non-mutual reality" comprised of two different conversations at each end of the link. Here we compare detailed case studies of a copresent and a remote music lesson, in order to show how this effect arises, and how it impacts conduct during the lesson.

Keywords: video mediated communication; conversation analysis; music education; distance learning

## Introduction

When a student and tutor come together for the purpose of an instrumental music lesson, intuition suggests that the principal activity would be playing. However conversation is important, not just as a way to analyse musical contributions, but to organise them within the lesson flow. Participants may respond to talk with performance and vice versa, or even spend periods of time exchanging purely musical contributions (Duffy \& Healey, 2014). For example the tutor could give a verbal instruction that the student should action through performance, or the student could ask a question that the tutor answers through demonstration with their instrument. Activities are managed conversationally; discussion interleaved with performance, demonstration and musical experimentation, resulting in a rich multi-modal social interaction. The musical contributions include unscripted exchanges of short musical fragments intertwined with lesson dialogue. Analysis of their shape and timing shows that they are managed in ways analogous to conversational turn-taking. For example, a tutor's musical contribution can be used to initiate student self-repair in their performance (Duffy \& Healey, 2013). Non-verbal communication such as gaze, or maintaining spatial configurations with respect to each other and the music stand, are also an important part of student-tutor interaction (Duffy \& Healey, 2012).

The transition between speakers is an essential part of the organisation of turn-taking in conversation (Sacks, Schegloff, \& Jefferson, 1974). The preference for just one person to talk at a time requires participants to work together to minimise gaps and overlaps. Anticipating the possible end of a speaker's turn allows a listener to prepare to take the floor when an opportunity presents itself. Interactive turn-taking
phenomena such as backchannels, or making a bid for the floor for a turn at talk, require very precise timing. The timing of the transition between speakers is sometimes referred to as turn offset. It is usually reported as positive if there is a pause between speakers, and negative if there is an overlap (Stivers et al., 2009). Longer pauses and overlaps do occur, but the average turn offset in natural speech tends towards a short pause. A positive turn offset in the range of $0-200 \mathrm{~ms}$ is most likely to be perceived as a smooth turn transition (Stivers et al., 2009; Heldner \& Edlund, 2010).

Remote music tuition using video conferencing is a popular way to support music education in geographically remote areas but has also become an important part of urban mainstream conservatoires, for example to manage temporary separation when students or tutors have to travel to perform, or to manage international auditions. However the medium of communication is known to change aspects of conversational turn-taking, and this has important implications for videomediated remote music tuition (Duffy et al., 2012). Even minor disruptions to the transmission characteristics of the medium of communication, such as the latency and delay associated with video mediated communication, can seriously affect turn-taking (Whittaker, 2003).

Qualitative video analysis and conversation analysis (CA) have been used to examine video-mediated workplace communication (Heath \& Luff, 1991) and how participants complete collaborative tasks in video-mediated environments (O’Conaill, Whittaker, \& Wilbur, 1993; Heath, Luff, \& Sellen, 1997; Ruhleder \& Jordan, 2001). However there have been relatively few studies of the detailed effects of videomediated communication (VMC) on the timing of conversational turn-taking, and the results are inconsistent, driven by subtle differences in experimental set up. For example, some studies include signal delay (Ruhleder \& Jordan, 2001) whilst others exclude it (Sellen, 1992); in some cases specifically to isolate other interactional factors. Some studies compare video-mediated interaction (with or without delay) to same-room conditions, whilst others compare it to other lower quality remote communication systems or audio only scenarios (O'Conaill et al., 1993; O'Malley, Langton, Anderson, Doherty-Sneddon, \& Bruce, 1996). Studies which have included delay as part of their experimental set-up (O'Conaill et al., 1993; Ruhleder \& Jordan, 2001) suggest a further subtle effect; changes in the time of arrival of utterances with
respect to 'local' sound. Ruhleder and Jordan (2001) suggest that two people having two fundamentally different conversations with each other raises serious questions about what it means to 'share' a conversation in distributed settings. This leads to some interesting questions in terms of remote music lessons. How might the medium change the turn transitions observed in co-present lessons when they are mediated by video conference? How might the transition between 'speakers' be affected by the inclusion of musical contributions?
In order to investigate these questions, a detailed study was made of student-tutor interaction during a co-present and a remote music lesson, using CA and qualitative video analysis. CA has previously been used to examine aspects of instrumental music tuition (Ivaldi, 2014; Nishizaka, 2006; Szczepek Reed, Reed, \& Haddon, 2013), as well as the effect of medium on conversational turn-taking. This fine grained analysis of a same-room and a separated lesson allows us to examine both the turn-taking characteristics unique to a music lesson, and how these are affected by the medium of video. This work is part of a larger study of a number of co-present and remote music lessons (Duffy, 2015).

## Methodology

Two one-to-one lessons featuring woodwind instruments were observed, filmed and analysed in detail; a co-present ('same room') lesson and a video-mediated remote lesson. The co-present lesson featured a male student studying ABRSM grade 8 clarinet performance and was filmed during one of his regular weekly lessons at the junior school of a London Conservatoire. The female tutor had taught the student for many years. The remote lesson featured a female oboe student taking part in an ensemble residency with Aldeburgh Young Musicians, filmed during a remote music tuition study at Aldeburgh Music in Suffolk (Duffy et al., 2012). The student had been working with the tutor during the residency, but had not previously taken regular lessons with her. Both students had advanced to a similar level of proficiency; they were largely comfortable with the technical challenges of their instrument and capable of exploring musicality and expression. Both tutors were experienced in one-to-one tuition, but not video mediated tuition. The scope of this study was to examine student-tutor interaction, and did not consider teaching effectiveness between conditions.

Conversational turns are defined as the period during which a participant holds the floor, until there is a change in speaker (Sacks et al., 1974, pp.702-703). Turns in the footage from each lesson were coded using ELAN (Brugman, 2004). A separate tier was created for analysis of each of the following types of contribution: student talk, tutor talk, student play and tutor play. This data was exported as a transcript with timecode information so that calculations could be made such as turn frequency, mean turn duration and turn onset in relation to the preceding turn. Pauses between turns were coded as a positive offset, and overlap as a negative offset, similar to the approach used by Stivers et al. (2009). This allowed calcula-
tion of a net offset for a period of time or subset of turn types. Backchannels were excluded from the distribution, similar to the approach used by Sellen (1992), since they are not a bid for the floor or intended to initiate a change in speaker. As discussed, a difference between this analysis and existing literature is that we consider the transitions between musical, as well as verbal contributions. As a result, the following categories of turn transition were identified:

1. Talk following talk.
2. Talk following play.
3. Play following talk.
4. Play following play.

Established notation for conversation analysis, as described in the appendix of Sacks et al. (1974), was adapted to analyse musical contributions to lesson dialogue (Table 1).

| $(0.2 \mathrm{~s})$ | Elapsed time (seconds) used to denote pauses or silence <br> $-(1.4 \mathrm{~s})$ |
| :--- | :--- |
| Long single note and duration |  |
| $\uparrow--(2.3 \mathrm{~s})$ | Individual notes in a musical phrase and phrase duration <br> Rising passage of notes |

| $\overline{\{\text { first octave }\}}$ | Additional information for music notation <br> duration of period of overlap |
| $=0.6 \mathrm{~s}]$ | Latching (no interval between two pieces of talk) |

Table 1: Transcription notation.
The two rooms used for the remote lesson were adjoining suites at the same organisation (see Duffy et al. (2012) for more details). A separate video camera was placed in each suite, in addition to the video conference equipment, in order to capture student and tutor position with respect to the screen and provide a separate audio recording for each location. There was a small delay in visual processing caused by additional software being tested during the lesson. A delay was added to the audio so that audio and visuals arrived synchronised in each location. Audio samples from each room were synchronised and analysed using clearly visible audio transients which did not overlap with local sounds. Whilst the rooms were geographically close, the delay was of the same order as the latency experienced in a typical transatlantic video call ( 0.9 s ). This delay was constant, but in reality the magnitude of the delay would vary somewhat over the duration of the call, depending on the signal journey through different servers and exchanges.

## Results

First we will look at some general effects of the medium on the lessons analysed. Whilst the co-present lesson was slightly longer than the consolidated sections of the videomediated class analysed, they both contained similar proportions of instances of turns at talk ( $73 \%$ and $71 \%$ table 2 ) and instances of musical contributions ( $27 \%$ and $29 \%$ table 2 ). However the turn structure within this was quite different. The co-present lesson contained 753 turns in total whilst the
video mediated lesson contained just 234, and the average length of both turns at talk and musical contributions were significantly longer for the video-mediated lesson. Net mean offset for the remote lesson was 337 ms , 143 ms longer than the co-present lesson offset of 194 ms (table 3). These results are consistent with findings that video-mediated conversations are characterised by fewer turns of greater length and reduced overlapping speech (Cohen, 1982; O'Conaill et al., 1993; Sellen, 1992).

Table 2: Turn structure of co-present vs. remote lesson.

|  | co-present | remote |
| :--- | :---: | :---: |
| instrument | clarinet | oboe |
| total duration (mins) | 36 | 27 |
| number of turns at talk | 550 | 165 |
| as a \% of total turns | $73 \%$ | $71 \%$ |
| number of musical contributions | 203 | 69 |
| as a \% of total turns | $27 \%$ | $29 \%$ |
| total lesson contributions | $\mathbf{7 5 3}$ | $\mathbf{2 3 4}$ |
| average length of turns at talk (s) | 2.0 | 4.4 |
| average length of musical contributions (s) | 4.7 | 6.7 |
| total lesson average contribution length (s) | $\mathbf{2 . 8}$ | $\mathbf{5 . 1}$ |

Table 3: Net offset duration (ms) by transition type.

| $\%$ | $35 \%$ | $30 \%$ | $34 \%$ | $2 \%$ |  |
| mean (ms) | 39 | -40 | 993 | 124 | 337 |

Next we examine the net offset by transition type. In the co-present lesson, the net offset for turn transition type talk following talk, representing periods of student-tutor discussion, was 287 ms (table 3). This was slightly outside the range of $0-200 \mathrm{~ms}$ from the literature, but still showed a preference for a pause of the same order of size. For transition type play following talk, for example a student performing in response to a verbal instruction from the tutor, the co-present net offset was again in line with the literature ( 297 ms , table 3 ). In the remote lesson, the net offset for transitions of talk following talk decreased to 39 ms in line with our expectations from the literature, but the net offset for play following talk lengthened considerably to 993 ms .
Looking specifically at overlap by participant, the student showed a preference to play over tutor talk (33 instances of student play over talk overlap compared to 2 tutor instances table 4). One explanation for this is that in co-present lessons tutors were found to make long instructional turns to initiate student play, comprised of several utterances separated by
pauses, interspersed with backchannels by the student. The backchannels were placed with precision to show attentiveness without making a bid for the floor or disrupting the tutor's turn. Non-verbal cues enabled the student to determine when these turns were complete and they should start to play (Duffy, 2015, pp. 140-148). As the next example shows, in the remote lesson the student found this more difficult.

Table 4: Overlap duration (ms) by activity by participant

## Instructional turns

The tutor asked the student to play a scale. When the tutor paused after her first utterance, the student made physical preparations to play such as stepping back from the screen and raising her hands to the instrument body (transcript 1: line 1 and transcript 2 : line 2). However the tutor retained the turn, choosing to demonstrate by playing the scale herself (transcript 1 and 2: line 3). Towards the end of the scale the student raised her clarinet to her mouth again, this time placing the reed in her mouth (transcript 1: line 4 and transcript 2: line 5). However the tutor started a new utterance "so I mean you go C sharp to C sharp" and the student lowered her oboe again. This was the second abandoned attempt to play. At the end of this utterance the student nodded and raised her oboe for a third time. She placed the reed in her mouth and took an in-breath whilst the tutor talked (transcript 1: line 6). The tutor made no further utterances and finally the student moved into playing the scale. From the tutor room footage it was not clear why the student made two preparations to play which could not be followed through. From the student room footage it was clear that the student was placing these actions in the pauses that were interpreted as the end of the tutor's instructional turn. This happened several times, and towards the end of the lesson the student exclaimed "sorry sorry it's hard to know when to play". This example is analysed in more detail in Duffy (2015, pp. 350-359).

## Bidding for the floor to provide feedback

Transitions involving turns following play did not follow the literature. Both talk following play and play following play

```

Transcript 2: The tutor initiates a scale - tutor room audio
tended towards overlap in the co-present lesson, rather than a short pause ( -61 ms and -70 ms table 3). Talk following play tended towards overlap in the remote condition ( -40 ms table 3). Play following play tended towards a pause in the remote condition (net offset 124 ms ) but the proportion of this type of turn was significantly reduced to just $2 \%$, or 4 turns. All but one incidence of talk over play overlap was made by the tutor, in both the co-present and remote lesson (table 4), evidencing the tutor's preference to talk over student play when a problem was been diagnosed in order to provide feedback. This did not appear to be as disrupted by the medium as the previous example, perhaps because the length of the note during which the tutor bid for the floor was often of the same order as the duration of the delay (Duffy, 2015, pp. 245-263), so the tutor's interruption still arrived before the student could start the next musical phrase. What is beginning to emerge is asymmetry in the preferences for taking a turn to talk or play between the participants, some of which are disrupted more by the medium than others.

## Local differences in turn placement

Next we will look at an example which demonstrates the effect of the delay on the placement of a single turn. Audio waveforms from each room illustrate the effect in addition to the transcripts (figure 1). Coloured blocks have been annotated using Logic Pro 9 to highlight the different position of parts of the dialogue shown in transcript 3. The tutor waveform is narrower because the camera in the tutor room was further away from where the tutor was positioned, as a result the waveform has smaller amplitude (vertical height representing volume). This does not affect our analysis. The two audio samples were synchronised using the visual transients in the tutor's utterance "ba ba ba ba ba ba" (line 3 of transcript 3). Transcript 3 shows the difference in turn transition and sequence between the two rooms.

* a door slams shut as an observer leaves the room
```

Transcript 3: Turn sequence discrepancy between rooms
There are two main differences between the audio samples. The first relates to the student's utterance "Yeah fine" in line 2 (circled section of the waveform in figure 1). This utterance was made with respect to the tutor's turn in line 1 . In the student room audio the response followed straight on, after the noise of a door slamming at the end of the tutor's turn. In the

Figure 1: Audio discrepancy between rooms.
tutor room audio there was a 0.8 second pause after the tutor said "Cause the A sharp is always there from the crotchet rest". When the student utterance "Yeah fine" arrived, the tutor had already started talking again, so it overlapped with the start of the tutor's next comment "You've just got it". From the student's perspective, she had replied as soon as she heard the tutor's comment. However her reply was delayed in its return to the tutor by 0.9 s . When the student's response arrived, the tutor had already started to talk again having only heard silence, and so she talked over the student's response. As a result, the student's utterance "Yeah fine" was placed within a pause in the tutor's speech, but transformed into an overlap with tutor speech when received in the tutor's room. Several examples of similarly misapplied feedback are reported in Ruhleder and Jordan (2001).

The next example shows how turn sequence can be changed. Examining the student audio first, the musical phrase in line 1 of transcript 4 includes a pause notated in the score before a phrase is repeated. The student makes this pause 0.4 seconds in duration and starts the repeated phrase in line 2 . However the tutor appears to talk over this second phrase with "May-maybe a" (line 3). This is unusual, the tutor usually waits until the end of a musical phrase to start talking, the only overlap being with the final note (Duffy \& Healey, 2013); here the tutor starts talking mid-phrase. It is also unusual that the student does not stop playing, instead the tutor stops talking and the student continues. The tutor interjects again with "yeah" but the student still continues. The tutor then talks again straight after the last note of the phrase. Now the student stops playing, immediately looking up from the music and at the screen.
Looking at the tutor room audio, shown in the second half of transcript 4 , we see that the tutor started the utterance "May-maybe a" during the notated pause in the student's performance (transcript 4: line 2a). However the delay in trans-

Transcript 4: Relative position of tutor interruption.
mission of this utterance to the student room, meant that it arrived after the student had started to play the next phrase in line 2. In the tutor's room "May-maybe a" was interrupted by the student starting her second phrase in line 3 a and the tutor stopped talking. Her next utterance "yeah" in line 4a started during a long note played by the student, which could be interpreted as a bid for the floor. However when this utterance arrived in the student room, the long note was already complete and the student had moved on to the next phrase. From the tutor's perspective she had tried unsuccessfully to take the floor at the end of the first phrase.

## Discussion

The short fragments of music which occur during an instrumental lesson have been shown previously to be managed conversationally, and share some characteristics with turns at talk. Here we see that participants exhibit different preferences for how they manage transitions between verbal and musical contributions. The tutor more often leads lesson
flow, placing more of the responsibility for turn placement onto the student in their responses. The tutor is also more likely to bid for the floor during student play, whereas the student rarely interrupts the tutor in talk or play. Differences in preferences have also been reported in turn-taking associated with the roles of the teacher and students in a classroom (McHoul, 1978). The signal delay associated with VMC disrupts these preferences, exhibiting a greater effect on the student. Ruhleder and Jordan (2001) suggest that the mechanisms which are most affected by signal delay are conversational turn-taking, sequence organisation and repair; affecting trust and confidence between the participants. The phenomenon analysed here may explain student frustrations previously reported during remote music lessons (Duffy \& Healey, 2012). This study highlights a number of opportunities for further work. For example, it is not known if participants could acclimatise to aspects of the disruption to lesson interaction over time. A longitudinal study is recommended which follows student-tutor pairs taking both co-present and remote lessons. In this way, any effect caused by change in participants across conditions will also be controlled. There may also be different, more effective, ways to represent the naturalistic teaching interaction remotely through alternative technologies (Duffy \& Healey, 2017).

# When Do Vehicles of Similes Become Figurative? Gaze Patterns Show that Similes and Metaphors are Initially Processed Differently 

Frank H. Durgin (fdurgin1@swarthmore.edu)<br>Swarthmore College, Department of Psychology, 500 College Avenue<br>Swarthmore, PA 19081 USA<br>Rebekah Gelpi (rgelpi1@swarthmore.edu)<br>Swarthmore College, Department of Psychology, 500 College Avenue<br>Swarthmore, PA 19081 USA

#### Abstract

Recent emphases on differences between metaphors and similes pose a quandary. The two forms clearly differ in strength, but often seem to require similar interpretations. In Experiment 1 we show that ratings of comprehensibility are highly correlated across simile and metaphor sentences differing only in the presence or absence of "like". In Experiment 2 we show that comprehensibility ratings for figurative forms predict both early (first pass) and late (second pass) fixation durations for metaphor vehicle, but only late fixation durations for vehicles in similes. Simile vehicles appear to initially be processed similarly to literal comparisons, with figurative interpretation occurring later. These observations are consistent with the different pragmatic strengths, and similar interpretations of the two forms.

Keywords: simile; metaphor; analogy; career of metaphor, implicature, eye-movements

## Introduction

Theories of figurative speech differ in emphasizing either (abstract) categorization (e.g., Glucksberg \& Keysar, 1990) or analogical comparison across domains (e.g., Tourangeau \& Sternberg, 1982). Bowdle and Gentner (2005) proposed that unfamiliar figurative usages tend to be preferred in simile form ("Moonlight is like bleach") whereas familiar ones are preferred in metaphor form ("Alcohol is a crutch"). They suggest that the surface form of a simile mirrors the cognitive processing (analogical reasoning) needed for an unfamiliar figurative meaning.

But it isn't the case that mere comparison captures analogical comparison. Aristotle is sometimes described dismissively as a comparison theorist (e.g., Tourangeau \& Sternberg, 1982), but Israel, Harding and Tobin (2004) rightly point out that Aristotle is a metaphor-first theorist. Aristotle has also been characterized as considering metaphors to be implicit analogies (Levin, 1982). Similes, on this view, might be figurative to the extent that they require cross-domain implicit analogical reasoning.

Glucksberg and Haught (2006) observed that adding an off-category adjective (e.g., "Moonlight is (*like) romantic bleach") disrupts the preference scheme identified by Bowdle and Gentner (2005). From this Glucksberg and Haught seek to argue that figurative categorization is the only plausible account of metaphor. They argue that their adjectival noun-phrases are dis-preferred in simile form
because similes refer to literal referents. But non-existing categories like "romantic bleach" block comparison generally, and do not differentiate literal from figurative comparison. Moreover, they seem to violate the need for distinct domains required for analogy to work.

In this paper we will adopt the strategy of contrasting online comprehension of similes both with metaphor and with literal comparisons (as recommended by Israel et al., 2004). By this means we will test whether similes are simply interpreted literally, as Glucksberg and Haught (2006) argued, or if they also differ from literal comparisons in ways that clarify their normal designation as figurative.

In Experiment 1 we will show how similar the comprehensibility ratings of associated metaphor and simile forms are. Despite previously recognized differences in strength (e.g., Glucksberg \& Keysar, 1990), aptness (e.g., Kennedy \& Chiappe, 1999), and preference (e.g., Bowdle \& Gentner, 2005), we find that comprehensibility judgments are relatively similar across both simile and metaphor forms for simple vehicles without adjectival modification. This suggests similar interpretations are reached for the figurative meaning of the vehicle in each figurative form.

In Experiment 2, we will use measures of gaze during reading to show that initial reading of similes more closely resembles that for literal comparisons than that for metaphors. Metaphors show reliable effects of figurative comprehensibility during initial first-pass reading; similes and literal comparisons do not show such comprehensibility effects early on. However, during second-pass reading, fixation durations on simile and metaphor vehicle both show strong correlations to ratings of figurative comprehensibility. This suggests that the figurative interpretation of a simile vehicle may simply be computed later than that of a metaphor.

## Experiment 1: Comprehensibility Ratings

## Methods

Materials (for Experiments 1 and 2) Seventy-five metaphors were gathered or updated from previous studies (Katz, Paivio, Marschark \& Clark, 1988; Bowdle \& Gentner, 2005; Thibodeau and Durgin, 2011). For gaze analysis (Experiment 2), each sentence was extended with a few words intended to be largely neutral with respect to
interpreting the sentence (e.g., "A smile is (like) a magnet for people."). A set of literal comparison statements was developed using the same vehicles (e.g., "A black hole is like a magnet in space."). To balance the number of sentences that did not include "like" and were not figurative, we also included 25 literal categorization statements filler sentences unrelated to the 75 experimental items. Three lists of 100 items were constructed in which one third of the 75 items appeared in each of the three forms (metaphor, simile, literal comparison) along with the 25 fillers.

Participants and Task A total of 91 adults were recruited through Amazon's Mechanical Turk to make ratings of comprehensibility of the critical word in each sentence. A third were assigned to each of the three lists of stimuli.

## Results and Discussion

As shown in Figure 1, comprehensibility ratings of metaphor and simile vehicles were highly correlated across items, $R_{73}=0.85, p<.001$. A common factor, produced by averaging the figurative rating sets by item accounted for $92 \%$ of the variance in the simile ratings and $93 \%$ of the variance in the metaphor ratings. There was, of course, no correlation between this common rating measure for figurative vehicles and the ratings given for the same words in literal comparisons with the same vehicles, $R_{73}=0.01$, ns.

It appears that ratings for both figurative sentence forms are typically based on similar figurative meaning, defined in relation to the topic.

Figure 1. Correlation between comprehensibility ratings for each figurative vehicle across figurative sentence forms.

## Experiment 2: Gaze Measures when Reading Comparisons, Similes and Metaphors

The rating data of Experiment 1 are consistent with the assumption of many scholars that there is good reason to suppose that similar figurative meanings are often achieved by sentences in simile and metaphor forms, even if they may sometimes diverge in understanding. However the rating data reflect post-interpretive evaluations and do not bear on the question of whether the initial cognitive encounter with
the vehicle (e.g., during reading of the metaphor) is substantially different in similes and metaphors. In order to better understand how comprehension may unfold differently for the two figurative forms, we next measured gaze patterns during reading of these same sentences.

## Methods

Participants Thirty-six Swarthmore College undergraduate students who were native English speakers participated in partial fulfillment of an introductory course requirement.

Design and Procedure The linguistic materials were identical to those used in Experiment 1, except that 6 practice items were developed to allow participants time to adapt to the task. One third of the 75 experimental items appeared in each of three forms (metaphor, simile, literal comparison) for each participant, according to one of three lists, and were randomly ordered and intermixed with 25 (filler) literal categorization sentences. Sentences were presented one at a time on a monitor in front of the participant after first establishing gaze on a fixation point just to the left of the presentation of the sentence. Participants were to read the sentence and respond by pressing a key when they had comprehended it. The sentence was then removed, and an easy multiple-choice comprehension test followed, asking which of four terms was most relevant to the meaning of the sentence they had just read (e.g., for "A smile is (like) a magnet for people", the correct answer was "attract"). Subjects made their choice using a game-pad with an appropriate spatial mapping to the choices on the screen. The entire experimental session took about 20 minutes.

Gaze Recording Gaze was tracked at 1000 Hz , using an Eyelink 1000 (SR Research). The experimental code was implemented in Experiment Builder (SR Research), and gaze parameters during reading were extracted using custom software in conjunction with the area-of-interest definition tools provided by Experiment Builder.

## Results and Discussion

Analysis Strategy Our principal interest was to compare the immediate processing of similes to the processing of metaphors, as measured by gaze parameters, and to secondarily use literal comparisons as an alternative comparison condition for similes. We used item-wise rating data from Experiment 1 as a predictor in LMER models. For the figurative items these ratings were averaged across figurative conditions. For gaze variables, we first used model comparisons to test whether the ratings had predictive value that differed between figurative sentence types. For example, if metaphor vehicles are treated as figurative words, while simile vehicles are treated as literal words, we might expect ratings of figurative interpretability from Experiment 1 to predict only the metaphor forms, and not the simile forms. To test for this we compared LMER models that included an interaction term (between ratings
and sentence type) with those that did not. Such model comparisons produce a Chi-square statistic. We also used LMER modeling to compare similes with literal comparisons. For overall comprehension time, we conducted a single overall analysis since comprehension

Gaze Behavior: Overview. The analysis of gaze behavior data is organized into five reading events relative to the target word (i.e., the vehicle) region: (1) Duration of initial fixation(s) on the critical word, (2) the subsequent frequency of regressions back out to the left (3) the duration of time

Figure 2. Mean comprehension times (mean response latency computed in log space by item) for metaphors (left), similes (middle), and literal comparisons (right) as a function of item comprehensibility (ratings). Best fit and SE shown.
time was expected to be correlated with comprehensibility ratings for all sentences.

Comprehension Time Participants' main task was simply to indicate comprehension of the sentence after reading it by pressing a key. The distribution of times was skewed, so centered $\log$ transformations of these times were used for statistical modeling. The main LMER model included sentence type (metaphor, simile and comparison) and comprehensibility ratings from Experiment 1 as predictors.

Error terms included subjects and item as well as the slopes for sentence form by subjects and by items, and the slopes of ratings by subjects. Model comparisons showed that including the interaction between sentence type and rating did not explain reliably more variance than a model without the interaction, $X^{2}(2)=0.27, p=.875$, indicating that the relation to ratings did not differ by sentence type. Rather for all three sentence types, ratings predicted comprehension time, $t(117.3)=3.54, p<.001$ (Satterthwaite approximations of $d f$ will be reported throughout; see Luke, 2006). However, compared to the similes, response times were reliably longer for the literal comparison sentences, $t(48.6)=3.94, p<.001$. Consistent with effects previously observed for apt or conventional figurative vehicles (e.g., Bowdle \& Gentner, 2005; Glucksberg \& Haught, 2006), comprehension time was marginally shorter for the metaphors than similes, $t(35.1)=$ 1.93, $p=.062$. The observed relationship of rated comprehensibility and comprehension time is shown in Figure 2 separately for each sentence type. These data reflect the expected relationships between comprehensibility ratings and comprehension time.
between first fixating the critical word and finally reading past the word, (4) the likelihood of refixating the word after passing it, and (5) if refixation occurred, the total time taken fixating the word after first passing it.

Our primary interest is in differences associated with the presence of "like" in advance of the figurative word, since the simile and metaphors forms used are otherwise identical. Comparisons between the literal comparisons and similes are also of interest, however, given that we are asking whether the figurative vehicle words in similes are initially processed literally.

Gaze Data Transformation and Truncation Duration data associated with gaze patterns were also log transformed to reduce skewing and were centered for analyses. Transformed durations that were more than 4 standard deviations above the transformed mean for that measure were truncated to 4 SDs. The proportion of data affected by this method was less than $1 \%$ each measure discussed. Ratings were centered (by subtracting off the mean) prior to analysis.

Gaze Behavior 1: First Fixation Duration. If participants initially seek to understand metaphor vehicles figuratively, but simile vehicles literally, the duration of their first fixation on the critical word might correlate with ratings of comprehensibility for figurative items only for metaphors.
Consistent with this hypothesis, comparison of LMER models of the figurative sentence data, with and without interactions terms, showed that the relationship of FFD to ratings differed for the two figurative forms, $X^{2}(1)=7.32$, p $=.007$. As expected, separate models of the two condition indicated that FFD for the figurative vehicle was related to
the rated comprehensibility in the metaphor form, $t(35.6)=$ $4.06, p<.001$, and not in the simile form, $t(68.0)=0.10$, ns. Models of FFD contrasting the two comparison sentence forms (literal comparisons and similes), found no differences in FFD between the two forms $\left(X^{2}(2)=2.74, p=\right.$
the various forms. Indeed, model comparisons indicated that the relation of GPT to rated comprehensibility differed reliably between simile and metaphor forms, $X^{2}(1)=9.8, p$ $=.002$. In these models, GPT was also reliably longer for metaphors than similes, $t(37.6)=2.84, p=.007$. Separate

Figure 3. Top row: First fixation duration (FFD). Bottom row: Go Past Time (GPT). Geometric means (by item and sentence type) for the figurative vehicle (or equivalent) are shown as a function of mean rated comprehensibility.
.254. The data for each form are plotted in the top panels of Figure 2. This pattern is consistent with the idea that the figurative vehicle in a simile is initially treated as a literal referent, as argued by Glucksberg and Haught (2006a). In contrast, initial encounters with metaphor vehicles produced effects consistent with an immediate search for a figurative interpretation.

Gaze behavior 2: Go past time. Go past time (GPT) is defined as the entire duration from first entering the critical word until finally passing to the right of the critical word. GPT for each sentence form is shown in bottom panels of Figure 3 as a function of comprehensibility rating. Because GPT includes FFD, FFD was included as a covariate in LMER analyses of GPT (the analyses come to the same conclusions without the covariate).

Again, we first sought to test whether there were reliable relationships between GPT and rated comprehensibility for figurative items, and, if so, whether these differed between

LMER models showed that, for metaphor sentences, GPT was reliably related to figurative comprehensibility ratings, $t(64.4)=2.60, p=.011$. This was not the case for similes, $t(74.1)=1.49, p=.141$ (where the trend was in the opposite direction, consistent with delays for highly conventional metaphors presented as similes).

Models comparing GPT for the similes and literal comparison sentences5 indicated that including the interaction of ratings and sentence type in the models made no reliable difference, $X^{2}(1)=2.75, p=.097$. A separate model of literal comparisons confirmed that here was also no reliable relationship between GPT and rated comprehensibility, $t(76.9)=0.70, p=.486$. Thus, prior to exiting the critical word to the right in the simile form, the figurative vehicle may still be treated primarily as a referent to the literal comparison category as the reader passes on the rest of the sentence.

Gaze Behavior 3: Returns to the Target Word From the Right Participants often returned to the critical word after they had already read beyond it. Indeed, this happened in roughly $59 \%$ of trials ( $60 \%$ of metaphor trials, $58 \%$ of literal comparison trials and $57 \%$ of simile trials). Is the likelihood of such Regressions In (RI: if the critical word was refixated on a given trial after exiting to the right) related to rated comprehensibility? LMER models of RI for the figurative sentences showed a reliable relationship existed between rated comprehensibility and the likelihood of RI, $t(59.9)=2.29, p=.026$, and that this effect did not reliably differ between metaphors and similes, $X^{2}(1)=$ 0.003 , $n s$. But LMER models of RI for comparison sentences also showed a reliable main effect of rated comprehensibility, $t(38.4)=2.27, p=.029$, and no evidence of an interaction, $X^{2}(1)=0.04, n s$. Thus, RI was more likely, for all sentence forms, as comprehensibility decreased.

Gaze Behavior 4. Second Pass Total Time (P2TT) Given that a reader had refixated the critical word after having read more of the sentence, was the total time spent refixating it before responding related to rated comprehensibility? Total comprehension time was included as a covariate because it was highly correlated with P2TT. Whereas FFD and GPT both distinguished similes from metaphors, understanding a simile typically requires reaching a similar understanding to the understanding required for a metaphor. When during reading comprehension might this happen?

LMER models of P2TT for the figurative sentences indicated that the relation between P2TT and comprehensibility ratings was highly reliable for these two forms, $t(63.0)=2.77, p=.007)$, but did not differ between the figurative sentence forms, $X^{2}(1)=0.37, p=.548$. Thus, P2TT appears to be similarly related to comprehensibility ratings for similes and metaphors, as shown in Figure 4. In contrast, LMER models of the comparison statements (i.e., similes and literal comparisons analyzed together) failed to show reliable relationship between ratings and P2TT, $t$ (39.9)
$=1.71, p=.095$, but also failed to detect reliably different effects of ratings for similes and literal comparisons, $X^{2}(1)=$ $0.36, \mathrm{p}=.548$.

To resolve the mixed evidence regarding similes in these two analyses, we modeled the effect of ratings on each sentence type separately, both with and without the total comprehension time as a covariate. For literal comparisons, there was no evidence that P2TT was related to comprehensibility ratings either with the covariate included, $t(64.3)=0.56, p=.580$, or without it, $t(59.9)=0.99, p=$ .327. Conversely, consistent with overall analyses of figurative sentences, in individual analyses of each of the figurative forms P2TT was similarly, but weakly related to comprehensibility when the covariate was included $($ metaphor: $t(49.3)=1.82, p=.075$; simile: $t(37.5)=1.94, p$ $=.060)$ and highly reliably related to comprehensibility when the covariate was not included in the models (metaphor: $t(34.4)=3.13, p=.004$; simile: $t(58.0)=2.92, p$ $=.005$ ). Recall that the overall relationship of comprehensibility and P2TT for figurative items in our combined analyses was reliable even with total response time included as a covariate (i.e., $\mathrm{p}=.007$, above). A similar analysis without the covariate also provided strong evidence of an overall relationship, $t(52.4)=2.99, p=.004$.

Does P2TT help to explain overall response time differences for figurative items? To test whether P2TT, itself, can account for longer overall overt comprehension responses, a new analysis of overall response time was conducted (for trials displaying RI) with and without P2TT as a covariate. Without P2TT included, there was strong evidence of a relationship between ratings of comprehensibility and comprehension time for these trials, $t(23.7)=3.08, p=.005$, but when P2TT was included as a covariate, no evidence of the relationship between response time and comprehensibility remained, $t(58.1)=1.50, p=$ .138. For figurative items, then, it appears that P2TT likely represents time used for computing a figurative interpretation of the sentence.

Figure 4. Geometric mean second pass total gaze duration (P2TT) by item as a function of rated comprehensibility for each sentence form. Only the 1431 trials where regression into the critical word occurred are included.

## General Discussion

In Experiment 1, we observed that ratings of comprehensibility for vehicles in simile or metaphor form were highly correlated. The average figurative ratings from Experiment 1 were used in Experiment 2 to try to predict gaze variables related to the figurative vehicle during reading. We reasoned that the similar comprehensibility ratings of similes and metaphors observed in Experiment 1 reflected similar ease or difficulty with deriving the appropriate figurative meaning of the vehicle; we sought evidence of when this might unfold during reading.

Gaze patterns for metaphor vehicles, but not simile vehicles, reflected rated figurative comprehensibility from the very first fixation. Metaphor vehicles that were judged less comprehensible were subjected to longer initial periods of analysis. In contrast, similarly-rated similes, did not show immediate effects. For similes, as for literal comparisons, initial measures of processing time for their vehicles in similes were unrelated to rated comprehensibility.

But simile processing resembled metaphor processing during second-pass reading of the sentence. Both simile and metaphor vehicles showed comprehension-related durations of fixation. These second-pass durations were related to the rated comprehensibility of the word in the sentence both for metaphors and for similes. This pattern was not found for literal comparisons.

The difference between similes and metaphors at first fixation might be regarded as reflecting the weaker pragmatic assertion involved in declaring that something is like something rather than that it is something (RubioFernández, Geurts \& Cummins, 2016). To say that something is like something else implies that it is also unlike it. In this sense similes are sensibly experienced as weaker than metaphors at first pass, even if the ultimate interpretation of what is being said about the topic ultimately requires accessing a figurative or abstract interpretation of the vehicle.

Overall, these data suggest that similes are initially treated similarly to literal comparisons, consistent with the arguments of Glucksberg and Haught (2006). However, the second pass data and the ratings data both suggest that sentence comprehension for simile forms still requires identifying a figurative interpretation. We think this supports Aristotle's assertion of the figurative nature of simile that is embedded within his longer discussion of metaphor. Aristotle ( $400 \mathrm{BC} / 1991$ ) wrote "A simile is also a metaphor, for there is little difference." This quote clearly implies that metaphor (literally a "carrying-over" of meaning) is the larger category.

Our study has used similes derived from metaphors. The data show that reading such similes differs substantially from reading their corresponding metaphors. However, the data also support the idea that the interpretive demands for the figurative vehicle may ultimately be similar in both forms. This distinguishes simile from literal comparison.

#### Abstract

The principal aim of a cognitive model is to infer the process by which the human mind acts on some select set of environmental inputs such that it produces the observed set of behavioral outputs. In this endeavor, one of the central requirements is that the input to the model be represented as faithfully and accurately as possible. However, this is often easier said than done. In the study of recognition memory, for instance, words are the environmental input of choice-yet because words vary on many different dimensions, and because the problem of quantifying this variation has long been out of reach, modelers have tended to rely on idealized, randomly generated representations of their experimental stimuli. In this paper, we introduce new resources from largescale text mining that may improve upon this practice, illustrating a simple method for deriving feature information directly from word pools and lists.

Keywords: recognition memory; word frequency; word length; feature frequency; orthographic similarity; semantic similarity; corpus analysis; vector space models

## Introduction

In cognitive modeling, there is a close interdependence between representation and process. A model consists in both a data structure (an abstract representation of environmental input), and an algorithm (the process that operates over the data to simulate behavior). The choice of structure for the underlying data is critical, as it can profoundly influence the choice of algorithm. Valid representational assumptions are of vital importance, in that they reduce the degrees of freedom available to the modeler, thereby constraining model selection.

Since the inception of memory research, psychologists have relied on verbal stimuli to study learning and forgetting (Ebbinghaus, 1885). In episodic and semantic memory, the majority of data has been-and is still-generated from experiments with word lists, and memory models are routinely assessed in terms of their ability to fit data on verbal remembering (Monsell, 1991). However, when it comes to words, the choice of data structure is complicated by the fact that words vary on a remarkable number of lexical and semantic dimensions (Baayen, Milin, \& Ramscar, 2016), which may or may not contribute to how they are learned and remembered. Historically, it has been impossible to reliably quantify all these points of variation. Memory modelers have thus tended to rely on randomly generated representations, which have been carefully selected to preserve the relevant properties of the data.

While this practice has been expedient, it is no longer strictly necessary. As large-scale corpora - and the technology to mine them-have become widely available (Gilquin \& Gries, 2009; Halevy, Norvig, \& Pereira, 2009; Recchia \& Jones, 2009), it has become not only possible, but relatively straightforward, to construct not merely plausible, but accurate representations of the stimuli used in a given experiment (Baayen, 2010). This is an important advance, as problems can arise when the selected
representation does not faithfully reflect the environment. For instance, global matching models of episodic memory have considerably more difficulty reproducing behavioral data when supplied with realistic semantic representations (Johns \& Jones, 2010). Improving the quality of our data structures could thus improve the quality of our process models.

Further, while the words selected for memory experiments are commonly assumed to vary randomly, in line with their selection procedure, this may not always be the case. For one, certain properties - such as semantic similarity - may be systematically skewed, and thus poorly represented by a normal distribution (Johns \& Jones, 2010). For another, there may be accidental variation between the word pools used by different research groups (van Heuven et al., 2014), which could produce conflicting results. Given renewed interest in replicability in the psychological and brain sciences (Open Science Collaboration, 2015), providing a more detailed account of the stimulus properties that produce a given effect should be a principal research aim (Ramscar, 2016).

The overarching goal of this paper is to enumerate a simple technique for investigating the lexical and semantic characteristics of a specific word pool, and to discuss how this can be fruitfully applied to the interpretation of empirical results in episodic memory.

## Word Frequency

Word frequency is a measure of a word's occurrence in the language, and a proxy for an individual subject's experience with that word. Frequency has long been a variable of central importance in cognitive models, as it is one of the strongest predictors of verbal processing and remembering (Baayen, Milin, \& Ramscar, 2016; Balota et al., 2007). In some models, frequency is treated as a causal variable-e.g., in a model of visual word recognition, frequency might function as an internal counter, in which each occurrence of an item increments its baseline activation upward (Coltheart et al., 2001). In others models, frequency is treated as an informative correlational variable, and items of a given frequency class are assigned specific feature values (Shiffrin \& Steyvers, 1997).

Setting the details aside, virtually all models incorporate frequency in one respect or another. Given the significance of frequency as an explanatory variable, its accuracy of measurement, relation to other lexical and semantic variables, and instantiation in cognitive models are all matters of some theoretical importance. Yet in spite of this, many researchers are still working with outdated measurements and methods, which are not being updated as the field advances. One particularly remarkable example of this is that the KučeraFrancis norms (1967), collected fifty years ago, are still widely used among psychologists to determine word frequency. This is the case even though they have been known for decades to be unreliable (particularly for lower frequency words), and are, on assessment, consistently the worst performing norms across an array of lexical processing tasks (Brysbaert \& New, 2009). Frequency values collected today are derived from corpora orders of magnitude larger.

Another source of concern is that word frequency itself is
routinely treated as a categorical variable, rather than a continuous one, even though dichotomizing a random variable can seriously jeopardize reliability (MacCullum et al., 2002; Hemmer \& Criss, 2013). Further contributing to this problem, the standard method for binning words into high and low frequency bands fails to take into account the skewed nature of the distribution. Indeed, in an analysis of several classic studies, high frequency items were found to have considerably larger standard deviations than their low frequency counterparts, and a sizeable percentage of 'low' frequency items were shown to fall at, or above, what should have been the border between the groups (van Heuven et al. 2014).

That influential psychometric tests have been predicated on such unreliable measures raises serious questions about their validity (Ramscar et al. 2014). Nevertheless, this binary division remains common in both experimental design and in modeling.

## Word Frequency Effects in Recognition

One domain in which it is still commonplace to bin experimental items into high (HF) and low frequency (LF) bands is recognition memory. Models of recognition offer an illustrative test case for why representational assumptions are important to cognitive modeling, and how they might be refined with simple data mining techniques. To clarify this example, we first briefly review recognition memory as an experimental paradigm and as a modeling domain.

In tests of single item recognition, subjects study a list of words, and then at test, are asked to discriminate words encountered at study (targets) from non-studied words (foils). The difficulty of the task lies in the fact that subjects must differentiate between words seen at study and words encountered in everyday life-i.e., they must distinguish between general familiarity with the test items and familiarity that is specific to the recognition task.

Global matching models have predominated as explanatory models of recognition performance (Hintzman, 1988; Murdock, 1982; Shiffrin \& Steyvers, 1997). These models are premised on the idea that item recognition depends not only on the characteristics of the item itself, but also on other items present concurrently in memory. When a specific item is presented at test, the available item and context cues form a joint probe of memory. This search process yields a match value between the test item and the contents of memory. If this value exceeds some threshold, the item is recognized as 'old'; if it fails to meet this criterion, the item is rejected as 'new'. A grounding assumption of global matching models is that studied items will have higher match values, on average, than unstudied lures. However, item recognition is rarely perfect, and much effort has been expended in identifying how interference can arise at retrieval. Noise sources are frequently categorized into two types: item noise (McClelland \& Chappell, 1996; Shiffrin \& Steyvers, 1997) and context noise (Dennis \& Humphreys, 2010). Item noise arises from spurious feature matches with other studied items; context noises arises from interference from extra-experimental contexts in which the tested item has occurred.

Among the findings that global matching models are designed to capture, one of the hallmarks is the mirror effect for word frequency: This is the finding that when HF and LF words are present in equal numbers at study, LF items are better recognized at test, garnering both more hits and fewer false alarms (Glanzer \& Adam, 1985). One way to capture this frequency effect is to assign different parameter values to HF and LF words, thereby generating different distributions of feature values, and hence, of featural similarity between items.

Such a representational choice reflects the fact that words are comprised of an array of surface and semantic properties that are known to vary with frequency, and to affect processing and remembering (Landauer \& Streeter, 1973; Schulman, 1967).

For example, in the Retrieving Effectively from Memory (REM) model, the parameter settings generate HF items with more common, overlapping features than LF items (Steyvers \& Shiffrin, 1997). Because these features are less diagnostic, the self-match between HF targets and their own memory traces is weaker than for LF targets; because they are more common, the likelihood of a chance feature match between HF targets and HF foils will be greater. This yields the canonical lower hit-rate and higher false-alarm rate for HF items.

## Representational Assumptions

Global matching models have shown considerable success in capturing the relevant empirical data, ranging from word frequency effects to differential forgetting (Clark \& Gronlund, 1996). Despite these undisputed successes, there are potential drawbacks in how they represent their list items. For one, these representations commonly lump together semantic, phonemic, and orthographic features into a single, indistinguishable feature set, making it impossible to tease apart how each dimension contributes to recognition performance. For another, representations are randomly generated, rather than empirically derived.

In the influential REM model, for example, a single parameter controls the mean and variability of the distribution that item features are sampled from (Steyvers \& Shiffrin, 1997). To capture qualitative differences in item similarity between word frequency bands, the parameter is adjusted separately for high and low frequency items. However, the specific parameter settings are unconstrained by the actual properties of the stimulus set. Instead, parameters are set either by convention or by best fit to the behavioral data.

Concerns have been raised with this type of practice. In particular, such flexibility leaves the resulting models open to the criticism that they could be made to fit a wide variety of results (Roberts \& Pashler, 2000). Conversely, they might require significant theoretical adjustments to account for the results when supplied with a realistic representation of the list items (see Johns \& Jones, 2010 for an illustration). Finally, if different experiments produce contradictory results, there is no straightforward way to trace back these differences to the characteristics of the lists.

The theoretical claims of this class of models could be strengthened by deriving the model parameters directly from the lexical and semantic characteristics of the experimental word pool, or test list. This could be accomplished in a number of ways. In the simplest case, the actual feature distribution of the stimuli could be used to determine the closest choice of parameter settings. Another option would be to generate the input representation directly from the stimuli, using either the real feature values, or adjusted feature values (which could be made more robust by incorporating noise, or various smoothing mechanisms; see e.g., Chen \& Goodman, 1999). Here, we detail a simple procedure for deriving feature information for lexical items as a function of their frequency class.

## Corpus Investigation

The following investigation was conducted 1) to illustrate how various lexical and semantic feature information can be derived directly from word pools and recognition lists, 2) to examine how these feature values can be expected to vary as a function of item frequency, and 3) to assess whether standard word pools mimic these differences (and each other).

## Verbal Properties and Frequency Class

In the study of semantic and episodic memory, different word pools make use of somewhat different sampling procedures and controls. Thus, our first goal was to establish a neutral, independent baseline, in which words were sampled without any special consideration other than frequency.

| Zipf value | fpmw | Examples |
| :---: | :---: | :---: |
| 1 | 0.01 | antifungal, bioengineering, farsighted, harelip, proofread |
| 2 | 0.1 | airstream, doorkeeper, neckwear, outsized, sunshade |
| 3 | 1 | beanstalk, cornerstone, dumpling, insatiable, perpetrator |
| 4 | 10 | dirt, fantasy, muffin, offensive, transition, widespread |
| 5 | 100 | basically, bedroom, drive, issues, period, spot, worse |
| 6 | 1000 | day, great, other, should, something, work, years |
| 7 | 10,000 | and, for, have, I, on, the, this, that, you |

Figure 1: The Zipf scale is a logarithmic scale that divides the frequency spectrum into seven discrete classes (van Heuven et al. 2014).

Word Frequency Words and their frequencies were extracted from the state-of-the-art 51 million word SUBTLEXus corpus (Brysbaert \& New, 2009). Frequency classes were assigned according to the Zipf scale, which is calculated for an individual item as $\log _{10}$ (frequency per billion words). The Zipf scale has a number of advantages over the typical binary division between HF and LF words, namely that it is a logarithmic scale reflecting the psychological interpretation of frequency, and its divisions are fine-grained, creating seven distinct classes rather than the traditional two (van Heuven et al., 2014). For purposes of comparison, a Zipf value of 3 or lower corresponds to LF words; 4 or higher to HF words (Figure 1).

Recognition Lists To create recognition lists, 10 items were selected at random (without replacement) from a given frequency bin. Half of these items were labeled targets, and the other half foils, replicating the standard list construction procedure. This sampling procedure was repeated until there were 1000 such lists for each frequency class.

The aim was to compare lists created in each band on four dimensions: word length, feature frequency, and orthographic and semantic similarity of targets to foils. These particular dimensions were chosen to be illustrative, and because they are known to be important contributing factors to item recognition. For word length and feature frequency, counts were computed for each item, and averaged over the entire list. For orthographic and semantic similarity, the similarity of each target to the distractors present at test was computed, and similarly averaged.

To preface, these analyses successfully replicate wellestablished findings on each of these dimensions, while providing a straightforward method for determining the actual empirical trends of a given frequency range, or item set.
Methodology Notably, the comparatively small number of types in the higher frequency ranges placed constraints on the construction of recognition lists (Figure 2). Specifically, list length was necessarily kept small, and while lists were created for Zipf values 1-6, 7 was excluded, as it comprised only 13 distinct word types, all of them function words.

This type distribution is a consequence of the universal scaling law for word frequencies, commonly known as Zipf's Law (1949). The idea is this: Say, an English text is selected, and each of the word types that occur in the text are arranged in order of their frequency, from most to least common, and assigned a numerical rank. Then, the full contents of the text that is, all of its word tokens - are thrown into a bag, shook,
and one word is selected at random. Zipf's Law states that the probability of drawing a given word is inversely proportional to that word's rank ordering. The law formalizes the notion that while a few words in a language are very common, the greater part are exceedingly rare.

Figure 2: The number of distinct word types in the SUBTLEXus corpus for each value of the Zipf scale.

Word Length Word length, whether computed in terms of letters or phonemes, has an inverse relationship with frequency, with word lengths tending to increase as frequency declines (Piantadosi et al., 2011; Sigurd, Eeg-Olofsson, \& Van Weijer, 2004; Wright, 1979; see Figure 3).

Figure 3: Average word length of list items increases as frequency declines.

Feature Frequency Feature frequencies represent the empirical n-gram frequencies of individual letters and letter combinations, and can be conceptualized as a measure of orthographic distinctiveness (Figure 4).

Feature frequency is known to vary with word frequency. On average, rarer words contain both more unusual letters, and more unusual combinations of letters (Malmberg et al. 2002; Zechmeister, 1969).

Orthographic similarity Orthographic similarity was computed as Levenshtein edit distance, a string metric that calculates the minimum number of edits (such as insertions, deletions, or substitutions) required to transform one word into the other (Figure 5).

Given that rare words are more orthographically distinctive (Landauer \& Streeter, 1973; Andrews, 1992), it stands to reason that in a recognition list context, they should be less orthographically similar to frequency-matched distractors than more common words (Hall, 1979).

Figure 4: The five panels depict the average feature frequencies of list items in SUBTLEXus as a function of their Zipf value. The overall trend indicates that higher frequency items are comprised of higher frequency features. Moreover, the larger the n-gram, the greater the separation between frequency classes. For unigrams, a more pronounced pattern of separation between Zipf bands is observable when minimum (rather than average) feature frequency is used.

Figure 5: Average orthographic similarity between targets and distractors declines as a function of frequency.

Semantic similarity Semantic similarity values were obtained from word2vec trained on the 300 billion word Google News corpus. word2vec is a two-layer neural network that produces word embeddings (Mikolov et al., 2013), and is considered state of the art in semantic space modeling (Baroni, Dinu, \& Kruszewski, 2014). word2vec was implemented with gensim, a Python framework for vector space modeling (Řehůřek \& Sojka, 2010), which adopts the continuous skip-gram architecture. The skip-gram model weights proximate context words more highly than distant ones, yielding better results for lower frequency words.

In a recognition task in which list items are randomly sampled from a given frequency band, the semantic similarity between targets and distractors should tend to decrease with frequency (Figure 6). This outcome is all but assured by the distributional properties of the lexicon: In the SUBTLEXus corpus, LF words comprise $80 \%$ of word tokens (van Heuven et al., 2014) and fully $94 \%$ of word types (Figure 2). The
semantic spread from which LF words are sampled will thus be far greater than that for HF items.

Figure 6: Average semantic similarity between targets and distractors declines across the HF range of the Zipf scale, implying that a set of randomly sampled words will be less semantically similar, on average, the lower their frequency class.

Figure 7: Average semantic similarity between targets and distractors across the LF range of the Zipf scale. While a slight ( $n s$ ) trend in the opposite direction is observable in the lower range of the scale, this is almost certainly a methodological artifact. If the missing data in Figure 8 is included as 0 -counts, the apparent trend reverses, and the pattern resembles that seen in Figure 6.

In making these calculations, there is an important methodological issue to consider-in particular, the problem, well-known to linguists, of data sparsity (Sinclair, 1997): While any given sample of language will provide ample evidence about its common words and phrases, it will provide little or none about its rarer, more informative elements (Church \& Gale, 1995). Not only will many perfectly legitimate words (and word co-occurrences) fail to occur in even very large swaths of text, but even most of those that do will occur only a few times, making their estimation unreliable. This is the basic problem of data sparsity and it is one that plagues semantic similarity analyses in the lower frequency ranges (Figures 7, 8).

Figure 8: Data loss for the semantic similarity analyses as a function of frequency class. Semantic similarity values were not available for all the words sampled, and the proportion of words with no data points grew as frequency decreased. For Zipf rank 1, fully $25 \%$ of data was lost.

Figures 6 and 7 show the similarity distributions for item pairs that were known to our word2vec model. However, given the significant data loss for LF items, looking solely at returned values constitutes selection bias, as it implies that unobserved pairs-for which the model cannot supply a score-likely have the same distributional properties as observed pairs. In fact, it is reasonable to assume that unobserved pairs are much less similar, on average. One way of addressing this issue is to assign item pairs with null values a similarity score of 0 . When these scores are included, the trend observable in the HF range (Figure 6) is also clearly observable in the LF range.

In the absence of knowledge, assigning 0 -counts is a useful heuristic. However, given that problems with data sparsity increase as frequency declines, this solution may disproportionately penalize the lowest frequency words. In future work, similarity-based smoothing techniques might be used to better estimate similarity values for unobserved pairs (c.f. Yarlett, 2007).

Interim Summary Our analyses of words in the SUBTLEXus corpus replicates and extends a number of well-known findings on the relationship between a word's frequency and its lexical and semantic features, including that:

1) word length increases as word frequency declines,
2) feature frequency increases with word frequency, with the rate of increase dependent on feature length,
3) orthographic similarity between targets and foils increases with word frequency,
4) semantic similarity between targets and foils increases with word frequency (though the calculation of similarity scores for LF item pairs requires careful consideration).

Available Analyses In the analyses reported here, pure lists were created for each frequency class, average feature information was extracted, and similarity measures were computed as a function of the mean similarity of a target to its foils. The purpose of this was largely illustrative; many variations on this procedure are possible, depending on the requirements of the model, or the empirical task.

One obvious choice point is the sampling method. For example, word selection could be constrained by specific lexical properties (e.g., limited to nouns, or words of length $n$ ), as is common practice in the design of word pools. Similarly, list composition could be varied by sampling specific proportions of words from different frequency bands.

Another matter of some importance concerns the choice of comparisons and statistical measures. Similarity can be computed relative to other targets, distractors, or both; it can also be calculated as an average, or in terms of "max" similarity (e.g., the top $10 \%$ of most confusable items). Likewise, when assessing the use of rare letters and rare letter combinations, it may be more useful to know the minimum feature frequency, or the median, rather than the mean.

Finally, while we chose to delimit our focus to just a few dimensions, there are many more lexical properties that systematically vary with frequency. For instance, rare words are more likely to be judged as abstract (Galbraith \& Underwood, 1973; Pavio, Yuille, \& Madigan, 1968), to be acquired later (Carroll \& White, 1973), and to be regular (Bybee \& Hopper, 2001).

## Word Pools

In the study of semantic and episodic memory, different word pools make use of somewhat different sampling procedures and controls. One concern is that different word
lists may vary in systematic ways from each other, producing variability in results; another is that they may have distinctly different properties from the language 'at large'. To check the validity of these worries, we compared the word pools of two representative cognitive memory labs, with an average h -index among the principle investigators of 20 , and published theoretical disagreements. These word pools were compared against a recognition word list devised by Dye, Jones, \& Shiffrin (2017) (Figures 9, 10).

The Dye et al. (2017) word list was deliberately constructed to increase the semantic and orthographic similarity of LF items, as reflected in Figures 9 and 10. In a recognition list experiment, this had the predicted effect of diminishing the standard mirror effect for word frequency, by bringing the false alarm rate for low and high frequency items into line.

Figure 9: A comparison of average semantic similarity of targets to foils across three word pools.

Notably, while the Dye et al. word list clearly differs from the two standard word pools, these word pools are not identical to each other either. In particular, though both pools are similarly distributed in terms of frequency and semantic similarity among items, in Word Pool 2, orthographic similarity among items is substantially increased compared to Word Pool 1 , and is matched across HF and LF items. This may produce differences in reported results, as orthographic similarity is known to modulate false alarm rates (Malmberg, Holden, \& Shiffrin, 2004).

Finally, it is worth noting that none of these 'controlled' word pools reflect the properties expected from random sampling, as illustrated in our exploration of the SUBTLEXus corpus. In particular, while the distribution of orthographic and semantic similarity values for LF and HF items are largely overlapping for the standard word pools (Figures 9, 10), a truly random selection of these items shows significant separation between frequency bands (Figures 5, 6).

These examples illustrate how the properties of word lists can be readily and fruitfully compared both to each other, and to larger corpora. In future work, we plan to expand this analysis to include more widely used word pools, such as the Toronto word pool (Friendly, Franklin, Hoffman, \& Rubin, 1982), a modified version of the Kucera \& Francis word pool (1967), and a categorized word pool (Murdock, 1976).

#### Abstract

Considerable behavioral evidence has been cited in support of the COVIS dual-system model of category learning (Ashby \& Valentin, 2016). The validity of the inferences drawn from these data critically depend on the accurate identification of participants' categorization strategies. In the COVIS literature, participants' strategies are identified using a model-based analysis inspired by General Recognition Theory (Maddox, 1999). Here, we examine the accuracy of this analysis in a modelrecovery simulation. We find that participants can appear to be using implicit, procedural strategies when their responses were actually generated by explicit rule-based strategies. The implications of this for the COVIS literature are discussed.

Keywords: categorization; COVIS; dual-systems accounts; model-recovery; GRT

## Introduction

Categorization studies rarely examine individual differences. Rather, researchers look at group performance to draw conclusions about the likely underlying mechanisms of category learning (Kurtz, 2015). For these inferences to be valid, the participants in each group must all learn in a qualitatively similar way (Maddox, 1999). Then, relatively little information is lost by averaging. However, severe interpretative difficulties can arise if participants learn in a variety of ways, as then the average will likely not represent the behaviour of any single person (Siegler, 1987).

This issue is more than hypothetical, as there is substantial evidence, and a degree of consensus, that different participants use qualitatively different strategies in categorization tasks (e.g., Nosofsky \& Zaki, 2002; Raijmakers, Dolan, \& Molenaar, 2001; Wills, Inkster, \& Milton, 2015). For example, some participants categorise stimuli on the basis of just one stimulus dimension (as in Figure 1B), or do so initially, even if optimum performance on the task requires using multiple stimulus dimensions (as in Figure 1B, where the participant's strategy is single-dimensional but the optimal classification strategy is diagonal).

COVIS (COmpetition between Verbal and Implicit Systems; Ashby \& Valentin, 2016) is one model that aims to predict when and why participants use different strategies.

COVIS assumes that categorization is mediated by two, parallel, competing systems: an Explicit System and a Procedural System. The Explicit System is assumed to implement rule-based strategies (such as in Figure 1B). Therefore, COVIS predicts this system will optimally learn category structures that are implementations of simple rules (such as in Figure 1A). If rule-based strategies result in poor accuracybecause the category structure is not rule-based and thus difficult to verbalise-COVIS predicts the Procedural System will gain control of responding. As the Procedural System is predicted to implement a variety of strategies (including the one demonstrated in Figure 1A), it is capable of implementing the optimum strategy for information-integration category structures (the structure, but not the strategy, shown in Figure 1B).

Typical COVIS-supporting experiments look for a differential effect of an experimental manipulation (e.g. feedback timing) on rule-based and information-integration category structure learning (for a review, see Ashby \& Valentin, 2016). The category structure manipulation is hoped to elicit a switch in the learning system controlling responding: because participants are learning a rule-based or informationintegration category structure they will use the appropriate strategy and so be using the Explicit or Procedural System, respectively. If the experimental manipulation affects one category structure condition more than the other, the experimenter infers that it affects the accuracy of one system more than the other, thereby providing evidence for a dual-system model of category learning.

For these experiments, the presence of subsets of qualitatively-different participants can be particularly problematic. Critically, the conclusion that the experiment supports a dual-system model depends on the assumption that the participants in each category structure condition used the most appropriate system to learn those structures. In other words, that participants used the Explicit System to learn the rule-based category structure, and the Procedural System to learn the information-integration category structure. If this is not the case, any differences in overall accuracy between category structure conditions might be due to varying rates of

Figure 1: Two example strategies implemented on two category structures: A) a unidimensional category structure with a diagonal (GLC) strategy applied, B) an information-integration category structure with a unidimensional rule applied. Category structure: dots represent Category A, and squares Category B. Responses: Filled symbols indicate a participant responded "A", open symbols indicate they responded " B ".
sub-optimum strategies between conditions, rather than to the existence of two category learning systems.

To illustrate this point, consider an experiment that examined the effect of deferring feedback and found it caused a reduction in performance by $10 \%$ for a particular category structure (such as in Smith et al., 2014). In the ideal case, all participants classifying a particular category structure would be using the same optimum strategy and all those in the relevant condition would be similarly affected by the manipulation; participants with deferred feedback would score $10 \%$ less than those with immediate feedback. Here, we could use standard group-accuracy analyses validly. However, if some participants were using other, sub-optimum strategies then drawing conclusions from the experiment is harder. One possibility is that the manipulation, within a given category structure, changes the relative proportions of different strategies used in each condition (feedback type). This would change average accuracy because, given a particular category structure, the highest accuracy for each strategy varies. A second possibility is the manipulation has a differential effect depending on the strategy type being used. For example, the manipulation could have had no effect on people using the optimum strategy, but could severely affect performance reliant on sub-optimum strategies (see Schnyer et al., 2009, for a similar argument).

To avoid the possibility that any dissociation in accuracy is due to the effects of sub-optimum strategies rather than
two competing systems, COVIS-supporting experiments use a strategy analysis informed by General Recognition Theory (GRT; Ashby \& Gott, 1988). This analysis is used as a manipulation check to determine which strategy each participant is using. This approach (hereafter, GRT analysis) assumes that strategies can be modeled by a (usually linear) decision bound that passes through stimulus space (such as those in Figure 1). For each participant, a variety of strategy models are fitted to their responses. The one that best represents that participant's pattern of responding is selected. Then, each participant's strategy is compared to the category structure they were assigned to learn. If enough participants are found to be using the optimum strategy for the category structure they were assigned, then the category structure manipulation is assumed to have elicited a corresponding shift in category learning system. Under this assumption, any dissociations in accuracy can be validly ascribed to the existence of two systems.

Using GRT analysis as a manipulation check is logically valid if and only if GRT analysis consistently and accurately identifies participants' strategies. In other words, GRT analysis must be able to correctly identify strategies under a variety of circumstances such as differing category structures, experimental manipulations and levels of noise. Unfortunately, recent evidence from our lab suggests that GRT analysis does not accurately recover the strategies participants use for information-integration category structures. For in-
stance, Edmunds, Milton, and Wills (2015) extended an experiment by Ashby, Maddox, and Bohil (2002) looking at feedback type by asking the participants to verbally describe their strategies. A substantial number of responders classified as using the Procedural System on the basis of GRT analysis nevertheless reported using an explicit rule-based strategy (which have been predictive of behaviour in other procedures; Wills, Milton, Longmore, Hester, \& Robinson, 2013).

One possible explanation for this contradiction is that participants did not accurately report their strategies. Two pieces of evidence speak against this interpretation. First, verbal reports successfully predict participants' performance in other tasks (Lagnado, Newell, Kahan, \& Shanks, 2006). Second, Carpenter, Wills, Benattayallah, and Milton (2016) found more frontal and medial temporal lobe activation for participants learning an information-integration category structure than for participants learning a rule-based structure. These brain regions are typically associated with explicit processing (Nomura et al., 2007), implying that classification of an information-integration category structure is at least as explicit in their study as classification of a rule-based structure.

A more interesting explanation for the disparity in strategies found by Edmunds et al. (2015) is that the GRT analysis is wrong. For example, because GRT analysis normally uses just the training stimuli rather than a broad range of transfer stimuli, perhaps it is biased towards the optimal strategy for each category structure? Work by Donkin et al. (2015) provides some support for this conjecture. Specifically, Donkin et al. found that including transfer stimuli from across the stimulus space reduced the proportion of participants classified as using the optimal (diagonal) strategy for an information-integration category structure.

The possibility that GRT analysis does not accurately recover the strategies participants use makes determining whether category learning is mediated by two learning systems more difficult. Consider an experiment that found that feedback delay harmed information-integration category learning but had no effect on unidimensional rule-based category learning. Furthermore, suppose that GRT analysis found that all the participants used the optimum strategy for the category structure they were presented with. If GRT analysis were accurate, we might conclude that the source of this interaction was the presence of two different systems. However, if GRT analysis was inaccurate this inference would not be the only one we could make. For example, if GRT analysis, in the information-integration conditions, falsely identified an explicit conjunction rule strategy as a diagonal (procedural) strategy, an alternative account might be that feedback delay impacts learning once participants are using sufficiently complex rules. This would be consistent with a single-system account and would potentially cast doubt on all of the COVISsupporting studies that used this method.

However, a limitation of all work to date is that one can never be sure whether GRT analysis contains significant flaws, because one does not know which strategy participants
were actually using. When employing data from real participants, all we have are multiple forms of assessment of their strategy (GRT analysis, verbal reports, brain activations etc.), all of which provide indirect and potentially flawed information. Using one measure to assess the quality of the others includes the circularity of assuming one of the measures is correct. In the current article, we use a model-recovery approach to break out of this loop.

Model recovery involves simulating hypothetical participants' responses according to the strategy models defined by the strategy analysis. By simulating responses we circumvent many of the problems with Donkin et al. (2015) and Edmunds et al. (2015), as now we know exactly which model each (simulated) participant is using. From these hypothetical, simulated participants we can then use GRT analysis to identify the strategies from the responses to see whether GRT analysis is capable of recovering the correct generating model. This model-recovery procedure is recommended as best practice for any cognitive modeling analyses (Heathcote, Brown, \& Wagenmakers, 2014) but has yet to be done for GRT analysis.

## Simulation of Smith et al. (2014)

Below, we use model-recovery techniques to demonstrate that current GRT analyses misidentify participants' strategies in the context of levels of performance accuracy reported in published work. Further, we demonstrate that it is possible for all participants to be using rule-based strategies but to still find a) an interaction between an experimental manipulation and category structure, and b) that the majority of participants are (incorrectly) identified by GRT analysis as using the optimum strategy for each category structure.

The experiment we chose for this demonstration is by Smith et al. (2014); a recent, representative example of empirical work within the COVIS framework (Ashby \& Valentin, 2016). This experiment investigated the effect of deferring feedback on category learning. Participants were randomly assigned to learn either a rule-based or informationintegration category structure (as in Figure 1) with one of two possible reinforcement schedules. In the immediate feedback condition, on each trial participants were shown a stimulus, then made their response and were immediately given corrective feedback for that trial. In the deferred feedback condition, the stimuli were shown in groups of six. The participants made responses for all six stimuli but only received corrective feedback at the end of the block. Smith et al. found that learning of the rule-based category structure was unaffected by this change in feedback timing, whereas learning of the information-integration category structure was "eliminated" (p. 454) with deferred feedback.

As well as being representative of the majority of COVIS experiments (Ashby \& Valentin, 2016), the work reported in Smith et al. (2014) is interesting to simulate as it is representative of the direction that the role of GRT analysis is beginning to take in newer COVIS experiments (see also, Smith
et al., 2015). In these newer studies, the authors move away from using the GRT analysis to ensure that participants were using the optimum strategy, and therefore category learning system, in each condition. Instead, they use the GRT analysis to determine the strategies that participants use in order to discern whether deferring feedback alters the strategies participants use in "a theoretically meaningful way" (p. 452). Smith et al. (2014) conclude that deferred feedback pushed participants in the information-integration condition away from classification via the Procedural system towards classification via the Explicit system. These conclusions would of course be substantially undermined if their GRT analysis failed to correctly identify the strategies participants used.

The possibility of a misidentification of participant strategies would also open the way for an alternative, singlesystem, account of their results. As previously discussed, verbal report data from Edmunds et al. (2015), and neuroscience evidence from Carpenter et al. (2016), indicate that participants sometimes learn information-integration category structures using complex, verbalisable rules-despite the GRT analysis pointing towards procedural (GLC) strategies in these cases. Perhaps this is also happening in Smith et al. (2014)? Specifically, we hypothesize that the majority of participants in the immediate information-integration category structure condition of Smith et al. are using a conjunction or another two-dimensional rule-based strategy, but this is mis-identified as an implicit (GLC) strategy by Smith et al.'s GRT analysis. The possibility of this kind of misidentification seems particularly acute in this study because those authors did not include a conjunction rule (or any other complex rule) in the set of models for their GRT analysis. Research by Donkin et al. (2015) suggests that failing to include complex rules in a GRT analysis increases the proportion of participants that are identified as procedural (GLC) responders.

## Method

To see whether it was possible that all the participants in Smith et al. (2014) were using rule-based strategies, we first generated a set of hypothetical participants. These participants' responses were generated from unidimensional and conjunction strategy GRT generating models that best fit either the unidimensional or information-integration category structures used by Smith et al. The unidimensional models where straight lines that passed perpendicularly through either the $x$-axis or the $y$-axis. Stimuli that lay on one side of the line were assigned "Category A" and those on the other "Category B." The conjunction models consisted of two lines perpendicular to each other that partitioned off a quarter of the space. The stimuli in that quarter were assigned "Category A" and those outside "Category B."

We then added various levels of noise to these hypothetical participants and calculated their accuracy. Twenty participants were generated for each level of noise, category structure and generating strategy. Then we performed the GRT analysis, which included three model types: unidi-

Figure 2: Simulation of Smith et al. (2014); bars are empirical data; plot points are the simulation. Smith did not report standard deviation.
mensional, diagonal (GLC) and random models (Maddox \& Ashby, 1993). Note that although some simulated participants' responses were generated by a conjunction strategy, this strategy type was not included in the GRT analysis. This was to keep the GRT analysis as similar as possible to the one conducted by Smith et al. (2014). We then selected 21 simulated participants (i.e. the same $N$ as Smith et al., 2014) for each condition such that, as far as was possible, they had a) the same average accuracy as that reported by Smith et al. (p. 451, their paper; Figure 2, current paper), b) the same number of "strong learners" (p. 541, their paper), and c) were identified by GRT analysis as using the same distribution of strategy types reported by Smith et al. (p. 452-453, their paper; Table 1, this paper).

## Results

In addition to the simulated participants having the same average accuracy (see Figure 2) and same distribution of GRT-recovered strategies (see Table 1) as the real participants in Smith et al. (2014), it was also possible to replicate Smith et al.'s statistical tests. For the simulated participants, the critical interaction between category structure and task was significant, $F(1,80)=10.64, p=.002$. Furthermore, as in Smith et al. (2014), performance in the two rulebased conditions were statistically indistinguishable, $t(40)=$ $0.44, p=.663$, as was the comparison between the unidimensional and information-integration immediate conditions, $t(40)=1.22, p=.228$. Whereas, the difference between the two information-integration category structure conditions did reach significance, $t(40)=4.98, p<.001$

Table 1 shows that it is possible to generate the statisti-
cal pattern and strategy model results reported in Smith et al. (2014), without resorting to a second Procedural System. Instead, all the so-called implicit responders found by Smith et al. (2014) could have been using rule-based strategies that were misidentified by the GRT analysis.

Table 1: GRT analysis of simulated participants for Smith et al. (2014). Counts in bold are from real participants, as reported by Smith et al. (2014), and are also the simulation results (the simulation exactly reproduces the observed distribution of recovered models). Remaining counts show how the two groups of generating models used in this simulation (UD and CJ) were recovered by the GRT analysis. So, for example, of the 18 UD generating models used in the UD-Imm condition, 13 were correctly recovered as UD.

|  | Recovered strategies |  |  |  |
| :--- | :---: | :---: | :---: | :---: |
|  | UDx | UDy | GLC | RND |
| UD-Imm. | $\mathbf{1 3}$ | $\mathbf{1}$ | $\mathbf{1}$ | $\mathbf{6}$ |
| Gen. model: UD | 13 | 1 | 1 | 3 |
| Gen. model: CJ | 0 | 0 | 0 | 3 |
| UD-Def. | $\mathbf{1 5}$ | $\mathbf{2}$ | $\mathbf{0}$ | $\mathbf{4}$ |
| Gen. model: UD | 15 | 2 | 0 | 2 |
| Gen. model: CJ | 0 | 0 | 0 | 2 |
| II-Imm. | $\mathbf{0}$ | $\mathbf{3}$ | $\mathbf{1 6}$ | $\mathbf{2}$ |
| Gen. model: UD | 0 | 3 | 0 | 1 |
| Gen. model: CJ | 0 | 0 | 16 | 1 |
| II-Def. | $\mathbf{2}$ | $\mathbf{1 3}$ | $\mathbf{3}$ | $\mathbf{3}$ |
| Gen. model: UD | 2 | 4 | 0 | 0 |
| Gen. model: CJ | 0 | 9 | 3 | 3 |

Strategies: UDx $=$ Unidimensional based on the x -dimension, $\mathrm{UDy}=$ Unidimensional based on the $y$-dimension, GLC $=$ General linear classifier, RND $=$ Random

## General Discussion

The influential COVIS model of category learning is supported by a great deal of behavioural data (Ashby \& Valentin, 2016). Predominantly, this evidence comes from a single experimental methodology which examines the effect of a factor on rule-based and information-integration category learning. COVIS predicts that its two systems can implement different strategy types, and so each will learn one of these category structures better than the other. Critically, the validity of the inferences from this paradigm hangs on correctly identifying the strategy each individual used to complete the learning task. This is because the experiments investigating COVIS cannot directly control which system participants use to respond. Instead, they manipulate the category structures and hope that this encourages participants to use the optimum system, and thus the correct strategy, for that category structure. Of course, participants may continue to use the sub-optimum system for a particular category structure. Thus, identifying the strategies participants use is crucial: if the participants are using the correct strategy for that category structure, then the experimenters assume that they must also be using the cor-
rect learning system for that structure. Then, any differential effects of a manipulation on each category structure can be attributed to the existence of two systems of category learning, not differing numbers of sub-optimal responders.

Despite its importance for the COVIS model, there is experimental (Edmunds et al., 2015) and modeling (Donkin et al., 2015) evidence to suggest that GRT analysis may be biased towards concluding that participants were using the optimum strategy for the category structure. To explore this possibility, we simulated an experiment by Smith et al. (2014) and showed that it was possible to reproduce their means, inferential statistics and strategy analysis using only participants who used rule-based strategies. Simulated participants classified the information-integration category structure using a conjunction rule, but were recovered by the strategy analysis as using a diagonal (GLC) strategy. This raises the possibility that participants in Smith et al. were, correspondingly, using rule-based strategies in classifying the informationintegration category structure. In other words, Smith et al. cannot be construed as clear evidence for dual-system accounts of category learning, as a single-system (rule-based) account also fits all the data (accuracy and GRT analysis) they presented.

## Implications for the COVIS model

The reported simulation demonstrates an inferential weakness in experiments argued to support COVIS: GRT analysis is not accurate enough to act as a manipulation check. It cannot determine whether manipulating the category structure successfully elicited a corresponding switch in the categorisation system underlying participants' responses. Consequently, it is difficult to judge whether a particular COVISsupporting dissociation is due to the existence of two distinct learning systems, or rather due to participants using different explicit strategies to learn each category structure. This increases uncertainty over conclusions of a swathe of COVIS-supporting studies that rely on comparing rule-based and information-integration category structures (see Ashby \& Valentin, 2016, for a partial list).

In relation to the experimental work by Edmunds et al. (2015), and Edmunds, Wills, and Milton (2016), this simulation also strengthens the evidence that participants can correctly report their categorisation strategies. In those experiments, participants learning information-integration category structures consistently reported using complex, rulebased strategies. In contrast, the GRT analysis identified these participants as using the correct (i.e. diagonal) strategy. In the above simulation, it was shown that participants using a conjunction rule were likely to be misidentified in GRT analysis as using a diagonal (GLC) strategy. Therefore, it seems plausible that all participants learn information-integration category structures explicitly, using rule-based approaches, but GRT analysis misidentifies some of these as using an implicit (GLC) strategy.

## Conclusions

The simulation reported above indicates that drawing conclusions from GRT analysis is risky. This has a knock on effect on the COVIS-supporting studies that rely on this analysis as a manipulation check. More investigations need to be done to understand which strategies participants use and how they are affected by the category structure being learned before we can be sure that experimental dissociations in this literature support a dual-system model of categorization. In other words, we advocate closer attention to due process in the evaluation of dual-system (and single-system) models.

# Experimental Investigation into the Continuous Pattern of the Relationship Between Color Focality and Short-Term Memory Performance for Colors 

Siyuan Fang (siyuanfang@asagi.waseda.jp)<br>Graduate School of Human Sciences, Waseda University, 2-579-15 Mikajima<br>Tokorozawa City, Saitama Prefecture 359-1192, Japan<br>Tatsunori Matsui (matsui-t@waseda.jp)<br>Faculty of Human Sciences, Waseda University, 2-579-15 Mikajima<br>Tokorozawa City, Saitama Prefecture 359-1192, Japan

#### Abstract

Past studies reported that language-specific color focality has substantial influence on the short-term memory (STM) performance of colors of the speakers of the language, which we call the "focality effect." This study attempts to clarify the continuous pattern of this effect, that is, the manner in which correct recognition possibilities and misrecognition error distances of colors, which are two aspects of the STM performance for colors, change in a gradual fashion along the continuum of color focality. Our experiment, which tests the Japanese language, finds that a U-shaped relationship exists between the focality and the possibility of correct recognition, and that the misrecognition error distance increases as the focality decreases. We speculate that the subjects' frequent and conscious employment of the memorization strategy of coding colors using linguistic categories is one important cause of the detected effect patterns.

Keywords: color focality; short-term memory; continuous pattern; color discriminability; basic color terms

## Introduction

While color sensation changes gradually along the perceptual dimensions of hue, lightness, and chroma (Munsell, 1919), in languages, this is conceptualized into a series of categories. Every language contains a set of basic color terms in its lexicon, such as black, white, red, green, blue, yellow, brown, gray, orange, pink, and purple in the English language (Berlin \& Kay, 1991). The categories signified by the basic color terms (called "basic color categories" for short) are natural categories that have their inner structures formed around their prototypes. This means that within a basic color category, the member colors differ in their focality, namely their "closeness" to the prototype, or in other words, their goodness as a typical example of the category (Rosch, 1973).

In this case study, which tests the Japanese language, we aim to experimentally evaluate the universality of the phenomenon that language-specific color focality influences short-term memory (STM) for colors of the speakers of the language, which we call the "focality effect." More important, we attempt to clarify the continuous pattern of this effect if its existence turns out to be supported in our experiment.

The focality effect first appears in the English language in Heider (1972). In her experiment, Heider used a simplified version of the color array that Berlin and Kay (1991) used. The array was composed of 160 Munsell color chips, 24 of which were selected as test chips. Eight of these chips were focal colors, that is, the colors of the highest focality for
each of the eight chromatic basic color categories that were shared by numerous languages but generally corresponded to the English categories Red, Green, Yellow, Blue, Brown, Purple, Pink, and Orange (Roberson, Davies, \& Davidoff, 2000; Roberson, J. Davidoff, \& Shapiro, 2005). The other 16 chips were of lower focality for these categories, and thus were classified as nonfocal colors. The selection and categorization of the test chips were based on the color-naming data gathered by Berlin and Kay (1991). In each trial in Heider's experiment, a subject was required to watch a color chip for 5 s and then search for it in the color array after a 30-s interval, where the chip was hidden from the subject. For either stimulus type, two indexes of STM performance were measured. The first index was the "memory accuracy score (MAS)," which was defined as the mean number of correct recognitions for this stimulus type across the subjects. The second index was the "error distance score (EDS)," which measured the mean error distance across the incorrect trials of this stimulus type. The English-speaking subjects showed superior performance for both measures of the focal colors relative to the nonfocal ones. Roberson et al. (2000) employed the same experimental paradigm and stimuli. Regarding the English-speaking subjects, a focality effect similar to that reported by Heider was detected in terms of MAS. However, no focality effect was found in terms of EDS. Roberson et al. (2005), which also used this experimental paradigm and stimuli, found that the mean $d^{\prime}$ score (a modified version of MAS) of the test chips that were focal only in Himba (a language mainly spoken in Southern Africa) were significantly higher than that of the test chips that were focal only in English. This effect was also detected in the language of Berinmo, which is mainly spoken in Papua New Guinea. The index of EDS was not used in this study.

Overall, these studies have provided some evidence for the universal existence of the focality effect across languages in terms of MAS. On the other hand, no robust focality effect has been observed in terms of EDS. More empirical evidence is necessary to test whether the focality effect exists for these two STM performance measures. Because no Asian language has been studied in this field, we regard the Japanese language to be suitable as our target language. Furthermore, in these studies, color focality was treated as a categorical variable with only two values: "focal" and "nonfocal." This precluded
any elaborate descriptions of the focality effect. Therefore, in this study, we quantified the concept of color focality in a continuous fashion and delved into the continuous pattern of the focality effect, that is, how STM performance for colors changes gradually along the continuum of color focality.

## Experimental Settings

## Participants, Materials and Environment

Twenty-two subjects ( 11 males and 11 females of ages $M=$ 31.45 and $S D=14.34$, all native Japanese speakers with no color-related art experience), who are either undergraduate or graduate students at Waseda University, took part in the experiment. They all passed the Ishihara Color Vision Test (38 plates, International Edition), and no one reported having color vision deficiencies. Hence, these subjects were considered to have normal color vision.

A color array of Heider (1972)'s design was used. Its layout is shown in Figure 1. This array was made of cardboard $(58.5 \mathrm{~cm} * 28.5 \mathrm{~cm})$, and had color chips embedded in its white surface. Thirty colors (called "test colors" for short) were tested in the formal trials of Session 1. These colors were mounted on the white surface of a $5.0 \mathrm{~cm} * 5.0 \mathrm{~cm}$ piece of cardboard when being presented to the subjects. Chips in the Munsell Book of Color (Glossy Edition) were used.

Figure 1: Layout of color array.
The experiment was performed indoors with fluorescent lighting (type: National FHF 32EX-N-H, daylight color, color temperature: 5000 K ). The experimenter and subject being tested sat opposite each other at a table. The distance between the stimuli and the subject's eyes was controlled at 50 cm . A cardboard separating the two persons was erected along the middle of the table, making the subject unable to see the experimenter's face when observing the stimuli, waiting during the 30 -s interval, and filling out the answer sheets.

## Procedure

The entire experiment, which was carried out in Japanese, consisted of two sessions.

Session 1, which used a procedure similar to that used by Heider (1972), aimed to measure the subjects' STM performance for the test colors. This consisted of 33 trials. In each trial, a test color was presented to the subject for 5 s and then
retrieved by the experimenter. After a 30 -s interval, the color array was presented to the subject, and the subject was asked to report which color in the array he/she thought was the previously presented one by writing the coordinates of the color on an answer sheet. There was no conversation between the experimenter and the subject. Each test color was tested at least once with each subject, and for each subject, the order of color testing was randomly determined. Thus, for each subject, there were three repeated trials, which were intended to prevent the subject from using a strategy of excluding the already tested colors. Before the formal experiment began, a two-trial training session using a different set of test colors was conducted. For each subject, the colors tested during the training were randomly selected.

After all 33 formal trials were completed, a questionnaire was given to the subject. This questionnaire asked the subject to report freely on the strategies that he/she adopted to memorize the test colors during this session.

Session 2 was targeted to elicit the coverage of six basic color categories corresponding to the six Japanese basic color terms akairo (red), pinkuiro (pink), kiiro (yellow), orenjiiro (orange), chairo (brown), and murasakiiro (purple) (Uchikawa \& Boynton, 1987). Then, the focality of each test color was quantified using a modified version of Berlin and Kay (1991)'s method. First, the subject was required to write on six answer sheets (one for each basic color term) all colors that he/she thought could be named by the term. The answer sheets were provided to each subject in random order. Next, the subject was asked to report the colors they thought were the best examples of each of the six basic color terms. This was accomplished by writing the coordinates of the colors on an answer sheet. Multiple answers were allowed for each term, but the subject was instructed to narrow his/her selections as much as possible.

## Statistical Analysis and Results

## Variable Definitions

Focality Score We used the data obtained from Session 2 to specify the coverages of the six basic color categories over the array, and quantified the focality of the test colors. We first computed the six attributes for each test color: Red Index, Pink Index, Yellow Index, Orange Index, Brown Index, and Purple Index. These attributes measured the intersubject naming consistency of the color in terms of each basic color term. The Red Index was defined as the percentage of subjects who named the color as red, and the other five indexes were similarly defined. Then, we designated the Overall Index (OI) of a color as the largest of the six single-term-based indexes of the color. We classified a color into the color category Red if its OI was its Red Index, the color category Pink if its OI was its Pink Index, and so forth. Figure 2 shows the distribution of the nonzero OIs and the partition of the six basic color categories.

For each basic color category, most of the colors having the largest OIs were also frequently selected as the best examples
during the second part of Session 2. Thus, it is reasonable to deem the OI of a color as reflecting the appropriateness of the color as a typical example of the category to which the color belongs. In this manner, we defined the focality score (FS) of a color as its OI value.

Figure 2: Distribution of Overall Indexes of test colors (colors within area covered by thin diagonal stripes) and other relevant colors, and partition of the six basic color categories. Color depth represents Overall Index magnitude. [*: Orange Index = Brown Index]

Discriminability Score We defined the discriminability score (DS) of a test color on the color array as the average of the color differences between the test color and its eight adjacent colors. In this study, a color difference was defined as a Euclidean distance in the CIE L*a*b* color space. Thus, before calculating color differences, we transformed the Munsell coordinates of all relevant colors into CIE xyY coordinates using the O.S.A.-developed conversion tables (Newhall, Nickerson, \& Judd, 1943), then XYZ coordinates, and finally the $L^{*} a * b *$ coordinates. In the final transformation step, the parameter values of the CIE D50 standard illuminant, which resembled the light source used in this experiment, were used.
STM Performance Index 1: Memory Accuracy Score We adopted MAS as one index of STM performance. It measures the probability for which a color can be accurately recognized. Since FS is continuous in our study, it is necessary to take MAS also as continuous. We defined the MAS of a test color as the percentage of the trials where the subjects correctly recognized the color.
STM Performance Index 2: Error Distance Score The EDS is adopted as another index of STM performance. EDS measures the expected error extent in the case of misrecognition. As in Heider (1972)'s and Roberson et al. (2000)'s studies, the EDS for a test color is defined as the mean of the color differences between the test color and the colors mistaken for the test color in the incorrect recognition trials.

## The Relationship Between FS and MAS

In order to determine the continuous pattern of the relationship between FS and MAS, we first conducted regression analyses on the FS data and the original MAS data of the
test colors to obtain a general impression of the relationship pattern. No statistically significant linear relationship could be detected ( $R^{2}=0.066, P=0.171\left[B_{F S}=0.152, P=0.171\right]$ ), but a significant quadratic relationship was found $\left(R^{2}=0.237\right.$, $P=0.026\left[B_{F S}=-1.064, P=0.045 ; B_{F S * F S}=1.073, P=\right.$ $0.021]$ ).

Brown and Lenneberg (1954) found that color discriminability could facilitate STM performance for colors, which we call the "discriminability effect." Later, Heider (1972) and Lucy and Shweder (1979) pointed out that because the colors in the color array were unequal in discriminability, it was possible that it was color discriminability, not color focality, that caused the detected variance in STM performance for colors. This possible source of distortion was checked by using the following procedure. First, we looked into the relationship between DS and MAS. A significant positive linear regression model could be established between these two variables ( $R^{2}=0.353, P=0.001\left[B_{D S}=0.024, P=0.001\right]$ ). Then, regression analyses investigating the relationship between FS and DS were conducted. These analyses produced neither a significant linear model $\left(R^{2}=0.014, P=0.534\left[B_{F S}\right.\right.$ $=1.710, P=0.534])$ nor a significant quadratic one $\left(R^{2}=\right.$ $0.029, P=0.675\left[B_{F S}=-7.032, P=0.618 ; B_{F S * F S}=7.712, P\right.$ $=0.527])$. Nevertheless, we noticed that a slight U-shaped relationship could be recognized when we scrutinized the scatter plot. This means that the possibility that DS mediated the FS-to-MAS relationship could not be ruled out. Hence, we conducted partial linear and quadratic regressions on FS and MAS while excluding the influence of DS on MAS. No significant linear relationship was found $\left(R^{2}=0.054, P=0.217\right.$ [ $\left.B_{F S}=0.111, P=0.217\right]$ ), but a significant quadratic one was detected $\left(R^{2}=0.233, P=0.028\left[B_{F S}=-0.893, P=0.037\right.\right.$; $\left.B_{F S * F S}=0.885, P=0.018\right]$. This is plotted in Figure 3A). This is similar to the results of the initial regressions, and indicates that a significant quadratic relationship exits between FS and MAS even if DS has been treated as a control variable.

Figure 3: (A)Relationship between Focality Score and Memory Accuracy Score (corrected);(B)Relationship between Focality Score and Error Distance Score (corrected) in the general case, with a data point unexplained by the regression model depicted by a magenta-colored rhombus.

## The Relationship Between FS and EDS

The continuous pattern of the relationship between FS and EDS was investigated in the following manner. First, to obtain a preliminary impression of what the relationship pattern looks like, we carried out linear and quadratic regression analyses on the FS data and the original EDS data. Only the quadratic model reached statistical significance (quadratic model: $R^{2}=0.250, P=0.027\left[B_{F S}=-30.113, P=0.019\right.$; $\left.B_{F S * F S}=22.376, P=0.041\right]$; linear model: $R^{2}=0.110, P$ $=0.084\left[B_{F S}=-4.694, P=0.084\right]$ ). Then, a positive linear relationship was found between DS and EDS through a regression analysis ( $R^{2}=0.299, P=0.003\left[B_{D S}=0.692, P=\right.$ $0.003])$. In order to remove the distorting influence of the discriminability effect (as in the case of MAS), the regressions on the FS and EDS data were repeated but with the impact of DS on EDS partialed out. A significant quadratic model appeared $\left(R^{2}=0.221, P=0.044\left[B_{F S}=-22.166, P=0.041\right.\right.$; $\left.\left.B_{F S * F S}=15.895, P=0.085\right]\right)$, but not a linear one ( $R^{2}=0.121$, $P=0.070\left[B_{F S}=-4.110, P=0.070\right]$ ). This resembles the results of the initial regressions.

Nevertheless, there exists a test color that appears to be isolated from the cluster of other high-FS test colors at the EDS coordinates. Owing to the employment of the least squares method, this data point could have exerted a disproportionately strong influence on the relationship pattern. In order to determine what pattern the relationship actually takes in the general case, we reran the regressions on the corrected dataset but did not include this data point. This time we obtained a linear relationship ( $R^{2}=0.236, P=0.010\left[B_{F S}=-5.669, P=\right.$ 0.010], which is plotted in Figure 3B), instead of a quadratic one. (When adding FS*FS to the regression as a predictive variable, neither $B_{F S}$ nor $B_{F S * F S}$ achieved significance, although the model remained significant). The removed color is $5 \mathrm{YR} 4 / 8$. It was mistaken as the color one-unit above it ( 5 YR 5/12) in all its misrecognition cases. This misrecognition pattern is difficult to explain by the strategy of linguistic categorical color coding which will be discussed later. We thus conjecture that it might result from other memorization strategies, which needs further exploration.

## Memorization Strategies

In the questionnaire conducted at the end of Session 1, the subjects reported a total of six memorization strategies. For each strategy, Table 1 offers a brief description and shows how many subjects reported it.

## General Discussion

## The Continuous Patterns of the Focality Effect

Our experimental results demonstrated that in the Japanese language, color focality can affect STM performance for colors in a statistically significant way in terms of both correct recognition possibility and misrecognition error distance. With regard to the continuous patterns of the focality effect, a significant U -shaped quadratic regression function can be established between FS and MAS, which implies that STM per-

| test color as a cue |

formance is best for colors at the two terminals of the focality continuum, and begins to decrease as the focality moves toward the intermediate level. In addition, a significant negative linear regression function can be established between FS and EDS under general circumstances. This suggests that the average error distance in the case of misrecognitions for a color decreases as its focality increases.

## One Cause of the Focality Effect Patterns

To determine what caused the continuous patterns, we examined the memorization strategies reported by the subjects (Table 1). We noticed that the strategy of encoding colors using linguistic color categories, which has the highest number of reports, might have played an important role in the formation of the detected focality effect patterns.
A detailed description of the procedure of this strategy in a single trial is as follows: The subjects consciously encoded the test color using the basic color terms while observing the test color. The basic color terms were used as reference points, which means that the subject anchored the test color to the central points of the basic color categories, namely, the most typical colors of these categories. The subject then retained this linguistic code in his/her STM during the waiting
period. Finally, during the phase of color searching, the subject decoded the code to recover the test color.

For convenience of discussion, color focality is generally divided into the levels of "high," "medium," and "low," and their respective ways of being coded are described as follows: A high-focality color can be encoded using only one basic color term since it is, or is substantially close to, the central point of the basic color category. With regard to a mediumfocality color, its coding needs some modifiers in hue and (or) lightness besides a basic color term, for example, bright orange, dark brown, and purplish pink. For a low-focality color, because it is situated at the border region between two basic color categories, the two basic color terms corresponding to the two categories are used to constitute the code for this color.

With the employment of this strategy, it is obvious that the correct recognition possibility for a color is mainly determined by 1) how easily the code for the color can be retained in STM during the waiting period, and 2) the semantic ambiguity of the code for the color, or in other words, how accurately the encoded color can be recovered from the code. Since codes for colors of all three types can be formed by just a few words, they will not cause a memory burden. This implies that the rate of successful retaining should be high for each color type. On the other hand, the variable of semantic ambiguity bears a much larger intertype variance, which indicates its chief role in mediating the impact of color focality on STM performance for colors. For a high-focality color, its code generally consists of a sole basic color term, which possesses a fairly plain meaning since any Japanese speaker is able to understand the definition of a basic color term. Thus, during the searching phase, the signifier of the code can be pinpointed in high precision. By contrast, the modifiers in the code for a medium-focality color have much vaguer meanings. Even if the subjects have carried the code into the decoding phase without mistakes, they will find themselves lost in numerous candidates, all of which more or less match the description. This will surely lower their chances of finding the one that they have actually coded. Following this logic, the code for a low-focality color, which involves basic color terms but no modifiers, should also be regarded as unequivocal in meaning. The central points of the basic color terms, as in the case of a high-focality color, can serve as reliable reference points for the localization of the encoded color. In brief, the semantic ambiguity of color codes, which negatively influences the likelihood of correct recognition for colors, is low for high- and low-focality colors and high for medium-focality colors. Thus, high- and low-focality colors tend to have higher rates of correct recognition than those of medium-focality ones. This is exactly what our experimental results have shown. In addition, owing to the fact that for any color the semantic ambiguity of its code is a languageinherent and thus subject-independent attribute, this continuous pattern can be expected to have a high degree of intralanguage consistency, or in other words, a high likelihood to be
replicated if the experiment is repeated using the same language.

With regard to the misrecognition error distance of a color, within the framework of linguistic categorical coding, this mainly depends on which parts of the code the subjects have forgotten, and how many times each of these parts have been forgotten. For a high-focality color, once a subject has forgotten the sole basic color term during the waiting period, in the searching phase he/she is unable to tell the basic color category to which the test color belongs. His/her selection will thus be random, although other memory clues, such as the visual image of the test color, can be of help. It is easy to imagine that under this circumstance, a large error will occur. The loss of the basic color term for a medium-focality color or both of the basic color terms for a low-focality color will lead to similar consequences. For a medium-focality color, when only the modifiers have been forgotten, given that the basic color term has become the only guide, the central point of this basic color category may pull the subjects' selections toward it. In this case, a misrecognition is expected to occur, but within a moderate error range that is approximately half the "category radius." Following the same logic, with regard to the code for a low-focality color, when one of its two basic color terms has been forgotten, the remaining one will tend to drag the subjects' selections toward the central point of the category it represents. On this occasion, because the test color is situated at the border region of the category, a selection with a error distance of approximately one categoryradius long might take place. Note that owing to the small total number of memory losses suggested by the small memory burden imposed by the color codes, it is possible that some of these "forgetting types" did not occur in our experiment. Thus, one explanation for the focality effect pattern that we detected is that our subjects have never forgotten the basic color terms in the codes for the high- and medium-focality colors. In addition, the small sample size of memory losses means that the distribution of occurrence frequency across the forgetting types can hardly be consistent across experiments even when using the same language. In other words, if the experiment is repeated, a substantially different frequency distribution across the forgetting types will occur, which will lead to a very different focality effect pattern.

## The Universality of the Focality Effect Patterns

Several past studies on STM performance for colors, which used English-speaking subjects, also recorded their subjects' memorization methods. Lucy and Shweder (1988) recorded the subjects' incidental remarks on memorization strategies during the course of their experiments, and they carried out a questionnaire on memorization strategies when the experiments were finished. They provided a quantitative report which showed that the strategy of linguistic categorical coding was the most frequently adopted, followed by the strategies of direct retention of visual image, present object association, and absent object association. This coincides well with the results of our questionnaire. Brown and Lenneberg
(1954), Lucy and Shweder (1979), and Garro (1986) also reported the use of linguistic categorical coding by their subjects, although they did not provide detailed statistics. The fact that linguistic categorical coding is employed as a chief memorization strategy by both Japanese speakers and English speakers suggests that its applicability is possibly universal across languages. Moreover, considering the hypothesized close ties of this strategy to the formation of the continuous patterns of the focality effect, this further implies that all languages may share a common language-based mechanism for focality-effect generation.

In terms of the focality effect pattern for the possibility of correct recognition, considering its presumed intralanguage consistency, it can be expected to be observed in other languages. This conjecture is supported by the agreement between the FS-to-MAS relationship detected in our experiment and the superiority of focal colors to nonfocal colors in correct recognition possibilities reported by Heider (1972), Roberson et al. (2000) and Roberson et al. (2005). On the other hand, even if the use of the strategy of linguistic categorical coding is universal across languages, because of the lack of intralanguage consistency, it is difficult to find a consistent focality effect pattern across languages in terms of the misrecognition error distance. A comparison of the results of Heider (1972)'s and Roberson et al. (2000)'s studies and our study demonstrated such interlanguage inconsistency.

A trivial case as it might be, reports show that there exit languages that possibly lack basic color terms, e.g., Piraha and Warlpiri (Everett, 2005; Wierzbicka, 2008; but see Regier, Kay, \& Khetarpal, 2009). This means that the linguistic definition of color focality and the memorization strategy of linguistic categorical coding possibly cannot be applied to such languages. Thus, the discussions in this section may be unsuitable for these languages.

## Conclusion and Implications for Future Work

This study is the first to probe into the continuous patterns of the focality effect. Our experiment confirmed the existence of the focality effect in the Japanese language, and clarified its continuous patterns in terms of correct recognition possibility and misrecognition error distance, which were two aspects of short-term memory performance. Correct recognition possibility is highest at the ends of the continuum of color focality, and decreases as color focality moves toward the medium region from either end. In addition, misrecognition error distance for colors, in the general case, decreases as color focality increases. We speculate that the subjects' frequent and conscious use of memorization strategies, especially the strategy of encoding colors using linguistic color categories, played an important role in the formation of focality effect patterns. The interstudy agreement on the recordings of memorization strategies suggests that the employment of linguistic categorical coding is possibly universal across languages. For this reason, and also owing to its likely high intralanguage consistency, we expect that the focality effect pattern
for correct recognition possibility that we detected can also be found in other languages. Empirical evidence for more languages is needed to evaluate this hypothesis. In addition, it is also interesting to see whether this focality effect pattern can also be found in the categories of other domains. These domains can be simple perceptual categories such as shapes and phonemes, complicated multimodal concepts such as animals and tools, or even emotionally or socially meaningful signals such as human facial expressions.

# Deconstructing Social Interaction: The Complimentary Roles of Behaviour Alignment and Partner Feedback to the Creation of Shared Symbols 

Nicolas Fay (nicolas.fay@gmail.com)<br>School of Psychological Science, University of Western Australia, 35 Stirling Highway, Crawley WA 6009, Australia<br>Bradley Walker (bradley.walker@uwa.edu.au)<br>School of Psychological Science, University of Western Australia, 35 Stirling Highway, Crawley WA 6009, Australia<br>Nik Swoboda (nswoboda@fi.upm.es)<br>Department of Artificial Intelligence, Universidad Politecnica de Madrid, Calle Ramiro de Maeztu, 7, 28040 Madrid, Spain

#### Abstract

This paper experimentally tests the contribution of two distinct aspects of social interaction to the creation of shared symbols: behaviour alignment and concurrent partner feedback. Pairs of participants ( $\mathrm{N}=120$, or 60 pairs) completed an experimental-semiotic game, similar to Pictionary, in which they tried to communicate a range of recurring meanings to a partner by drawing on a shared whiteboard (without speaking or using numbers of letters in their drawings). The opportunity for sign alignment and/or concurrent partner feedback was manipulated in a full factorial design. Each process made a distinct contribution to the evolution of shared symbols: sign alignment directly influenced communication success, and concurrent partner feedback drove sign simplification and symbolization. These complimentary processes led to the interactive evolution of effective and efficient human communication systems.

Keywords: Human Communication, Interaction, Icon, Symbol, Cultural Evolution, Language Evolution

## Introduction

Human cognition and behaviour is dominated by symbol use, evident from our everyday use of numeric and linguistic systems. But where do these symbols come from? This question is presented by Harnad (1990) as the symbol grounding problem: how shared meanings can arise from arbitrary symbols in the absence of a pre-established shared symbol system. A solution to the symbol grounding problem was offered by Peirce (1931), who suggested that symbols evolved from iconic signs that share a non-arbitrary correspondence between the sign and its meaning.

This icon-to-symbol transition has been convincingly demonstrated in experimental-semiotic communication games. These experiments examine the creation of novel human communication systems under controlled laboratory conditions (for reviews see Fay, Ellison, \& Garrod, 2014; Galantucci, 2017; Tamariz, 2017). They do this by using a paradigm in which human participants communicate without using their existing shared language. Typically, participants communicate in a novel modality, for example, through drawing (Galantucci, 2005; Garrod, Fay, Lee, Oberlander, \& MacLeod, 2007; Healy, Swoboda, Umata, \& King, 2007; Roberts, Lewandowski, \& Galantucci, 2015) or
by gesture (Christensen, Fusaroli, \& Tylén, 2016; Fay, Arbib, \& Garrod, 2013; Schouwstra \& de Swart, 2014; Stolk, Verhagen, \& Toni, 2016) and the experimenters examine how the communication systems arise and evolve over repeated interactions.

A key finding is the importance of iconic signs and social interaction to the creation of shared symbols (Galantucci, 2005; Garrod et al., 2007). In Garrod et al. (2007), pairs of participants tried to communicate a set of recurring meanings to their partner by drawing on a shared whiteboard. Like the game Pictionary, participants were not allowed to speak or use letters or numbers in their drawings. This procedure forced participants to create a novel communication system from scratch. Over repeated interactions three things happened: communication success improved, the signs used were transformed from complex iconic signs to simpler, more symbolic signs, and participants increasingly used the same signs to communicate the same meanings (i.e., their signs aligned; see Figure 1). This pattern, the creation of an effective inventory of shared symbols, has been widely replicated (Caldwell \& Smith, 2012; Fay, Garrod, Roberts, \& Swoboda, 2010; Garrod, Fay, Rogers, Walker, \& Swoboda, 2010; Theisen, Oberlander, \& Kirby, 2010).

These studies indicate that social interaction is crucial to the creation of effective and efficient human communication systems, but they are not clear on the precise mechanisms driving these outcomes. To better understand this, the present experiment isolates two important aspects of social interaction - behaviour alignment and concurrent partner feedback - and investigates the contribution of each to the evolution of shared symbols.

Pickering and Garrod (2004) argue that linguistic alignment drives successful communication. While there is a correlation between referential alignment and communication success (Fay, Lister, Ellison, \& Goldin-Meadow, 2014; Fusaroli et al., 2012; Reitter \& Moore, 2014), the causal role of referential alignment on communication success is unclear. If referential alignment directly influences communication success, then prohibiting interacting participants from aligning their signs will lower communication success.

Concurrent partner feedback can take a variety of forms. During conversation, listeners are co-narrators who provide verbal feedback (e.g., saying "mhm" while listening to a speaker) and visual feedback (e.g.,
frowning or nodding), that improves the flow of conversation (Bavelas, Coates, \& Johnson, 2000; Clark \& Krych, 2004; Mein, Fay, \& Page, 2016). Like listeners in a conversation, participants engaged in an experimental-semiotic game can signal their attention and understanding by annotating their partner's sign, e.g., by adding a tick mark (see Figure 1). During conversation listeners can indicate a communication breakdown and initiate a repair (e.g., by asking the speaker for clarification; Dingemanse et al., 2015; Schegloff, 2000). In addition to these information expansion requests, listeners can drive information contraction by indicating their understanding (e.g., by saying "yeah, yeah"). So, concurrent partner feedback during an experimental-semiotic game may drive communication success and sign simplification/symbolization.

The present experiment examined the influence of sign alignment and concurrent partner feedback on communication success and sign symbolization. It also tested if each process operates independently or if they interact.

Figure 1. Sign simplification and alignment for the meaning 'Museum' across 6-games between a pair of participants in the present experiment. Participants alternated drawing and identifying roles from game to game. At Game 1 Museum was communicated using a complex iconic sign that included a dinosaur, an exhibit space and two viewers. By Game 6 the sign has lost much of its initial iconicity, evolving into a simpler, more symbolic representation, communicated by the dinosaur's spine. In addition, partners' signs became increasingly similar, or aligned, across games.

## Method

The experiment received approval from the University of Western Australia Ethics Committee. All participants viewed an information sheet before giving written consent to take part in the study. The information sheet and consent form were both approved by the aforementioned Ethics Committee.

## Participants

One-hundred and twenty undergraduate students ( 84 females) participated in exchange for course credit or payment. Participants were tested in unacquainted pairs in testing sessions lasting 1 hour. All participants were free of any uncorrected visual impairment.

## Task and Procedure

Participant tried to graphically communicate a series of confusable meanings to their partner. Like the game Pictionary, participants were prohibited from speaking or using letters or numbers in their drawings. The Director would draw each meaning from their ordered list ( 16 targets plus 4 distractors; see Table 1 for a complete listing) and their partner, the Matcher, would
try to identify each meaning from their randomly ordered list of the same meanings.
The task was administered using a virtual whiteboard tool (Healy, Swoboda, \& King, 2002), which recorded all drawing activity. Each participant sat at a computer terminal where drawing input and meaning selection was made via a standard mouse. For the Director, each to-be-communicated meaning was highlighted in white text on a dark background at the top of the interface. Holding down the left mouse button initiated drawing. Director drawing was restricted to black ink and Matcher drawing was restricted to green ink (to distinguish between participants). By clicking an erase button on the interface participants were able to erase parts of the drawing. All drawing and erasing activity was displayed simultaneously on the Director and Matcher's shared virtual whiteboards. When the matcher believed they had identified the director's intended meaning they clicked the relevant button at the top of their interface, where there was a list of buttons corresponding to the competing meanings. Meaning selection brought the current trial to an end and initiated the next trial. No time limit was imposed, and participants were given no explicit feedback with regard to their communication success. Participants communicated remotely across networked computers and were unaware of their partner's identity.

Table 1. The set of meanings that Directors communicated to Matchers (distractor meanings given in italic). Target and distractor meanings were fixed across conditions and throughout the experiment.

The experiment examined the contribution of behaviour alignment and concurrent partner feedback to communication success and sign symbolization. Participants were randomly assigned to one of four conditions that represented a combination of the factors of interest: +Alignment + Feedback ( $\mathrm{N}=30$, or 15 dyads), +Alignment -Feedback ( $\mathrm{N}=30$, or 15 interacting), -Alignment +Feedback ( $\mathrm{N}=30$, or 15 dyads) and -Alignment -Feedback ( $\mathrm{N}=30$, or 15 dyads). In the -Alignment conditions participants were instructed not to copy their partner's drawings. They were told they would have to use a different sign to that used by their partner to communicate each meaning. In the -Feedback conditions Matchers were unable to provide within-trial feedback. Specifically, they were unable to draw while acting as the Matcher (this functionality was removed from the virtual whiteboard tool). In this condition the Director clicked a send button when they had finished their drawing. Once done the list of competing meanings became available for selection by the Matcher. Thus, Matchers were unable to interrupt the Director's communication and bring the trial to an end.

## Results

Participants followed the instructions not to align their signs（manipulation check）．Not being able to align their signs reduced communication success．By contrast，eliminating the opportunity for concurrent partner feedback did not directly affect communication success．Concurrent partner feedback affected sign simplification；when feedback was eliminated the signs produced were more complex．Sign alignment also affected sign simplification，but the effect was much weaker compared to the effect of concurrent partner feedback．See Figure 2 for examples of sign alignment and simplification in the different conditions．

Figure 2．Sign alignment，simplification and symbolization for the meaning＇Parliament＇across 6－ games between participants in the different experimental conditions．Participants instructed not to copy their partner＇s sign for each meaning did so：one participant drew a building with a flag to communicate ＇Parliament＇and their partner drew a speaker at a podium（－Alignment＋Feedback condition）；another drew a parliamentary speaker with a hammer，and their partner drew a series of buildings（－Alignment－ Feedback condition）．When permitted to copy their partner＇s signs，sign alignment was observed：onto a flag（＋Alignment＋Feedback condition），or people seated around a table（＋Alignment－Feedback condition）．These examples highlight the diversity of signs used to communicate the same meaning in the present study．Concurrent partner feedback had a strong effect on sign simplification and symbolization： with feedback the signs were dramatically simplified across games（＋Feedback conditions），and without feedback they retained considerable sign complexity （－Feedback conditions）．

## Manipulation Check：Sign Alignment

Participants in the－Alignment conditions were instructed not to copy the drawings produced by their partner．Sign alignment was quantified by rating the similarity of pairs of drawings of the same meaning from each pair（at Game 1－2，2－3，3－4，4－5，5－6）on a Likert scale from 0－9，where $0=$ very dissimilar and $9=$ very similar（BW）． 4800 pairs of drawings were rated for similarity（16 meanings X 5 pairs of adjacent games X 15 pairs X 4 conditions）．Sign alignment scores for the drawings produced in the different conditions are shown in Figure 3．The results indicate that participants followed the－Alignment instructions： those permitted to copy their partner＇s signs showed
increasing sign alignment across games，whereas those not permitted to copy their partner＇s signs returned lower overall sign alignment scores that did not change across games．

Drawing alignment scores were entered into a mixed－design ANOVA that treated Alignment （＋Alignment，－Alignment）and Feedback（＋Feedback， －Feedback）as between－participant factors and Game （1－2，2－3，3－4，4－5，5－6）as a within－participant factor． This returned a statistically significant Alignment by Game interaction $\left[F_{\text {Linear }}(1,56)=50.849, p<0.001, \eta_{p}^{2}=\right.$ $0.564]$ ．The interaction effect is explained by the increase in sign alignment scores across games in the ＋Alignment conditions $\left[F_{\text {Linear }}(1,29)=131.622, \quad p<\right.$ $\left.0.001, \eta_{p}^{2}=0.819\right]$ and a null effect of Game in the －Alignment conditions $\left[F_{\text {Linear }}(1,29)=0.851, p=0.364\right]$ ． The Alignment manipulation worked．

Figure 3．Change in sign alignment scores（plotted for each pair）for the different conditions across games 1－6．The horizontal dashed red line indicates neutral sign alignment．The dark blue straight line is the linear model fit and the light grey shaded area is the $95 \%$ confidence interval．

No outliers were identified using the Interquartile Range rule（Moore，McCabe，\＆Craig，1993）．Drawing alignment scores were entered into a mixed－design ANOVA that treated Alignment（＋Alignment， Alignment）and Feedback（＋Feedback， －Feedback）as between－participant factors and Game （1－2，2－3，3－4，4－5，5－6）as a within－participant factor． This returned a statistically significant Alignment by Game interaction［ $F_{\text {Linear }}(1,56)=50.849, p<0.001, \eta_{p}^{2}=$ $0.564]$ ．The interaction effect is explained by the strong increase in sign alignment scores across games in the＋Alignment conditions［ $F_{\text {Linear }}(1,29)=$ 131．622，$p<0.001, \eta_{p}^{2}=0.819$ ］and a null effect of Game in the－Alignment conditions［ $F_{\text {Linear }}(1,29)=$ 0．851，$p=0.364]$ ．

The Alignment manipulation worked：participants who were allowed to copy their partner＇s drawings did so，and increasingly did so across games，whereas those who were prohibited from doing so did not copy their partner＇s drawings．

## Communication Success

Communication success was operationalized as the percentage of meanings accurately identified by the Matcher. Figure 4 shows the change in communication success (\%) across games 1-6 in the different conditions. The results show an increase in communication success across games in all conditions, but the increase is stronger in the +Alignment conditions compared to the -Alignment conditions.

One outlier ( $0.28 \%$ of data) was identified using the Interquartile Range rule (see Moore et al., 1993). This value was replaced by next lowest value. The communication success scores were then entered into the same mixed-design ANOVA used previously. This returned a statistically significant Alignment by Game interaction $\left[F_{\text {Linear }}(1,56)=135.151, \quad p<0.001, \quad \eta_{p}^{2}=\right.$ $0.707]$. In all conditions communication success improved across games: +Alignment conditions $\left[F_{\text {Linear }}(1,29)=117.268, p<0.001, \eta_{p}^{2}=0.802\right]$ and -Alignment conditions $\left[F_{\text {Linear }}(1,29)=38.435, p<0.001\right.$, $\left.\eta_{p}^{2}=0.570\right]$. However, the improvement in communication success (differences score: game 6 game 1) was stronger in the +Alignment conditions ( $M=24.17, S D=12.031$ ) compared to the -Alignment conditions $(M=13.96, S D=13.993), \quad t(58)=3.030$, $p=0.004, d=0.782$. The same pattern of results was returned when the communication success data was analyzed using logistic mixed effects modeling.

Sign alignment improved communication success, establishing a causal link between behaviour alignment and communication success. By contrast, concurrent partner feedback did not directly influence communication success [ $p=0.871$ ].

Figure 4. Change in communication success (plotted for each pair) for the different conditions across games $1-6$. The dark blue straight line is the linear model fit and the light grey shaded area is the $95 \%$ confidence interval.

## Sign Simplification and Symbolization

Following Garrod et al., (2007) simpler signs were considered to be more symbolic. Sign complexity was measured using Pelli et al.'s (2006) information
theoretic measure of perimetric complexity [Perimetric complexity $=$ (inside + outside perimeter) ${ }^{2} /$ ink area]. Previous work indicates this to be an effective scalefree measure of drawing complexity (Fay et al., 2010; Garrod et al., 2007; Tamariz \& Kirby, 2014). Sign complexity scores for the drawings produced in the different conditions are shown in Figure 5. Sign complexity tended to decrease across games in all conditions, but sign complexity was lower in the +Feedback conditions compared to the -Feedback conditions.

Figure 5. Change in sign complexity (plotted for each pair) for the different conditions across games 1-6. The dark blue straight line is the linear model fit and the light grey shaded area is the $95 \%$ confidence interval.

Ten outliers ( $2.78 \%$ of data) were identified using the Interquartile Range rule. These values were replaced by the next highest value. The sign complexity scores were then entered into the same mixed-design ANOVA used previously. This returned a statistically significant three-way Alignment by Feedback by Game interaction $\left[F_{\text {Linear }}(1,56)=4.140, p=\right.$ 0.047, $\eta_{p}^{2}=0.069$ ]. To understand the three-way interaction separate Alignment by Game ANOVAs were carried out for each level of Feedback. For the + Feedback conditions this returned a main effect of Game [ $\left.F_{\text {Linear }}(1,28)=73.809, p<0.001, \eta_{p}^{2}=0.725\right]$ with no other effects reaching statistical significance (ps> 0.304). So, both +Feedback conditions showed a similarly strong decrease in sign complexity scores across games, and there was no statistical evidence that sign alignment affected sign symbolization. A different pattern was returned by the -Feedback conditions. ANOVA returned a statistically significant Alignment by Game interaction $\left[F_{\text {Linear }}(1,28)=6.608\right.$, $\left.p<0.016, \eta^{2}=0.191\right]$. This interaction effect is explained by the statistically significant decrease in sign complexity scores across games in the +Alignment -Feedback condition $\left[F_{\text {Linear }}(1,14)=34.912\right.$, $\left.p<0.016, \eta_{p}^{2}=0.714\right]$ and the null effect of Game in the -Alignment -Feedback condition [ $F_{\text {Linear }}(1,14)=$ 2.825, $p=0.115]$. So, in the absence of concurrent partner feedback, sign alignment reduced sign
complexity. Without either interactive process there was no statistical evidence of a reduction in sign complexity across games.

Receiving concurrent partner feedback was important to sign simplification and symbolization. In the absence of concurrent partner feedback sign alignment reduced sign complexity, but not to the extent of concurrent partner feedback.

## Discussion

The present study investigated the precise role played by two distinct aspects of social interaction to the evolution of effective and efficient human communication systems: behaviour alignment and concurrent partner feedback. By experimentally manipulating the opportunity for behaviour alignment and concurrent partner feedback in a full factorial design, the experiment demonstrated that each process made a distinct contribution to the evolution of shared symbols: sign alignment directly influenced communication success and concurrent partner feedback drove sign simplification and symbolization. See Lister and Fay (in press) for a theoretical model of this process. Together, these complimentary processes explained the interactive evolution of effective and efficient human communication systems.

Our findings provide a solution the symbol grounding problem (Harnad, 1990). Complex iconic signs ground shared meanings. Once grounded, social interaction drives sign simplification and alignment, the mechanisms through which effective and efficient shared symbols arise. This explanation offers a convincing candidate process through which iconic signs evolve into symbols, as originally proposed by Charles Sanders Peirce over 100 years ago.

Other-initiated repairs are a frequent feature of conversation, and similar repair mechanisms are seen across a range of different languages (Dingemanse et al., 2015). Repairs - from a generic 'huh', to specific information requests - signal trouble and correct breakdowns in communication (Schegloff, 2000; Schegloff, Jefferson, \& Sacks, 1977). Other-initiated repairs were a frequent feature of communication in the +Feedback conditions, especially in the early games of the task ( $25.83 \%, 17.92 \%, 13.75 \%, 11.25 \%$, $7.91 \%, 2.91 \%$ of trials at Game 1-6). Yet, there was no evidence that this feedback directly affected communication success (19.16\%-point improvement in communication success from game 1 to 6 with partner feedback, and a 19.95\%-point improvement in communication success from game 1 to 6 without partner feedback (collapsed across the alignment conditions). By contrast, concurrent partner feedback was crucial to sign simplification and symbolization.

Why might other-initiated repairs not directly affect communication success? A simple answer is that people may not be sensitive to problems in communication in the first place. This was examined in a study in which conversation partners, who communicated via text-chat, were swapped with participants engaged in a separate and unrelated conversation (Galantucci \& Roberts, 2014). Participants failed to notice their conversation partner had changed (beyond chance level), despite the incoherent change in topic. This finding suggests that
communication is noisy and error-prone, and that people tend to be insensitive to communication problems. Perhaps our task is too simple to be able to detect the positive influence of other-initiated repairs on communication success. Against this, our experimental paradigm was sensitive to the positive influence of behaviour alignment on communication success.

Our experimental findings demonstrate that behaviour alignment directly influenced communication success. By contrast, there was no statistical evidence that other-initiated repairs directly affected communication success. This pattern of results supports models of dialogue that downplay the role of high-level cognitive processes, and stress the importance of behaviour alignment, via low-level processes such as priming, to successful communication (Garrod \& Pickering, 2004; Pickering \& Garrod, 2004). In the present study, although partner feedback did not directly affect communication success, it proved crucial to sign simplification and symbolization, which improved the smooth and efficient flow of communication (see also Bavelas et al., 2000; Mein et al., 2016).

#### Abstract

We propose a neural network model that accounts for the emergence of the taxonomic constraint in early word learning. Our proposal is based on Mayor and Plunkett (2010)'s neurocomputational model of the taxonomic constraint and overcomes one of its limitations, namely the fact that it considers artificially built, simplified stimuli. In fact, while in the original model the visual stimuli are random, sparse dot patterns, in our proposed solution they are photographic images from the ImageNet database. In our model the represented objects in the image can be of different size, color, location in the picture, point of view, etc.. We show that, notwithstanding the augmented complexity in the input, the proposed model compares favorably with respect to Mayor and Plunkett (2010)'s model.

## Introduction

A central issue in the current understanding of early lexical acquisition concerns how infants learn the reference of words. Quine (1960) famously raised the point that for every word heard in a given circumstance, there are several possible references: in order to infer the appropriate one, infants have to rule out several possible alternatives. An influential solution to the issue has been proposed by Markman (1989), suggesting that infants rule out inappropriate references by means of three constraints. By the whole object constraint children assume that novel words refer to objects as a whole, rather than to their parts, substance, color, or other properties. By the mutual exclusivity constraint children assume that two labels usually do not refer to the same object. Last, but central to this paper, by the taxonomic constraint children extend words to taxonomically-related objects (at the level of basic categories): when a child hears the word "dog" pronounced by a caregiver while pointing at a specific dog, she generalizes the reference of "dog" to all dogs, not just to the one in front of her.

Here we propose a neural network model that accounts for the emergence of the taxonomic constraint in early word learning, and can process realistic visual stimuli ${ }^{1}$. This is the first step towards the development of a model able to cope with visual and auditory stimuli that are both realistic.

[^324]Our starting point is Mayor and Plunkett (2010)'s neurocomputational model of the taxonomic constraint. The model consists of two self-organizing maps (a visual and an acoustic map) connected with Hebbian connections. The model successfully explains how it is possible to generalize a single word-object association to a whole class of objects. Essentially, this is the result of Hebbian learning creating wordobject associations over a previous conceptual organization of the visual and acoustic space.

Here we want to go beyond one limitation of Mayor and Plunkett (2010)'s model, namely the fact that it considers artificially built, simplified stimuli: in their model the visual stimuli are random, sparse dot patterns, in the style of (Posner, Goldsmith, \& Welton Jr, 1967), whereas the acoustic stimuli are manipulations of acoustic signatures extracted from sounds produced by a speaker, leading to a simplified acoustic input stimulus.

Would the model still work if we considered realistic visual inputs, instead? In order to address this question, we have expanded the original model's visual component making it able to process realistic visual stimuli, that in our case are images taken from the ImageNet dataset. More precisely, we have added to the visual component of Mayor and Plunkett (2010) an InceptionV3 deep network (Szegedy et al., 2015) which is at the state of the art in the image classification task. The deep network processes the visual scene in the image, builds a representation for it, and feeds the representation to the visual self-organizing map.

In order for the whole model to work, these representations need to contain a description of the main object of the visual scene, independent from the context. Understanding the nature of the image representations built at the various levels of the network is indeed one of the main points of debate in deep neural networks (Zeiler \& Fergus, 2014; Zhou, Khosla, Lapedriza, Oliva, \& Torralba, 2014; Agrawal, Girshick, \& Malik, 2014). In order to assess whether the InceptionV3 deep network feeds into the visual self-organizing map meaningful object representations, we performed several clustering experiments. These experiments investigated whether representations deriving from images of objects can be clustered
together by off-the-shelf clustering algorithms. They showed that the representations provided by InceptionV3 are reasonably well organized. A further test investigated whether the visual self-organizing map could organize the representations received from the deep neural networks in a topologically satisfactory manner.

We then tested the whole model to see if it still exhibits a taxonomic responding, generalizing learned word-object associations to the whole category. Results show that our model, despite starting from more realistic visual stimuli, does replicate Mayor and Plunkett (2010)'s success on taxonomic responding when few joint word-object associations are considered.

## Mayor and Plunkett (2010)'s model

Mayor and Plunkett (2010) neurocomputational model of taxonomic constraint (Figure 1) is based on two Self-Organizing Maps (SOMs): a visual map and an acoustic map, representing the primary visual cortex and the primary auditory cortex respectively.

The stimuli presented to the two maps are artificially built: the visual stimuli are random dot patterns, whereas the auditory stimuli are extracted from the acoustic signatures of uttered words; the acoustic signatures are manipulated in order to create simpler inputs.

Learning is a two-phase process. First, the two maps are independently trained to learn to categorize the visual and the acoustic stimuli. This first learning phase is preliminary to word learning, and unsupervised. The two maps are trained using the standard learning algorithm for self-organizing maps. In short, a stimulus $x$ is presented to each neuron of the map, and the Best-Matching Unit (BMU) is selected: this is the unit $i$ whose weight vector $w_{i}$ is closest to the stimulus $x$ (i.e. $i=\arg \min _{j}\left\|x-w_{j}\right\|$ ).

The weights of the best matching unit and of its surrounding units are updated in order to maximize the chances that in the future the same unit (or the surrounding units) will be selected as the best matching unit for the same stimulus or for similar stimuli. At iteration $n+1$, the weights for neuron $j$ are updated as follows:

$$
\begin{equation*}
w_{j}(n+1)=w_{j}(n)+\eta(n) h_{i, j}(n)\left(x-w_{j}(n)\right) \tag{1}
\end{equation*}
$$

where $\eta$ is the learning rate, and $h_{i, j}$ is the neighborhood function between $i$ and $j h_{i, j}(n)$ is defined as $h_{i, j}(n)=$ $\exp \left(-d_{i, j}^{2} / 2 \sigma(n)^{2}\right)$, where $d_{i, j}$ is the distance between $i$ and $j$ on the map's grid, and $\sigma(n)$ is the width of the gaussian.

After a while, the two maps learn to adequately represent the stimuli of their training set in a topologically significant way: close units respond similarly to similar stimuli. The neural activation $a_{j}$ of a neuron $j$ in response to a stimulus $x$ is defined as: $a_{j}=e^{-\frac{q_{j}}{\tau}}$, where $q_{j}$ is the quantization error
(i.e., the distance between the input vector $x$ and $j^{\prime}$ s weight vector: $\left.q_{j}=\left\|x-w_{j}(n)\right\|\right)$ ), and $\tau$ is a normalization constant.

Once the visual and acoustic maps have stabilized into a topological organization, proper word learning can start. This is the Hebbian Learning phase, in which the two kinds of stimuli are simultaneously presented to the model. For each joint presentation of a visual and acoustic stimulus, the synapses between the two maps are strengthened. In particular, for each neuron $v$ on the visual map and neuron $p$ on the acoustic map, the Hebbian connection $u_{v, p}$ is strengthened proportionally to the resulting neural activations $a_{v}$ and $a_{p}$, as follows:

$$
\begin{equation*}
u_{v, p}(n+1)=u_{v, p}(n)+1-e^{-\lambda a_{v} a_{p}} \tag{2}
\end{equation*}
$$

where $\lambda$ is the Hebbian training learning rate.
A single Hebbian learning event, combined with the previously acquired categorization capabilities of the visual and acoustic SOMs, allows the model to generalize the association to other stimuli belonging to the same category.

Once training is complete, the model is tested for its ability of comprehension and production. Comprehension is assessed by considering what visual category is retrieved when a word is presented to the auditory map and activation is propagated via Hebbian connections. Production is assessed by considering what word is produced by the auditory map when a visual stimulus is presented to the visual map, and activation is propagated through Hebbian connections.

The ability of the model to extend the learned word-object associations to other words and objects belonging to the same category is measured by the Taxonomic Factor which is the percentage of correct word-object associations generated by the model. Results show that when the SOMs are adequately trained the Taxonomic Factor reaches $80 \%$ after a single Hebbian learning trial.

One of the limitations of Mayor and Plunkett (2010)'s original model is that it uses artificially built input stimuli that are much simpler than what would derive from realistic contexts. Here we address this limitation, for what concerns the visual module, by introducing deep convolutional neural networks as shown in the next sections.

## Deep Convolutional Neural Networks

In the last few years research on deep networks contributed to reach human (sometimes super-human) performances on several difficult tasks (Hinton et al., 2012; Li \& Wu, 2015; Socher, Bauer, Manning, \& Ng, 2013; Yue-Hei Ng et al., 2015). In particular, in 2011 a deep convolutional model achieved for the first time super-human performances in a visual pattern recognition task and, in the following year, the AlexNet Convolutional Neural Network (CNN) model won the ImageNet competition by a significant margin (Krizhevsky, Sutskever, \& Hinton, 2012) over traditional competitors. These successes contributed to a growing interest in deep networks and today deep-network-based models are at the forefront of research in many different areas and are
setting performance records in tasks of interest for the cognitive sciences community such as image (e.g., (Russakovsky et al., 2015)) and speech recognition (e.g., (Xiong et al., 2016)).

Despite unheard performances achieved in many different tasks, deep models present important shortcomings that are far from being completely addressed. The most important problem from the point of view of the forthcoming discussion is the difficulty they present for what concerns the understanding of their internal working. Consequently, recent research investigated ways to make sense of the contents of the network providing interesting insights. For instance, Zeiler and Fergus (2014) use "deconvolution networks" to visualize the patterns that causes the activation of nodes in each layer; in Zhou et al. (2014) scenes are iteratively simplified or occluded to investigate which image patches and which objects contribute to the activation of nodes in a given layer; in (Agrawal et al., 2014) the authors investigate the presence of grand-mother-cells and of distributed representations in deep networks.

While the understanding of the representations built by these networks is still scattered and incomplete, some of the insights seem to be well supported. An important one concerns the hierarchical organization of the features: low-level (coarser) features are nearest to the network input, while higher-level (more abstract) features are nearest to the output (for an idea of the kind of features extracted at the different levels see for instance (Zeiler \& Fergus, 2014)). Interestingly this organization mirrors a well known characteristic of the representations in the primate inferior temporal (IT) cortex, and hence it hints at a possible cognitive justification of this computational model. To this regard it is interesting to mention that recent research investigated the connection between the representations built by several computational models and the representations in the IT cortex and found that deep neural networks are among the best models (Serre, 2016; Kriegeskorte, 2015). For instance, in (Khaligh-Razavi \& Kriegeskorte, 2014), the authors investigate a wide range of computational models and suggest that deep CNNs are, not only the best performing in term of accuracy, but also the best at explaining the IT representation (albeit still in an incomplete way).

Given the great accuracy they achieve and the possible cognitive plausibility of the CNNs, we have chosen to use these particular models as the visual component of the word-object association model we propose in the next section.

## Proposed model

In order to solve the problem of the lack of realism in the visual stimuli in the Mayor and Plunkett (2010) model, we propose to replace the input of the visual SOM with a representation built by a CNN as shown in Figure 2.

The long term objective of this research is to find a cognitively plausible model able to reproduce the word-object association abilities observed in infants using realistic image and audio stimuli. In this paper we keep a simplified auditory input and focus instead on providing a visual module capable

Figure 2: The proposed model: the visual component contains a deep convolutional network (InceptionV3) in order to process realistic images. The representation built by the deep neural network is then fed into the visual SOM. The acoustic component, on the contrary, only contains an acoustic SOM, as in Mayor \& Plunkett (2010)'s model, and can only process simplified acoustic stimuli.
of handling realistic images. In fact, in this proposal the auditory input is a mere placeholder that does not provide any real processing ability.

In practice, we shall assume that an oracle provides the auditory SOM with a perfect representation of the auditory stimulus, or label, in the form of a binary vector. The vector contains a 1 in position $i$ if the utterance provided to the auditory module corresponds to the $i$-th label; it contains a 0 otherwise.

The visual module shall, on the contrary, be able to cope with realistic images and, while we still assume that each image contains a main object corresponding to the concept to be learned, we pose no additional constraints. Images for a given concept can, for instance, be of different size, color, location in the picture, point of view, etc.. For instance, the "dogs" concept may be represented by images of dogs of different size, color, breed and be portrayed in different contexts, under different illuminations and poses.

The visual module is the concatenation of the InceptionV3 network and the SOM network we already introduced. InceptionV3 is a stack of Inception Modules, which parallelize and combine several convolution and pooling operations providing a richer output while still maintaining a small number of parameters. At the end of the stack of inception modules the
model contains a pooling layer of length 2048 which is fully connected with a shallow feed-forward neural network which is then used to classify the input image.

In the Inception architecture a representation of the input is propagated through the layers up to the top of the network where it is used to train the classifier. A question worth investigation is if and where a good representation of the concept in the input image is created by the deep network. In this paper we work under the assumption that such representation exists and argue that it has to be found in the last pooling layer (just before the fully connected neural classifier). Based on this assumption, we propose to use the vector containing the value of the 2048 neurons in that layer as the representation of the stimuli for the visual SOM. To verify the validity and the consequences of this assumption, we performed two sets of experiments: in the "Representation Quality" sub-section of the Experiments section we investigate the nature of the proposed representation, while in the subsequent section (Word Learning) we investigate the quality of the complete model. In our simulations we used the pre-trained Inception network provided by the TensorFlow library ${ }^{2}$.

The complete system is trained as outlined in the "Mayor and Plunkett (2010)'s model" section. In summary, given the representation from the CNN and the simplified auditory input, the two SOMs (composed by $20 \times 30$ neurons each) are trained to cluster together similar representations using the standard SOM training algorithm. In our tests, the two SOMs attain their best topological organization of the objects in the training set after 60 epochs (the learning rate is set to 0.3 and decreases linearly at each epoch). Afterwards, the association between the visual and the auditory input is created using Hebbian connections between the two maps: two stimuli belonging to the same category are presented together to the model, the visual stimulus is processed to extract its representation and presented along with the auditory stimulus to the corresponding SOMs. Finally the SOMs activations are used to update the Hebbian connections using the update rule in Formula 2.

To better cope with the variability in the input representation, we introduce two variations to the Hebbian training (with respect to the procedure outlined in (Mayor \& Plunkett, 2010)): $i$ ) we allow the network to learn from an increasing number of stimuli pairs (in the original paper a single pair of stimuli is presented to the network), this allows us to study how performances increase as the number of presentations grows; $i i$ ) we suppress the activation of a neuron in a SOM if its activation value is below 0.6.

## Experiments

In the following two sub-sections we investigate two important facets of the proposed model. In particular, in the "Representation Quality" Section we show that the representation found in the last pooling layer of the InceptionV3 network al-

[^325]lows one to cluster the input images into groups that correlate well with the classes assigned with the images themselves. This is arguably an evidence that such a representation can be usefully exploited as the input of the SOMs. In the "Word Learning" Section we focus on the complete model, replicate part of the experiments in (Mayor \& Plunkett, 2010), and compare our results with those reported in that paper.

All the experiments have been performed on two datasets. A first dataset is composed by 10 classes associated with 100 stimuli each, for an overall 1.000 stimuli. A second dataset contains 100 classes associated with 100 stimuli each, for an overall of 10.000 stimuli. Since the results for the two datasets are very similar, for the sake of readability we focus on the smaller dataset and refer to (Fenoglio, 2016) for the details of the experiments on the larger dataset. The code for the complete model along with the datasets used can be found at https://github.com/ ml-unito/nNsTaxonomicResponding.

## Representation Quality

In order to assess the quality of the representation found in the last pooling layer of the InceptionV3 model, we investigate how well these representations can be clustered together. For each image we extract the representation found in the last pooling layer of the deep network, we then cluster the resulting representations using a K-means and an agglomerative algorithm. For both algorithms the number of clusters is set to 10 . The clustering experiments have been conducted using the scikit-learn python library ${ }^{3}$.

Figures 3 and 4 report results for K-means clustering. Analogous results hold for agglomerative clustering. In particular, Figure 3 reports, for each class, a bar showing how the class objects are partitioned among clusters; Figure 4 reports, for each cluster, a bar showing the distribution of the classes within it. We then investigate the topological organization provided by the visual SOM out of the representations created by the deep model. We report in Figure 5 a representation of the topology found by the visual SOM after 60 learning epochs.

Discussion The experiments show that the two clustering algorithms are able to find good, albeit not perfect, partitions for the representations. In particular, Figure 3 shows that the objects in 7 out of 10 classes are mostly assigned homogeneously to a single cluster: in two of the remaining cases the objects are almost all distributed among two classes, while in a single case (and only for the k-means clustering algorithm) the objects are distributed on three clusters. Figure 4 shows a similar picture, but from the point of view of the clusters: in almost all cases ( 8 out of 10) we have clusters which are almost pure. The remaining two clusters conglomerate objects from different classes acting almost as folders where all uncertain objects are put.

Overall, it seems that the clustering algorithms do find a way to partition the representations of the objects into co-

[^326]

Figure 3: Per class distribution of objects into clusters (Kmeans clustering). Colors represents different clusters. Blue is used to represent the cluster containing the majority of the objects of a given class; orange, yellow, and green are used to represent the second, third, and fourth most represented clusters.

Figure 4: Distribution of classes among clusters (K-means clustering).
herent clusters. This is consistent with what happens for the topological organization that the SOMs create for the representations provided by the deep networks. Figure 5 shows that, with the exception of few cases, the visual SOM is able to group all related objects into nearby spaces.

## Word Learning

In order to evaluate the performance of our model in the task of word learning, we calculate the Taxonomic Factor of the model as defined in (Mayor \& Plunkett, 2010). We do so by testing the model for its production skills: for each class, 100 images are presented to the visual module, the activation is propagated through the deep neural network, then fed into the visual SOM. The activation of the visual SOM's best matching unit is propagated through the Hebbian connections up to the acoustic SOM. At the end of the process the resulting most active unit on the acoustic map is identified. It will be considered correct if it belongs to the area of the acoustic map

Figure 5: SOM clustering of the visual stimuli representations
associated to that word ${ }^{4}$. The percentage of correct words produced by the model when tested through all the classes is the Taxonomic Factor.

We have performed a number of experiments where we varied the number of presentations per class used to update the Hebbian connections. Specifically we let the number of presentations vary from 1 to 15 . For each experiment we repeated the test over 1.000 different training sets (we kept fixed the SOM and let vary the images presented to the Hebbian learning module) and report the average taxonomic factor over an independent test set composed by additional 1000 images (100 images per class). Results are shown in Figure 6.

Figure 6: Taxonomic factor of the model, using an increasing number of pairs of stimuli per class during the training of the Hebbian Connection (on the x -axis).

Discussion The experiments show that the Taxonomic Factor steadily grows as more word-object associations are presented and reaches an accuracy above $80 \%$ (which is comparable with results in Mayor and Plunkett (2010)) at the fourth joint presentation.

[^327]
## Conclusions

In this paper we have proposed an extension of the Mayor and Plunkett (2010) model for taxonomic responding. We have addressed the issue of adding realism to the visual stimuli. As a difference with respect to the original model in which these inputs were random dot patterns, the model can now deal with realistic images as those in the ImageNet dataset. This is possible thanks to the insertion of a deep convolutional neural network in the visual component of the model. Notwithstanding the higher complexity of the stimuli considered, our model exhibits taxonomic responding with performances comparable to the original one.

In our future work we will address the issue of making the acoustic module work with realistic stimuli. It can be interesting to explore whether a deep neural network for acoustic processing, as for instance the one proposed in (Xiong et al., 2016), could be nested into the acoustic part of the model in a way similar to what we already did for the visual component.

We will also explore whether the model proposed here can be used to provide a mechanistic account of the whole object constraint proposed by Markman (1989) by which a word is associated to the whole object instead of anyone of its properties. We conjecture that a model as the one proposed, with the deep component that extracts a representation of an object out of a more complex visual scene, can be adequate to the purpose: the whole object constraint may naturally emerge from the association of the word to the object's representation formed by the deep network. Important to this regard is the current discussion about the nature of the object representation built by deep networks (Ullman, Assif, Fetaya, \& Harari, 2016; Tang \& Kreiman, 2017).

# How Many People Know? Representing the Distribution of Knowledge 

## Stanka A. Fitneva (Fitneva@queensu.ca) <br> partment of Psychology, Queen's University

Kingston, ON K7L 3N6, Canada

Abstract
The representation of the distribution of knowledge guides research aimed to explore adults' and 4-year-olds representation of the distribution of common (conventional and procedural) knowledge and expert knowledge associated
with five occupations in their community. In addition, we examined estimates of occupation-related everyday (nonexpert) knowledge. Both groups estimated that common
knowledge is more widely held than expert knowledge wit knowledge is more widely held than expert knowledge, with
everyday knowledge in between. For adults, but not children, everyday knowledge in between. For adults, but not children,
the distribution of expert knowledge was correlated with estimates of the proportion of people in each occupation.
Keywords:
development developmen

## Introduction

People act competently and adaptively in their physical and cial surroundings. Yet, their understanding of the physica his paradox likely rests in the social behavior: we rely on each other to fill the holes in our understanding (Keil, 2003). Understanding who knows what and how knowledge is structured is thus a critical aspect of human social cognition. Equally important, though less wel in the population. Distinguishing widely distributed from arrowly distributed knowledge could affect both the selectivity of our interpersonal interactions and the structure of our social networks.
Knowledge is clearly unevenly distributed. Some nowledge, such as conventional knowledge of common object labels and functions, is shared by all members of a nowledge, e.g, that grass is green, can be expected to be known by all in virtue of shared bodily experience. In contrast to this "common knowledge," other knowledge is privy to only groups of people within the community. The ivision of labor that characterizes most moder communities leads to conce different people
Surprisingly, the question of the relative spread of
different kinds of knowledge has received little attention Most of the literature on expertise has focused on explaining he attainment of expertise in various domains of activity (Feltovich, Ford, \& Hoffman, 1997) and on understanding of the clustering of knowledge in different kinds of experts Rozenblit, 2008). For instance, preschoolers appear to recognize that expertise is topic-specific and that being an
expert in one domain does not entail being an expert in other domains (Koenig \& Jaswal, 2011). Furthermore, by age 5, children appear to be able to link their skeletal understanding of knowledge domains (psychology, physics,
biology) with how knowledge is clustered in individual minds. That is, they can make an inference from what a person knows to what other things the person is likely to know (Keil et al., 2008).
With respect to the spread of knowledge, previous evidence exclusively for the existence of understanding of non-overlaps in knowledge. For instance, Lutz and Keil (2002) presented 3- to 5 -year-old children with a list of items representing the expertise of doctors and car
mechanics. Children were asked questions like "Who would mechanics. Children were asked questions like "Who would
know more about how to fix a broken arm?" While children identified above chance the relevant expert, this suggests sensitivity to non-overlaps in knowledge and that not everyone knows a given item. The data do not speak to the question of whether children recognize that expert knowledge is relatively narrowly distributed in the population
children' understanding of differences in havewledge For instance, a number of studies address children's understanding of the difference between child and adult knowledge (Aguiar, Stoess, \& Taylor, 2012; Fitneva, 2010; Fitneva, Ho, \& Hatayama, 2016; Taylor, Cartwright, \&
Bowden, 1991; VanderBorght \& Jaswal, 2009). Bowden, 1991; VanderBorght \& Jaswal, 2009).
Nevertheless, these studies only reveal that children identify Nevertheless, these studies only reveal that children identify
non-overlaps of knowledge between social groups. They don't address children's representation of the size of social groups and therefore fail to capture children's representation of the spread of different kinds of knowledge. Perhaps the only study that allows such an inference, Burton and mitchente knowledge to the self and denied its possession by a range of adults and children.
The question of children's representation of the distribution of knowledge has been also examined for conventional knowledge such as word meaning (Graham, Stock, \& Henderson, 2006; Henderson, Weighall, Brown, \& Gaskell, 2013). The dominant method here involves
examining whether children extend novel conventional knowledge (e.g., of an object label or a game rule) to a new person. Although the young children in these studies appear to appropriately extend conventional knowledge to others but restrict idiosyncratic knowledge such as desires to individuals, it is not clear that they see conventional knowledge as widely distributed. The reason is that in these
studies, new individuals are generally not introduced as randomly sampled from the population.
Recent evidence does suggest, however, that children are examples, Cimpian and Scott (2012) tested the belge. For to 7 year olds on how many people would know generic and non-generic facts. Children associated generic facts with "many" and non-generic facts with "few" people. Presumably this performance implies that children assume that generic information concerns how the world works and see adults as expe
2012). The
he question of how knowledge is distributed in the population highlights the social embeddedness of expertise.
Experts function within a community. The division of labor - in many cases the motivator for the development of expertise - would not be feasible and workable if it were not services, and ideas. Communicating and interacting with various experts both rests upon and develops relevan knowledge. This knowledge is neither conventional nor shared in the same way perception of color is. In contrast to conventional and common experiential knowledge, it can show considerable individual differences based on experience with the problem domains and or access
To sum up the goal of this study was to examine yo children's understanding of the distribution of expert, everyday, and conventional knowledge. In particular, we had three questions: 1) Do children associate exper knowledge with a smaller proportion of the population than common knowledge? 2) Do they associate it with a smaller Is the perceived distribution of expert knowledge related to the perception of number of experts in the community?
Even though past research has documented that by age four children understand that the knowledge of adult experts is not co-extensive (Lutz \& Keil, 2002), they may nevertheless associate expert knowledge with large portions more narrowly distributed than common and everyday knowledge. This would be consistent with children seeing adults as omniscient (Piaget, 1959), or at least people capable of exceptional performance in more than one domain. Alternatively, we expected that even 4 -year-olds might associate expert knowledge with a smaller portion of is because even very young Canadian children have first hand contact with experts (e.g., doctors) and observe the exchange of goods, services, and ideas ensuing from the division of labor.
There are a number of ways in which people can develop nderstanding of the spread of expertise. One of them is occupations. If this is the case, participants' estimates of the proportions of experts among adults would correlate with their estimates of the proportion of people with expert
knowledge. Thus, the study included questions asking participants to estimate the prevalence of differe ccupations in their community
mong the youngest to demonstrear-old children who ar overlaps in the knowledge of adults (Lutz \& Keil, 2002) At this age, children are also sensitive to relative magnitude.

## Method

## Participants

Thirty-six 4 -year-old children and 18 adults participated in the study. The children lived in the mid-size urban
community of Kingston Ontario and the adults were community of Kingston, Ontario and the aduits were
students at Queen's University in the same city. Six children were excluded due to not completing the study (2), self professed silly attitude (1) and clear pattern in responding (i.e., going up / down the scale, 3). Thus the final sample included 30 children (average age 54 months, range 48-60; 19 girls, 11 boys).

## Materials

We asked participants to indicate their perception of the distribution of expert knowledge, everyday knowledge in he same domains, and common knowledge. The expert Iledge pertained to five occupations: farmers, builder pilots, car mechanics, and doctors. These occupation vary in frequency in the community (more builders, car mechanics and doctors relative to farmers and pilots). An example of an expert knowledge question is "How many corresponding everyday knowledge question was "How many grown-ups know how to take their temperature?" The five common knowledge items referred to conventional knowledge, e.g., How many grown-ups know many grown-ups know how to lock their front door?" To examine whether the reported spread of expert knowledge corresponded to participants' perceived number of experts in the community, we also asked an occupation-focused question in each domain, e.g., "How many grown-ups in Kingston are doctors?"' Participants were also presented individual characteristics and behaviors, e.g., "How many grown ups in Kingston go to work / have pets?" These property questions aimed to further prompt thinking about wider and narrower sets of the population
Children answered the questions on a 5 -point scale with a slider. The five points depicted with pie charts $0 \%, 25 \%$,
$50 \%, 75 \%$, and $100 \%$ of the population. Note that this scale $50 \%, 75 \%$, and $100 \%$ of the population. Note that this scale
was not designed for recording realistic estimates of prevalence. This would have required a logarithmic scale and we were not aware of evidence of successful use of such a scale with children.
For the adults, the questions were presented on a piece of paper. The instructions and a figure representing a $0-100$
scale with the pie charts used with the slider appeared on op of the page.

## Procedure

Adults Adult participants answered the questions by writing down their answers next to each question. They were free to 100 range. Adults received course credit for participating.

Children The experiment began by explaining to children hat they will be asked questions about grown-ups. Afte that, the experimenter informed them that they were to
answer the questions by moving the slider to the pie chart hat showed the relevant proportion of grown-ups who know. As a warm-up, children were asked to position the slider in the all, none, and half positions. Children were also asked "How many grown ups in Kingston are shorter/talle han you?"' to provide practice answering with the slider
Children were asked the experimental questions in the
same random order, with the property questions interspersed among them. Although children were free to position the slider anywhere on the $0-100$ scale, they used the five points, consistent with the directions they received.
Subsequently, children were asked whether or not thei arents knew the items, e.g., Do mom and dad know how o fix a broken arm?" These questions aimed to provide an information in their homes. The study included several additional questions the data from which have not yet bee nalyzed. These questions were presented later and do not affect the current results. Parents also answered question regarding their child's familiarity with a large set occupations.

## Results

Figures 1 and 2 show respectively adults' and children's builder, car mechanic, doctor, farmer, and pilot, and relate expert and everyday knowledge. In addition, they show the groups' estimates of the prevalence of common knowledge.
The research questions identify two key comparisons in the data: expert - common knowledge and expert everyday knowledge. In addition, we examined the proportion of people in the five occupations and the proportion of people in the five occupations and the
distribution of expert knowledge related to these occupations in the population. Thus, the analytical approach ncluded a combination of targeted t -tests and analyses of ariance and correlation

## Adults

As Figure 1 suggests, on average, adults associated expert nowledge with a significantly smaller proportion of the than common knowledge ( $M_{\text {eppert }}=9.93 ; M_{\text {comm }}$ $=92.16 ; t(17)=36.36, p<.001)$.

Figure 1. Adults' estimates of the proportion of the population in five occupations and of the distribution of related expert and everyday knowledge. Adults' appears on the right. Error bars represent $\pm 1 \mathrm{SE}$

Figure 2. Children's estimates of the proportion of the population in five occupations and of the distribution of related expert and everyday knowledge. Children's estimate of the distribution of common knowledge appears on the right. Error bars represent $\pm 1$ SE.

We conducted an area (5) x question (occupationfocused, expert knowledge, everyday knowledge) repeated measures ANOVA to assess the differences in adults assessments of the prevalence of the five occupations, expert knowledge, and everyday knowledge. Both main of area $(F(4,68)=42.7, p<.01)$ reflected that some occupations and related knowledge were perceived as more common in the community than others. Of key interest, was the effect of question, $F(2,34)=138.2, p<.01$. As Figure 1 suggests, there was a significant difference in the estimates of the distribution of expert and everyday
knowledge $(M)=9.93 ; M$ $<.001)$. Furthermore, there was no difference in participants' responses to the occupation and expert
knowledge questions, $t(17)=1.08, p=0.295$. Given the significant interaction effect between area and question $(F(8,136)=47.7, p<.01)$, we conducted two follow-up
analyses. First, we examined the difference between expert and everyday knowledge items in each area. Although always in the expected direction, this difference was significant in three of the five areas (the exception being farmer and pilot).

Second, as we were interested in the relationship between participants' perceptions of the proportion of we calculated the correlation between these variables (rathe than their difference). The correlations ranged from .45 to .89 ( $p$ 's $\geq .06$ ) suggesting an overall significant relation between these variables.
In sum, adults recognized that expert knowledge is less prevalent than common knowledge. Furthermore, their linked to their beliefs about the proportion of people in each occupation.

## Children

As Figure 2 suggests, 4 -year-olds associated the common knowledge items on average with $79 \%$ of the population, which was significantly larger than their estimate of the prevalence of expert knowledge $53 \%, t(29)=5.1, p<0.01$. (professional, expert knowledge, everyday knowledge) repeated measures ANOVA on children's responses to the questions about the distribution of expert and everyday knowledge and occupations. The analysis only showed a significant effect of question type, $F(2,58)=6.2, p<.01$. Children associated expert knowledge with a significantly smaller proportion of the population than everyday
knowledge $\left(M_{\text {evpert }}=53 ; M_{\text {evervay }}=67 ; t(29)=3.61, p<\right.$ .01 ). The difference in children's estimates of the number of professionals in the population and the distribution of expert
knowledge was not significant $t(29)=135, p=0.19$. The knowledge was not significant, $t(29)=1.35, p=0.19$. The correlations between children's answers to these two questions in the individual areas ranged between .3 and .45 to reach significance. Interestingly, chil
people in the five occup was higher than their estimate of the proportion of people with related expert knowledge ( $53 \%$ ) but lower than thei estimate of the distribution of everyday knowledge ( $67 \%$ ). The next analysis examined 4 -yea--old's responses to the answers were averaged across area. Common knowledge was attributed to parents on average $90 \%$, significantly more often than either expert or everyday knowledge (both $t \mathrm{~s}<.01)$. Everyday knowledge was more likely to be attributed to parents than expert knowledge ( $M_{\text {expert }}=35$; $M_{\text {everpdy }}=64,(29)=4.86, p<.0$ ). . except car mechanic.

## Discussion

The present findings enrich our understanding of children's and adults' representation of the spread of different kinds of knowledge. Adults showed clear differentiation between expert knowledge and related everyday knowledge as well Furthermore, their estimates of the distribution of expert knowledge closely corresponded to their estimates of the frequency of different occupations. Children also indicated that expert knowledge is less widely distributed than everyday knowledge and common knowledge. Past research has revealed that children recognize that different adult The current study extends these findings to demonstrate the both children and adults see differences in the spread of different kinds of knowledge.
It is important to note that children's responses in the present study are unlikely to be affected by generic language that distinguishes knowledge that most people have from idiosyncratic knowledge of individuals. A widely and narrowly known novel facts (Cimpian \& Scott, 2012). Generic language did not distinguish the stimuli in the different conditions in present study. Thus, 4 -year-olds not only judge widely and narrowly held knowledge based on linguistic cues but have built representations of how knowledge in their environment varies in its spread.
How do people arrive at these representations, especially
with regards to expert knowledge? One possible route to representing the spread of expert knowledge is through considering the frequency of different occupations. Indeed, there was a clear relationship between adults' estimates of the proportion of people winh he target occupations and proportion of people with occupation-related knowledge. However, no such relationship was evident in the of different occupations were in-between the spread of expert and everyday knowledge. This finding suggests that children may not arrive at a representation of the distribution of knowledge considering the frequency of experts. It is possible that children's estimates of the distribution of expert knowledge and people in relate occupation questions focused on social actors while the expert knowledge questions focused on mental states associated with activities. For young children, tracking activities may be easier (given that their estimates were lower and thus more realistic) than the social agents associated with those activities.
Another route children can take to developing nnderstanding of whether something is widely or narrowny
known is through observations of adults in the family. Indeed, the analyses revealed that children crisply differentiated expert, everyday, and common knowledge when asked whether their parents have that knowledge. Children appear to believe that the number of people in
$50 \%$. This conflicts with a number of assumptions adult make about expertise, e.g., that a person does not have a pportunity to develop professional expertise in many areas extend expertise to other domains (Taylor et al., 1991). It may not be warranted, however, to make much of the absolute value of these numbers. First, children may have very well been providing relative answers (e.g., "many" vs. "few") and, second, the scale was not conducive to capturing realistic estimates of the small proportion of explore in future research whether children can work with ogarithmic scale.
On the flip side, even though high, children's estimate of he number of people in different occupations suggests tha hey realize that not everyone has the same profession (only half do!!). In other words, although they may consider adul to be well rounded, they do not consider them omniscient.

Clearly, the present conclusions are limited by th cupations that were represented and the associated item chosen for the study. As the analyses suggested, the magnitude of the difference between expert and everyda nowledge varied substantially across areas. The domain ere intentionally chosen to vary in the representation of he different occupations in the community. This could have farmers could have led to floor effects in the answers to both knowledge questions. It is also possible that the variability by area is due to the particular items chosen for the study Nevertheless, even though the effect sizes varied across occupation for both age groups, their direction was | consistent. |
| :--- |
| In conc |

conclusion, the present study is one of the first to provide clear evidence pertaining to adults' and children' eliefs about the relative spread of common, expert, and恠 been what everyone in their community is likely and expert knowledge, i.e., knowledge obtaine complement our current understanding of people' epresentation of the clustering of knowledge (Danovitch \& Keil, 2004; Keil et al., 2008) and help build comprehensive picture of the social landscape in people's minds which supports adaptive behavior in the face of ncomplete knowledge

# The Effects of Shared Storybook Reading on Word Learning: A Meta-Analysis 

Zoe Flack<br>University of Sussex

Andy Field<br>University of Sussex

Jessica Horst<br>University of Sussex

#### Abstract

Although a rich literature documents pre-literate children's word learning success from shared storybook reading, a full synthesis of the factors which moderate these word learning effects has been largely neglected. This meta-analysis included 37 studies with 2,256 children, reflecting 104 effect sizes, investigating how the number of target words, tokens, story repetitions, reading styles and related factors moderate children's word comprehension. Dialogic reading styles, tokens, the number of words tested and story repetition all moderated word learning effects. Children's age, who read, number of target words and time between story and test were not moderators. These results provide information to guide researchers and educators alike to the factors with the greatest impact on improving word learning from shared storybook reading.

# Children Learn Words Better From One Storybook Page at a Time 

Zoe M. Flack (z.flack@sussex.ac.uk)<br>School of Psychology, University of Sussex, Pevensey 1 Building, Brighton, BN1 9QH UK<br>Jessica S. Horst (jessica@sussex.ac.uk)<br>School of Psychology, University of Sussex, Pevensey 1 Building, Brighton, BN1 9QH UK

#### Abstract

Two experiments tested how the number of illustrations in storybooks influences 3.5-year-old children's word learning from shared reading. In Experiment 1, children encountered stories with either two illustrations, one illustration or one large illustration (in the control group) per spread. Children learned significantly fewer words when they had to find the referent within two illustrations presented at the same time. In Experiment 2 a gesture was added to guide children's attention to the correct page in the two illustrations condition. Children who saw two illustrations with a guiding gesture learned words as well as children who had seen only one illustration per spread. Results are discussed in terms of the cognitive load of word learning from storybooks.

Keywords: word learning; cognitive load; extraneous information; storybooks; illustrations.

Sharing illustrated storybooks is a common activity for parents and young children (e.g., Rideout, Vanderwater, \& Wartella, 2003) and provides a richer source of vocabulary than everyday conversation (Montag, Jones, \& Smith, 2015). Several studies demonstrate that the styles of illustrations influence how well children learn from books (e.g., Tare, Chion, Ganea, \& DeLoache, 2010). However, little is known about how the number of illustrations influences learning. The current experiments investigate how well children learn new words from storybooks when they view one or two illustrated scenes at a time.

Pre-literate children rely on illustrations to help them make sense of the story content (for a review see, Wagner, 2013). Specifically, in an eye-tracking study, Justice, Skibbe, Canning, and Lankford (2005) found 4 -year-old kindergarten children looked longer at the illustrations than the print that accompanied texts, indicating that even with some emerging print awareness, children look primarily at illustrations. In another eye-tracking study, Evans and SaintAubin (2005) found that even with a range of illustration styles, preschool children spent the majority of their time looking at illustrations and only $6 \%$ of their time looking at the printed text (see e.g., Roy-Charland, Perron, Boulard, Chamberland, \& Hoffman, 2015; Roy-Charland, SaintAubin, \& Evans, 2007).

Pre-literate children have a growing awareness of reading conventions, such as, print conveys meaning and is read from left-to-right and top-to-bottom (for a review see International Reading Association \& The National

Association for the Education of Young Children, 1998; Snow, Burns, \& Griffin, 1998). However, because they cannot yet read, young children are unlikely to know when the reader has moved from the left-hand page to the righthand page. That is, children may be unable to determine which illustrated scene represents which part of the story. Thus, multiple illustrated scenes displayed simultaneously may make it more challenging to associate new words with their illustrated representations.

Evidence suggests that word learning is even more challenging for children when increasing amounts of perceptual information are presented simultaneously. For example, children struggle to learn object names when target objects are presented in less predictable locations (Benitez \& Smith, 2012), with many extraneous objects (Horst, Scott, \& Pollard, 2010) and with multiple combinations of extraneous objects, rather than the same combinations repeatedly (Axelsson \& Horst, 2014). Such findings are consistent with cognitive load theory (Sweller, 1998, 1989 or see, Paas, Renkl, \& Sweller, 2003 for a review), which explains how working memory capacity is inherently limited and is especially problematic in situations with extraneous information. Thus, reducing extraneous perceptual information helps children focus on the target information, which then improves learning. For example, Son, Smith, and Goldstone (2008), reduced cognitive load by providing simplified depictions of novel objects and found that this promoted better generalization of novel objects than more complex examples. Whether decreasing the number of illustrated scenes presented simultaneously in a storybook also decreases the cognitive load of word learning from shared storybook reading remains unknown.

In the current experiments we investigate whether decreasing the number of storybook illustrations presented simultaneously increases preschool children's ability to learn words incidentally from shared storybook reading. All children were presented with three storybooks that included illustrated scenes of a family's activities. The same two novel objects were included across the scenes and were named on the pages on which they were depicted (four pages for each object). Critically, all children heard the same three stories and saw the same 10 illustrations per story, however, the number of illustrations presented simultaneously and guidance varied across conditions. In Experiment 1, children saw either two illustrations (one
scene on each page of the open book) or one illustration (only on the right-hand page with the other side blank). Children in a control condition saw a large storybook (cf. Big Book Reading, Tse \& Nicholson, 2014) with one illustrated scene the same size as the two illustrations combined because we were concerned that another difference between the other conditions was the length of time needed to visually scan the two illustrations rather than one illustration. If decreasing the number of illustrations also decreases the cognitive load of word learning from storybooks then children should learn more words when they see only one illustration at a time. In contrast, if the number of illustrations does not affect cognitive load, then children should learn words equally from one- or twoillustration books. In Experiment 2, we investigate whether guiding children's attention to the correct page with a simple gesture helps children focus on the correct page and improves word learning-even with two illustrations.

## Experiment 1

## Method

Participants Thirty-six 3.5-year-old children ( $M=41.99$ months, $S D=1.76$ months, range $=38.87-45.14$ months) participated. Children were monolingual, British-English speakers from predominantly middle-class families. All children were typically developing with no reported speech or language difficulties. Twelve children each were randomly assigned to one of the three conditions: one illustration ( $M=41.87, S D=0.65,6$ girls), two illustrations ( $\mathrm{M}=42.85, S D=0.43,6$ girls), or control condition (one large illustration, $M=41.92, S D=0.45,6$ girls). There was no difference in maternal education levels between conditions, Fisher's Exact Test $=3.71, p=.98$. Two mothers each in the one and two illustrations conditions and three mothers in the control condition had completed high school (GCSEs and/or A-levels) and/or completed a vocational diploma or access course. Eight mothers each in the one and two illustrations conditions, and six in the control condition had an undergraduate degree and/or an undergraduate degree with a postgraduate certificate (e.g., Postgraduate Certificate in Education (PGCE), an additional teaching qualification). One mother each in the one illustration and control conditions had a Master's degree and one mother in each condition had a doctoral degree. One mother in the two illustrations condition and one mother in the control condition declined to answer this question. Parents were reimbursed for travel costs and children chose a small gift as a thank you for participating (e.g., a colouring book).

Storybooks. Stimuli included three 10-page storybooks slightly modified from Horst, Parsons, and Bryan (2011) The Very Naughty Puppy, Nosy Rosie at the Restaurant, and Rosie's Bad Baking Day. Each storybook depicted and named the same two novel objects four times. Each object had a function: the orange inverted slingshot functioned like
a hand mixer (tannin) and the metal kinetic wheel was used like a rolling pin (sprock). Throughout each story, objects were named incidentally and were not the focus of the story. The objects appeared twice on their own pages and twice together. We used real photographs edited with the poster edges feature in Photoshop to make them look like drawings typical of a commercially available children's book. Across storybooks there was no difference in the number of words per page, $M=45, S D=9.34, F(2,24)=0.98, p=.39$.

All children heard the same stories and saw all the illustrations for each story. The only difference between conditions was the way storybooks were printed (see Figure 1): children either heard stories with two A4 illustrated scenes per open spread, one A4 illustrated scene per spread (i.e., the left-hand page was always blank), or one A3 illustrated scene per spread. In the ISO A-series paper system (i.e., European standard), A3 pages ( 29.70 x 42.00 cm ) are twice the size of A4 pages ( $21.00 \times 29.70 \mathrm{~cm}$ ), thus the A3 condition served as a control condition where the storybooks included only one illustration per spread (as in the one A4 illustration condition) but included the same overall illustrated area as the two A4 illustrations condition). Because the one illustrations condition differed from the two illustrations condition in both surface area and amount of items/details, we wanted to include a control condition to disentangle which of these was driving any potential effects. Equating the number of items/details would have precluded presenting all children with the same illustrations; therefore, we tested surface area as the control condition. Data from all three conditions were collected at the same time.

Figure 1. Page 5 in Rosie's Bad Baking Day as seen by children in the 2 illustrations, 1 illustration and 1 large illustration conditions, respectively. Note, in the 2 illustrations condition page 4 is viewed at the same time as page 5.

Test stimuli. An A4 test booklet with images of four novel objects per right-hand page was used on the test trials (the left-hand pages were blank). On each page, four objects were presented on a plain white background without any other contextual information. Across test trials the targets (tannin and sprock) were presented with four additional novel objects that the children had not previously seen, so that each trial would present children with a different combination and it would not appear that a question was being repeated. Finally, a practice trial page included images of four known objects: a dog, a plane, a duck and a chair.

Procedure. Each child was tested individually in a children's lab at the university. During the reading phase, the experimenter sat opposite the child and held the storybook upright, to her side, with the pages facing the child, like a preschool teacher would when reading to a group of children during "circle time." The parent sat on a seat in a different corner of the room. All children were read each of the three stories. For each child all three stories were presented in the same format (e.g., two illustrations per spread). No dialogic techniques, such as giving definitions for novel words or pointing, were used during the readings. Story-order was counterbalanced across children.

After reading the final story, the experimenter proceeded to the test phase, which began with four warm-up trials to get the child used to pointing to pictures in the test booklet and to ensure the child understood the task. The experimenter opened the test booklet to one of the warm-up trial pages and asked the child to point to one of the familiar objects (e.g., "can you point to the plane?"). Across the four counterbalanced warm-up trials, children were asked to point to an object in each quadrant of the page. Next, the experimenter tested word learning. On each trial the experimenter turned to a different test page and asked the child to point to one of the novel objects. In total children were asked to point to each target novel object twice (see also Werchan \& Gómez, 2014). On half of the trials one target was present (e.g., sprock with three other novel objects) and on half of the trials both targets were present (e.g., sprock and tannin with two other novel objects). These latter trials ensured that children were not simply choosing the correct object because it had been the only one they had previously seen (for a review of this issue see (Axelsson \& Horst, 2013). Trial order, page and quadrant were counterbalanced across participants.

To confirm that children do not dislike books with only one illustration per page, we also asked children to rate their enjoyment of the individual stories and found no differences in enjoyment across stories or conditions, therefore for brevity these data are not included here but are available from the authors upon request.

## Results

Children in the one illustrations condition $(M=0.75, S D=$ $0.34, t(11)=5.14, p<.001, d=1.48$ ) and in the control (one large) condition ( $M=0.75, S D=0.30, t(11)=5.75, p<$ $.001, d=1.66$ ), chose the target object more than expected by chance (.25) see Figure 2, Left Panel. However, with Bonferroni's correction ( $p=.017$ ), children in the two illustrations condition did not chose the target object more than expected by chance $(M=0.44, S D=0.28, t(11)=2.28$, $p=.04, d=.66$ ). To test for differences between illustration formats, children's proportions of correct choices were entered into an ANOVA with illustration format (two, one, one large) as between-subjects factor. The ANOVA yielded a main effect of illustration format, $F(2,33)=4.10, p=.03$, partial $\eta^{2}=0.20$. Planned contrasts showed that children who saw two illustrations learned fewer words than children
who saw one illustration per spread, $t(33)=2.87, p=.007$, partial $\eta^{2}=0.20$. There was no difference in word learning between one illustration in A4 or one illustration in A3 $t(33)$ $=0.00$, ns. Thus, illustration size did not affect word learning, but the number of illustrations did.

Figure 2. Proportion of correct word learning trials for Experiment 1 (left) and Experiment 2 (right). Error bars represent +1 SEM.

## Discussion

Many illustrated storybooks are printed with two illustrations per spread (e.g., In the Night Kitchen by Maurice Sendak or Dinosaur Roar! By Paul and Henrietta Stickland)—if not more (e.g., The Incredible Book Eating Boy by Oliver Jeffers contains 6 illustrations on pages 7-8). Further, some books include a combination of one or more illustrations per spread (e.g., The Smartest Giant in Town by Julia Donaldson). Our goal is not to suggest that all of these books be reprinted. Therefore, we conducted a supplementary experiment to provide children with additional support so that they can learn from storybooks with multiple illustrations.

Because young children do not necessarily know when the text is referring to the left- or right-hand page, they may benefit from a non-verbal gesture to look to the correct page. Specifically, a non-verbal signal may help children to focus on the correct illustration at the correct time, thus improving their chances of learning new words from the storybook (cf. Booth, McGregor, \& Rohlfing, 2008).

Thus, in Experiment 2 we again read children storybooks with two illustrations per spread, but included a quick sweeping hand gesture to indicate which page we were reading from. We chose a sweeping gesture over other possible techniques to keep the manipulation visual without additional auditory information. We did not use a pointing gesture because we wanted to perform the same gesture on every page and some pages did not include a novel object, while others included both novel objects. Thus, this
sweeping gesture allowed us to maintain an incidental word learning task, rather than providing ostensive reference. If storybooks with one illustrated scene per spread are more helpful than storybooks with two illustrated scenes because children do not know which page to look at, then guiding them towards the correct page should improve word learning to similar levels as those from single illustration displays.

## Experiment 2

## Method

Participants An additional twelve 3.5 -year-old children ( $M$ $=40.45$ months, $S D=1.30$ months, range $=38.45$ to 45.03 months, 6 girls) participated. Children were monolingual, British-English speakers with no reported speech or language difficulties. Two mothers had completed high school (GCSE's and/or A-levels), seven had an undergraduate degree or an undergraduate degree with a postgraduate certificate. One mother had completed a Master's degree, one a doctoral degree and one declined to provide this information. Parents were reimbursed for travel costs and children chose a small gift as a thank you for participating (e.g., a colouring book).

Stimuli. The same stimuli were used as in the two illustrations condition in Experiment 1.

## Procedure

All children were read the three storybooks with two illustrations per spread. The procedure was the same as in Experiment 1 except that before reading each page, the experimenter smoothly swept her open hand from the top of the page to the bottom, thereby drawing children's attention to the correct page.

## Results

Children learned the words from the story (see Figure 2, Right Panel). Specifically, children chose the target object more than expected by chance $(M=0.88, S D=0.17, t(11)=$ 12.84, $p<.001, d=3.71$ ). Our goal was to determine whether adding a simple gesture would be sufficient to improve children's word learning from storybooks with two illustrations per spread. Thus, we compared the word learning performance of children in the current study to children in the two illustrations condition of Experiment 1. Children who had the additional support to guide their attention to the correct page learned words significantly better than children who did not have that support, $t(22)=$ $4.58, p<.001, d=8.78$.

## Discussion

In Experiment 2 we investigated whether orienting children's attention to the correct storybook page with a simple gesture while reading could diminish the effects of cognitive load from multiple illustrated scenes found in Experiment 1. Adding the gesture did not significantly
increase the amount of time needed to read the story, but did significantly improve children's word learning compared to reading without a guiding gesture.

The rates of word learning observed in Experiment 2 are similar to other studies using dialogic reading techniques, such as pointing or asking questions (Walsh \& Blewitt, 2006). For example, Ard and Beverly (2004) read storybooks to 3 - and 4 -year-old children either verbatim or with one of three dialogic techniques; added questions, added comments, or both questions and comments. Children learned approximately $75 \%$ of the new vocabulary with the dialogic reading techniques included but only $53 \%$ with verbatim readings. Although the efficacy of the use of dialogic techniques to improve children's word learning from storybooks is not in doubt, multiple dialogic techniques are often employed in combination, making it harder to compare effects across the literature for individual techniques (see Wasik, Hindman, \& Snell, 2016 for a recent review). It is therefore particularly exciting to see that such a simple gesture could have such powerful effects on children's learning.

## General Discussion

Across two experiments we investigated whether decreasing the number of storybook illustrations presented simultaneously increases preschool children's ability to learn words from shared storybook reading. In Experiment 1 we read children 10-page stories with either one, two, or one large illustration per spread. Children learned the new words better when presented with only one illustration per spread, regardless of the image size, even though all children saw the same number of illustrations overall. In Experiment 2 we read children the same stories with two illustrations per spread, but added a small sweeping gesture to indicate which page we were reading. Although children in this condition were presented with multiple illustrations at once, they were able to learn more words than expected by chance and more words than children presented with the same number of illustrations but no guidance on which page to attend to. Taken together these findings suggest that children's word learning is improved by helping children focus on the relevant information by either reducing the number of illustrations presented (Experiment 1) or directing their attention to the correct illustration (Experiment 2).

These findings are consistent with cognitive load theory (Paas et al., 2003; Sweller, 1988, 1989), which suggests that extraneous information can prevent optimal learning. The more information children need to think about, the more challenging the task. Consequently, removing extraneous perceptual information may improve learning (see, e.g., Son et al., 2008). For example, kindergarten children are better able to learn information from science lessons when the extraneous information of a highly-decorated classroom is removed (Fisher, Godwin, \& Seltman, 2014). Similarly, reducing the amount of extraneous information in graphs improves children's mathematics skills (Kaminski \&

Sloutsky, 2013) and removing extraneous information in ABC books improves alphabet learning (Chiong \& DeLoache, 2012). In the current study, in the two illustrations format, children are faced with processing additional materials-which in some cases may even provide conflicting information-slowing down the process of word learning. Children do not know when the story moves from one illustration to the other. In contrast, in the one illustration format, the child is provided with only the relevant scene, which corresponds with the text they are currently hearing, thereby reducing the cognitive load associated with understanding the story and the new words. Similarly in Experiment 2, children are directed towards the relevant scene, thereby reducing cognitive load.

Although children in the current studies learned target words better when presented with single illustrations, there may be benefits for other types of learning from multiple illustrations. For example, story comprehension may be better supported by having more to look at, particularly as visual attention to illustrations during storybook reading predicts story comprehension (Kaefer, Pinkham, \& Neuman, 2016).

The current findings may also be informative for research comparing e-books (i.e., storybooks presented on screens) with traditional two-illustration paper storybooks. Some studies report a deficit in learning from e-books (e.g., Segers, Takke, \& Verhoeven, 2004) while others do not (e.g., Korat \& Shamir, 2007). One explanation for this discrepancy is that e-books often contain added manipulative features, which may hinder learning. For example, e-books often contain additional games (e.g., de Jong \& Bus, 2002) or interactive dictionary features (e.g., Korat, 2009). Previous research indicates that added manipulative features such as pull-tabs hinder learning from paper books (Tare et al., 2010), however some features of ebooks may be helpful in the same way as dialogic techniques by highlighting key information at the right time. Another explanation is that e-books are often presented only one illustration at a time (e.g., Verhallen \& Bus, 2011), which could be an additional confounding factor when comparing between storybook media types. The current findings suggest that such single illustrations help children focus their attention on relevant information and may aid learning especially when children are exploring books without an adult.

The current experiments demonstrate that reducing the number of simultaneous illustrations to just one at a time improves children's word learning from shared storybook reading. This has important implications for educational research and suggests that even seemingly minor differences in illustration format can result in significant differences in how well children learn. These findings should help shape future storybook research design, and provide useful practical solutions, which could be used by teachers and parents alike and may inform our understanding of how to create eBooks and other media that children may encounter without an adult. Furthermore, in an age of seemingly
endless possibilities, they provide a stark reminder that less is sometimes more.

#### Abstract

Some studies hypothesize a strong interdependence between speech and tool use development in the first two years of life. To help understand the underlying mechanisms, we present the first robotic model learning both speech and tool use from scratch. It focuses on the role of one important form of body babbling where exploration is directed towards self-generated goals in free play, combined with imitation learning of a contingent caregiver. This model does not assume capabilities for complex sequencing and combinatorial planning which are often considered necessary for tool use. Yet, we show that the mechanisms in this model allow a learner to progressively discover how to grab objects with the hand, how to use objects as tools to reach further objects, how to produce vocal sounds, and how to leverage these vocal sounds to use a caregiver as a social tool to retrieve objects. Also, the discovery that certain sounds can be used as a social tool further guides vocal learning. This model predicts that the grounded exploration of objects in a social interaction scenario should accelerate infant vocal learning of accurate sounds for these objects' names.

Keywords: tool use; speech development; free play; exploration; imitation learning; social tool use; goal babbling

## Introduction

Some studies hypothesize that there might be a strong interdependence between speech and tool use development in the first two years of life (Gibson, Gibson, \& Ingold, 1994). Tool use and language seems to require similar information processing capabilities allowing the production and perception of sequential combinations of increasing complexity, from reaching to spoon self-feeding and from words to stories. In addition to showing similar compositional properties, speech and tool use might share some neural correlates involving Broca's area (Higuchi, Chaminade, Imamizu, \& Kawato, 2009). Those common neural correlates could have an evolutionary origin in the hominid lineage, where a selection pressure for complex tool use, language and social behaviors might have together driven the increase in brain planning capabilities (Morgan et al., 2015). In particular, the development of tool use precursors follows several overlapping phases of behaviors: 1) body babbling, where babies learn to control their body parts, 2) interacting with a single object, and 3) exploring object-object interactions (Guerin, Kruger, \& Kraft, 2013). From pointing movements to the control of a rake, new representations and physical understanding are developed to allow the planning of tool use actions composed of combinations of more simple actions, e.g. grasping the rake. During the same period, infants progressively learn how to efficiently use their vocal tract, comprising many complex actuators from the larynx to the lips. At birth, they produce immature protophones like squeals, growls or quasi-vowels, and by the end of their first year they are able to produce the speech-like syllables of their native language (Oller, 2014). Those syllables then form words which become the basis
of syntactic combinations essential to language expressiveness. Infants do not only explore tool use and vocalizations by themselves, driven by intrinsic motivations (Moulin-Frier, Nguyen, \& Oudeyer, 2013), but also spend a great part of their time interacting with their parents and other social peers where imitation is thought to be one of the important developmental pathways (Meltzoff, 1999). For instance, infants imitate the vowels produced by an adult speaker by 6 month of age (Kuhl, 2004), and 1.5-year-olds imitate demonstrations of a rake-like tool function to retrieve an out-of-reach toy (Chen \& Siegler, 2000).

In order to investigate hypotheses about the joint development of speech and tool use, we seek to build an embodied model of tool use and speech learning. Existing robotic models of tool use showed first insights into how relations between tools and other objects could be learned from grounded experimentation. In (Stoytchev, 2005), a robotic arm focused on learning rake-like tool affordances from the exploration of already implemented stereotyped arm behaviors. In (Tikhanoff, Pattacini, Natale, \& Metta, 2013), the iCub robot was given its arm's forward model and inverse optimization methods which led to stereotyped grasping. A recent series of robotic models considered the learning of tool use from scratch, without any kind of pre-programmed reaching skills (Forestier \& Oudeyer, 2016a, 2016b, 2016c). Those models studied the developmental progression of robotic agents between phases of behaviors with objects, and the evolution of their strategies to reach goals. They have shown interesting similarities with infant development in terms of developmental trajectories and strategy choice dynamics.

Recent computational models of vocal development make use of a simulated vocal synthesizer that the learning agent must control in order to produce vocalizations, with human sounds as targets to be imitated (Warlaumont, Westermann, Buder, \& Oller, 2013; Philippsen, Reinhart, \& Wrede, 2014). In (Moulin-Frier et al., 2013), the agent chooses the strategy that shows the best competence progress: either autonomously training to reach phonetic goals, or trying to imitate human sounds. They show that the intrinsic motivation for learning progress self-organizes coherent infant-like developmental sequences. Those models of language acquisition study several developmental pathways to the learning of forward and inverse models of a simulated vocal tract, from autonomous exploration to human sounds imitation. However, agents are not situated into a physical environment where vocalizations have a meaning related to objects.

Several works study joint action and language learning (Cangelosi et al., 2010), but give an advanced knowledge of the linguistic interaction protocol to the learning agent who has to associate predefined actions or objects to predefined
labels and learn the semantic compositionality. Also, agents learn actions without a nested tool use property.

In this paper we describe the first model that jointly considers the early development of both tool use and speech. Such a model could allow the investigation of hypotheses about the mechanisms underlying the observed links between tool use and speech development. In a previous work, we showed that the Model Babbling learning architecture (Forestier \& Oudeyer, 2016b) allows the development of tool use in a robotic setup, through several fundamental ideas. First, goal babbling is a powerful form of exploration to produce a diversity of effects by self-generating goals in a task space (Baranes \& Oudeyer, 2013). Second, the possible movements of each object define a task space in which to choose goals, and the different task spaces form an object-based representation that facilitates prediction and generalization, as explained by (Chang, Ullman, Torralba, \& Tenenbaum, 2016). Also, cross-learning between tasks updates all skills while exploring one in particular. A novel insight was that early development of tool use could happen without a combinatorial action planning mechanism: modular goal babbling in itself allowed the emergence of nested tool use behaviors.

Here we extend this architecture so that the agent can imitate caregiver's sounds in addition to autonomously exploring. We hypothesize that these same algorithmic ingredients allow a joint unified development of speech and tool use. Our learning agent is situated in a simulated environment where a vocal tract and a robotic arm are to be explored with the help of a caregiver. The environment is composed of three toys, one stick that can be used as a tool to move toys, and a caregiver moving around. The caregiver helps in two ways. If the agent touches a toy, the caregiver produces this toy's name, but otherwise produces a distractor word as if it was talking to another adult. If the agent produces a sound close to a toy's name, the caregiver moves this toy within agent reach.

We show that our learning architecture based on Model Babbling allows agents to learn how to 1) use the robotic arm to grab a toy or a stick, 2) use the stick as a tool to get a toy, 3) learn to produce toy names with the vocal tract, 4) use these vocal skills to get the caregiver to bring a specific toy within reach, and 5) choose the most relevant of those strategies to retrieve a toy that can be out-of-reach. Also, the grounded exploration of toys accelerates the learning of the production of accurate sounds for toy names once the caregiver is able to recognize them and react by bringing them within reach, with respect to distractor sounds without any meaning in the environment. Our model is the first to allow the study of the early development of tool use and speech in a unified framework.

## Methods

## Learning Environment

The learning environment ${ }^{1}$ is composed of a simulated 2D robotic arm and a simulated vocal tract that the agent controls

[^328]to interact with a caregiver and toys. In each trial, the agent observes the current environmental state and then executes a motor trajectory, either corresponding to moving the motors of the arm or of the vocal tract, and gets the associated sensory feedback composed of the trajectory of each object and the sound produced by the agent or the caregiver (see Fig.1).

Simulated Robotic Arm The simulated 2D robotic arm has 3 joints, with its base fixed at position $[0,0]$. Each joint rotates from $-\pi \mathrm{rad}$ to $\pi \mathrm{rad}$ and the 3 segments of the arm have length $0.25,0.15$ and 0.1 , so the arm has length 0.5 . The framework of Dynamical Movement Primitives (Ijspeert, Nakanishi, Hoffmann, Pastor, \& Schaal, 2013) is used to generate smooth joint trajectories from motor parameters. Each of the 3 joints is controlled by a DMP starting at the rest position of the joint (position 0 ) and parameterized by 7 weights: one weight on each of 6 basis functions and one weight representing the end position of the joint trajectory. To sum up, the agent provides a set of 21 trajectory parameters which are translated through DMPs to a set of smooth 50-steps trajectories for the arm's joints which gives a smooth 2D trajectory to the robotic hand.

Tool and Toys In the environment of the robotic arm, 3 toys can be grasped with the hand or with the help of a stick. The stick has length 0.25 and is considered grasped as soon as the hand reaches the handle side (orange) within a distance of 0.1 . At the end of the movement the stick is dropped and stays at its current position while the arm is reset to its rest position for the next iteration. The toys are reset to a random location every 20 iterations, at a distance between 0 and 1 from the center so possibly at an unreachable position.

Simulated Vocal tract A vocal tract is simulated through the DIVA model (Guenther, 2006) and allows the production of different sounds that we can classify into vowels. In the DIVA model, a set of parameters defines a vocal tract contour where each represents one component of a Principal Component Analysis of midsagittal MRI vocal tract profiles (see Fig.1b), from the jaw and tongue to the lips position. Here we use only the first 7 articulatory parameters, controlling most of the vocal tract shape's variability. From a vocal tract contour defined by a set of parameters, the DIVA software computes the corresponding sound and outputs its first 2 formants, which are often considered to give enough information to distinguish common English vowels. The DMP framework generates smooth trajectories of vocal parameters, as described above for arm parameters, to allow the simulated vocal tract to produce simple words composed of several vowels. Each of the 7 articulators is controlled by a DMP parameterized by 4 weights: the starting and end position of the parameter trajectory, and weights on 2 basis functions. Given a set of 28 trajectory parameters provided by a learning agent, the DMPs output a set of smooth 50 -steps trajectories for the 7 articulators that we use in the DIVA model, which through the DIVA software generates a smooth trajectory of the first two formants (called $F 1$ and $F 2$ ).

Figure 1: Agent's robotic and vocal environment. (a) Agent's 3 DOF arm, controlled with 21 parameters, grabs toys with its hand, or uses the stick to reach toys. Caregiver brings a toy within reach if the agent says its name. (b) Agent's vocal environment representing sounds as trajectories in the two first formants space. Agent's simulated vocal tract produces sounds given 28 parameters. When agent touches a toy, caregiver says toy's name. Some sounds corresponding to random parameters are plotted in red, and some sounds produced when imitating caregiver's /uye/ word in blue (best imitation in bold, error 0.3).

Sounds: from Vowels to Words The simulated vocal tract controlled through DMPs has the potential to produce words composed of a sequence of 3 vowels in the set $\{/ \mathrm{o} /, / \mathrm{u} /, / \mathrm{i} /$, $/ \mathrm{e} /, / \mathrm{y} /\}$. See Fig. 1 (b), "Motor babbling" condition, for an example of 200 trajectories corresponding to random sets of 28 parameters. We define a set of 6 words that the caregiver produces perfectly: $\{/ \mathrm{yeo} /$, /euy/, /iuo/, /uye/, /eou/, /oey/\}. A sound trajectory produced by the vocal tract is recognized if its distance to the perfect word is lower than 0.4.

Caregiver's guidance A simulated caregiver is given two roles to help the learning agent. First, at the beginning of the experiment, the caregiver chooses randomly a label for each toy from the set of 6 words. When the agent touches a particular toy with its hand, the caregiver then produces the sound trajectory corresponding to the label of this toy. If the agent does not touch any toy with the arm, the caregiver produces one of the distractor sounds, as if she was talking to another adult. Second, if the agent produces a sound trajectory recognized by the caregiver as the label of a toy, the caregiver moves the corresponding toy in between herself and the agent so that it becomes reachable by the agent with the hand. The caregiver is reset to a random position at each iteration.

Sensory Feedback Before choosing a motor command, the agent receives the state of the environment (or context) as the 2 D position of the caregiver, the stick and the 3 toys (so 10D). At the end of the movement, the agent receives a sensory feedback $s$ in the sensory space $S$ (60D), from the different objects in the environment. First, the trajectory of the hand is represented as its $x$ and $y$ positions at 5 time points: steps 1 , $13,25,38,50$ of the 50 -steps trajectory ( $S_{\text {Hand }}, 10 \mathrm{D}$ ). Similarly, the trajectories of the stick and the 3 toys during the movement are represented in 10 dimensional sensory spaces
( $S_{S t i c k}, S_{T o y_{1}}, S_{T o y_{2}}, S_{T o y_{3}}, 10 \mathrm{D}$ each). Sound, either produced by the agent or by the caregiver, is represented by the position of the first two formants at 5 time points ( $S_{\text {Sound }}, 10 \mathrm{D}$ ).

## Unified Modular Learning Architecture

The goal of a learning agent is to use its robotic arm and vocal tract to discover a diversity of sensory effects, and collect data to learn repertoires of skills in the form of inverse models allowing to reproduce these effects. Consequently, the agent is not given a priori a single target task to be solved, but a modular object-based representation of task spaces. The agent learns a set of sensorimotor models mapping a motor space to one particular sensory space (see Fig. 2). For instance, model 1 learns to move the hand from arm parameters, model 2 learns to move the stick, model 3,4 , and 5 learn to move one of the toys, and model 6 how to produce sounds with the arm, which will be possible by touching one of the toys with the hand so that the caregiver produces the corresponding label. Controlling vocal tract, model 7, 8 and 9 learn to move one of the toys by involving caregiver's help, and model 10 learns to produce diverse sounds autonomously.

Exploration through Model Babbling In order to actively explore and learn the 10 sensorimotor models from experimentation with the environment, learning agents use the Model Babbling architecture developed in (Forestier \& Oudeyer, 2016b) that we extend to handle the 2 motor spaces: the robotic arm and the vocal tract. First, the agent performs some random exploration of motor spaces, 500 with the robotic arm and 500 with the vocal tract, to get an initial sampling of those spaces. Then, at each iteration, the learning agent first chooses to train one of the 10 models, chosen randomly (e.g. from the robotic arm to the hand sensory space). A particular goal is then randomly chosen in

Figure 2: Learning Architecture. Agent controls 2 motor spaces and receives sensory feedback about 6 objects. Each arrow represents one of the 10 sensorimotor models learned.
the sensory space corresponding to the chosen model (e.g. a particular 2D trajectory of the hand). The agent then uses the corresponding inverse model to infer a motor command in the corresponding motor space (e.g. arm parameters) to reach the goal. Exploration happens in goal choice and in the new motor parameters that inverse models infer with generalization mechanisms and adding exploration noise.

Imitation of Sounds When the agent is choosing to train to produce sounds with its vocal tract (model 10), instead of always choosing random goals, it does this for half of the iterations (chosen randomly), and the other iterations are focused on trying to imitate the caregiver, by randomly choosing one of the sounds previously produced by the caregiver as a goal.

Forward and Inverse Models Each sensorimotor model provides a forward model and an inverse model, with the same implementation as in (Forestier \& Oudeyer, 2016b). The forward model predicts which sensory trajectory would be observed given the current context and a motor command to execute. The inverse model infers a motor command that could reach a desired goal given the current context. When a motor command $m$ is executed (either 21 parameters for the robotic arm or 28 for the vocal tract) in a context $c$ and a sensory feedback $s$ is received in $S$, all the sensorimotor models that share the same motor space are updated. New information comes as a tuple ( $m, c_{i}, s_{i}$ ) with $s_{i}$ being a subset of $s$ variables corresponding to the respective sensory space, and $c_{i}$ being the subset of $c$ relevant for this sensorimotor model. The relevant context for models 1 and 10 is empty, which means that hand trajectories and vocal sounds produced by the agent do not depend on the current position of other objects. The context for model 2 is the position of the stick, and for models 3,4 , and 5 , the position of the stick and of the corresponding toy. For model 6 , all toys are relevant, and for models 7, 8 and 9, the caregiver and the toy is useful. Given a database of ( $m, c_{i}, s_{i}$ ) experiments, an inverse model infers a probable motor command $m$ to reach a goal $s_{g}$ in a context $c_{i}$ by looking for the nearest neighbor $s_{N N}$ in $S_{i}$ of $s_{g}$ and retrieving the associated motor parameters $m_{N N}$ that were used to reach $s_{N N}$. It then outputs $m_{N N}$ plus Gaussian noise ( $\sigma=0.05$ ) to explore new parameters.

## Results

We ran 500 independent trials of 80000 iterations (or robot experiment) each. We measured how agents learned to move objects by giving them new goals in new contexts, and we analyzed the accuracy of the learned vocalizations.

## Competence to Reach Toys

After 80000 iterations of training, we measured the performance of each agent to retrieve a toy depending on its current position with its preferred method: with the hand, with the stick used as a tool or involving caregiver's help. Fig. 3 shows the mean competence of all agents to retrieve toys depending on the current position of the toys. The competence error to retrieve a toy is measured by the distance between a goal trajectory given to the agent, where the toy is moved towards the center, and the actual trajectory that the agent succeeds to give to the toy. The agent chooses the strategy expected by its inverse models to best reach the goal trajectory for the toy given the current context (position of the stick, toys and caregiver) and its past experience of 80000 iterations.

In most toy locations, the normalized competence of learning agents is significantly better ( $46 \%$ on average) than the normalized competence of a random agent ( $0 \%$ ). Our learning architecture thus allows to successfully reach new goals in multiple sensory spaces with multiple available strategies. Local variations reflects differences in strategy preferences and performances. For instance, where the hand cannot reach for the toy anymore, the agent still thinks this is a good strategy as it worked in a similar context (before the limit), but the hand strategy leads there to a bad performance. More training would refine the inverse models and the choice of strategy.

Figure 3: Competence after 80000 iterations. $0 \%$ means that competence to retrieve a toy there is as bad as with random agents, $100 \%$ says that agents perfectly retrieve a toy there.

## Three Strategies to Reach Toys

Fig. 4 shows the preference for the hand, tool and vocal strategies to retrieve a toy depending on the distance of the toy. In the center region, where agents can retrieve toys with all three strategies, agents choose most often the hand strategy (around $65 \%$ of the trials) and less the other two (around $15 \%$ to $20 \%$ each). In the second region, unreachable with
the hand, this strategy is still used around $50 \%$ of the trials, and the two other between $20 \%$ and $30 \%$. In the last region where the only useful strategy is to say the name of the toy so that the caregiver brings it closer, the vocal strategy is used more often: at distance 1 from center, it is used in $49 \%$ of trials, hand strategy in $38 \%$, and tool strategy in $13 \%$.

Figure 4: Strategy preferences depending on the distance of the toy. The two vertical bars shows the hand and stick limits.

## Vocal Learning with Caregiver's Feedback

The agents learn to produce vocalizations both with goal babbling and imitation of the caregivers' sounds. For each agent, three of caregiver's sounds (randomly selected) are toy names and the three others are distractors: sounds that have no special meaning for the agent. We measure errors to reproduce caregiver's sounds as the distance between the sound trajectory produced by the caregiver and the best imitation of the agent. We group the results into two categories: errors of sounds that serve as toy names and as distractors. From the 500 runs we could retrieve error data for 1482 toy names and 1482 distractors. Fig. 5 shows the distribution of errors after 80000 iterations. First, $88 \%$ of sounds have an error lower than 0.4 , and thus are successful imitations. Second, the median error for toy names is 0.23 and for distractors is 0.30 . Imitations of toy names are more accurate than of distractors: a Mann-Whitney U test gives $p<10^{-72}$. Errors distribution above 0.4 is similar for the two categories, but few toy name sounds have an error just below 0.4 compared to distractors: their distribution is shifted towards smaller errors.

## Discussion

This unified robotic model allows to study the interaction between the early development of tool use and speech. Results show that agents learn to 1) use the robotic arm to grab a toy or a stick, 2) use the stick as a tool to get a toy, 3) learn to produce toy names with the vocal tract, 4) use these vocal skills to get the caregiver to bring a specific toy within reach, and 5) choose the most relevant of those strategies to retrieve a toy, for instance preferring to use caregiver's help when the toy is out-of-reach. Interestingly, learning the production of accurate sounds for toy names was faster than for distractor sounds because inverse models often select the use of vocal-

Figure 5: Distribution of accuracy of imitations of caregivers' sounds after 80000 iterations. Below 0.4 vocal error, sounds are recognized as imitations by the caregiver. Imitations of toy names are more accurate than imitations of distractors.
izations to retrieve toys through the caregiver. Grounding vocal interaction between agent and caregiver in a play scenario thus accelerated the learning of toys' names production.

The proposed unified Model Babbling architecture does not integrate sequencing and combinatorial planning mechanisms and agents were not given initial teleological understanding of speech or tool use. However, with goal babbling and an object-based representation of task spaces, our architecture still allowed agents to learn behaviors showing a nested tool use structure, e.g. reusing movements of the stick to move a toy, or sound trajectories produced with the vocal tract so that the caregiver brings a toy. This suggests that observing infants using tools or asking for help with toys should not necessarily be interpreted as a correlate of capabilities for combinatorial sequencing and planning of actions.

It should be noted that for the agents in our model, involving the caregiver to move toys through vocalizations is a strategy with no special status with respect to the other strategies. This social interaction emerges from the same drive to refine sensorimotor models as in the learning of hand or stick movements. The production of sounds that can be understood by the caregiver as toy names to make it react and help can thus be interpreted as an emergent form of social tool use.

Those results offer a new prediction: exploration and play with objects in a grounded interaction scenario with a caregiver accelerates infant vocal learning of accurate sounds for the names associated to these objects. This hypothesis is consistent with experimental data from infant development research. First, (Clerkin, Hart, Rehg, Yu, \& Smith, 2017) shows that the objects that are frequent in the visual field of $81 / 2$ to $101 / 2$ mouth-old infants are also the objects for which infants acquire the name early. They explain that the particular distribution of object frequency in visual field can help linking the heard label to the good object in a scenario where the caregiver says the name of an object. However, this data is also consistent with our hypothesis: the most frequent objects in the visual field are the ones that the infant will most often choose goals for, and will engage caregiver's help by trying to
vocalize those toys' names. Infants could thus receive more vocal feedback for those words and learn to produce them earlier. This view also fits with recent data about the bodyobject interaction measure. In (Thill \& Twomey, 2016), the authors use a measure of the extent to which adults could easily interact with a named item and show that it predicts better the age of acquisition of the name of an item than its concreteness or imageability. In other words, the easier the interaction with an object is, the sooner its name will be acquired. Furthermore, caregiver's nonvocal feedback can also help vocal learning. Indeed, (Goldstein, King, \& West, 2003) provides evidence that a nonvocal feedback mechanism such as reacting to infant's vocalizations by smiling, or touching the infant can shape vocal babbling in real time. In our experiment, the caregiver reacts to a toy's name by giving the toy to the agent, which guides vocal learning. Such a mechanism could also be an important pathways to infant vocal development.

Our unified robotic model of speech and tool use gives a basis for future research in modeling interactions between their early development. From this study, we derived experimental predictions that could drive new experiments with infants and allow us to test and refine the model.

# What counts as math? <br> Relating conceptions of math with anxiety about math 

Ruthe Foushee (foushee@berkeley.edu)<br>Rachel Jansen (racheljansen@berkeley.edu)<br>Mahesh Srinivasan (srinivasan@berkeley.edu)<br>Department of Psychology, University of California, Berkeley<br>Berkeley, CA 94704

#### Abstract

What do people think of when they think of "math?" We propose that individuals may have very different working definitions of the category of math, and that those with broader math conceptions may have less math anxiety. In Study 1, we introduce a method for indexing the "breadth" of individuals' math conceptions, and show that there is an inverse relation between conception breadth and math anxiety. These results suggest that math anxiety is related both to how expansive individuals perceive math to be, and how skillful they feel at the activities they think it could involve. Study 2 attempts an intervention on students' conceptions of math with a sample of middle school students. We find the same inverse relationship in students between math conception breadth and math anxiety as found in adults. We discuss ongoing work that further explores qualitative variation in math conceptions, and the lessons this may hold for intervening on math anxiety.

Keywords: math anxiety, conceptual structure, intervention

## Introduction

Recent U.S. initiatives in early science, technology, engineering, and math (STEM) highlight the growing importance of STEM education (e.g., White House Press Briefing, 2016), as well as the need for professionals in those fields to better represent the population. However, multiple barriers to an educated and diverse STEM workforce remain. One such barrier is psychological: an estimated $25-50 \%$ of U.S. college students are math anxious (Jones, 2001; Yeager, 2012), with women disproportionately affected (Hembree, 1990). Math anxiety refers to the tension or fear associated with the prospect of doing math (Ashcraft, 2002). In addition to being associated with lower math performance, math anxiety causes math-anxious individuals to generally avoid math. Given the national goal of broadening STEM participation, math avoidance might be the most devastating byproduct of anxiety about math, as it implies that math-anxious individuals will choose to end their formal math training as soon as possible.

Here, we are interested in how individuals' ideas of what math is-i.e., their math conceptions-might be a factor in their math anxiety and avoidance. "Math" can be used to refer to a wide range of activities, involving diverse skill sets and forms of reasoning. Individuals may differ in how they implicitly define the category of math, however, and properties of those definitions may be linked to their math anxiety.

Of particular interest in the present studies is what we will call the "breadth" of an individual's math conception. Guided by the idea that category structures can differentially license inferences (e.g., Ross \& Murphy, 1999), our studies test the
hypothesis that having a working math conception that is narrow (i.e., limited to a few branches of the math taxonomy, like arithmetic operations and numeric notation) might facilitate generalization of negative associations across the category. If this makes individuals confident about disliking math, rather than disliking only arithmetic or algebra, it could make them wary of future topics labeled as "math" that might have otherwise been appealing. In contrast, anxiety about the math category, and any new topics that are labeled as "math," might be harder to maintain if it encompasses many diverse subtopics and skills, ranging from the concrete (e.g., algebraic notation) to the abstract (thinking about infinity). In other words, insofar as math anxiety consists of anxiety generalized across the category of things construed as math, having a "broad" math conception may serve as a protective factor against the propagation of math anxiety.

As a first test of these ideas, we explore whether adults and children have different conceptions of what counts as math, and whether individuals with broader math conceptions may be less susceptible to math anxiety, such that math conception breadth and math anxiety will be inversely related.

## Origins of Math Anxiety

The origins of math anxiety are unclear. While research on math anxiety is motivated in large part by its impact on math performance, there is evidence suggesting the reverse direction of causation, as well. Much of this evidence comes from longitudinal studies where performance in an earlier year is more strongly correlated with math anxiety in a later year than earlier anxiety is with later performance (see Carey, Hill, Devine, \& Szücs, 2016, for a review). The relation between math anxiety and performance might be most accurately described as reciprocal, with early math difficulty leading to math anxiety, and math anxiety in turn leading to low performance, via avoidant behavior and increased constraints on processing (Carey et al., 2016).

In thinking about the relation between math conception and anxiety, we have thus far focused on a particular direction of causality, namely that narrow math conceptions might be a risk factor for developing math anxiety. But one could imagine a reciprocal relationship here, too. A child could acquire a math conception that is narrow, maybe via their early schooling, and find that they dislike or struggle with the contents of the category of math, leading them to become math anxious. Their math anxiety could in turn lead them to avoid engaging with new aspects of math that they might otherwise like or ex-
cel at, leading them to maintain both their narrow conception of math and their math anxiety.

In light of recent findings that math anxiety can be transmitted between generations, it is just as important to alleviate math anxiety in adults (i.e., so that they don't transmit it to children) as it is to intervene directly in children. Prior work has found that teachers' math anxiety may "spread" to their students (Beilock, Gunderson, Ramirez, \& Levine, 2010). This is especially problematic because aspiring teachers with math anxiety tend to gravitate toward teaching earlier grades, where they will be able to engage less with math (see Hadley \& Dorward, 2011), but where they will also be interacting with students in the early school years, when children are most impressionable. Parents' math anxiety can also affect their children. In one study, children of math anxious parents learned less during the school year than did children of non-math-anxious parents-but only if these parents frequently gave their children homework help (Maloney, Ramirez, Gunderson, Levine, \& Beilock, 2015). Given this evidence for the intergenerational transmission of math anxiety, our studies focus both on adults and children.

## Relating Math Conceptions and Math Anxiety

In principle, individuals could have 'math conceptions' that range from narrow (Math is the symbolic operations one learns in school) to broad (Math relies on logic, spatial reasoning, and pattern recognition).

Here, we develop a new measure to characterize the breadth of math conceptions. This measure presents participants with a diverse list of activities or topics, ranging from "sewing" to "playing soccer" or "physics." Participants are asked to indicate whether each item "could involve math," and, in some cases, to explain why. The idea is that when asked to answer whether a given activity "could involve math," individuals will be encouraged to come up with some rationale for how it could or could not involve math, and that their flexibility in categorizing activities as "math" will depend on the breadth of their (implicit) definition of the category. The point here is not that individuals typically construe an activity like "playing soccer" as involving math. Instead, our interest is in whether individuals vary in how flexible they are in categorizing activities that are not conventionally thought of as "math" as involving math. We present a diversity of activities to math, that can be related to math via diverse aspects of mathematical reasoning or subtopics, thus revealing the capacity and/or bounds of an individual's math conception. If an individual's conception of math is itself broad and diverse, we expect that it will be able to support explanations for the math-involvement of a wide range of activities. We thus operationalize breadth of math conception in the following studies as the number of activities that individuals say "could involve math." In Study 1, we also ask participants to rate their own skill at these same activities.

We hypothesize that broader math conceptions will relate to lower math anxiety in that they will afford individuals with more opportunities to recognize their own math engagement
or expertise, and dilute the negative impact of components of math that individuals have negative associations with. Related to this, we expect self-assessed skill with activities classified as involving "math" to mediate the proposed relation between conception breadth and math anxiety. Study 1 examines the relation between math conception and math anxiety in adults, taking subjective skill into account. Study 2 tests for the same relation in middle-school children, within the context of a intervention study that tests the effect of broadening math conceptions.

## Study 1: Adult Math Conception \& Anxiety

Study 1 examined the relation between math conception and math anxiety in adults via an online survey composed of seven counterbalanced blocks probing participants' math attitudes and associations.

## Stimuli \& Methods

Participants A total of 62 U.S. adults were recruited via Amazon's Mechanical Turk ( 31 female, 19-74 years, $M=$ $33.24, S D=10.25$ ). Participants were compensated for their participation, and the study took approximately 15 minutes to complete.
Math Conception In one block, participants saw a randomized list of topics and activities (e.g., "architecture," "cooking," "exercising"). Participants were asked to indicate whether. . e each activity or topic listed involves math or does not involve math. They responded by dragging each item into one of three boxes, labeled "Math," "Not Math," and "Not Sure." The more items categorized as involving math, the broader we considered their math conception to be (see above). We included the item "Math" as a control.
Activity Skill In another block, participants saw the same items in a new randomized order, and rated their skill at each item (How good would you say you are at each of these things?). They responded on a five-point Likert scale from 'Not at all good' to 'Very good.' We included a control item (For this question, respond 'Good'), as well as an opt-out scale option ('NA') for participants who had no experience with the item.
Math Anxiety We assessed participants' math anxiety using the single item math anxiety scale (SIMA; Núñez-Peña, Guilera, \& Suárez-Pellicioni, 2013). This measure asks simply, On a scale from 1 to 10, how math anxious are you? The SIMA has been validated on a large sample of U.S. college students. It shows the expected negative correlation with math achievement measures, high test-retest reliability, and is consistent with lengthier, established measures of math anxiety, like the Shortened Math Anxiety Rating Scale (sMARS; Alexander \& Martray, 1989, $r=.77$ ).
Other Measures We collected several other measures of participants' attitudes toward and history with math. One block assessed participants' "math mindset:" an analogy
to intelligence mindsets made specific to math (Yeager \& Dweck, 2012). Five items probed participants' beliefs about the fixedness of math ability (e.g., Math is a gift: you either have it or you don't.), which they responded to using a fivepoint Likert scale of agreement. Two blocks consisted of a single, open-ended question, one asking participants for an informal definition of math (Please describe what you think math is in the space below), and one eliciting their personal math history (Please write a brief summary of your experience with math from childhood until now). In the final block, we collected demographic information, including the number of semesters of college they had completed, and a list of all math classes they had taken.

## Results \& Discussion

Qualtitative Variation in Math Conceptions There was substantial variation in the activities that participants categorized as involving math (Figure 1). All participants appropriately responded that "Math" involved math, which we took as confirmation of their attention to the task. Items obviously involving math were categorized as such by the vast majority of participants (e.g., finance), while those representing related disciplines (e.g., biology), daily activities (e.g., cooking), and abstract, creative and language-related tasks (e.g., composing music, reading) received the fewest math-categorizations. In a separate study, we elicited explanations for participants' categorizations of a similar list of items. In that study, both adults and children frequently used contrast categories (e.g., "No, that's music!"), often from the humanities, to explain why items could not involve math. This type of explanation implies that participants perceived the categories of music, art, and even science as exclusive with math. Such a picture of what math is (and isn't) is consistent with the idea of a narrow math conception, and echoes what mathematician Paul Lockhart famously lamented as the sorry byproduct of American math education:

The first thing to understand is that mathematics is an art. The difference between math and the other arts, such as music and painting, is that our culture does not recognize it as such. [...] Nevertheless, the fact is that there is nothing as dreamy and poetic, nothing as radical, subversive, and psychedelic as mathematics. It is every bit as mind-blowing as cosmology or physics (mathematicians conceived of black holes long before astronomers actually found any), and allows for more freedom of expression than poetry, art, or music (which depend heavily on properties of the physical universe). Mathematics is the purest of arts as well as the most misunderstood. (Lockhart, 2009).

Math Conception \& Anxiety To answer whether breadth of math conception and math anxiety are related, we conducted a linear regression on individuals' math anxiety and the number of items they categorized as math, controlling for the number of semesters of college they had completed.

Table 1: Descriptive statistics for four blocks in Study 1. 'Items Categorized as Math' is out of a total of 32, and was analyzed as a proxy for the breadth of participants' math conceptions. 'Math Anxiety' is on a 10-point self-report scale. 'Self-Assessed Skill' represents the mean skill rating on a 5point Likert scale, across all items for all participants. 'Math Mindset' is coded to be on a 5-point scale indexing how fixed individuals believe math ability to be, with larger values indicating more fixed mindsets.

| Variable | $M$ | $S D$ |
| ---: | ---: | ---: |
| Items Categorized as Math | 13.10 | 5.35 |
| Math Anxiety | 4.44 | 3.04 |
| Self-Assessed Skill | 3.28 | 0.44 |
| Math Mindset | 2.13 | 0.99 |

In accordance with our predictions, math anxiety was negatively related to the number of items participants categorized as math, even controlling for education $(F(1,61)=6.44$ $p<.05$ with an $R^{2}$ of .082 ; see Figure 2). This supports the idea that individuals with broader math conceptions are less likely to experience math anxiety, and that this relation may not be attributable to exposure to topics in math alone.

To address whether the relation between math conception and anxiety is due in part to individuals' perception of their own skill at things they think might involve "math," we analyzed self-assessed skill and anxiety. For each individual, we took the mean skill of the items they had categorized as involving math and those they had categorized as not involving math. We dropped items for which participants reported having had no experience. A linear regression on self-reported skill and math anxiety revealed a significant negative correlation between math anxiety and mean self-assessed skill for items the individual was able to relate to math ( $\beta=-1.98$, $S E=0.60, t=-3.29, p<.01$ ), but no correlation between math anxiety and self-assessed skill for items judged to not involve math ( $\beta=0.11, S E=0.69, t=0.154, p=.88$ ). This asymmetry is important because it suggests that it is not just individuals who are less confident overall who suffer from math anxiety-if this were the case, we would have expected to find that lower skill related to higher anxiety for both items judged to involve math and items judged to not involve math.

In Study 1, both the number of items construed as involving math and participants' perceived skill at those items were related to math anxiety. As discussed above, one of the most dangerous features of math anxiety is its tendency to make individuals avoid math and thus fail to take advantage of opportunities to discover new aspects of mathematics they might excel at or appreciate. The fact that mean self-assessed skill at activities categorized as involving math was negatively related to math anxiety lends support to the idea that broad conceptions may be a protective factor in math anxiety, attenuating the impact of negative associations that individuals might have with activities they think could involve 'math.' Having a

Figure 1: Number of participants in Study 1 who labeled each activity as involving math.

Figure 2: Plot of linear regression line showing relationship between breadth of conception and math anxiety in Study 1, controlling for education ( $\alpha=6.93, \beta=-0.18, p<.05$ ).
broad math conception does not mean that an individual has to feel confident and have positive associations with all activities that they think involves math, but it could mean that negative associations with specific topics (like geometry or algebraic notation) will have less of an impact on their associations with the category as a whole.

## Study 2: Middle School Intervention

We were interested in whether students would exhibit the same qualitative variation in math conceptions and link between breadth and anxiety that we had seen with adults in Study 2. Additionally, as a first pass at investigating the causal relation between math conception and anxiety, and potential educational implications, we designed a brief intervention intended to broaden students' math conceptions.

## Stimuli \& Methods

Study 2 consisted of an interactive origami activity followed by four measures administered to participants in two
between-subjects conditions, BASELINE and Broad. Only participants in the BROAD condition received an explanation for the ways in which the activity had involved math before completing the other assessments.

Participants A total of 80 6th, 7th, and 8th grade students at a school in Gujarat, India participated (33 6th-graders, 7 girls; 21 7th-graders, 9 girls; 26 8th-graders, 9 girls). All 6thgrade participants were excluded for sharing answers ( $n=$ 33), leaving 477 th- 8 th grade students in our sample. Participants were tested in groups of $10-15$ assigned to the BASELINE or BROAD conditions in a classroom at their school.

Origami Activity Students sat in a circle on the floor around two experimenters who guided them through folding an origami crane. A third experimenter circulated to answer any questions, and students could also refer to printed, diagrammatic instructions distributed before the activity. All experimenters avoided using explicit math language during the folding instruction (e.g., reference to "angles," "half," "diagonal"), opting instead for generically narrated demonstration (e.g., "fold the paper like this"). Each student folded a paper crane, which they got to take home.

Construal Following the origami activity, students in both conditions answered whether the activity they just did could involve math (Yes/No/Not Sure), and to explain why. In addition, they rated how enjoyable and difficult they had found the activity, on a five-point Likert scale (from 'Not at all-' to 'Extremely-').

Intervention In the Broad condition-but not in the BASELINE condition-an experimenter then gave a brief explanation of how the origami activity involved and related to math (e.g., ... you have to think about spatial relations, and things like measurements of the different sides and angles. When designing new pieces of origami, you have to think creatively and flexibly, and use what you already know to come to new conclusions, like you have to do in math).

Avoidance The next measure participants completed was intended to indirectly access their math avoidance. The survey consisted of 6 items, each asking about a different school subject (e.g., How excited are you to learn a new topic in [math/Hindi] class?). Participants responded on a 5-point scale (from 'Not at all excited' to 'Extremely excited'). ${ }^{1}$

Math Anxiety We administered a child math anxiety questionnaire adapted from Ramirez, Gunderson, Levine, and Beilock (2013) by Barner et al. (2016), for use in India. The questionnaire consisted of 16 questions regarding students' experiences with math, which students responded to using a 5-point face scale (from 'Not nervous at all' to 'Very, very nervous'). The experimenter explained the scale and completed three warm-up questions with the students beforehand

[^329]

Figure 3: Number of participants in Study 2 who answered "yes" when asked whether each item could involve math.

Table 2: Means and standard deviations for each condition.

|  | Concept |  | Anxiety |  |
| ---: | ---: | ---: | ---: | ---: |
| Condition | $M$ | $S D$ | $M$ | $S D$ |
| BASELINE | 20.96 | 7.24 | 1.78 | 0.47 |
| BROAD | 24.61 | 5.96 | 1.60 | 0.36 |

to ensure understanding of the measure.
Math Conception The math conception measure was a variant of the one used in Study 1. We included 40 age- and place-appropriate items, and adjusted the wording used in the prompt from Study 1. Here, participants answered Could this activity involve math? (Yes/No/Not Sure), which we anticipated would encourage flexible thinking about the items and about math.

## Results \& Discussion

Qualitative Variation in Math Conceptions Participants indicated that an average of 22.74 out of 40 items could involve math. As in Study 1, there was considerable variation across items in the proportion of participants who judged them as involving math (Figure 3).

Math Conception \& Anxiety Participants received an average math anxiety score of 1.69 (out of 5 ). We were interested again in whether math anxiety scores were related to conception breadth, which we examined in our total sample, collapsing across condition. In middle-schoolers, as with adults, math anxiety was negatively related to the number of activities students categorized as math, $(F(1,44)=4.15$, $p<.05$ with an adjusted $R^{2}$ of 0.07 ; see Figure 4).

Conception Intervention We next analyzed math conception and math anxiety for our two conditions separately. If such a brief intervention were successful, we should expect conception scores to be higher in the Broad condition, and anxiety scores to be lower. While conception and anxiety

Figure 4: Linear regression showing relationship between breadth of conception and math anxiety in Study $2(\alpha=2.10$, $\beta=-0.02, p<.05)$.

Figure 5: (a) Boxplot of anxiety scores by condition. (b) Boxplot of conception score by condition.
might be slightly different in the anticipated direction between the two conditions (Table 2), the differences between group means is not significant (as determined by one-way ANOVAs for math conception: $F(1,45)=3.54, p=.066$, and anxiety: $F(1,45)=2.31, p=.14)$. The trend for math conceptions in particular is promising (see Figure 5): in the BaSELINE condition, there was more spread in the magnitude of participants' conception scores, while those in the Broad condition had generally 'broader' conceptions. Thus, it may be that with a different or merely more sustained intervention, students' math conceptions could be broadened.

Influence of Construal Out of the 47 participants analyzed, 36 said that the origami activity could involve math. Participants on average enjoyed the activity $(M=4.43, S D=$ 0.62 ) and did not find it difficult ( $M=2.28, S D=0.71$ ). This raises the possibility that we may not have found a robust intervention effect because our elicitation of construals of the origami activity as math itself served as an intervention on breadth of conception. In particular, given that all participants-including those in the BASELINE condition-
were asked to consider whether an enjoyable and easy activity could involve math before completing any of the surveys, they may have been primed to think more broadly and favorably of math.

## Discussion \& Future Directions

The above studies offer preliminary evidence for the intuition that individuals may have substantially different ideas of what constitutes math. Here, we have introduced the idea of math conceptions to describe these qualitatively different definitions of the category of math, and focused especially on their "breadth" to explain why certain types of math conceptions might make math anxiety more or less likely. Strikingly, the measure we introduced as a proxy for the breadth of individuals' math conceptions showed the hypothesized inverse link to math anxiety, in both adults and children, though it should be noted that the samples for Studies 1-2 differed in more than age. We see the remarkable dissimilarity of the two populations and contexts as adding strength to our results.

While this link between our measure of math conception breadth and math anxiety is promising, we imagine there is a great deal of additional variation among math conceptions that could be captured in future studies. Eliciting and analyzing participants' explanations for their categorization decisions may be one especially fruitful way to access other qualitative dimensions of math conceptions, alongside canonical methods to access category structure, like primed similarity judgments.

Without robust evidence for the efficacy of our intervention (Study 2), we cannot speak to the potential directionality of the math conception-anxiety relationship. Our ongoing work is exploring this question through an interactive intervention on adults' math conceptions, as well as an adaptation of the math conception measure for use with young children prior to being formally educated in math. Exploring math conceptions in young children, as well as directly assessing math skill in future studies with adults, will also address the heretofore unconsidered possibility that a third variable (like actual proficiency in math) is responsible for both responses on our current conception measure and levels of math anxiety. The ultimate goal of these lines of research is to understand and describe the character of individuals' implicit math categories, and leverage this knowledge to inform interventions aimed at reducing math anxiety in adults and children.

## Acknowledgments

We would like to thank the Amrit Vidlaya school in Gujarat, India for their generosity and enthusiasm about our project and Catherine Berner for assistance with data collection.

#### Abstract

The Associative Read-Out Model (AROM) suggests that associations between words can be defined by the log likelihood that they occur together more often in sentences than predicted by their single-word frequency. Moreover, semantic relations can be defined by associative spreading across many common associates. Here, we addressed developmental effects of associative and semantic priming. Thus, we manipulated sentence-co-occurrencebased direct (syntagmatic) and common (paradigmatic) associations between prime and target words in $2^{\text {nd }}$ and $4^{\text {th }}$ graders. Syntagmatic associations decreased response times and error rates in both, $2^{\text {nd }}$ and $4^{\text {th }}$ graders. Paradigmatic associations increased errors rates in 2nd graders, whereas they decreased errors rates in 4 th graders. These results suggest that $2^{\text {nd }}$ graders profit from syntagmatic, i.e. contiguity-based associations, while a benefit from paradigmatic-semantic relationship probably develops from generalizing across many of these simple associations.

## Introduction

Starting with pioneer work of Meyer and Schvaneveldt (1971) a wide range of studies revealed that a target word (e.g. "chair") is processed faster and more accurate when a semantically associated prime word (e.g. "table") was presented before (e.g. Bentin et al., 1985; Neely, 1976). Interestingly, studies differentiating between various types of associations (e.g. Becker, 1980; Lucas, 2000; McNamara, 2005) and/or individual differences like age (e.g. review Chapman et al., 1994, McCauley et al., 1976) revealed inconsistent results with regard to the size and direction of the semantic priming effect. From a developmental perspective, the presence (or absence) of the semantic priming effect may be an indicator of the development and organization of semantic knowledge (e.g. Lucas, 2000; McCauley et al., 1976; Meyer \& Schvaneveldt, 1971). On the one hand, recent research revealed greater semantic priming effects (i.e. greater difference between primed and
non-primed condition) for younger children and elder people (see review Chapman et al., 1994). On the other hand, various studies, investigating processes of different types of relations in semantic priming tasks, revealed that younger children show priming effects if words are directly associated only, and not if they exclusively provide a category relation (e.g. McCauley et al., 1976). So far, empirical evidence points towards a greater facilitation by functional/associative relations in comparison to pure semantic relations in children, but also an increasing sensitivity for thematic and taxonomic relationships over age (Arias-Trejo \& Plunkett, 2013). In line with this, younger children tend to freely associate words that have a syntagmatic relation from mere common occurrence in sentences relation (e.g. "good" and "boy") rather than a paradigmatic relation due to the same form class (e.g. "good" and "bad") in comparison to older children and adults (e.g. White, 1985; Woodrow \& Lowell, 1916). This effect is also known as the syntagmatic-paradigmatic shift that occurs in an age range between 5 and 9 years (e.g. Brown \& Berko, 1960; Entwisle, 1966, Nelson, 1977).

To our knowledge, however, the relative reliance on syntagmatic and/or paradigmatic information has not yet been addressed during visual word recognition. As German children start reading at the age of 6 , we hypothesized that word-decoding abilities sufficient for syntagmatic effects should be apparent around the age of 7 years, i.e. in the $2^{\text {nd }}$ grade, while a stronger reliance on paradigmatic information should be observable around the age of 9 , i.e. in the $4^{\text {th }}$ grade. So far, most semantic priming studies used free association performance of adults to predict semantic priming (e.g., Lucas, 2000), though already Jung (1905) stated that free associations are diagnostic for interindividual differences. Therefore, it is questionable whether its usage as an independent variable for the study of children is appropriate (see Hofmann \& Jacobs , 2014). To derive a semantic long-term memory structure from
experience with a sample of text (Hofmann et al., 2011), a recent interactive activation model (IAM; McClelland \& Rumelhart, 1981) relies on co-occurrence statistics. The Associative Read-Out Model (AROM, Hofmann et al., 2011) is the first IAM with an implemented semantic layer. It defines two words as associated, if they co-occur more often together in sentences than predicted by their single occurrence frequency (Dunning, 1993; Quasthoff et al., 2006). Thus, it reflects a symbolic Hebbian learning approach (Hebb, 1949) by suggesting higher association strengths for words that are occurring more often together than predicted by the frequency-driven orthographic activation.

The AROM already successfully predicted behavioral and electrophysiological data for tasks, in which memory is explicitly required. Hofmann et al. (2011) showed that the correct identification of studied words as well as the false recognition of non-studied words is significantly higher for words with many associations in a recognition memory task. This result has recently been extended by Stuellein et al. (2016) in an EEG study by showing significant response time, P200 and N400 effects for words with many associations. It was an open question, however, to what extend these results were induced by pure direct associations and/or indirect associations like semantic feature overlap (Stuellein et al., 2016). As the AROM defines words as associated by the frequency of their common occurrence, it is in line with localist theories proposing direct associative links between symbolic representations to capture the meaning of a word (e.g., Anderson, 1983; Collins and Loftus, 1975). Whereas distributed models define the meaning of a word by a distribution across subsymbolic 'hidden' units (e.g. McClelland and Rogers, 2003), this assumption is in line with other co-occurrence based models, defining the meaning of a word by latent factors determining with which words they co-occur (e.g. Landauer and Dumais, 1997). In the tradition of distributed models, one can assume that words that often occur together in similar sentence contexts might share similar semantic features. In line with the idea, that the meaning of a word is determined by its surrounding context (Firth, 1957; Harris, 1951), common associates of two words can possibly be considered as common features (Hofmann and Jacobs, 2014). As a consequence, a more complex AROM, that would be able to simulate the dynamic co-activation of such semantic features, was discussed to be a plausible option to accommodate both perspectives (Stuellein et al., 2016).

In a recent study, Roelke et al. (2016, subm.) also tested the AROM in an implicit memory task. During primed lexical decision, a full factorial manipulation of direct association (strong/no) and the number of common associates (many/no) of prime and target revealed strong effects in adult participants. Prime and target words with direct and many common associates facilitated visual word recognition. In contrast, we also have preliminary evidence
of inhibitory priming effects at a very long SOA (Schmidt, 2015). These results are in line with recent studies, showing only facilitating effects for pure associative relations and inhibitory or facilitatory effects for semantic relations that are dependent on the time that the prime is processed (e.g. see Plaut \& Booth, 2000).

## The present study

To investigate whether the AROM can be used to address the syntagmatic-paradigmatic shift by relying on direct (associative, syntagmatic) and indirect (semantic, paradigmatic) relations, we tested $2^{\text {nd }}$ and $4^{\text {min }}$ grade students from two German elementary schools, using primed lexical decision. In line with recent results, we expected smaller semantic priming effects for younger children for semantic (indirect) relations. Furthermore, we expected greater semantic priming effects for associative (direct) relations in comparison to semantic (indirect) relations for all children, because these depend on an abstraction of experience-based knowledge.

## Methods

## Subjects

For all participating students, parents signed written consent in advance.

Second grade. Behavioral data were collected for $952^{\text {nd }}$ grade students of two primary schools in Solingen, Germany. Two students did not complete the experiment due to the task difficulty. Another eleven participants had to be excluded because of reading/writing disorders and two participants because of lacking German skills. The mean age of the remaining 75 students (female $=45$ ) was 7.46 years ( $S D=.502$ ). According to their parents, 62 ( $82.7 \%$ ) participants had learned German as their first language. Three children (4\%) learned Turkish as their first language, followed by Italian ( $\mathrm{N}=2,2.7 \%$ ) and Russian ( $\mathrm{N}=2,2.7 \%$ ). The remaining students came from a variety of linguistic background. For one student, data for the native language was missing.

Fourth Grade. Behavioral data were collected for $864^{\text {th }}$ grade students of two primary schools in Solingen, Germany. Ten students had to be excluded because of reading/writing disorders. The mean age of the remaining 76 students (female=52) was 9.54 years $(S D=.738)$. According to their parents, 62 participants ( $81.6 \%$ ) had learned German as their first language. Five children ( $6.6 \%$ ) learned Turkish as their first language, followed by Italian $(\mathrm{N}=4,5.3 \%)$ and Polish ( $\mathrm{N}=2,2.6 \%$ ). The remaining students came from a variety of linguistic background.

## Materials

Corpora. The word stimuli were taken from the word corpus "childLex", which is based on approximately 5000 German books for children between 6 and 12 years (Schroeder et al., 2015; status: September 2014). The books vary in length and content with about 5000 to 15,000 words per book. We used words that were among the list for 6 to 10 year old children. As the childLex corpus is not openly available for analyses, co-occurrence statistics were taken from the German corpus of the "Wortschatz" project (status: December 2006; Quasthoff et al., 2006). This corpus is largely composed of online newspaper (1992-2006). Based on 800 million tokens and 43 million sentences, two words were considered to be directly associated when they co-occurred more often together in sentences than predicted by their single occurrence frequency (Dunning, 1993). Indirect associations were defined as the number of common direct associates.

Stimuli. The stimulus set consisted of 160 primes and 160 targets. The 160 primes and 80 targets were German nouns. The remaining 80 targets consisted of 40 pronounceable pseudowords and 40 random letter strings. Pseudowords were created by changing one to three consonants of real nouns. 80 targets were German nouns that were split into four word conditions in a $2 \times 2$ design with the factors direct association (high vs. low) and indirect relation (high vs. low). Prime and target were considered to provide a low direct association, when they were not associated at all (association strength $=0$ ) and as high directly associated, when they were beyond a $2,5 \%$-quantile criterion (association strength > 3) of all possible stimuli ( $\mathrm{N}=6,975$; cf. Hofmann et al., 2011, for a formal definition of association strength). They were considered to provide a low indirect relation, when they had less than 65 common associates (below a $2,5 \%$-quantile criterion of all possible stimuli) and were considered to provide a high indirect association, when they had more than 300 common associates (beyond a $2,5 \%$-quantile criterion of all possible stimuli; cf. Bordag, 2007, for counts of common associates). From the childLex corpus, the word features frequency, word length and Orthographic Levenstein Distance (Yarkoni et al., 2008) were counterbalanced between the four word conditions for prime and target words to rule out confounding effects (condition differences $\mathrm{p}>.05$ ). Raw Lemma-Frequency was $\log 10$ transformed and words below and beyond a $2,5 \%$-quantile frequency criterion of all possible stimuli were excluded. Word and nonword length was limited from 3 to 6 letters. Before counterbalancing to rule out confounding variables, a manual examination of the stimulus set excluded inappropriate words for children (e.g. those with sexual content), prime and target pairs with the same first letter and compounds (e.g. "snowball").

## Procedure

Cover story. The instruction was embedded in a cover story, adapted from a children's lexical decision task by Richter et al. (2013). Children were asked to help an extraterrestrial named Reli, who came to earth to learn the language of the earthlings, to distinguish between real words and nonwords (Target). To further explain the appearance of the prime words, students were told that another extraterrestrial named Gudra also wanted to learn the language of the earthlings (Prime). Students were told that other children were helping Gudra, so that they had to read her word but that they did not have to react.

Semantic Priming Task. The semantic priming task was performed by groups of eight to ten students at the same time in a quiet room, separated from the rest of the class. Before the experiment started, the time course of the experiment was written on the blackboard and the task was explained to the children in front of the class. Each student worked on his/her own on a separate laptop. Students were asked to put on headphones and to leave on the headphones during the whole task. Before the task started, a detailed instruction was presented once more in a videoclip with the extraterrestrial Reli.

First a fixation cross was presented for 1000 ms on the screen. Then a prime word was presented in grey letters for 600 ms . The students were asked to read the prime but not to press a button. After the prime word, a blank screen appeared for 200 ms , after which the target word was presented in black letters. Students were asked to press a green button with their right forefinger on the keyboard ("K"), if the presented stimulus was a real word and to press a red button with their left forefinger on the keyboard ("D") if the presented stimulus was a nonword. The target word stayed on the screen until the student pressed one of the two buttons. Following another blank screen for 500 ms , the word "Bereit?" ('ready?') was presented in red letters on the screen and students were asked to press a yellow button ("space") with one of their thumbs on the keyboard, if they wanted to go to the next trial (s. Figure 1).
To get used to the task, five exercise trials were presented at the beginning. For the exercise trials, feedback was provided whether the response was correct or not. For the main task, no feedback was provided. During the main task, two breaks were included, each after 56-57 trials. The students decided on their own by pressing the yellow button when to continue with the main task.

Figure 1: Time course of the experiment
At the beginning of the main task and after every break two "icebreaker trials" were included, that were excluded from data analyses. For every participant, the order of the presented prime-target pairs was randomized. Students were asked to react as fast and as accurate as possible.

Data Analysis. Results were analyzed using general linear mixed-effect models with the fixed effects grade ( $2^{\text {nd }}$ vs. $4^{\text {th }}$ class), direct association (low vs. high) and indirect association (low vs. high), their interaction terms and the random intercepts subject and item. The dependent variables were accuracy and response times. For accuracy analysis we used binary logistic regression and for response time analysis we used linear model. Because the degrees of freedom are not exactly known in LMM analyses, we chose 2 standard errors as significance criterion (i.e. $\mathrm{t}>=2$; cf . Baayen et al., 2008, footnote 1; Masson \& Kliegl, 2013). Incorrect responses and those plus/minus a 3 standard deviation criterion from average for each subject and condition were excluded from response time analyses. We only report main effects and interactions between the experimental factors that are significant. When models revealed significant interactions between at least two of the experimental factors, post-hoc t-tests were conducted.

## Results

## Accuracy

Grade and direct association and the significant interactions grade*direct association and grade*indirect association led to significant contributions to the model (all $t^{\star} \mathrm{s}>=2$ ). The positive effects of grade ( $\beta=1.273, t=7.08, S E=.18$ ) and direct association ( $\beta=1.191, t=3.12, S E=.382$ ) indicate that direct associations increased accuracy, and that $4^{\text {th }}$ grade students made fewer mistakes than $2^{\text {nd }}$ grade students (s. also Figure 2). The analysis also revealed a significant interaction between direct associations and grade ( $\beta=-$ $0.360, t=-2.95, S E=.122$ ). Moreover, we obtained an interaction of indirect association and grade ( $\beta=-0.395$, $t=-3.33 S E=.119$ ).
Post-hoc t-tests revealed that for $2^{\text {nd }}$ graders words that were
high directly associated ( $M=3.50, S D=1.90$ ) led to fewer errors ( $t=-9.89, p=.000$ ) than words that were low directly associated ( $M=5.71, S D=2.60$ ). For $4^{\text {th }}$ graders high directly associated words ( $M=1.74, S D=1.24$ ) led also to significantly fewer errors ( $t=-12.32, p=.000$ ) than words that were low directly associated ( $M=3.95, S D=2.08$ ).
Furthermore, for $2^{\text {nd }}$ graders words with many common associates ( $M=4.84, S D=2.29$ ) led to significantly more errors ( $t=2.481, p=.015$ ) than words with few common associates ( $M=4.37, S D=2.16$ ). Whereas for $4^{\text {th }}$ graders words with many common associates ( $M=2.68, S D=1.82$ ) led to significantly fewer errors ( $t=-2.116, p=.038$ ) than words with few common associates ( $M=3.01, S D=1.48$ ).

## Response time

Grade and direct association led to a significant contribution to the model (all $t$ 's>=2). The positive effects of grade $(\beta=1.103, t=8.99, S E=.12)$ and direct association ( $\beta=0.19, t=3.06, S E=.08$ ) indicate that $4^{\text {th }}$ grade students responded faster than $2^{\text {nd }}$ grade students and in general students responded faster for words that were directly associated (s. Figure 3).

Figure 2: Mean accuracy (error rates) in $2^{n d}$ and $4^{\text {th }}$ grade students
Note: Error bars are standard errors.

Figure 3: Mean response times in $2^{n d}$ and $4^{\text {mit }}$ grade students Note: Error bars are standard errors.

## Discussion

To test whether the AROM can account for a developmental shift from associative-syntagmatic (direct) to semanticparadigmatic (indirect) relations during visual word recognition, we analyzed the performance of $752^{\text {nd }}$ grade and $764^{\text {n }}$ grade children of two German elementary schools in a semantic priming task. Direct (syntagmatic) associations decreased errors in $2^{\text {nd }}$ graders as well as in $4^{\text {th }}$ grade students. The analysis of indirect (paradigmatic) relations revealed a significant interaction of grade and paradigmatic associations: while paradigmatic associations led to inhibitory effects in $2^{\text {nd }}$ graders (more errors), they led to facilitating effects in $4^{\text {th }}$ graders (fewer errors). Thus, children may develop the ability to generalize across common associations between the second and the fourth grade.

Our results fit into a reading development model, in which category knowledge is gradually abstracted and develops from functional, event-based knowledge. Response differences may result from the addition from new structures within an associative network, instead of a complete reorganization (e.g. McCauley et al., 1976). Consistent with this, Nelson (1977) assumed that children first represent semantic knowledge as spatial or temporal scripts (e.g. "eating lunch") and gradually abstract and define categories from this script-based knowledge. Our results also show that the Associative Read-Out Model (Hofmann et al., 2011) is sufficient to define both, associative-syntagmatic and semantic-paradigmatic perspectives by co-occurrence statistics, and thus provides a computational window into developmental effects of visual word recognition. Future more explicit simulations with an

AROM thus may capture individual differences such as age by differential associative excitation and inhibition scaling parameters within the semantic representation layer.

The syntagmatic-paradigmatic shift in children is well known (e.g. Entwisle, 1966). De Saussure's (1959) coined the term "syntagmatic" as an associative relation between words that typically co-occur in a linear combination (cf. Hofmann \& Jacobs, 2014). He further proposes a second type of relation, i.e. that words are associated when "they have something in common" (1959, p. 123). In computational linguistics, the number of common associates is used to define paradigmatic relations: "For example, the semantic similarity of the words red and blue can be derived from the fact that they both frequently co-occur with words like color, flower, dress, car, dark, bright, beautiful, and so forth" (Rapp, 2002, p. 1). We think that simple withinsentence co-occurrence provides an intelligible, transparent and performance-independent explanation of differential effects during reading development.

We are aware of the fact, that the priming effects might also be driven by factors like positional-syntactic information (e.g. Hofmann, Biemann, \& Remus, 2017). Thus, future studies may also investigate the influence of syntactic information by using not only simple nouns from the word corpora, but also words from other syntactic classes or prime-target pairs spanning differential word classes (e.g., verbs, adjectives etc.). Further studies may also investigate whether computational models that reduce the amount of latent semantic dimensions can provide generalization capabilities that may account for more variance than the simple amount of common associates (e.g. Landauer \& Dumais, 1997).

Acknowledgments We like to thank all children and schools for their contribution to this study. Moreover, we thank Chris Biemann for giving advice concerning the word corpus and our student Azize Elia Walldorf for all her help during data acquisition. This work was partially supported by a grant by the Deutsche Forschungsgemeinschaft to MJH (HO5139/2-1).

#### Abstract

Even newborn infants are able to extract structure from a stream of sensory inputs and yet, how this is achieved remains largely a mystery. We present a connectionist autoencoder model, TRACX2, that learns to extract sequence structure by gradually constructing chunks, storing these chunks in a distributed manner across its synaptic weights, and recognizing these chunks when they re-occur in the input stream. Chunks are graded rather than all-or-none in nature. As chunks are learned their component parts become more and more tightly bound together. TRACX2 successfully models the data from four experiments from the infant visual statistical-learning literature, including tasks involving lowsalience embedded chunk items, part-sequences, and illusory items. The model also captures performance differences across ages through the tuning of a single learning rate parameter. These results suggest that infant statistical learning is underpinned by the same domain general learning mechanism that operates in auditory statistical learning and, potentially, in adult artificial grammar learning. ${ }^{1}$

## Introduction

We live in a world in which events evolve over time. Consequently, our senses are bombarded with information that varies sequentially over time. One of the greatest challenges for cognition is to find structure within this stream of experiences. Even newborn infants are able to do this (Teinonen, et al. 2009; Bulf, Johnson \& Valenza, 2011), and yet, how this is achieved remains largely a mystery.
Two possibilities have been suggested (see Theissen, et al., 2013 for a detailed discussion). The first, characterised as statistical learning, involves using frequency and transition probabilities to construct an internal representation of the regularity boundaries among elements encountered. The second possibility suggests that elements that co-occur are recalled and simply grouped together - or chunked - into single units. Over time, these chunks can themselves be grouped into super-chunks or super-units. According to this view behaviour is determined by the recognition of these chunks stored in memory and associated with particular responses. What distinguishes these accounts

[^330]is that the former argues that it is the probabilistic structure of the input sequence that is represented and stored, whereas the later argues that specific cooccurring elements are stored, rather than the overarching statistical structure. Ample evidence in support of both of these views has been reported.
We will argue that this is a false dichotomy: both transitional probability learning (statistical learning) and chunking co-exist in one system that smoothly transitions between these apparent modes of behaviour. The appearance of two modes of learning is an illusion because only a single mechanism underlies sequential learning; namely, Hebbian-style learning in a partially recurrent distributed neural network. Such a system encodes exemplars (typical of chunking mechanisms) while drawing on co-occurrence statistics (typical of statistical learning models). An important corollary of this approach is that chunks are graded in nature rather than all-or-none. Moreover, interference effects between chunks will follow a similarity gradient typical of other distributed neural network memory systems.
Chunks are most frequently thought of as all-ornothing items. Who thinks of "cups" and "boards" when they see the word "cupboard"? Or "foot" and "ball" when they encounter the word "football"? Indeed, chunks like these have essentially the same status as "primitive" words like "boat" or "tree", which are not made of component sub-words. But new chunks do not suddenly appear ex nihilo in language. Rather, they are generally formed gradually, their component words becoming more and more bound together with time and usage. For example, when we encounter the words "smartphone", "carwash", or "petshop", we still clearly hear the component words. We hear them less in words like "sunburn" and "heartbeat". We hear them hardly at all in "automobile." How long did it take for people to stop hearing "auto" and "mobile" when they heard or read the word "automobile"? Like "automobile", it is likely that in a few years the current generation will no longer hear "smart" and "phone" when they hear the word "smartphone". This simple observation involving the graded nature of chunks is at the heart of the chunking mechanism in TRACX2.
These ideas were implicit in our initial presentation of the TRACX model (French et al., 2011). In TRACX we showed that a connectionist autoencoder, augmented with conditional recurrence, could extract chunks from a stream of sequentially presented symbols. TRACX
had two banks of input units, which it learned to autoencode onto two banks of identical output units. Sequential information was encoded by presenting successive elements of the sequence, first on the right input bank, then on the left input bank on the next time step. Thus, the sequence of inputs was presented in a successive series of right-to-left inputs, with learning occurring at each time step. However, if the output autoencoding error was below some pre-set threshold value (indicating successful recognition of the current pair of input elements), then, on the next time step, instead of the input to the right input bank being transferred to the left input bank, the hidden unit representation was put into the left input bank. The next item in the sequence was, as always, put into the right input bank. Weights were updated and the input sequence would then proceed as before. The result of this was that TRACX learned to form chunks of elements that it recognised as co-occurring (see French et al., 2011 for full details). TRACX successfully captured a broad range of data from the adult and infant auditory statistical learning literature and outperformed existing models of both chunking, notably, PARSER (Perruchet \& Vinter, 1998) and statistical learning (SRNs, Cleeremans \& McClelland, 1991).
TRACX2 (French \& Cottrell, 2014), which we use in this paper to segment and chunk sequential visual items, is an updated version of TRACX. TRACX2 removes the use of an all-or-nothing error threshold that determines whether or not the items on input are to be chunked. This effectively removes a conditional jump (i.e. an if-then-else) statement from the model, jump statements of this kind not being natural to neural network computation. In TRACX2, the contribution of the hidden-unit activation vector to the left bank of input units is graded and depends on the level of learning already achieved. TRACX (French et al., 2011) and TRACX2 (French \& Cottrell, 2014) were used to successfully model the segmentation of syllable (i.e., auditory) streams. In the present article, we use TRACX2 to model four experiments from the infant visual statistical learning literature. Visual statistical
learning paradigms involve showing infants sequences of looming colored shapes with varying degrees of statistical regularity embedded in the sequences. It was first developed as a visual analogue of the auditory statistical learning experiments (Kirkham, Slemner \& Johnson, 2002) and has yet to be captured by any modeling paradigm.

## The TRACX2 Architecture

TRACX2 was initially introduced by French and Cottrell (2014). The key to understanding TRACX2 is to understand the flow of information within the network. Over successive time steps, the sequence of information is presented item-by-item into the righthand bank (RHS) of input units. The left-hand bank (LHS) of input units is filled with a blend of the righthand input and the hidden unit activations at the previous time step, as shown in the following equation:

$$
\operatorname{LHS}_{\mathrm{t}+1}=\left(1-\tanh \left(\alpha \Delta_{\mathrm{t}}\right)\right) * \text { Hiddens }_{\mathrm{t}}+\left(\tanh \left(\alpha \Delta_{\mathrm{t}}\right)\right) * \mathrm{RHS}_{\mathrm{t}}
$$

where $\Delta_{t}$ is the absolute value of the maximum error across all output nodes at time $t, \mathrm{LHS}_{\mathrm{t}}$ is the activation across the left-hand bank of input nodes, Hiddens ${ }_{\mathrm{t}}$ are the hidden-unit activations at time $t, \mathrm{RHS}_{\mathrm{t}}$ is the activation across the right-hand bank of input nodes, and $\alpha$ is the sigmoid-"steepness" parameter, always set to 1 in the simulations presented here. If at time $t, \Delta_{t}$ is small, this means that the network has learned that the items on input are frequently together (otherwise $\Delta_{\mathrm{t}}$ could not be small). The contribution to the left-hand bank of input units at time $t+1$ of the hidden-unit activations, which constitute the network's internal representation of the two items on input at time $t$, is, therefore, relatively large and the contribution from the right-hand inputs will be relatively small. Conversely, if $\Delta_{t}$ is large, meaning that the items on input have not been seen together often, the hidden-layer's contribution at time $t+l$ to the left-hand input bank will be relatively small and that from the right-hand inputs will be relatively large. At each time step, the weights are updated to minimise output error (Fig. 1).
In layman's terms, this means that as you experience

Figure 1. Architecture and information flow in TRACX2. In all simulations reported in this paper, $\alpha=1$. When $\Delta$ is large (items not recognized as having been seen together before on input), almost all contribution to LHS comes from RHS. When $\Delta$ is small (items recognized as having been seen together before on input), almost all contribution to LHS comes from the Hidden layer (Hid).
items (visual, auditory, tactile) together over and over again, these items become bound to each other more and more strongly into a chunk until we no longer perceive its component parts.

## Modeling infant statistical learning

In this section we report on a total of four different simulations using TRACX2 of infant visual statistical learning behaviour. We used $\eta$ (the learning rate) as a proxy for development, with $\eta$ set to 0.0005 for newborns, 0.0015 for 2 -month-olds, 0.0025 for 5-month-olds, and 0.005 for 8 -month-olds. This is a typical parameter used to model age related differences in early learning (e.g., Thomas \& Johnson, 2006). There was a bias node on the input and hidden layers and momentum was always set to 0 . The key developmental hypothesis here is that, with increasing age, infants are progressively better at taking up information from an identical environment. This is consistent with the well-established finding that the average rate of habituation increases with increasing age during infancy (e.g., Bornstein et al., 1988; Colombo \& Mitchell, 2009; Westermann \& Mareschal, 2013). Finally, as has been used repeatedly elsewhere, we take network output error as a proxy for looking time in the infant (Mareschal \& French 2000; Mareschal, French, Quinn, 2000; Mareschal, Quinn, \& French, 2002; Mareschal \& Johnson, 2002; French, Mareschal, Mermillod \& Quinn, 2004; Westermann \& Mareschal, 2013). The idea here is that the amount of output error correlates with the number of cycles required to reduce the initial error, which corresponds to the amount of time or attention that the model will direct to a particular stimulus.
We begin by modeling the seminal Kirkham et al. (2002) visual statistical learning experiment demonstrating that age-related effects in the efficacy of learning can be accounted for by a simple and plausible parameter manipulation in TRACX2. We then show that TRACX2 can capture statistical learning in newborns, as well as their dependency on the complexity of the information stream (Bulf et al., 2011).

Finally, we show that, like 8 -month-olds (Slone \& Johnson, 2015), TRACX2 forms illusory conjunctions, normally taken as evidence of a statistical learning mechanism, but also shows decreased salience of embedded chunk items, normally taken as evidence of chunking. It, therefore, reconciles two apparently paradoxical behaviours within a single common mechanism.

## Visual statistical learning

Kirkham et al (2002) developed a visual analogue of the auditory statistical learning tasks initially developed by Saffran et al. (1996) and Aslin et al. (1998). Instead of listening to unbroken streams of sounds, infants were shown continuous streams of looming colorful shapes in which successive visual elements within a "visual word" were deterministic, but transitions between words were probabilistic (see Fig. 2, leftmost panel). Infants at three different ages were first familiarized to this stream of shapes, then presented with either a stream made up of the same shapes but with random transitions between all elements, or a stream made up of the identical visual words as during habituation. Kirkham et al. found that infants from 2 months of age subsequently looked longer at the random sequence than the structured sequence (even though elements are identical between streams) suggesting that the infants had learned the statistical structure of the training sequence.
We modelled this experiment by training the model with a sequence of inputs containing the identical probability structure to that used to train infants. The training sequence was identical in length to that used by Kirkham. The transitional probability within a visual word was $\mathrm{p}=1.0$, and between visual words $\mathrm{p}=.33$. Shapes were coded using localist, bipolar (i.e., $-1,1$ ) orthogonal encodings in order minimize effects due to input similarity. The RHS and LHS input vectors were comprised of 12 units.
Network performance was evaluated by averaging output error over all three of the possible two image "visual words" in the sequence. This was then

Figure 2. (leftmost panel) Illustration of visual sequences used to test infants (after Addyman \& Mareschal, 2013). (middle and rightmost panels) Left-hand panel: Infant performance reported in Kirkham et al. (2002) and, right-hand panel: TRACX2 performance with the familiar structured and novel non-structured sequences. (Error
is the maximum error of the network over all output units; SEM error bars.)
compared to the average output error for a set of three randomly selected two-image "visual non-words" that were neither words nor part-words, and, consequently, occurred nowhere in the training sequence. This is analogous to the word/non-word testing procedure used in auditory statistical learning studies (e.g., Saffran et al., 1996), and completely equivalent to testing the networks with a structured sequence (from which they would have extracted visual words) and a fully random sequence (in which no previous words or part-words exist). The model, like infants of all ages, looked longer at the randomised sequence than the structured sequence (Fig. 2, rightmost panel).

## Visual statistical learning in newborns

Bulf, Johnson, and Villenza (2011) asked whether the sequence-learning abilities demonstrated by Kirkham et al (2002) were present from birth. They tested newborns (within 1 week of birth) on black and white sequences of streaming shapes. In their "High Demand Condition", the sequence had the same statistical structure as in Kirkham et al. That is, the sequences were made up of 3 visual words, each made up of two shapes with a constant transition probability of 1.0 defining the word, and transitional probabilities of . 33 between words. They also introduced a "Low Demand Condition" in which the sequences were made up of only two words ( each consisting of two shapes with internal transition probabilities of 1.0) leading to transition probabilities at word boundaries of 0.5 (instead of the .33 previously used). The reasoning here was that newborns had more limited information processing abilities and may therefore struggle with a more complex sequence, already proving to be a challenge for 2 month olds.

Figure 3. Newborn performance as reported in Bulf \& Johnson (2011) in left panel and TRACX2 performance in right panel for familiar structured and novel nonstructured sequence.
Again, we modelled this study using TRACX2, in the same way as above, but by (1) reducing the learning rate to 0.0005 , and (2) creating both high-demand and low-demand sequences. In the low-demand condition
(LDC), there were two pairs of images, each made up of two different images (i.e., a total of 4 separate images). In the high-demand condition (HDC) there were three pairs of images, each made up of two different images (i.e., a total of 6 separate images). In the simulation for both the high-demand and lowdemand conditions, TRACX2 saw sequences of 120 words. Statistics were averaged over 30 runs of the program, with each run consisting of 10 simulated subjects. Figure 3 shows both the infant data and the model results. As with the infants, TRACX2 did not discriminate between the structured training sequence and the random sequence in the high demand condition (with the lower learning rate) but did discriminate between the two sequences in the low demand condition.

## Learning embedded and illusory items.

One consequence of chunking is that elements within a chunk become less salient as the chunks are increasingly consolidated. In contrast, statistical learning mechanisms predict that learners should form illusory items from elements that accidentally appear together on occasion. Slone \& Johnson (2015) explored whether infants' learning mechanisms would lead to the reduced salience of embedded items or to the emergence of illusory chunks, as a means of testing whether chunking or statistical learning underpins infant learning. To do this, they presented 8 -monthsolds with sequences structured as depicted in Figure 4a. Infants in the "Embedded Pair Experiment" did not differentiate embedded pairs from part-pairs that crossed word boundaries, but both were differentiated from the word pairs. Infants in the "Illusory Item Experiment" did not differentiate the illusory triplets from the part triplets, but both were differentiated from the actual triplets. This is perplexing because one result suggests that infants utilize chunking, whereas the other results suggests that they engage in statistical learning. TRACX2 captures both of these results well, with the caveat that the model is designed to produce the smallest error on the best learned patterns. (Figs. 4b, 4c). If we consider output error to be a measure of attention (the higher the error, the more attention the infant pays to that item), then we can say that TRACX2 is designed to orient to novel test patterns most (i.e., shows a novelty preference). In short, when modeling a novelty preference, the greater TRACX2's Error on output, the longer the looking time for infants.
Familiarity preferences are, in some sense, the inverse of novelty preferences. This means that the smaller the error for an item, the more attention the infant pays to that item. Thus, to model familiarity preferences we subtract the error on output from the maximum possible
error and call this "Inverse Error" (Fig. 4c). So, when modeling a familiarity preference, the greater TRACX's Inverse Error, the longer the infants' looking time.
Such shifts in orienting behaviour are common in infant visual orienting, and have been related to the complexity of the stimuli and the depth of processing (Roder, Bushnell, \& Sassville, 2000; Hunter \& Ames, 1988; see Sirois \& Mareschal, 2004, for a process account of the familiarity-to-novelty shift in a neural network model of habituation). Thus, TRACX2 captures both the reduced salience of embedded chunk items and the appearance of illusory conjunctions within a single mechanism, thereby reconciling apparently paradoxical infant behaviours.

## Discussion

TRACX2 (French \& Cottrell, 2014) is an updated version the TRACX architecture (French et al. 2011). As in the original architecture, TRACX2 is a memorybased chunk-extraction architecture. Because it is implemented as a recurrent connectionist autoencoder in the RAAM family of architectures (Pollack, 1989), it is also naturally sensitive to distributions statistics in its environment. In TRACX2, we replace the arbitrary all-or-none chunk-learning decision mechanism with a smooth blending parameter. TRACX2 learns chunks in a graded fashion as a function of its familiarity with the material presented. An implication of this is that chunks are no longer to be thought of as "all-or-none" entities. Rather, there is a continuum of chunks whose elements are bound together more or less strongly.
TRACX2 was used to model a representative range of infant visual statistical learning phenomena. No

previous models of these behaviours exist. As with the auditory learning behaviours, TRACX2 captures infants' apparent use of forward and backward transitional probabilities, the diminishing sensitivity to embedded items in the sequence, and the emergence of illusory words. However, it is important to understand that TRACX2 is not simply internalising the overall statistical structure of the sequence, but encoding, remembering and recognizing previously seen chunks of information. This is a fundamentally different account of infant behaviours than has previously been proposed (Krogh, Vlach \& Johnson, 2013).
TRACX2 can use frequency of occurrence or transitional probabilities equally well and fluidly to learn a task (as is the case with 8-month-olds; Marcovitch \& Lewkowicz, 2009). This would suggest that categorizing learning either as statistical or memory-based is a false dichotomy. Both can happen in a single system, with different behaviours seeming to appear depending on the constraints of the task, the level of learning and the level of prior experience. Moreover, the idea that infant looking time is determined by the recognition of regularly re-occurring items (chunks or individual items) is consistent with the recent evidence suggesting that local redundancy in the sequences is the prime predictor of looking away in infant visual statistical learning experiments (Addyman \& Mareschal, 2013).

TRACX2 also suggests that there are no specialised mechanisms in the brain dedicated to sequence learning. Instead, sequences emerge from the application of fairly ubiquitous associative mechanisms, coupled with graded top-down re-entrant processing.

(b)

(c)

Test type

Figure 4. (a) Familiarisation and testing items for embedded pairs (left panel) and illusory items (right panel) (after Slone \& Johnson, submitted). (b) Infant data (left-hand side of figure, familiarity preference, Experiment 1) and TRACX2 performance (right-hand side, SEM error bars). (c) Infant data (left-hand side of figure, novelty preference, Experiment 2) and TRACX2 performance (right-hand panel, SEM error bars). (Figure (a) permission pending).

Although there may be differences in the speed and richness of encoding across modalities, there is nothing intrinsically different in the way TRACX2 processes visual or auditory information. This suggests than any modality-specific empirical differences observed can be attributed to encoding differences rather than core sequence-processing differences.
In conclusion, we believe that chunking cannot be viewed as an all-or-nothing phenomenon. Chunks are learned and over the course of being learned their component parts become more and more tightly bound together. This is a fundamental principle of TRACX2. The results of the present paper suggest that infant statistical learning is underpinned by the same domain general learning mechanism that operates in auditory statistical learning and, potentially, also in adult artificial grammar learning. TRACX2, therefore, offers a parsimonious account of how infants find structure in time.

# Risk, Cognitive Control, and Adolescence: Challenging the Dual Systems Model 

Joanna Fryt (jfryt@up.krakow.pl) Tomasz Smolen (tsmolen@up.krakow.pl) Karolina Czernecka (czernecka.karolina@gmail.com)<br>Department of Psychology, Pedagogical University of Krakow ul. Podchorazych 2, Krakow, Poland

#### Abstract

According to the dual systems model, adolescence is a period of imbalance between cognitive and motivational systems that results in increased tendency towards risk. In the study, we investigated the effects of rewards on risk-taking and cognitive control in 90 adolescents (13-16) and 96 adults (1835 ). Our results challenge the assumptions of the model as we observed that rewards lead adolescents to more conservative decisions in one of the risk tasks used in the study. We also observed that in cognitive control tasks, rewards influenced reaction latencies, but not the efficiency of control processes.

Keywords: risk taking strategy, cognitive control, sensitivity to rewards, dual systems model

## Introduction

As a developmental period, adolescence is commonly characterized by risk-taking, sensation seeking, impulsivity and the importance of peers. Such characteristics clearly serve an adaptive function during the transition to adulthood, fostering tendencies towards independence, novel experiences and social networks (Spear, 2000). At the same time, they expose adolescents to the negative consequences of their actions, with typical examples being reckless driving, experimenting with psychoactive substances or unprotected sex. In our study, we investigated adolescent sensitivity to rewards and its consequences for risk-taking and cognitive control.

## The Dual Systems Model

The dual systems model by Steinberg (2008) is one of the most influential propositions attempting to explain adolescent behavior that is well established in cognitive and neurodevelopmental research (Defoe, Dubas, Figner, \& van Aken, 2015; Geier, 2013). According to the model, adolescence can be characterized by a functional imbalance between the hyperactive motivational system, responsible for increased sensitivity to rewards, and the still maturing cognitive control system, responsible for reaction inhibition and effective management of information. In both human and animal adolescents, greater sensitivity towards pleasure, positive feedback and rewarding effects of social interactions are observed (Somerville \& Casey, 2010; Spear,
2011). In humans, it has been established that early (11-13 years old) and middle adolescence (14-16 years old) are the periods of highest sensitivity to rewards. The presence of salient incentives coupled with the immaturity of control processes is believed to result in increased tendency towards risk.

Risk-taking, defined as a propensity towards actions "with the highest outcome variability" (Defoe et. al., 2015), is the most studied consequence of adolescent sensitivity to rewards. More precisely, risk-taking is a preference for actions leading to a big gain of low probability over actions leading to a small gain of high probability. According to the dual systems model, adolescents take more risks in the presence of salient incentives and when they are emotionally aroused. Studies focusing on age differences in risk-taking show that adolescents do manifest stronger tendency towards risk than adults, but only under specific task demands or in specific social contexts. A meta-analysis by Defoe et al. (2015) revealed that in studies using probabilistic gambling tasks (e.g. Iowa Gambling Task, Columbia Card Task, Balloon Analogue Risk Task), these specific task demands include primarily immediate outcome feedback, i.e. participants are informed of their gains and losses immediately after each decision. In studies using fastpaced driving tasks (e.g. Stoplight Task, driving simulators), it is usually the presence of a peer observer that encourages adolescents to take risks (e.g. Chein, Albert, O'Brien, Uckert, \& Steinberg, 2011; Cascio et al., 2015). It seems unclear whether these two types of risk task measure one or more types of risky behavior. The use of probabilistic gambling tasks allow a better understanding of economic risk preference. In fast-paced driving tasks, the risk is more impulsive and more similar to everyday situations.

Beyond the risk context, the assumptions of the dual systems model are tested in a rewarded vs. neutral antisaccade paradigm. Interestingly, some results show that cognitive control is enhanced in adolescents, but not in adults, where it is financially rewarded (Geier, Terwilliger, Teslovich, Velanova, \& Luna, 2010; Padmanabhan, Geier, Ordaz, Teslovich, \& Luna, 2011). Such an effect does not correspond to the implication of the model that adolescent risk-taking stems from weaknesses of control processes. Rather, it indicates that adolescent sensitivity to rewards can
in fact be adaptive and promote cognitive efficiency. Unfortunately, the effect seems to be difficult to replicate. Subsequent studies show individual differences such as increase, decrease or no change in cognitive control in adolescent response to rewards (Geier \& Luna, 2012; Paulsen, Hallquist, Geier, \& Luna, 2015). One study using the Continuous Performance Test showed a similar increase of performance in children, adolescent and adults in the rewarded condition (Strang \& Pollack, 2014).

## The Challenges for the Dual Systems Model

Despite the fact that the dual systems model does not specify whether tendency towards risk is adaptive or maladaptive (Strang, Chein, \& Steinberg, 2013; Shulman et al., 2016), it is criticized mainly for its generality and the fact that it adopts a deficit perspective on adolescence (Pfeifer \& Allen, 2012; Telzer, 2016). Actually, results from many studies contribute to the image of adolescence as the period of greatest lability, vulnerability to social evaluation, and decision making which may be suboptimal or even lifethreatening. However, a high propensity towards risk may not be the domain of all but the most susceptible adolescents (Bjork \& Pardini, 2015). An interesting new development for the model might be offered by research demonstrating that adolescent sensitivity to rewards can lead not only to risk-taking, but can also be channeled towards safe (Cascio et al, 2015; Telzer, Ichien, \& Qu, 2015) or prosocial behavior (Telzer, Fuligni, Lieberman, \& Galvan, 2013; 2014).

The conceptualization of adolescent risk-taking within the model and beyond it remains, however, the most intriguing issue. Are adolescents impulsive risk-takers, who, due to the immaturities of their control processes, cannot override risky tendencies in the presence of salient incentives (Willoughby, Good, Adachi, Hamza, \& Tavernier, 2013)? Or is risk-taking rather a decision strategy adopted whenever it seems profitable? When we view risk-taking as a strategy, we can also see adolescents as having more control over their behavior than is assumed in the model. Decision strategies can vary depending on the task and the type of risky behavior (e.g. economic risk, driving risk). Adolescent sensitivity to rewards (e.g. financial rewards, immediate outcome feedback) can be similar or different in various risk tasks. Nevertheless, it seems to be associated with emotional arousal. Finally, an issue worth examining is whether cognitive control in adolescents is indeed weaker than in adults and more sensitive to rewards.

## Hypotheses

To sum up, we expected that adolescents would be more sensitive to rewards than adults and that the difference in sensitivity would manifest in more efficient cognitive control and a higher tendency towards risk when performance is rewarded. Also, as the dual systems model does not provide a direct link between the presence of reward and its possible effect on risk-taking and cognitive
control, we hypothesized that the effect may be mediated by the most obvious variable: emotional arousal.

Taking into consideration all of the above, we can formulate the following predictions.
Risk (1) When rewarded according to their performance, people will manifest more risk-taking compared to a noreward condition.
Cognitive control (2) When rewarded, people will exhibit more efficient cognitive control.
Developmental changes (3) The simple effects expected in hypotheses (1) and (2) will be larger for adolescents than for adults.
Arousal (4) People will report higher arousal when rewarded according to their performance, compared to a noreward condition. (5) The arousal level will be a substantial mediator between the type of condition, risk level and cognitive control efficiency.

## Procedure

The one hundred and eighty six subjects ( 81 men) were recruited either via parent-teacher conferences in local schools (adolescents) or online advertisements (adults) from two groups: adolescents $(N=90$, mean age $=13.82, S D=$ 0.89 , range $=[13,16])$, and adults $(N=96$, mean age $=$ 25.04, $S D=4.03$, range $=[18,35])$. Parental consent was obtained for all under age participants. The study was conducted in schools (adolescents) and the university psychological laboratory (adults). Participants were informed that the anonymized data would be used only for the scientific purposes of the study and that they could ask questions, withdraw their participation at any moment, and receive performance feedback after the study was completed.

The session lasted for about 90 minutes and consisted of two conditions, with a fifteen-minute break in between: (a) a set of tasks with rewards depending on the performance and (b) a set of tasks without any rewards. In each condition, participants performed four tasks, each preceded by a training session. Two tasks were cognitive control tasks (Stroop task, Antisaccade task), while the other two measured the tendency to take risks (Spaceride task and Stock Market task). The order of conditions and of the tasks within sets were randomized. In the middle of each condition (after performing two computer tasks), participants were asked to complete the SUPIN arousal scale. Therefore, each person performed four computer tasks and the SUPIN scale twice, once in a rewarded and once in an unrewarded condition.

Participants were paid for their attendance with vouchers (to a clothing store, a bookstore, or a movie theatre). The value of the vouchers depended on performance in each task in the rewarded condition and varied from $\$ 5$ to $\$ 15$ (mean \$10, equivalents in PLN).

## The Tasks

The tasks were selected so as to measure different aspects of risk-taking and cognitive control. In contrast to the Stock

Market task, which investigates the tendency to make risky decisions based mostly on deliberative thinking, the Spaceride task was designed to detect the tendency to take risk in emotionally stimulating conditions. As two aspects of cognitive control, interference inhibition and response inhibition were measured separately by the Stroop task and the Antisaccade task. The SUPIN Scale was introduced to control the level of positive and negative affect during each research condition, as a possible moderator of task results.
Stock Market The task resembles a financial game in which participants use virtual currency to buy shares in two fictitious companies. In each turn of the game it was possible to buy a number of shares of one or two companies or no shares at all. The only restriction was the amount of money the participant had at a given moment, which was shown on the right side of the screen. The participant had 60 seconds to take a single decision, and 20 decisions to make during the game, which was also displayed on the screen. During the game the participant could see the history of changes of the prices of each companies' shares displayed on a chart. After each decision they also saw a table showing the current values of stocks and how much money they had earned or lost so far. The price changes were probabilistic (independent and normally distributed). The expected gain (mean price change) from investing in any of the companies was the same; however, the variance of the price changes was small for one company (safe) and large for the other (risky). The difference between the companies was revealed to participants at the beginning of the task.
Spaceride The task fulfilled a function similar to the "Stoplight" task (Chein et al., 2011), in which participants in a car-driving context had to quickly decide whether or not to take a risk to reach their destination as quickly as possible. The Spaceride task has the form of a game in which the participant controls a spaceship seen from above. The task was to fly as quickly as possible to the end of the cosmic route. There were a number of danger zones where there was a risk of collision with asteroid. Those zones were marked by a sound signal, a light on a radar, and the appearance of distant asteroids in the background. A cloud of fog also sometimes appeared and covered the spaceship and its surroundings, making it impossible to see asteroids approaching. In each danger zone, the participant had to decide whether to slow down and avoid a collision or speed ahead, risking a collision with an asteroid. A collision would immobilize the spaceship for longer than it would take to fly through a danger zone.
Stroop task The task (Stroop, 1935) was used to evaluate participants' ability to inhibit interference. In each trial of the task, one of four words ("red", "brown", "blue" or "green") appeared on the screen displayed in one of the four colors (also red, brown, blue, or green). In congruent trials ( $50 \%$ of trials), the color was the same as the meaning of the word (e.g. the word "brown" written in brown), while in incongruent trails the word was written in one of the other three colors (e.g. the word "red" written in blue, meaning interference was present). The participants had to press one
of four keys corresponding to the displayed color of the word as quickly as possible and ignore the meaning of the word. To motivate the participants for a better response, a status bar visible on the top of the screen was additionally introduced. After every response the bar changed color to green when the response was correct, or to red when it was wrong. The faster the response, the shorter the bar, so the participant could see the accuracy and speed of every reaction during the game.
Antisaccade task The task (Unsworth, Schrock, \& Engle, 2004) served as a measure of response inhibition. The participant had to inhibit the tendency to look at a sudden presentation of a peripheral lure stimulus and instead look at its mirror location in order to perceive the target stimulus (arrow) and correctly react to it (press one of three keys depending on the direction of the arrow). Feedback was additionally introduced in the present task to inform participants of their accuracy. The feedback took the form of a screen-wide rectangle displayed in green (in the case of a correct response) or red (when the reaction was wrong). Modified SUPIN Scale The scale (Brzozowski, 2010) was derived from Watson \& Clark's Positive and Negative Affect Schedule. Both positive and negative affect were measured, forming two subscales of the questionnaire. The scale consisted of 20 adjectives describing various emotions. Participants indicated on a five-point Likert scale (from 1 - "very slightly or not at all" to 5 - "extremely") how well each adjective described their current state. On the basis of the results of our preliminary study, we altered seven items of the scale to achieve better psychometric characteristics. The modified version of the scale was used in the present study.

## Results

Statistics and data analysis One person did not finish the whole set of tasks, while 60 had their results removed for one task due to low accuracy (in the Antisaccade task) or outlying value; however, their remaining results were still used in the analysis.

A generalized linear mixed model using binomial distribution was fit to the Antisaccade task. The "Mediation" package in R was used for mediation analysis. Multi-factor analysis of variance with repeated measures was applied in all other analyses.

Condition (rewarded or not rewarded), group (adolescents or adults), and interaction between condition and age group were independent variables. The condition factor was applied within subjects while the age group was applied between subjects. We also controlled for position in series (first or second) and performance in analysis concerning risk tasks. Dependent variables (DV) were: number of correct responses in the Antisaccade task; Stroop effect in the Stroop task; proportion of high risk stocks in all stocks purchased (risk measure), and number of stocks purchased (alternative DV) in the Stock Market task; duration of pressing the break button (risk measure) and duration of pressing the break or accelerate button (alternative DV) in
the Spaceride task. Alternative DV in the Spaceride task was logarithmized due to its skewness ( $\gamma_{1}=2.17$ before and 0.29 after transformation). The performance measure in the Stock Market task was the amount of "money" in the last trial, and in the Spaceride task it was the negative time of the journey. DV in the Antisaccade task was accuracy, and in the Stroop task it was Stroop effect. We also examined reaction latencies in Antisaccade and Stroop tasks.
Cognitive control There was neither an effect of condition nor an interaction between condition and age group in the Antisaccade task $(\beta=0.027, p=.47$; and $\beta=-0.03, p=.56$ respectively, deviance $=1695.8$ ) and the Stroop task $(F[1,136]=0.2, \mathrm{p}=.66$; and $F[1,136]=1.75, p=.19$, respectively, $\eta^{2}=.037$ ). However, there was a significant difference between adolescents and adults in reaction latencies in the Antisaccade task ( 734 ms for adolescents and 695 ms for adults, $F[1,164]=10,84, p=.001)$ and a nearly significant difference between conditions ( 707 ms for not rewarded and 719 ms for rewarded, $F[1,152]=3.58, p=$ $.06, \eta^{2}=.19$ ). There also was a significant difference between the rewarded and unrewarded condition in reaction latencies in the Stroop task ( 936 ms for unrewarded and 906 ms for rewarded, $F[1,136]=101.97, p<.001, \eta^{2}=.12$ ).
Risk The performance in the Stock Market task did not depend on condition $(F[1,180]=0.1, p=.75)$, age group $(F[1,182]=0.59, p=.44)$, nor interaction between these two factors $\left(F[1,180]=1.65, p=.2, \eta^{2}=.032\right)$. Neither did the performance in the Spaceride task depend on any of these predictors $(F[1,182]=0.13, p=.72 ; F[1,183]=2.52$, $p=.11 ; F[1,182]=1.24, p=.27$, respectively, $\left.\eta^{2}=.051\right)$.

There also was neither effect of condition $(F[1,182]=$ $0.81, p=.37)$, age group $(F[1,183]=0.87, p=.35)$, nor interaction between condition and age group on risk $\left(F[1,182]=0.008, p=.93, \eta^{2}=.0078\right)$ in the Stock market task or $(F[1,182]=0.028, p=.88 ; \mathrm{F}[1,183]=1.57, p=.21$; and $F[1,182]=0.26, p=.61$, respectively, $\eta^{2}=.01$ ) in the Spaceride task.

However, there was a significant effect of condition (242 for the unrewarded condition and 223 for the rewarded condition, $F[1,181]=8.96, p=.0031$ ) and age group (200 for adolescents and 262 for adults, $F[1,182]=18.65, p<$ .001 ) and a nearly significant effect of interaction between condition and age group $\left(F[1,181]=3.43, p=.065, \eta^{2}=\right.$ .35) when alternative DV was used in the Stock Market task (see Figure 1), as well as an effect of interaction between condition and age group in the Spaceride task $(F[1,182]=$ $4.75, p=.031)$. The effect of condition or age group in the latter task was not significant $(F[1,182]=1.08, p=.3$; $F[1,183]=0.44, p=.14$, respectively, $\eta^{2}=.019$, see Figure 2).

Arousal The arousal differed significantly depending on condition ( 2.34 for not rewarded condition and 2.5 for rewarded condition, $F[1,180]=43, p<.001, \eta^{2}=.034$ ), but it was not a mediator between condition and alternative DV in the Stock Market task (proportion mediated $=-.06,95 \%$ $\mathrm{CI}=[-.44, .25], p=.63)$.

Figure 1: Quantity of stock purchased in the Stock Market task (alternative DV) in unrewarded and rewarded condition for adolescents and adults. Error bars indicate $95 \%$ confidence intervals.

Figure 2: Logarithm of total time for which the accelerate or break buttons were pressed in the Spaceride task (alternative DV) in unrewarded and rewarded conditions for adolescents and adults. Error bars indicate 95\% confidence intervals.

## Discussion

The first important observation made in the present study is that participants were sensitive to rewards in risk tasks, but this sensitivity leads adolescents and young adults to different decision strategies, depending on the context of the task. Adolescent decisions, however, cannot be interpreted as an increase in tendency towards risk, which challenges the assumption of the dual systems model (Geier, 2013). In the Stock Market task we observed that adolescents generally purchased less stocks than adults and the number of purchased stocks decreased even more in the rewarded condition (Fig. 1). In the Spaceride task there were no differences between adolescents and adults in time taken to press the break or accelerate button in danger zones in the no-reward condition. However, in the rewarded condition adolescents pressed the brake and accelerator buttons more than adults, making the difference between the groups significant (Fig. 2). It is interesting why the presence of rewards led adolescents to purchase less stocks in the market and steer the spaceship more boldly through danger zones. Possibly, when they had the opportunity to earn real money, participants chose a strategy that leads, as they believe, to better performance in the task. If purchasing stocks in the market is generally perceived as leading to both big gains and big losses-the option with "the highest outcome variability" as Defoe et al. (2015) define riskthen purchasing less stocks when real money is earned can be interpreted as a strategy that protects participants from loss. Otherwise, flying more boldly through danger zones cannot be seen as a strategy preventing collisions. It should be noted that while in the Stoplight task (Chein et al., 2011) participants decide whether to stop at a yellow light or drive through the crossroads, in the Spaceride task it is possible to brake and accelerate through the entire length of danger zones. Flying more boldly (such as the "speed-brake-speed" strategy) in dangerous areas is related to maintaining high speed and attempting to slow down just before asteroids. Less bold flying is slower, but makes attempts to avoid collision more effective. Summing up these results, it appears that adolescents made more conservative decisions than adults in one of the tasks and more risky decisions in the other. The context of tasks is therefore a variable that determines whether adolescents manifest risk-taking or riskaversion. We can speculate that more conservative decisions could be caused by a lack of familiarity with the contexts in which risk can occur (e.g. economic risk).

According to our hypothesis, participants reported higher emotional arousal in the rewarded condition. Such results suggest that the presence of a salient incentive leads to a greater motivational effort that manifests itself in higher reported arousal. We failed, however, to show that arousal mediates the relation between the presence of reward and risk-taking (or other decision strategy). As adolescents are viewed as impulsive risk-takers (Willoughby et al., 2013), the dual systems model predicts that high arousal in the rewarded condition enhances risk-taking because highly aroused adolescents cannot override risky tendencies. In our
study, however, participants seemed to be able to make decisions irrespective of their arousal and did not allow it to negatively influence their performance. It might be the case that arousal leads to impulsive decision-making only in specific circumstances. For example, high arousal may trigger risk-taking only in individuals in a negative emotional state (such as anxiety) or under high cognitive load (see, e.g., Zangeneh, Blaszczynski \& Turner, 2008). If the participants were in optimal emotional and cognitive state, reward-related arousal alone might not have been sufficient to cause a break-down in control processes and an increase in risk-taking. It is also possible that rewarding participants resulted in a higher but still optimal level of arousal, increasing not risk-taking, but effort. These explanations remain speculative and need further studies, but it seems that the dual systems model may oversimplify the proposed link between arousal and risk-taking.

Interesting results that challenge the dual systems model assumptions were also observed for the cognitive control measures. Firstly, adolescents were less accurate and slower in the Antisaccade task, while no differences between adolescents and adults were observed in the Stroop task. Thus, the antisaccade task seems to be more difficult for adolescents, a result which is consistent with previous studies (Geier \& Luna, 2012; Paulsen et al., 2015) showing that performance in the Antisaccade task improves with age. Secondly, we found that reward had no effect on both the accuracy in the Antisaccade task and the Stroop effect. However, in the rewarded condition participants exhibited longer latencies in the Antisaccade task and shorter latencies in the Stroop task. These results are not surprising given the fact that participants were informed that they were being rewarded for accuracy in the first task and for response speed in the second. The intriguing issue here is why the presence of rewards influenced not the measures of cognitive control efficiency (reaction inhibition and interference control), but reaction latencies in the tasks. It is possible that rewards enhance not a measured skill (i.e. control processes) that might be difficult to improve, but the motivational effort to do well in the task. Such an interpretation seems to be consistent with the effects of reward observed in the risk tasks, where again not the performance (e.g. money earned in the Stock Market, driving time in the Spaceride), but the decision strategies (e.g. purchasing more or less stocks, driving more or less dynamically) were enhanced. Additionally, we failed to observe interaction between age, condition and cognitive control efficiency, which is contrary to the dual systems model and consistent with the behavioral results of Paulsen et al. (2015). The effects of reward on reaction latencies in both tasks were similar in adolescents and adults.

To conclude, the results obtained in the study challenge the assumptions of the dual systems model about the universality of adolescent risk-taking. Risk-taking as a consequence of the weakness of control processes and sensitivity to incentives possibly manifests itself in certain circumstances. In our study, adolescents made decisions
which cannot be considered unequivocally risky or impulsive, despite the rewards. Further studies should help determine more precisely what set of circumstances triggers different behavioral responses in the presence of incentives and thus contribute to the development of the model.

#### Abstract

Previous studies have shown that one can exploit "wisdom of crowds" by oneself. This is achieved by aggregating multiple "quasi-independent" estimates from the same person. However, previous methods were not necessarily easy to utilize. Therefore, we propose an efficient method based on perspective-taking. The procedure is as follows: First, one makes her/his own estimation. Second, one estimates again based on a different perspective ("general public"). Then these two estimations were averaged. Two experiments revealed that our method effectively induced the wisdom of crowds by oneself. More importantly, participants in our method made estimations more quickly than those in a previously proposed method, suggesting that our method required a relatively diminished cognitive load for participants. Further investigation suggested that our method was immune to adverse effects of confidence. Therefore, the present findings show that our method could be effective and efficient method for inducing the wisdom of crowds in one mind.

Keywords: Estimation; Judgments under uncertainty; Perspective taking; Judgment aggregation; Wisdom of crowds; Wisdom of crowds in one mind

## Introduction

"Wisdom of crowds" (Surowiecki, 2004) is the well known phenomena, such that the aggregation of multiple estimates made by large number of people is more accurate than the estimate of a single individual. Recently, an intriguing concept, termed "wisdom of crowds in one mind" has been discussed in the research field of judgment and decision making (e.g., Rauhut \& Lorenz, 2011). In examining this issue, researchers have discussed how a single person can exploit "wisdom of crowds" in her/his mind. Herzog and Hertwig (2014a) argued that this is achieved by averaging "quasi-independent" multiple estimates from the same person. A person's estimate is not always constant and has some variance, even for the same problem. Using such inconstancy and variance, s/he can exploit the "wisdom of crowds in one mind". For example (see Figure 1), there is a question with correct answer $50 \%$. A person's first estimate was $30 \%$. Imagine that $\mathrm{s} /$ he was asked to make the second estimate, then her/his second estimate was $80 \%$. The average of two estimates would be $55 \%$; a result more
accurate than the first estimates. Previous studies have proposed some methods about how to exploit the wisdom of crowds in one mind. Vul \& Pashler (2008) proposed a method in which individuals make estimations for the same problem twice, with a time lag (2-weeks) between estimations. Herzog \& Hertwig (2009) proposed the method called dialectical bootstrapping. In this method, people are asked to make an estimation twice. In the second estimation, they are provided an instruction (shown in Table 1, see "dialectical" condition). This instruction asks individuals to provide a different estimation from the first one, by considering new knowledge that was once overlooked, or searching out incorrect assumptions or considerations present in the first estimate. These studies generally showed that the average of the first and second estimates were more accurate than the first estimate, and that the benefit of averaging was larger than in the control condition (i.e., just making estimations twice without any time lag or instructions). Effectiveness of these methods has been

Figure 1. An example of wisdom of crowds in one mind. The red numbers indicate the distance between first or averaged estimate and correct answer.
confirmed repeatedly in subsequent studies (see Herzog \& Hertwig, 2014b for review).

However, these methods are not necessarily easy to utilize. In the method proposed by Vul and Pashler (2008),
the time lag suggested (i.e., 2 weeks) is necessary to exploit the wisdom of crowds within the mind of a single individual. In the dialectical bootstrapping proposed by Herzog and Hertwig (2009), a rather complicated instruction (Table 1) is necessary. Furthermore, the first estimate has to be presented to the person, which may not be necessarily efficient as a method for inducing the second estimate. In the present study, we propose a new method for exploiting the wisdom of crowds in one mind, based on previous findings on perspective-taking.

## Perspective-taking of the "general public" for exploiting the wisdom of crowds in one mind

## Perspective-taking

Perspective-taking is the cognitive action to take another point of view. This topic has been examined mainly in the research field of social psychology. Previous studies have revealed that perspective-taking changes peoples' subjective judgment or preference, such as stereotypes about a person (Galinsky \& Moskowitz, 2000). Furthermore, recent studies have indicated that perspective-taking prompts people to change estimates about objective values (e.g., the population of the city or the date of historical event). Yaniv \& Choshen-Hillel (2012) implemented a perspective-taking procedure in the advice-taking paradigm (for more information on the advice-taking paradigm, see Bonaccio \& Dalal, 2006 for review). In this experiment, participants were asked to generate an estimate about questions by taking into account estimated values by others (these values were given as advice). At this point, participants who were asked to generate estimation at the point of another person's perspective tended to accept advice more than those who were asked to generate their own estimation.

Based on these findings, it is predicted that estimations vary depending on the perspective an individual takes. Accordingly, we propose a method for utilizing wisdom of crowds in one mind by taking others' perspective. In our method, we implemented a perspective-taking procedure in the multiple estimates for the same question, to exploit the wisdom of crowds in one mind. Specifically, we propose the following procedure:
(1): A person makes her/his own estimation.
(2): S/he makes a second estimation based on a different perspective. Specifically, s/he takes perspective of the "general public" (Table 1, see "self-others" condition).
(3): Averaging the first and second estimations.

## Merits of perspective-taking of the "general public"

We believe that taking the perspective of the "general public" has some merits. First, different estimation may be easily induced. Although estimations by the same person tend to be analogous (e.g., control condition in Herzog \& Hertwig, 2009), people tend to believe that they differ from the general public in some ways. For example, in comparing driving ability, people tend to think that their ability is better than the general public (e.g., Svenson, 1981), suggesting that they believe "I am different from the general public!" Thus, a different estimation may be induced by taking the perspective of "general" individuals. Second, a different estimate may be induced irrespective of confidence about the first estimate. In making estimations, if people are confident about their estimates, they may not change their estimate when they are asked to make the second estimate. Previous studies on overconfidence (e.g., Koriat, Lichtenstein, \& Fischoff, 1980) reveal that people tend to be overconfident about the accuracy of their estimation. Thus, in inducing a different estimate from the same person, confidence (especially, as individuals tend to be overconfident) may adversely affect results, as s/he may be reluctant to change her/his first estimate when $s / h e$ is confident about the first estimate. For example, in the dialectical bootstrapping method (e.g., Herzog \& Hertwig, 2009), people are asked to make the "self" second estimate, even though they are provided an instruction to make a "different" estimate. Therefore, this method may be affected by the confidence in the first estimate, and an appropriately different estimate may not be induced in the second estimate. However, our method may correct for this. The current procedure asks individuals to make the second estimate from "other" people's perspective. Hence, it is expected that our method is relatively immune to the adverse effect of confidence, and the nature of changing the estimate, irrespective of confidence, may result in the effective utilization of the wisdom of crowds in a single mind. Third, anyone can imagine the general public. Leboeuf, Shafir, \& Bayuk (2010) showed that when participants were asked to

Table 1. Full text in instruction about three conditions.
Condition Instruction in the second estimate

Self-others How do you think people in general estimate about the following question? Make a second estimate after considering fully how people in general estimate about this.

Dialectical First, assume that your first estimate is off the mark. Second, think about a few reasons why that could be. Which assumptions and considerations could have been wrong? Third, what do these new considerations imply? Was the first estimate rather too high or too low? Fourth, based on this new perspective, make a second, alternative estimate.

Self-twice No instruction
take the perspective of a particular group ("family" in Study 2), the participants who actually identified with this group ("have a family" in Study 2) preferred the choice corresponding to the perceived group perspective (e.g., a family vacation). However, participants who were not associated with this type of group (e.g., single) were not influenced by this perspective-taking, suggesting that a perspective-taking procedure cannot work effectively for individuals that are not actually associated with the group. Given that people can compare their driving ability with general public (Svenson, 1981), people may be able to imagine the "general" public.

In the following sections, we shall report two behavioral experiments and discuss the effectiveness of our method.

## Experiment 1

We conducted a web-based behavioral study in order to examine whether our method effectively induced wisdom of crowds in one mind.

## Method

Participants A total of 452 participants were recruited for this experiment through a Japanese internet research company. Participants were randomly assigned into one of three experimental conditions (self-others, $n=150$; dialectical, $n=151$; self twice, $n=151$ ).
Tasks and materials Participants were asked to answer eight general knowledge questions, such as "What percent of the world's airports are in the United States?" (Vul \& Pashler, 2008). Participants answered questions twice following instructions (specific content will be reported the below).
Procedure In all conditions, participants first provided their own estimates about the questions. After answering all the eight questions, participants provided second estimates following the instruction for each condition (see Table 1). In the self-others condition, we instructed participants to take a "general public" perspective. In the dialectical condition, we gave the instruction of the dialectical bootstrapping based on Herzog \& Hertwig (2009). In the self-twice condition, no instruction was provided and participants just made second estimate again.

The order of the questions for the first estimate was randomized across participants and that for the second estimate was the same as in the first estimate.

## Analysis

In the following analyses, we calculated "\% MAD (= mean absolute distance) reduction averaging" (Herzog \& Hertwig, 2014a) as an index for the gained accuracy of averaging. First, absolute distance between an estimate and the correct answer was calculated per question for each participant. The mean values of these were computed as MAD. MAD indicated MAD of the first estimates, and $M A D_{\text {avg }}$ represents the MAD of the averaged estimates. Then, "\% MAD reduction averaging" was calculated for each
participant level as follows: $\left(\mathrm{MAD}_{1}-\mathrm{MAD}_{\text {avg }}\right) / \mathrm{MAD}_{1} .{ }^{1}$ See Figure 2 for examples.

$$
\% \text { MAD reduction averaging }=\frac{\text { Mean } A D_{1}-\text { Mean } A D_{\text {ave }}}{\text { Mean } A D_{1}}
$$

Figure 2. Examples of AD (absolute distance) and formula of $\%$ MAD reduction averaging. (a) is an example when averaged estimate is more accurate than first estimate and (b) is an example when averaged estimate is less accurate than first estimate.

## Results and discussion

Figure 3 shows \% MAD reduction averaging for each condition. In the self-others and dialectical conditions, \% MAD reduction averagings were significantly higher than zero (self-others: $\mathrm{M}=2.52, \mathrm{CI}=[0.08,4.75]$; dialectical: M $=2.20, \mathrm{CI}=[0.50,4.03])$. Therefore, averaged estimates reduced error compared to first estimates in these conditions. In contrast, in the self-twice conditions, \% MAD reduction averaging was not significantly higher than zero ( $\mathrm{M}=$ $1.34 \%, 95 \% \mathrm{CI}=[-3.43,0.67])$. Thus, this method did not

Figure 3. \% MAD reduction averaging.

[^331]significantly reduce error compared to the first estimates. A pairwise Wilcoxon rank sum test using a Bonferroni correction revealed that in the self-others condition and dialectical condition, \% MAD reduction averagings were significantly higher than that in self-twice condition ( $p$ $<.01 ; p<.05$, respectively). These results indicate that our method can exploit accuracy of averaging more effectively than the method without any instruction, as with the method proposed in Herzog \& Hertwig (2009).

Although no significant differences between self-others and dialectical condition was found ( $p>.1$ ), our method can exploit accuracy of averaging at least as effectively as the method proposed by Herzog \& Hertwig (2009) given that the mean value of $\%$ MAD reduction averaging in the selfothers condition was higher than that in the dialectical condition.

## Experiment 2

In Experiment 2, we used the same procedure with the following two exceptions. First, we measured the response time for the second estimate. Second, participants rated confidence about their first estimates, and we analyzed the relationship between the confidence and difference in the two estimates (i.e., first and second estimates).

## Method

Participants Japanese graduates and undergraduates from the University of Tokyo ( $N=77 ; 56$ men and 21 women; age $\mathrm{M}=20.90$, sd $=2.52$ ) participated in this experiment. They were randomly assigned into one of three experimental conditions (self-others, $n=25$; dialectical, $n=$ 24; self-twice, $n=28$ ).
Tasks and materials Participants were asked to answer twenty questions about general knowledge based on Herzog \& Hertwig (2014a). Questions were answered twice, with instructions, as in Experiment 1. In addition, in making first estimations, participants were also asked to rate their confidence for each estimation.
Procedure The experiment was individually conducted using a computer. In all conditions, participants first answered their own estimates about the questions, and rated confidence about their estimates on a 100-point scale. After answering all 20 questions, second estimates were made, following instructions, as in Experiment 1. In the self-others condition, we instructed participants to take the "general public" perspective. In the dialectical condition, we gave the instruction based on Herzog \& Hertwig (2009). In the selftwice condition, no instruction was given, and participants simply provided a second estimation.

The order of the questions for the first estimate was randomized across participants and that for the second question was the same as in the first estimate.

## Results and discussion

## Accuracy of averaging

In the following analysis, as in Experiment 1, we calculated "\% MAD reduction averaging" as an index for the gained accuracy of averaging. Figure 4 shows \% MAD reduction of the averaging for each condition. In the self-others condition, \% MAD reduction averaging was significantly higher than zero ( $\mathrm{M}=5.51 \%, 95 \% \mathrm{CI}=[1.26,9.56]$ ). In contrast, in the dialectical and self-twice conditions, \% MAD reduction averagings were not significantly higher than zero (dialectical: $\mathrm{M}=2.14, \mathrm{CI}=[-1.18,5.42]$; selftwice: $\mathrm{M}=1.60, \mathrm{CI}=[-0.24,3.54]$ ). Thus, these methods did not significantly reduce error compared to the first estimates.

Although a pairwise Wilcoxon rank sum test using a Bonferroni correction revealed that in the self-others condition, \% MAD reduction averaging was not significantly higher than that in the dialectical and the selftwice conditions ( $p s>.1$ ), the $\%$ MAD was higher in the self-others condition compared to the dialectical and the self-twice conditions. Given that the \% MAD reduction of

Figure 4. \% MAD reduction averaging.

Figure 5. Total response time in the second estimate.
the averaging was significantly higher than zero only in the self-others condition, our method could exploit accuracy of averaging effectively, compared to other methods.

## Response time in the second estimates

We analyzed total response time for the second estimate. Figure 5 shows total response time for each condition (selfothers: $\mathrm{M}=262.27, \mathrm{CI}=[222.80,303.69]$; dialectical: $\mathrm{M}=$ 412.19, CI = [327.23, 499.90]; self-twice: $\mathrm{M}=193.30, \mathrm{CI}=$ [164.67, 234.09].

Total response times were log-transformed and a pairwise t-test using a Bonferroni correction was conducted. It was found that in the self-others condition, participants finished second estimates more quickly than the dialectical condition ( $p<.05$ ). Total response time in self-others condition was longer than that in self-twice condition ( $p<.001$ ). These results suggest that participants in the self-others condition could exploit wisdom of crowds in one mind with diminishing more cognitive load than those in the dialectical condition.

## Further examination about the three methods

The difference in first and second estimates To confirm that our method exploited the difference of estimates, in the following analysis, we calculated median absolute distance (AD) to examine the distance between first and second estimates (Herzog \& Hertwig, 2014a). Median AD refers to the median absolute distance between the first and second estimates across 20 questions.

Figure 6 shows Median AD for each condition. In the self-others and dialectical conditions, median ADs were both larger than that in the self-twice condition (self-others: $\mathrm{M}=8.18, \mathrm{CI}=[7.02,9.28]$; dialectical: $\mathrm{M}=10.02, \mathrm{CI}=$ [8.48, 11.79], self-twice; $\mathrm{M}=2.45, \mathrm{CI}=[1.46,3.46]$; pairwise Wilcoxon rank sum test using a Bonferroni correction: $p s<.001$ ). There was no difference between self-others and dialectical condition ( $p>.1$ ). Therefore, these results showed that our method could induce the difference of estimates as in the dialectical bootstrapping.

Relationship between the difference in first and second estimates and confidence We examined the relationship between differences in the first and second estimates and confidence. Generally, if a person is confident about the first estimate, s/he may not change the second estimate. We predicted that since the participants in the dialectical and self-twice were asked to make "self" estimations, a negative correlation might be observed between the difference in the first and second estimates and confidence (i.e., s/he might not change the second estimate when $\mathrm{s} / \mathrm{he}$ was confident about the first estimate). However, this might not be true for the self-other condition because a person was asked to make estimate from other people's perspective in her/his second estimate.

We analyzed the relationship between the difference in the first and second estimates and the confidence about first
estimate. Absolute distance between the two estimates was calculated for each question within participants, and a correlation coefficient between the absolute difference and confidence in the first estimate was calculated for each participant. ${ }^{2}$

Figure 7 shows distributions of correlation coefficients for each condition. In the dialectical and self-twice conditions, $95 \%$ confidence intervals about correlation coefficients were less than zero (dialectical: $\mathrm{M}=-0.19, \mathrm{CI}=$ [-0.29, -0.086]; self-twice: $\mathrm{M}=-0.13, \mathrm{CI}=[-0.21,-0.060]$ ). In contrast, for the self-others condition, $95 \%$ confidence intervals about correlation coefficients included zero (selfother: $\mathrm{M}=0.03, \mathrm{CI}=[-0.040,0.10])$. These results indicate that participants in the self-other condition tended to make different estimations between the first and second estimations, irrespective of their confidence. However,

Figure 6. Median absolute distance.

Figure 7. Correlation between confidence and distance.

[^332]participants in the dialectical condition made analogous estimation in the second estimate as in that in the first estimate when they were confident in the first estimate. Given that wisdom of crowds in one mind tends to work when a person makes different estimations in the two estimations (e.g., Herzog \& Hertwig, 2009), our method is relatively immune to the adverse effect of confidence compared to the dialectical bootstrapping.

Furthermore, we analyzed the relationship between the accuracy and the confidence in the first estimate. The absolute distance between the correct answer and the first estimate were calculated for each question within participants, as an index for accuracy, and then we calculated a correlation coefficient between these two values for each participant. Figure 8 shows distributions of correlation coefficients. $95 \%$ confidence intervals included zero ( $\mathrm{M}=-0.0032$, $\mathrm{CI}=[-0.013,0.0080]$ ). This result indicates that confidence was not related with the actual accuracy.

Figure 8. Distributions of correlation coefficient between confidence and distance.

## General discussion

In the present study, we proposed a new method for utilizing the wisdom of crowds in one mind, and we examined whether our method was effective when compared to another method proposed in previous studies. Our findings were summarized as follows: First, we found that our method effectively induced the wisdom of crowds in one mind. Second, it was found that participants in our method made estimations more quickly compared to those in the previous method, suggesting that our method diminished cognitive load for participants. Third, we found that our method was relatively immune to adverse effects (e.g., confidence), given that the previous methods require a time lag or presentation of the first estimate (Vul \& Pashler, 2008; Herzog \& Hertwig, 2009).

Taken together, we believe that our method can be a more effective and efficient method for inducing wisdom of crowds in one mind.

# Experimental Investigation on Top-down and Bottom-up Processing in Graph Comprehension and Decision 

Misa Fukuoka (fukuoka@cog.human.nagoya-u.ac.jp)<br>Kazuhisa Miwa (miwa@is.nagoya-u.ac.jp)<br>Akihiro Maehigashi (mhigashi@cog.human.nagoya-u.ac.jp)<br>Graduate School of Informatics, Nagoya University, Japan

#### Abstract

Graph comprehension requires both bottom-up processing from the graph representation and top-down processing guided by knowledge and attitude. In the current study, we investigated which of the bottom-up process phases: extraction, interpretation, and decision: were affected by the top-down processing derived by the impressions and social attitudes. The experimental results showed that the top-down processing driven by impressions temporarily formed in specific contexts affected both the extraction of information and the following decision phase whereas top-down processing driven by attitude formed over a long time based on social norms affected only the decision phase. In the latter case, a decision was made without any need for bottom-up processing.

Keywords: graph representation, decision, bottom-up processing, top-down processing

## Introduction

People make decisions by perceiving and understanding external resources. Visual representations such as graphs are effective for such processes. Visual representations are known for making the understanding of information easier, as graphs and diagrammatic presentations including scatter plots reduce cognitive errors (Ancker, Senathirajah, Kukafka, \& Starren, 2006; Lipkus \& Hollands, 1999). On the other hand, graphical representations can also bias interpretation: e.g., Woller-Carter et al. (2012) confirmed that an intentionally biased graph produces information reading errors.

Previous studies have confirmed that understanding graphs is best achieved from both top-down and bottom-up processing. Freedman and Shah (2002) proposed a CI model for graph comprehension based on the text understanding CI model proposed by Kintsch (1988). The model assumed that there was an interaction between the two information processing stages; bottom-up from the visually represented information encoded in the external resources and top-down from knowledge stored in long-term memory.

Many studies have shown that the bottom-up processing of graphs depends on the graphical representations. Shah and Carpenter (1995) found that the contents of reading information changed depending on which of the independent variables were assigned to the x -axis or the graph legend. Sanchez and Wiley (2006) found that fascinating and attractive visual information distracted participant focus from the crucial information related to the primary task, which implied that such information should be carefully restrained to ensure participant focus on the target information.

In top-down processing, many experimental findings have been reported that have found that a participant's knowledge and attitudes toward the topics significantly influence an understanding of the information in the graphs. Freedman and Smith (1996) found in their experiments with scatter plot graphs that the participants read the information not only using the bottom-up processing that arises from perceiving plot patterns in the graph, but also using top-down processing which is based on pre-formed knowledge. Kanzaki and Miwa (2012) found that in experiments with line graphs, information reading was performed with both bottom-up and top-down processing, but the top-down processing did not violate the reading of the bottom-up processing.

CaMeRa (Tabachneck-Schijf, Leonard, \& Simon, 1997) demonstrated two stages of bottom-up processing. In the preceding extraction stage, primary symbolic information was drawn from the visual representation of the graph: e. g., a $y$-axis value in the experimental condition in which an experimental manipulation was made was greater than the value in the control condition, and there was a substantial difference between the two conditions. Such difference perceptions at this stage were formed based mainly on the perceptual information processing in the working memory without accessing domain knowledge in declarative memory. In the following interpretation stage, the experimental results represented on the graph were interpreted with an integration of the symbolic information drawn from the graphical representation and knowledge stored in declarative memory: e.g., a medical material x is effective for improving activity y .

In actual situations, the final decision stage, may follow from an understanding of the information drawn from the graph: e. g., sales promotion for the medical material x was decided on.

Figure 1 shows the bottom-up processing series: extraction, interpretation, and decision.

The first aim of the current study was to confirm the bottom-up processing series shown above. In particular, we examined whether internally extracted information, such as mentally represented difference between experimental conditions, that is constructed from information represented on the graph as an external resource, drove the following bottom-up information processing. We should note that how information is extracted from external resources is generally different for each person who reads the graph, implying that there is a possibility that different internal information could be extracted from identical external resources. Therefore, in

Figure 1: Top-down/ bottom-up processing model of graph comprehension and decision.
this study, we set up difference perception stage in which internal information is constructed from "extracted" information on the graph.

In Experiment 1, we constructed an experimental setting in which we had participants represent perceived difference independently from the external resource. Through the experiment, we explicitly confirmed that based on the internally represented information, the following interpretation and decision stages were performed.

Next, we considered impressions and attitudes to be the factors that drove the top-down processing. Impressions are usually temporarily constructed with insufficient information based on stimuli presented in a situation or a context (Wang \& Nelson, 2014). On the other hand, attitudes seem to be more continuously formed based on social and moral norms, and are directed toward people, places, and social policies (Greenwald \& Banaji, 1995).

The second aim of this study was to understand which of the initial or final bottom-up processing stages was affected by the top-down processing derived from impressions and attitudes. The research question was whether top-down processing affected only the final decision stage, or also affected the initial extraction. Many studies on human perception have indicated that top-down processing derived from beliefs and knowledge bias human perception; however, previous studies on graph comprehension have investigated top-down processing using the dependent variables related to the latter bottom-up processing phases.

In Experiment 2, we performed an experiment to examine the top-down processing derived from impressions; and in Experiment 3, we further investigated the top-down processing based on attitudes.

## Experiment 1

Experiment 1 consisted of Experiments 1 a and 1 b .

## Participants

56 undergraduates ( 29 males and 27 females: $M_{\text {age }}=18.64$, $S D_{\text {age }}=0.82$ ) from Nagoya University participated in Experiment 1a. The experiment was performed in small groups of at most eight members. 54 undergraduates from Nagoya University ( 30 males and 24 females: $M_{\text {age }}=18.46$, $S D_{\text {age }}=0.97$ ) participated in Experiment 1b. The experiment was performed as class practice in a cognitive science class.

## Materials

In Experiment 1a, an experimental context was introduced in which an ingredient $A$ that was expected to improve biological vitality was assumed, and the effect of ingredient A was examined using a laboratory rat experiment with a hamster wheel. Participants were presented with a graph that indicated the number of cases out of 20,000 in which the rats continued to perform the hamster wheel task for more than three minutes. Figure 2 shows the presented graphs in which there is a substantial difference in the number of cases for the experimental rat group in which ingredient A was given to the rats and the control group in which it was not.

Figure 3 shows the graphs used in Experiment 1b. The graphs had perceptual features identical to those in Experiment 1a but the information content was different. The perceptual features of the graphs implied that there was a difference in the number of cases between the two conditions; however, the reality was the same. The scalability of the $y$ axis of the graphs was manipulated; as a result, across all graphs, the numbers of cases were only 1190 (5.95\%) for the experimental group and $1110(5.55 \%)$ for the control group.

## Procedure

Based on the presented graphs, participants were instructed to indicate their opinion as an expert advisor about a nursing tonic that an assumed company was developing to improve biological vitality.

The experimental procedure consisted of the following four stages.
Graphical presentation Participants were assigned to one of three groups. Each group consisted of 18, 19, and 19 participants respectively in Experiment 1a and 19, 18, and 17

Figure 2: Graphs used in Experiment 1a.

Figure 3: Graphs used in Experiment 1b.
participants in Experiment 1b. The participants in each group were presented with one of the three graphs shown in Figures 2 or 3 . A score of 1 to 3 was assigned to each of the three types of graphs for the following regression analysis.
Difference perception After the graphical presentation, participants estimated the degree of difference in the number of cases between the two conditions and were asked if there were any differences in the two conditions on a five-point scale from 1 (strongly disagree) to 5 (strongly agree).
Interpretation Then, the participants were required to estimate to what degree ingredient A was effective in improving biological vitality on a five-point scale.
Decision Finally, the participants were asked whether ingredient A should be included in the nursing tonic the company was developing on a five-point scale.

The experiment took about 30 minutes.

## Result

Single regression analyses were performed with the score recorded in one of the four experimental stages as the independent variable and the score in the following stage as the dependent variable. Figure 4 shows the results of Experiment 1a. There were significant relationships found between the presented graphs and the difference perceptions ( $\beta=.51, t(54)=4.36, p<.001, R^{2}=.26$ ), the difference perceptions and the interpretations ( $\beta=.42, t(54)=3.35, p$ $<.01, R^{2}=.17$ ), and the interpretations and the decisions ( $\beta$

Figure 4: Results of the single regression analyses for Experiment 1a.

Figure 5: Results of the single regression analyses for Experiment 1b.
$\left.=.48, t(54)=4.01, p<.001, R^{2}=.23\right)$. The same analyses were performed for Experiment 1 b and Figure 5 shows the results, in which there were significant relationships found between the difference perceptions and the interpretations ( $\beta$ $\left.=.42, t(52)=3.30, p<.01, R^{2}=.17\right)$, and the interpretations and the decisions ( $\beta=.58, t(52)=5.11, p<.001, R^{2}=.33$ ); however, no significant relationships were detected between the presented graphs and the difference perceptions $(\beta=.14$, $\left.t(52)=1.01, p=.32, R^{2}=.02\right)$.

## Experiment 2

Experiment 2 was performed to investigate how top-down processing driven by impressions affected each of the bottom-up processing phases confirmed in Experiment 1. Experiment 2 consisted of the former and the latter sessions. For each participant, the former session was followed by the latter session; and between the two sessions, a 5 minute break was inserted.

## Participants

60 undergraduates ( 30 males and 30 females: $M_{\text {age }}=18.87$, $S D_{\text {age }}=0.65$ ) from Nagoya University participated in Experiment 2. The experiment was performed in small groups of at most eight members.

## Materials

The former session in Experiment 2 was performed to replicate Experiment 1b. In the latter session, the graphs were the same as those in Experiment 1b, but a further experimental setting was introduced to manipulate the participants' impressions toward the medical material in which a fictional ingredient, a "proten" or a "rubison," rather than ingredient $A$ was assumed. For the manipulation, reading material that described one of the two pharmaceutical companies was used to give the participants positive impressions about the one company developing the "proten" and negative impressions of the other company developing the "rubison."

In Experiment 2, two experimental contexts were introduced, with the assignment of each of the two contexts to the former or the latter session being counterbalanced. One context was the same as that in Experiment 1: i.e., the development of a medical ingredient to improve biological vitality was introduced. The other context was the
development of an ingredient to recover physical strength after fatigue. In the latter case, a rat experiment was assumed with a 100 meter running test.

## Procedure

Based on the graphs that indicated the experimental results, participants were instructed to indicate their opinion as an expert advisor about a nursing tonic to improve biological vitality, or as an expert advisor about an energy drink to recover physical strength after fatigue.

The experimental procedure consisted of the following five phases.
Impression manipulation Before the graphical presentation stage, in the former session, participants answered a questionnaire about their impressions of an ingredient A that had been developed by an company X they belonged to. In this stage, no information about the ingredient was provided. They estimated, on a five-point scale, their impressions about ten items, such as "ingredient A is reliable," with a higher estimation score meaning more positive impressions toward ingredient A .

The following four experimental stages, graphical presentation, difference perception, interpretation, and decision, were the same as in Experiment 1. Participants were assigned to one of three groups. Each group consisted of 20 participants respectively. The participants in each group were presented with one of the three graphs. In the final decision stage, participants were asked to decide whether ingredient A should be included in the nursing tonic or the energy drink, on a five-point scale.

In the latter session, the impressions of the ingredients "proten" or "rubison" were manipulated using reading materials in which information about company Y which is developing the ingredient was given. First, the participants were presented with a text describing the information about the company Y. One text included characteristics of an excellent company (e.g., There is an excellent welfare program in company Y.), to persuade participants to have a positive impression of the ingredient "proten." The other text had characteristics of an evil company (e.g., There is no welfare program in company Y.), and persuaded participants to have negative impressions toward the ingredient "rubison." One of the two texts was presented to each participant. Then, the participants answered the same questionnaire as used in the former session, in which they were asked to give their impressions of the ingredient "proten" or "rubison."

From the graphical presentation through to the decision stages, the same procedure was utilized as in the former session.

The total time for Experiments 2 was about an hour.

## Result

Multiple regression analyses were performed with two independent variables; i.e., a score recorded in one of the four experimental stages and an impression score; and a dependent variable; i.e., a score from the following phase. Figure 6 shows the results from the former session. The
results replicated Experiment 1b. There were significant relationships found between the difference perceptions and interpretations ( $\beta=.59, t(57)=5.50, p<.001, R^{2}=.38$ ), and the interpretations and the decisions $(\beta=.66, t(57)=6.30, p$ $<.001, R^{2}=.42$ ); however, no significant relationship was detected between the presented graphs and the difference perceptions ( $\beta=.23, t(57)=1.82, p=.07, R^{2}=.11$ ). There were no relationship found between the impressions and any of the three bottom-up processing phases; difference perception, interpretation, or decision $(\beta=.24, t(57)=1.95$, $p=.06, R^{2}=.11 ; \beta=.09, t(57)=.84, p=.40, R^{2}=.38 ; \beta=.05$, $\left.t(57)=.49, p=.63, R^{2}=.42\right)$.

The same analysis was performed for the latter session. Figure 7 shows the results, from which it can be seen that the difference perceptions were affected by the impressions ( $\beta$ $\left.=.28, t(57)=2.25, p<.05, R^{2}=.11\right)$ but not by the graphical presentations $\left(\beta=.18, t(57)=1.42, p=.16, R^{2}=.11\right)$, the interpretations were not affected by the impressions ( $\beta=.21$, $\left.t(57)=1.99, p=.05, R^{2}=.44\right)$ but by the difference perceptions ( $\beta=.58, t(57)=5.61, p<.001, R^{2}=.44$ ), and the decisions were affected by both the impressions ( $\beta=.31$, $\left.t(57)=3.27, p<.01, R^{2}=.57\right)$ and the interpretations $(\beta=.58$, $\left.t(57)=6.20, p<.001, R^{2}=.57\right)$.

Figure 6: Results of the multiple regression analyses for the former session in Experiment 2.

Figure 7: Results of the multiple regression analyses for the latter session in Experiment 2.

## Experiment 3

Experiment 3 was performed to investigate how top-down processing driven by attitudes affected each of the bottom-up processing phases. In Experiment 3, we investigated how the participants' social attitudes toward smoking affected their decisions about a smoking cessation policy.

## Participants

55 undergraduates ( 33 males and 22 females: $M_{\text {age }}=18.51$, $S D_{\text {age }}=0.86$ ) from Nagoya University participated in Experiment 3. The experiment was performed as class practice in a cognitive science class.

## Materials

An experimental context was introduced in which a health survey was conducted in an assumed city X. Participants were presented with graphs that indicated the survey results. Specifically, the graph showed how many of the 20,000 respondents suffered from pulmonary problems. The perceptual features of the graphs were the same as those in the preceding experiments. It was assumed that one group had a family with a smoker and the other group did not.

## Procedure

One week before the experiment, the participants answered a questionnaire to measure their social attitudes toward smoking. They estimated, on a five-point scale, their attitudes toward smoking behavior for 10 items, such as "smoking is only malevolent for society," with a higher estimation score indicating greater negative attitudes toward smoking.

Participants were assigned to one of three groups. Each group consisted of 18,17 , and 19 participants respectively. The participants in each group were presented with one of the three graphs. In the final decision stage, participants were asked to indicate their opinion, as a health consultant, about whether or not employees in an assumed company should be prohibited from smoking both inside and outside the company.

## Result

The same multiple regression analyses as those in Experiment 2 were performed. Figure 8 shows the result. The difference perceptions were not affected by the graphical presentations or by the attitudes $(\beta=.03, t(52)=.23, p=.82$, $\left.R^{2}=.002 ; \beta=.03, t(52)=.20, p=.84, R^{2}=.002\right)$, the interpretations were affected only by the difference perceptions ( $\beta=.66, t(52)=6.61, p<.001, R^{2}=.48$ ) but not by the attitudes ( $\left.\beta=.16, t(52)=1.63, p=.11, R^{2}=.48\right)$, and the decisions were affected only by the attitudes ( $\beta=.50$, $t(52)=4.18, p<.001, R^{2}=.28$ ) but not by the interpretations ( $\beta=.09, t(52)=.71, p=.48, R^{2}=.28$ ).

Figure 8: Results of the multiple regression analyses for Experiment 3.

## Discussion

The first aim of this study was to confirm a series of the bottom-up process phases, information extraction from graphs as an external resource, interpretation, and decision.

In Experiment 1a, bar graphs with assumed experimental results in two conditions were used. In Experiment 1a, we manipulated the differences in the values of the independent variable in two experimental conditions, and confirmed that bottom-up processing was driven by internally represented differences extracted from the graph as the external resource. In Experiment 1b, we used another set of graphs in which the values for the independent variable were equivalent, and obtained the same results as in Experiment 1a, indicating that bottom-up processes also arise based on the participants' internally represented differences. It is important that bottomup processing is performed from internally represented information that is extracted from an external resource, and independent of the actual information represented in the external resource.

In Experiment 1b, we used graphs in which the visually represented differences were equivalent to the actual differences in the graphs used in Experiment 1a, even thought there was no actual difference in the two conditions. As a result, no correlation was found between the internal differences represented by the participants and the pseudo differences in the graphs. This indicated that the participants in this study were not affected by the visual biases included in the external resource when extracting the information in the graphs. Previous studies have found that the reading quality of graphical information depends on critical thinking capabilities (e.g., Woller-Carter et al., 2012). The critical thinking abilities of the participants in our experiments appeared to be relatively high, which needs to be considered when interpreting the experimental results in this current study.

In Experiment 2, we manipulated the participants' impressions of the target topic. First, we found the same bottom-up process that had been confirmed in Experiment 1b in which top-down processing was not assumed.

The first finding was that the final decision was made based on both top-down processing derived from impressions and bottom-up processing from the extraction of information from the external resource. Previous studies have consistently confirmed that impressions significantly affect decision making. Kostopoulou et al. (2017) experimentally found that in medical diagnoses by home doctors, the first impression of the patients affected diagnostic planning decisions. Jaros et al. (2000) reported that a perceptual impression of foods at a glance affected food selection.

The latter session in Experiment 2 confirmed that topdown processing using impressions affected the extraction phase in the initial bottom-up processing phase. The halo effect is when the impressions about one specific characteristic affect the estimation of other characteristics that may not even be related to the initial characteristic (e.g., Murphy et al., 1993). In the latter session, we manipulated the impression of the office environments of an assumed
company that had developed a medical ingredient. The participants' estimation about the ingredient depended on the manipulated impressions, even though the efficacy of the ingredient had no explicit relationship with the office environments.

In Experiment 3, we manipulated another factor that drives top-down processing; that participant attitudes are formed over a long period based on moral and social norms. The experimental results showed that different from Experiment 2, the final decision was made only based on the participants' attitudes toward the target topic, rather than depending on the interpretation drawn from the bottom-up processing.

This finding about the relationship between attitude and decision was consistent with findings in previous studies. It has been found that attitudes are crucial in predicting behavior (Conner \& Armitage, 1998), and that there is a strong relationship between attitudes and behavior (Fazio et al, 1982).

An important point from Experiment 3 is that when making the final decision, top-down processing was not concerned with the bottom-up processing output. The topic dealt with in the current study was smoking; therefore, as this was a familiar social topic for everyone, this may have driven the strong top-down processing.

The results in Experiment 3 showed that the top-down processing did not affect the bottom-up processing initial extraction phase, implying that such initial bottom-up processing may be isolated by top-down processing.

In the current study, we examined two factors; impressions and social attitudes; that drive top-down processing. In summary, when one factor that is formed temporarily is followed by a specific context, impressions take a central role in the comprehension and decision making about graphical information, indicating that bottom-up processing functions are compatible with top-down processing. On the other hand, when another top-down factor is socially formed over a long period, such as social attitudes, bottom-up processing tends to be separated from top-down processing, with top-down processing predominating.

#### Abstract

A crucial aspect of everyday conversational interactions is our ability to establish and maintain common ground. Understanding the relevant mechanisms involved in such social coordination remains an important challenge for cognitive science. While common ground is often discussed in very general terms, different contexts of interaction are likely to afford different coordination mechanisms. In this paper, we investigate the presence and relation of three mechanisms of social coordination - backchannels, interactive alignment and conversational repair - across free and task-oriented conversations. We find significant differences: task-oriented conversations involve higher presence of repair - restricted offers in particular - and backchannel, as well as a reduced level of lexical and syntactic alignment. We find that restricted repair is associated with lexical alignment and open repair with backchannels. Our findings highlight the need to explicitly assess several mechanisms at once and to investigate diverse social activities to understand their role and relations.

Keywords: Social coordination, common ground; conversational repair; interactive alignment; backchannel.

## Introduction

A key question in cognitive science is how people coordinate knowledge and behavior in social interaction, a process sometimes referred to as grounding (Clark \& Brennan, 1991; Dale, Fusaroli, Duran, \& Richardson, 2013). Research over the past decades has highlighted processes like backchannels, conversational repair, and interactive alignment, but progress has been hampered by two challenges. First, these processes are rarely considered together, limiting our view of possible interrelations. Second, the study of such processes has been spread across disciplines and data types, limiting the possibilities for
prediction and generalization (de Ruiter \& Albert, 2017). Here we report on a principled comparison of backchannels, repair, and interactive alignment in two quite different types of contexts: free (FC) and task-oriented conversations (TOC). Engaging in conversation is a collaborative effort involving timely coordination at many levels. In their seminal 1991 article, Clark and Brennan (1991) suggest such coordination to be contingent on common ground, comprising mutual knowledge, beliefs and assumptions. The main mechanism for establishment and maintenance of common ground explored in their work is backchannels (Yngve, 1970). Backchannels are phatic signals such as head nods, eye blinks and vocal expressions of the type $u h$ huh, yeah, and okay (Bangerter \& Clark, 2003; Schegloff, 1982). In this study, we are concerned with vocal backchannels only. Even if such signals are often quite subtle, research suggests that speakers are very sensitive to these kinds of cues as ways of providing and monitoring positive evidence of mutual understanding, and their interruption can have detrimental effects on communication (Clark \& Krych, 2004).

A related phenomenon is conversational repair. While backchannels are mostly concerned with positive evidence of understanding, conversational repair refers to the interactional practices by which people signal and solve trouble in conversation (Schegloff, Jefferson, \& Sacks, 1977). Here we focus on the most interactive form of repair: other-initiated repair, a highly frequent conversational sequence where one participant initiates the repair procedure by means of a request for clarification like huh? or who?, and the other completes it. Formats for other-initiated repair frequently show lexical and syntactic repetition (Jefferson, 1972; Sacks, 1992), with a recent cross-linguistic study of informal conversation finding that $48 \%$ of all repair
initiating turns repeated part or whole of the prior turn (Dingemanse et al., 2015). Repair initiations can be ordered along a cline from weak (providing little indication of what or where the problem is, such as huh?) to strong (highlighting a specific element of a prior turn for clarification or confirmation, as in who?). While weak repair initiation is always possible, and so might be expected to be a default option, it has been suggested that the selection of repair formats follows a 'strongest initiator rule' (Clark \& Schaefer, 1989), according to which people select the most specific repair format possible, given constraints like noise and joint attention.

While backchannels and conversational repair are often thought to be of a more explicit, inferential character, the theory of interactive alignment in conversation suggests common ground to be established through low-level automatic priming processes (Pickering \& Garrod, 2004). It has been observed across many contexts and studies that interlocutors engaged in conversation often tend to adapt to each other's linguistic behaviors on many levels from prosody to syntax (Fusaroli \& Tylén, 2016). If an interlocutor, for instance, uses the phrase "I'm sure" to express confidence, there is an enhanced probability that the conversational partner will use similar wording later in the conversation even if other expressions would work just as well in that context (Fusaroli et al., 2012). Alignment is thought to percolate between levels of linguistic representation. Lexical alignment can for instance facilitate the alignment of other levels (e.g. syntactic choices), eventually leading to alignment of situation models of the ongoing activity, that is, common ground (Pickering \& Garrod, 2004). According to Pickering and Garrod, more explicit negotiation of common ground such as repair and backchannels are only recruited in cases of communication problems or misunderstandings. It should be noticed that a few alternative perspectives have been suggested: Brennan and Clark (1996) associate alignment with more explicit negotiations of shared conceptual representations, while others suggest a context-sensitive mechanism, which strategically selects for alignment or divergence according to the functional needs of the ongoing activity (Fusaroli, Raczaszek-Leonardi, \& Tylén, 2014; Healey, Purver, \& Howes, 2014). Common ground is often discussed as a unified concept foundational to conversation in general. However, different contexts of conversation are likely to afford different degrees of explication as well as different processes and mechanism for the establishment of common ground. Conversations among pilots and airport control towers thus require high levels of referential precision (Prinzo \& Britton, 1993), while the average dinner conversation may be more concerned with maintenance of social relations (Dunbar, Marriott, \& Duncan, 1997), to the point of ignoring referential misalignments (Galantucci \& Roberts, 2014).

To establish a more refined framework for the investigation of common ground, we propose an integrative approach comparing backchannel, alignment and repair
across diverse social activities. In particular, we focus on free spontaneously occurring interactions - traditionally favored by conversation analytic approaches - and a welldefined spatial navigation task to be jointly solved through conversation - traditionally favored by more cognitive and quantitative approaches. The investigation aims to determine how common ground is negotiated and maintained, and whether these processes are modulated by the social context. Moreover, we will investigate how the suggested mechanisms of common ground relate to each other: e.g. if repair and alignment are associated (Dingemanse et al., 2015), then measures of alignment will be tapping into both mechanisms.

We predict that (i) the different social contexts involve distinctive patterns in the dynamics and mechanisms of common ground, such that they allow an accurate classification of conversations as free or task-oriented. More specifically, (ii) baseline frequency of repair, interactive alignment, and backchannels may be higher in task-oriented interactions due to requirements for referential precision. (iii) The quality of the dynamics at work is also predicted to be different. Particularly, task-oriented conversations, aimed at coordinative precision and more tightly constrained by the lab context, will feature more restricted forms of repair. By contrast, free interactions, which often happen in more noisy environments and incorporate a wider range of activities, will involve more open forms of repair. (iv) The different indices of common ground are not independent from each other. For instance, we expect repair and alignment to be related because the repetition of linguistic forms across speakers is a key formal measure of both. The latter point underlines the importance of considering possible relations between repair and alignment when discussing measures and mechanisms of social coordination.

## Methods

## Free Social Conversations

We used 18 conversations from the DanTIN corpus (Steensig et al., 2013), 10 minutes per conversation, for a total of 4954 speech turns. Data collection was limited to spontaneous, naturally occurring conversations between families and friends. Participants often engaged in additional activities during these conversations (e.g., eating, or playing games). The average conversation involved 275 speech turns ( $\mathrm{SD}=55$ turns), with an average of 58 turns per interlocutor ( $\mathrm{SD}=52$ ). All conversations were in Danish. The corpus reflects the diversity of free social interactions, with seven conversations involving 2 participants, seven with 3, two with 4 , two with 5 participants, and one with 7 participants. We are currently extending this corpus to be better able to model the effects of number of interlocutors and participation framework.

## Task-oriented Conversations

We used the 44 task-oriented conversations that make up the DanPass corpus (Grønnum, 2009), totaling 9448 speech
turns. The conversations were aimed at solving the Map Task (Anderson et al., 1991). The average length of each conversation was 7.4 minutes ( $\mathrm{SD}=3$ ), with an average 214 turns per conversation ( $\mathrm{SD}=85$ ), and 107 per interlocutor ( $\mathrm{SD}=42$ ). All conversations were in Danish and involved only 2 participants in separate booths. We are currently extending this corpus to include co-present interlocutors.

## Backchannels

Backchannels were manually coded in $10 \%$ of the transcripts (2 free social and 5 task-oriented conversations). Based on this, an automatic procedure for coding backchannels was developed, based on turn length ( $<4$ words) and presence of the words "ja", "nej", "okay", "nå", "jo", "mmhm", "jamen", "mmm", and "åh". The system achieved substantial intercoder agreement with the manual coding (Kappa=0.62). As we are currently extending and validating the coding scheme, results based on the current version of this measure should be treated with caution.

## Conversational Repair

A trained analyst identified sequences of other-initiated repair and classified them according to three crosslinguistically attested format types: open request, which
 ra. restricted request, which restricts the problem space by requesting clarification of a specific element of the problematic turn; and restricted offer, which offers a candidate perception or understanding for confirmation (Dingemanse \& Enfield, 2015). In addition, 10\% of the transcripts ( 3 free social and 5 task-oriented conversations) were analyzed by a second coder. We obtained substantial intercoder reliability, corresponding to a Kappa of 0.67 for repairs in general, and 0.79 respectively for open and restricted repairs (the latter breaking down to 0.4 for restricted requests and 0.38 for restricted offers).

## Interactive Alignment

We calculated lexical and syntactic interactive alignment on a turn-by-turn basis. Each turn was lemmatized using the CST lemmatizer for Danish (Jongejan \& Haltrup, 2005) and parts of speech tagged using DKIE (Derczynski, Field, \& Bøgh, 2014). Lexical alignment was calculated as the cosine similarity between lemmatized words in adjacent speech turns uttered by different interlocutors. Syntactic alignment was calculated as the cosine similarity between 2 -grams

parts-of-speech in adjacent speech turns uttered by different interlocutors. To avoid possible lexical alignment confounds we regressed it out of syntactic alignment as in (Hopkins, Yuill, \& Keller, 2016).

## Data Analysis

To assess whether the free social vs. task-oriented nature of the conversations affected the development and maintenance of common ground, we employed mixed effects regression models to predict the presence of conversational repair (binomial variable), interactive alignment (continuous variable) and backchannels (binomial variable) on a turn-by-turn basis. We employed Task (binomial variable, FC vs. TOC), and Time within conversation (count variable, quantified as number of turns from the start) as fixed effects and conversation as random effects, including a random slope for Time. When the model did not converge, we removed first the random slope, then the fixed effect of Time. To determine whether the different social coordinative mechanisms are related to each other, we employed two mixed effects regressions. The first predicted the overall amount of repair initiations in a conversation (count variable) from the amount of backchannels and alignment, controlling for the offset of overall amount of conversational turns. The second predicted the presence of repair at a turn level (binomial variable) from the presence of backchannel and the level of alignment of that same turn. Finally, to establish how distinctive these mechanisms are, we produced a 5 -fold cross-validated predictive regression assessing whether one could use the presence and amount of conversational repair, interactive alignment and backchannels to identify the nature of the conversation. All analyses were run using R 3.3.2, RStudio 1.0.136, lme4 1.112, irr 0.84 and tidyverse 1.1.0.

## Results

## Backchannels

Backchannels were highly frequent in the corpora ( $54 \%$ of the speech turns), and more so in TOC ( $58 \%$ of speech turns), than in FC ( $48 \%$ of speech turns): $\beta=0.6, S E=0.04$, $p<.001$ (see Figure 1). Backchannels also increased over time ( $\beta=0.07, S E=0.03, p=.03$ ), but not differently in the two corpora ( $\beta=-0.02, S E=0.04, p=.57$ ).

## Conversational Repair

Conversational repair was highly frequent across both corpora, in line with previous findings in 12 other languages (Dingemanse et al., 2015). Repair initiations made up 3\% of speech turns, with an average 45.59 seconds ( $S D=54.8$ ) and 34.03 speech turns ( $S D=41.83$ ) between successive repairs. Task Oriented Conversations showed a higher frequency of repair ( $\beta=0.4, S E=0.18, p=.0274$ ) than Free Conversations, with 31.13 turns ( 51.13 seconds) between repair initiations in the former and 39.65 turns (61.3 seconds) between repair initiations in the latter; see Figure 1. Time was not a significant main effect $(\beta=-0.0007, S E=$ $0.0006, p=.3$ ), nor did it interact with Task ( $\beta=0.0007, S E$ $=0.001, p=.6$ ).

Open repair was much more frequent ( $38.5 \%$ of repair) in free social interactions, than in task oriented interactions (4\% of repair): $\beta=-2.82, S E=0.39, p<.001$. Open repair tended to decrease in frequency as conversations proceed ( $\beta$ $=-0.005, S E=0.003, p=.0607$ ), with no interaction with interaction type $(\beta=0.007, S E=0.004, p=.1275)$. Restricted request repair was not significantly different between corpora (FC: $17 \%$, TOC: $22 \%$ ): $\beta=0.4, S E=0.34$, $p=.23$ ). There was a marginal tendency for restricted request repair to increase over time ( $\beta=0.003, S E=0.0016$, $p=.0804$ ), with no interaction with interaction type ( $\beta=$ $0.002, S E=0.004, p=.5$ ), but the model did not converge with these factors. Restricted offer repairs were more frequent in TOC ( $74 \%$ of repair) than in FC ( $45 \%$ of repair): $\beta=1.97, S E=0.48, p<.001$. There was no significant main effect of time $(\beta=0.003, S E=0.0024, p=.185)$, but a significant interaction with interaction type ( $\beta=-0.006, S E$ $=0.003, p=.0415$ ) indicating a decrease in the TOC over time, but not in FC (see Figure 2).

Figure 2: Distribution of repair types in the two corpora.

## Interactive alignment

As illustrated by Figure 1, syntactic and lexical alignment is significantly lower in TOC than FC (lexical: $\beta=-0.14, S E=$ $0.15, p<.001$; syntactic: $\beta=-0.04, S E=0.009, p<.001$ ). Alignment significantly decreases over time for lexical ( $\beta=$ $-0.0002, S E=0.00001, p<.001)$, but not syntactic $(\beta=-$ $0.00005, S E=0.00004, p=.8$ ), and the decrease significantly interacts with Task, being smaller in TOC (lexical: $\beta=0.0001, S E=0.00007, p=.008$; syntactic: $\beta=$ $0.007, S E=0.00005, p<.001)$. These patterns hold when varying distance between speech turns (alignment over longer stretches of conversation, up to 5 turns of distance); increasing the unit of analysis (up to 4-grams of lexical or
syntactic units); or controlling for increased alignment in repair turns.

## Relations between repair, alignment and backchannels

The general level of conversational repair in a conversation was positively associated with the level of backchannel ( $\beta=$ $0.01, S E=0.003, p<.001$ ) and syntactic alignment $(\beta=$ $0.44, S E=0.18, p=.014$ ) and negatively associated with lexical alignment ( $\beta=-0.46, S E=0.19, p=.014$ ). At a turn level, conversational repair was associated with increased lexical alignment ( $\beta=0.98, S E=0.19, p<.001$ ), a result driven by the two restricted repair formats. A follow-up explorative analysis indicates that in TOC, alignment is indeed much higher for turns containing repair initiations than for other turns (Lexical: 0.168 vs. 0.102; Syntactic 0.091 vs. 0.048 ), but not so in FC (Lexical: 0.113 vs. 0.112 ; Syntactic: 0.074 vs. 0.087 ). Interactions between the different indexes did not significantly improve the likelihood of the model.

## Social coordinative mechanisms as discriminative patterns

Employing a combination of repair, interactive alignment and backchannels information, we were able to classify the transcripts according to their interaction type with an accuracy of $83.82 \%$ ( $95 \%$ CIs: $77.46 \%-88.97 \%$ ), a sensitivity of $84.71 \%$ and a specificity of $82.95 \%$, over chance accuracy of $51.46 \%$. General levels of repair in a conversation alone gave an accuracy of $61.4 \%$ ( $95 \%$ CIs: $53.7 \%-68.74 \%$ ). Interactive alignment gave an accuracy of 80.7\% (95\% CIs: 73.98\%-86.33\%). Backchannel gave an accuracy of $63.16 \%$ ( $95 \%$ CIs: $55.46 \%-70.39 \%$ ).

## Discussion

In this study, we compared different ways in which common ground may be established and maintained across both taskoriented and free conversations. We predicted that (i) we would find distinctive patterns of repair, backchannels and alignment. In particular, (ii) task-oriented conversation should show higher rates of repair, backchannels and alignment; (iii) task-oriented conversation should show lower rates of open requests for clarification; (iv) repair and alignment should be correlated because of the high frequency of repetition in restricted repair formats.

We found full support for (i): knowing the amount of repair, backchannels and alignment present in a conversation enables accurate ( $>80 \%$ ) discrimination between task-oriented and free conversations. We also found partial support for (ii): higher rates of backchannels and repair in TOC but not alignment; full support for (iii): lower rates of open requests, making restricted offers the most frequent in task-oriented interaction; partial support for (iv): lexical, but not syntactic alignment, is correlated with repair, an effect driven particularly by restricted repair formats. As such, our preliminary findings shed new light
on the relations between backchannels, conversational repair and interactive alignment as measures of social coordination. If further confirmed with a more controlled dataset, they might also help clarify the relations between informal and task-oriented interactions.

Four findings stand out. First, FC and TOC present clear differences in the mechanisms employed to negotiate and maintain common ground. As solving the MapTask requires the construction of a shared representation of the space to navigate and its landmarks, we observe more explicit negotiation (repair) and confirmation of common ground. In line with our previous work, we also find that alignment seems less crucial in TOC. This could be a consequence of a division of labor leading to complementary rather than repeated lexical and syntactic structure among individuals solving a task (Fusaroli, et al., 2012; Fusaroli \& Tylén, 2016). The higher alignment in FC might also indicate the prevalence of less explicit mechanisms to negotiate common ground, less likely to lead to face-loss (Bjørndahl, Fusaroli, Østergaard, \& Tylén, 2015; Brown \& Levinson, 1978). However, as a previous study reports an opposite result with TOC showing higher alignment than FC, ongoing work is implementing more conservative and comparable techniques, such as the use of surrogate pair (composed of interlocutors from different conversations) baselines (Healey, Purver, \& Howes, 2010; Hopkins, et al., 2016). Analogously, further investigation of the temporal decrease of alignment is warranted.

Second, repair in task-oriented interaction is strongly skewed towards restricted formats and particularly the restricted offer format. This provides novel support for the 'strongest initiator rule’ (Clark \& Schaefer 1989), according to which participants initiate repair using the strongest repair initiator possible given the circumstances. Prior work based on informal interaction found that noise and parallel involvements increased the likelihood of open repair (Dingemanse \& Enfield, 2015; Dingemanse et al., 2015), essentially by making it comparatively harder to initiate repair using restricted formats, which require having heard and understood as least part of the problematic source turn. Here we replicate this finding in an informal corpus of Danish interaction, and add a direct comparison with taskoriented interaction. The task-oriented condition takes away some common causes of perceptual and attentional difficulties, which should push people towards using more specific repair formats. This prediction is indeed met: in task-oriented interaction, the most specific ('strongest') repair initiation format is also the most commonly used.

Third, repair and alignment are intertwined. For instance, consider the following example, in which the restricted request consists in the repetition of all the words of the previous sentence, albeit in a slightly different order:

A: Vi var i Ikea [We were at Ikea]
B: Var I i Ikea, dig og ? [You were at Ikea, you and ?]
A: $m m h$

While alignment has often been cast as an implicit, automated background process, and repair as its explicit, and much rarer, "friend in need," our parallel investigation of repair and alignment reveals that widely used formal measures of alignment also pick up many restricted repair sequences. This is no surprise -after all, the crucial role of repetition in repair sequences has long been known- but it does point to the need for a reappraisal of the relationship between repair and alignment. Our findings suggest that the evidential base for a large part of the alignment literature may include many explicit repair sequences, belying the common assumption that alignment is an automated, lowlevel process.

Fourth, the combination of backchannels, repair and alignment allows us to classify interaction type with a high degree of accuracy. While these results still need to be generalized to a wider range of social activities and contexts, they open up new avenues for the possibility of classifying discourse data and contributing to the growing field of computer-assisted studies of dialog structure.
Although very encouraging, our findings should be viewed as preliminary. The two corpora differ in several aspects: the presence of a task: interlocutors' physical copresence (in FC but not TOC), number of interlocutors involved in the conversations ( 2 in TOC, 2 or more in FC), and familiarity (possibly higher in FC ). All these aspects are likely to affect conversational dynamics. We are currently extending the corpora to include full variation along these dimensions and account for them in the statistical analyses.

## Conclusions

A comparative assessment of three mechanisms for the negotiation of common ground - backchannels, conversational repair and interactive alignment - highlights important differences in free and task-oriented conversations, plausibly related to situational features and task demands. Our results point to interactions between these mechanisms, e.g. with restricted repair feeding lexical alignment, which suggests future research should further disentangle their reciprocal role. As a theory-driven quantitative comparative study of conversations, our approach shows how insights from conversation analysis, cognitive science and natural language processing can be combined to contribute to a cumulative science of human interaction.

# How do Speakers Coordinate Planning and Articulation? Evidence from GazeSpeech Lags 

Chiara Gambi (cgambi@exseed.ed.ac.uk)<br>Department of Psychology, 7 George Square<br>Edinburgh, EH8 9JZ UK<br>Matthew Crocker (crocker@coli.uni-sb.de)<br>Department of Computational Linguistics and Phonetics, C7.1 University Campus<br>Saarbrücken, 66123 Germany

#### Abstract

How do speakers coordinate planning and articulation of more than one word at the same time? Here, we test whether they dynamically estimate how long it takes to (i) plan and (ii) articulate the words they intend to produce as a means of achieving such coordination. German speakers named two pictures without pausing, while their eye-movements were recorded. In line with previous reports, after their gaze left the first picture, speakers took longer to start speaking (i.e., the gaze-speech lag was longer) when the name of the first picture was shorter. But while gaze-speech lags were also longer when the second picture was harder to name, the two effects did not interact. We argue that speakers' flexible planning abilities might be accounted for by reactive, rather than proactive planning mechanisms.

Keywords: planning; estimation; duration; coordination; gaze-speech lag.

## Introduction

Speakers plan ahead of articulation (Griffin \& Bock, 2000; Levelt, Roelofs, \& Meyer, 1999) and usually complete lexico-semantic planning for at least a whole phrase (Martin, Crowther, Knight, Tamborello, \& Yang, 2010; Smith \& Wheeldon, 1999), phonological planning for a whole word (Meyer, 1996; Smith \& Wheeldon, 2004), and articulatory planning for a whole syllable (Meyer, Roelofs, \& Levelt, 2003) before beginning to speak. While this allows for rapid and fluent speech production, the incremental nature of planning also raises the question of how speakers manage the timely coordination of planning and articulatory processes.

## Mechanisms for Flexible Advance Planning

Several studies have uncovered regularities in speakers' amount of advance planning; for example, suggesting that speech onsets are comparable across short and long words because speakers usually complete articulatory processing for only the first syllable of a word prior to speech onset (Damian, Bowers, Stadthagen-Gonzalez, \& Spalek, 2010; see also Meyer, Roelofs, \& Levelt, 2003). Importantly, in recent years it has also become clear that the amount of advance planning speakers perform is not fixed, but rather varies with properties of both the utterance and the speaker's recent experience (Konopka, 2012; Van de Velde,

Meyer, \& Konopka, 2014), or task context (Meyer et al., 2003).

We thus know a great deal about factors that can influence the coordination of planning and articulatory processes. On the contrary, we know very little about the mechanisms that underlie the timely coordination of these processes. For example, we know that planning style is influenced both by the accessibility of linguistic units, and by the ease-of-apprehension of the referent (Konopka \& Meyer, 2014). This suggests that the mechanism involved must be sensitive to the difficulty of the planning process at different stages, but there are at least two ways in which such a mechanism could operate.

One possibility is that a flexible planning system operates reactively. Once speakers encounter some difficulty, a compensatory mechanism is triggered. For instance, if accessing a particular word is difficult (i.e., takes time), attention might be (temporarily) shifted to another process (e.g., retrieving a different word). But in addition, the planning system might, at least in part, allocate resources to different processes in a proactive manner. Such a proactive planning mechanism could be learnt from previous experience with producing language (in general, or within a particular task), and indeed there is evidence that planning style can be primed by previous experience with the same sentence structure (Van de Velde et al., 2014). A proactive planning mechanism would of course be beneficial in maximizing fluency, as it may allow speakers to avoid future difficulties, by anticipating their likely occurrence and taking appropriate steps before they even arise. This idea is reminiscent of some models of motor control (e.g., Wolpert and Flanagan, 2011).

## Proactive Planning: Candidate Evidence?

To our knowledge, no language production study has investigated this issue directly. However, in one seminal study, Griffin (2003) suggested that speakers might estimate how long both planning and articulating a word will take, and then combine such estimates to determine how to time one process with respect to the other in order to minimize future disfluencies (i.e., to plan proactively).

To illustrate, imagine a speaker of German preparing to produce Abschlussballkleider (dresses for the high-school prom). Let us assume, for the purpose of illustration, that
the speaker retrieves Abschlussball (prom) and Kleider (dresses) separately (Sandra, 1990) ${ }^{1}$. If so, the speaker will need to get the first syllable of Kleider ready to be articulated by the time articulation of Abschlussball is ending. To do this, the speaker could estimate both how long it will take her to get Kleider ready (i.e., retrieval difficulty) and how long it will take her to say Abschlussball (i.e., articulation duration). She could then determine that she will probably have enough time to prepare Kleider while saying Abschlussball (a long word), so she can start speaking right away. But if the first word is short, such as Sport in Sporttitelseite (sport title page), she might instead have to delay speech onset in order to prepare more of the second word before starting to speak. Similarly, she may need to delay speech onset if the second word is particularly difficult to retrieve.

However, the evidence in support of Griffin's proposal is currently somewhat mixed. Griffin (2003) asked speakers to name two pictures one after the other, without pausing, while their eye-movements were recorded. Critically, the name of the picture that was mentioned first (word ${ }_{l}$ ) could be either short (monosyllabic) or long (plurisyllabic). In this task, speakers usually shift their gaze from the first to the second picture as soon as they have retrieved the phonological representation for word $_{1}$ (Griffin, 2001; Meyer \& Van der Meulen, 2000). The gaze shift generally occurs before overt articulation of word $_{l}$. Importantly, the interval between this gaze shift and speech onset (i.e., the gazespeech lag) is longer when word ${ }_{l}$ is shorter (a reversed word-length effect). According to Griffin (2003), this shows that speakers estimate word $_{1}$ duration: they begin speaking earlier (with respect to the gaze shift, thus leading to a longer gaze-speech lag), when word $_{l}$ is shorter in order to have more time to retrieve the second picture's name ( word $_{2}$ ) before, rather than during, articulation of word ${ }_{l}$.

However, while Meyer, Belke, Häcker, and Mortensen (2007) replicated Griffin's finding ${ }^{2}$, they also provided a different explanation. We know that speakers may begin retrieving the articulatory code of the first syllable of a word as soon as they complete phonological processing for this syllable (i.e., without waiting for phonological processing of the whole word to be completed); in turn, as soon as they have retrieved such code, they can begin speaking. But if word $_{1}$ is monosyllabic, the moment of the gaze shift (which coincides with completion of phonological processing for the whole word; see above) also happens to coincide with the start of articulatory retrieval. As a result, the gazespeech lag will last at least the time it takes to perform

[^333]articulatory retrieval for one syllable. By contrast, for a polysyllabic word $_{l}$ the gaze shift occurs only later (once articulatory retrieval of the first syllable is already underway), thus leading to a shorter lag.

## This study

If Meyer et al.'s (2007) explanation is correct, then the reversed-length effect on gaze-to-speech lags is not evidence that speakers estimate duration, contrary to Griffin's (2003) suggestion. Moreover, neither study demonstrates that speakers can combine estimates of retrieval difficulty with estimates of duration, because they did not manipulate the difficulty of retrieving word $_{2}{ }^{3}$. Here, we provide a test of this hypothesis: If speakers take into account not only word ${ }_{1}$ length (monosyllabic vs. polysyllabic words), but also word $2_{2}$ retrieval difficulty, gaze-speech lags should be affected by both variables. Moreover, the effects of the two variables should interact, reflecting the workings of a proactive planning mechanism underlying the tight coordination of articulation (of word ${ }_{l}$ ) and planning (of word ${ }_{2}$ ).
For word $_{2}$, we chose a manipulation that is both known to reliably affect the earliest stages of picture naming, and very easy to identify for participants: Pictures were either visually intact or degraded (see Figure 1). We reasoned this would provide the most favorable test of Griffin's proposal, as speakers were placed in ideal conditions for estimating the difficulty of retrieving word $_{2}$; although degradation does not affect the difficulty of retrieving word ${ }_{2}$ directly, it makes accessing the corresponding concept more difficult, which then has a knock-on effect on the time it takes to fully prepare word $_{2}$. To give speakers ample opportunity to adjust to the relevant level of difficulty, and to avoid carryover effects, degradation varied between participants.
As in previous studies, the gaze-speech lag should be longer when word ${ }_{1}$ is shorter. In addition, if speakers can estimate retrieval difficulty, it should also be longer when word $_{2}$ takes longer to retrieve. Crucially, there should be a significant interaction, with word $_{2}$ difficulty having a larger effect when word ${ }_{l}$ is shorter. As there is less scope for completing word ${ }_{2}$ retrieval during the articulation of word $_{1}$ when word $_{1}$ is short, speakers should aim to complete most of word $_{2}$ retrieval before speech onset; instead, when word ${ }_{1}$ is long, the speaker can benefit from extra time after the onset of articulation, and increases in word ${ }_{2}$ retrieval difficulty may not affect the gaze-to-speech lag as strongly.
If Meyer et al.'s proposal is correct, however, the gazespeech lag should only depend on word ${ }_{l}$ length, and the reversed-length effect on gaze-speech lags would not be evidence for a proactive planning mechanism. Given the potential theoretical relevance of Griffin's (2003) original interpretation of her findings, testing her claim in full, as we do in this study, would advance our understanding of the

[^334]mechanisms underlying flexible planning in language production.

## Method

## Participants

Thirty-two native speakers of German ( 24 female, $\mathrm{M}_{\text {age }}=$ 23.8 yrs, $\mathrm{SD}=2.6$ ), with self-reported normal vision and no language impairments, were paid 8 euros/hour to participate in this and another eye-tracking experiment (not reported here). One participant was replaced because of excessive head movements. Sample size was determined on the basis of previous research (Griffin, 2003; Meyer et al., 2007)

## Materials

We selected 128 black and white line drawings from the picture naming norms of Bates, et al. (2003). Of these, 64 pictures with high name agreement were used as left pictures. Left pictures were named first, so we refer to the left picture names as word ${ }_{l}$. For half the items (Long), word $_{1}$ ranged from 2 to 4 syllables ( 152 -syllable words, 11 3 -syllable words, and 64 -syllable words) ${ }^{4}$, with a mean length of 2.31 syllables ( $\mathrm{SD}=0.64$ ). The other 32 pictures had monosyllabic names (Short). Short and long names were yoked in pairs matched for name agreement (Short: $.93(.10)$, Long: $.91(.10) ; \mathrm{t}(31)=1.17, \mathrm{p}>.2$ ), log-frequency (Short: 2.62(.46), Long: 2.54(.45); $t(31)=1.51, p>.1)$ in SUBTLEX-DE (Brysbaert et al., 2011), and initial phoneme.

Sixty-four additional pictures were used as right pictures, and were always named second in the task (word $)^{2}$ ). Two right pictures were associated with each pair of left pictures. Right pictures had high name agreement ( $\mathrm{M}=.94$, $\mathrm{SD}=$ .11); word ${ }_{2}$ had a mean length of 2.14 syllables ( $\mathrm{SD}=.71$ ), a mean frequency of $2.53(\mathrm{SD}=.64)$, and was semantically and phonologically unrelated to each word ${ }_{1}$ it was paired with. We created degraded versions of all right pictures by superimposing a mask of ten parallel white lines (about 35pt apart, and about 15pt-thickness; see Figure 1); on average the mask deleted $35 \%$ of all non-white pixels ( $\mathrm{SD}=2.3 \%$, $\min =30 \%, \max =41 \%$ ).

## Design and Procedure

Length varied within participants and items, whereas Degradation varied within items but between participants. To control for differences due to uninteresting properties of the right pictures, we constructed two lists of items, reversing pairings of left and right pictures (e.g., if in list 1 Bank was paired with Hund, and Brücke with Krone, list 2 featured Bank - Krone and Brücke - Hund); 8 random orders were generated for each list.

[^335]Participants were first familiarized with picture names. After identifying their dominant eye, they were seated about 60 cm from a 24 -inch LCD monitor. A head-mounted Eyelink 2000 recorded data from the dominant eye (pupilonly, sampling frequency: 250 Hz ). Participants were asked to avoid head movements and blinking, and named the pictures in left to right order. It was stressed they should avoid pausing between the two words. A high-quality microphone (Philips SBC ME 570) recorded participants' productions for the entire duration of the trial ( 5.5 seconds); speech onset latencies, and the duration of the pause between names (if present) were then measured offline (in Praat; Boersma \& Weenink, 2010).

Figure 1: A sample trial illustrating manipulations of word $_{1}$ length (short vs. long) and word $_{2}$ retrieval difficulty (intact vs. degraded pictures).

Presentation was controlled using Experiment Builder (Version 1.10.165). Before each trial, a fixation dot was presented where the left picture would subsequently appear. As soon as the participant fixated it, the experimenter triggered presentation of the stimuli (this was also used for drift correction). The left and right pictures were then displayed simultaneously on opposite sides of the screen, 324 pixels (or about $9^{\circ}$ of visual angle) apart. All pictures were scaled to a dimension of $290 \times 290$ pixels, with surrounding interest areas measuring $405 \times 307$ pixels (i.e., $11^{\circ}$ of visual angle horizontally, $9^{\circ}$ vertically).

The eye-tracker was calibrated twice using a ninepoint calibration grid, first after two practice trials, and then halfway through the session. The first trial after the practice session was a warmup trial, and was not analyzed. A session lasted 15-20 minutes.

## Results

Only trials in which both pictures were named fluently (i.e., with no repetitions or filled pauses, and with a silent pause no longer than 200 ms between the words) and using the expected names were analyzed (intact group: 87.99\%; degraded: $83.01 \%$ ). Following Meyer et al. (2007), we also discarded trials on which the pictures were not fixated in the order of mention (only one trial, degraded group), and trials on which the right picture was not fixated before speech onset (intact: 148 trials, or $16.43 \%$; degraded: 34 trials, or
$4.00 \%)^{5}$, as on such trials the gaze-to-speech lag would have been negative.

For the remaining trials we analyzed speech onset latencies, first-pass gaze to the left picture (the sum of all fixations to the left picture before the shift of gaze to the right picture), and the gaze-speech lag (time between the end of the first-pass gaze to the left picture and speech onset). In all analyses, we fit linear mixed-effects models using the lme4 package (D. Bates, Maechler, \& Dai, 2014) in R (R, Version 3.1.3). Fixed effects were contrast coded and centered. Random effects structure was maximal (Barr, Levy, Scheepers, \& Tily, 2013). All $p$ values are from loglikelihood ratio tests; $95 \%$ confidence intervals for model estimates are from the confint function (method="Wald"). We report the critical speech-gaze lag analyses first.

## Gaze-Speech Lag

As expected, the gaze-speech lag was both shorter when word $_{l}$ was long than when it was short $(\mathrm{B}=65 \mathrm{~ms}, \mathrm{SE}=12, \mathrm{t}=$ 5.56, $\chi 2(1)=21.46, p<.001, C I=[42,88])$ and longer for participants naming degraded than intact right pictures $(\mathrm{B}=-$ $140 \mathrm{~ms}, \mathrm{SE}=62, \mathrm{t}=-2.24, \chi 2(1)=4.63, p=.031, C I=[-262,-17]$; see Table 1, top). Crucially, however, there was no interaction between Length and Degradation ( $B=-14 \mathrm{~ms}$, $\mathrm{SE}=21, \mathrm{t}=-.69, \chi 2(1)=0.47, p=.491, C I=[-55,26])$.

## Speech Onset Latencies

After removing a further 7 ( $0.40 \%$ ) outliers (longer than 2500 ms ), we found speech onset latencies were not affected by Length, whether alone $(\mathrm{B}=-14 \mathrm{~ms}, \mathrm{SE}=27, \mathrm{t}=-.50$; $\chi 2(1)=0.21, p=.645, C I=[-67,40])$, or in interaction with Degradation ( $\mathrm{B}=5 \mathrm{~ms}, \mathrm{SE}=25, \mathrm{t}=.19 ; \chi 2(1)=0.04, p=.846$, $C I=[-44,54])$. However, speech onset latencies were longer for participants in the degraded than in the intact group ( $\mathrm{B}=$ $125 \mathrm{~ms}, \mathrm{SE}=60, \mathrm{t}=-2.09 ; \chi 2(1)=4.80, p=.028, C I=[-243,-8]$; see Table 1, middle).

Table 1: Mean gaze-speech lag, speech onset latency, and first-pass gaze to the left picture, in milliseconds (standard deviation of participants' means in brackets), as a function of word $_{l}$ Length and Degradation.

| Gaze-speech lag |  |  |
| :---: | :---: | :---: |
|  | Degraded | Intact |

[^336]
## First-Pass Gaze to the Left Picture

The time spent looking at the left picture before gaze was shifted to the right was not affected by Degradation, whether alone $(\mathrm{B}=17 \mathrm{~ms}, \mathrm{SE}=27, \mathrm{t}=.63 ; \chi 2(1)=0.35, p=.555$, $C I=[-36,71]$; see Table 1, bottom) or in interaction with Length ( $\mathrm{B}=-10 \mathrm{~ms}, \mathrm{SE}=24, \mathrm{t}=-.43 ; \chi 2(1)=0.18, p=.668$, $C I=[-58,37])$. However, left pictures were fixated for longer if they had long than short names $(B=-66 \mathrm{~ms}, \mathrm{SE}=25, \mathrm{t}=-$ 2.70; $\chi 2(1)=7.21, p=.007, C I=[-115,-18])$, confirming that speakers shifted their gaze as soon as they completed phonological retrieval for word ${ }_{l}$.

## Discussion

We asked speakers to produce fluent two-word utterances and showed that the way they coordinate planning of the second word and articulation of the first word depends on both the length of the first word and the difficulty associated with retrieving the second word. The gaze-speech lag was shorter when participants were preparing to produce a long wordl and longer when word 2 was harder to retrieve.

However, we found no evidence for an interaction between word ${ }_{1}$ length and word ${ }_{2}$ retrieval difficulty. As expected, speakers in both groups took longer to articulate word $_{l}$ when it was polysyllabic ( 554 ms for the intact group, 539 ms for the degraded group) than when it was monosyllabic ( 401 ms for the intact group, 393 ms for the degraded group). This difference (about 150 ms ) is actually larger than the difference in speech onset times between the two groups of speakers (about 125 ms ). So, speakers in the degraded group could have had sufficient extra time during the production of a long word ${ }_{1}$ to compensate for the additional difficulty associated with retrieving the name of a degraded picture. In other words, if these speakers had planned proactively, they could have started speech earlier (with respect to the gaze shift) when word $_{l}$ was long than when it was short, as only in the latter case delaying speech onset would have benefitted fluency. Had they done so, gaze-speech lags would have been longer for participants in the degraded group than participants in the intact group (as we observed) but more so when participants were preparing to produce a short word $_{l}$, than when they were preparing a long word ${ }_{l}$.

This is not what we observed. Instead, participants in the degraded group appear to have used a different strategy, delaying speech onset regardless of word $_{l}$ length. Therefore, a strong version of Griffin's (2003) proposal is ruled out by our findings, as our speakers did not appear to be able to combine estimates of articulation duration with estimates of retrieval difficulty in order to precisely time articulation (of word $_{1}$ ) with respect to planning (of word $_{2}$ ).

Meyer and colleagues (2007)'s proposal, instead, is compatible with our results. First, it provides an alternative explanation of the reversed word-length effect on the gazespeech lag, which does not require a proactive planning mechanism. In addition, it may also explain the later speech onsets for speakers in the degraded group, as Meyer et al. (2007) recognized that speakers may not always start

Figure 2: First-pass gaze to the left picture, gaze-speech lag and speech onset latency (means and 95\% bootstrap CI), as a function of word $_{1}$ Length and Degradation.
articulation as soon as the articulatory code of the first syllable of a word has been retrieved.

We suggest that speakers in the degraded group buffered the first syllable of word $_{1}$ when word $_{2}$ representations failed to reach some activation threshold sufficiently early, or levels of competition within the production system (see Nozari, Dell, \& Schwartz, 2011) remained too high. ${ }^{6}$ Importantly, this type of planning mechanism can be considered reactive rather than proactive: It deals with difficulties (with word $_{2}$ retrieval) as they arise. It need not involve a mechanism that dynamically anticipates the likelihood of future difficulties, deploying different planning strategies depending on this likelihood being higher (i.e., when word ${ }_{l}$ is short) or lower.

Interestingly, based on our findings, it appears that speech is not planned proactively at the level of whole words. This appears to contrast with what we know about planning at the level of single sounds or syllables (e.g., Hickok, 2012), where there is evidence that speakers build forward models of upcoming speech movements that allow them to anticipate (and quickly correct, if necessary) what they are going to sound like (e.g., Niziolek, Nagarajan, \& Houde, 2013).

What might account for such discrepancy? We see at least two possibilities. First, research into forward models for speech has largely focused on speakers' ability to correct a

[^337]distortion in the spectral properties of the sounds they generate. We are not aware of any studies that investigated whether speakers anticipate and correct for the duration of a sound in a similar way as they do for spectral properties (e.g., pitch).

Second, in order to show the expected behavior under a proactive planning account, our speakers would have had to anticipate not just duration, but also retrieval difficulty. The latter is, unlike duration or pitch, a property of the process of planning itself, rather than an externally perceivable outcome of the planning process. As such, anticipating retrieval difficulty might involve a kind of "second-order" forward model. Speakers might be able to learn such forward models, but perhaps only with extensive training.

In conclusion, the reversed word-length effect cannot be interpreted as evidence that the flexibility of speakers' planning reflects the workings of a proactive mechanism. However, speakers are able to reactively compensate for retrieval difficulty, delaying speech onset when the need arises.

## Acknowledgments

We thank Raphael Morschett for assistance with preparation of the word lists and data collection. This research was supported by research funds assigned to the Chair of Psycholinguistics by the University of Saarland. # Automated Generation of Cognitive Ontology via Web Text-Mining 

Richard Gao (rigao@ucsd.edu) Thomas Donoghue (tdonoghue@ucsd.edu) Bradley Voytek (bvoytek@ucsd.edu)<br>Department of Cognitive Science, UC San Diego<br>9500 Gilman Drive, La Jolla, CA 92093-0515, USA

#### Abstract

A key goal of cognitive science is to understand and map the relationship between cognitive processes. Previous works have manually curated cognitive terms and relations, effectively creating an ontology, but do they reflect how cognitive scientists study cognition in practice? In addition, cognitive science should provide theories that inform experimentalists in neuroscience studying implementations of cognition in the brain. But do neuroscientists and cognitive scientists study the same things? We set out to answer these questions in a data-driven way by text-mining and automated clustering to build a cognitive ontology from existing literature. We find automatically generated relationships to be missing in existing ontologies, and that cognitive science does not always inform neuroscience. Thus, our work serves as an efficient hypothesis-generating mechanism, inferring relationships between cognitive processes that can be manually refined by experts. Furthermore, our results highlight the gap between theories of cognition and the study of their implementation.

Keywords: ontology; cognitive neuroscience; text-mining neuroinformatics, meta-analysis

## Introduction

## Ontology: Key Challenge in Cognitive Science

One of the fundamental goals of cognitive science is to study the set of processes that combine to give rise to "cognition". These processes can be thought of as abstractions to common, overlapping sets of behaviors. Constrained by methodological behaviorism, we can only observe behavior and label underlying cognitive processes after the fact. As such, they do not have direct grounding in the physical world, and thus need to be defined by the relational structure that link each other - an ontology. For example, attention and working memory are processes with different labels but are nonetheless woven together through behavior: one cannot allocate "working memory" without "paying attention". Thus, as we collect more observations to fill up the space of cognitive processes, we must be attentive in organizing what we know. This is the problem of mapping the ontological structure of cognitive processes, and has received extensive consideration previously (see, e.g., Poldrack \& Yarkoni, 2016).

## Neuroscience: Studying the Substrate of Cognition?

If cognitive processes are viewed as algorithms performing a set of computations, there must then exist a
physical substrate that is performing the computations. In the case of computer algorithms, the substrate consists of transistor elements. The brain, on the other hand, is a large part of the computational substrate of human cognition (along with our body and environment). Cognitive neuroscience, with the aid of neuroimaging, has revealed much about our cognitive processes, such as timing between consecutive steps in a cascade of processes. However, neuroimaging studies are almost always conducted in the laboratory, with specific physical and task constraints. Hence, one cannot be certain that cognitive neuroscience actually measures, or even attempts to measure, the full array of cognitive processes at play. For example, the consolidation of long-term memory is quite difficult to measure within the span of a single experiment, while visual perception can be easily studied. Conversely, observations in neuroscience may provide constraints for cognitive theories, but only if there is an overlap of interest in the same processes. Thus, we should understand the degree to which we are over- and under sampling cognitive processes while measuring the brain. This is the problem of adequate sampling of cognitive processes in cognitive neuroscience.

## Frameworks for Ontology-Mapping

The problem of ontology has been addressed previously. Notably, Poldrack and colleagues (2011) started a monumental effort in charting the ontological space of cognitive processes, as well as their related experimental tasks and disease correlates, aptly named the Cognitive Atlas. These authors hand-crafted hundreds of terms and their relations with each other, and invited researchers to contribute to documenting new relations - like a Wikipedia for cognitive science. While quality-controlled, curating these processes by hand relies on massive participation of the community, and must match the speed at which new evidence linking old processes is published. A complementary approach to human-generated relations is to let experts judge the validity of machine-generated relations, which can cover much more ground very quickly, saving human time and resources.

## Automated Generation of Cognitive Ontology

Here, we present an automated text-mining algorithm that scans through relevant literature databases and builds an
ontology through co-occurrences of cognitive terms mined from the Cognitive Atlas. In particular, we apply the mining algorithm to PubMed, as well as the proceedings to the Annual Meeting of the Cognitive Science Society, in an attempt to automatically generate an ontological structure supplementing the Cognitive Atlas. Furthermore, we search PubMed for cognitive terms in conjunction with neuroimaging terms to establish the cognitive ontology viewed through neuroscience. We note here that previous neuroinformatic works have tackled related challenges. In particular, Yarkoni et al. (2011) created Neurosynth as a meta-analysis of fMRI studies. Its strength lies in providing voxel-level identification of the neural support of cognition, though it necessarily ignores the massive body of electrophysiological research (EEG, MEG, etc.) in favor of certainty in spatial location. In addition, Voytek \& Voytek (2012) built BrainSCANR, an automated PubMed textmining application for similar purposes. However, that work focused primarily on aspects of neuroscience, with inclusion of brain regions and neurochemicals as keywords, while having a limited set of cognitive terms.

In the following sections, we describe the text-mining procedure, as well as an analysis of the word-relations constructed from the automatically generated databases. We present similarities of term-frequency in 4 databases: CogSci (CS), PubMed Cognitive (PMCog), and PubMed Neuro (PMNeu \& PMNeuMeth). We further explore latent structures within each database via hierarchical clustering to automatically generate an ontology of cognitive processes.

## Methods

All code available online at:
https://github.com/voytekresearch/IdentityCrisis

## Data Collection

Term Collection 803 cognitive terms were scraped from the "Concepts" page from the Cognitive Atlas. These were used as the main search terms below, and will thus be referred to as "cognitive terms."

CogSci Abstracts This database is constructed from the title and abstracts of the Presentations, Tutorials, Symposia, and Papers of the Annual Meeting of the Cognitive Science Society from 2010 to 2016. We look for the cognitive terms in each document, constructing a term-document matrix. We then built a co-occurrence matrix by noting all pair-wise co-occurrences of cognitive terms in each document. Data from all 7 years are aggregated. Terms with 50 or more occurrences are included in the clustering analysis (86).

PubMed Cognitive This database is constructed by searching in PubMed for pairs of cognitive terms in quotations, such as "attention"AND"working memory", plus a base phrase: ('AND("cognitive"OR"cognition")'), to ensure searches are constrained to hits relevant to cognition. Counts are recorded as the number of articles that include the search terms in the title or abstracts. Prior to pairs
search, we built a term-frequency vector measuring the occurrence of all 803 cognitive terms. Only individual terms with 500 or more hits ( 217 terms) were included in the pairs search to decrease search time. The number of hits for each pairs of terms ( $\mathrm{i} \& \mathrm{j}$ ) are recorded in the co-occurrence matrix as element $\mathrm{a}_{\mathrm{ij}}$. Search code was built upon the PubMed EUtils Tool API.

PubMed Neuro Method $\mathcal{\&}$ Neuro These databases are created as the one above, but in conjunction with a base phrase reflecting neuroimaging techniques,
('AND('+ '("fmri"OR"neuroimaging")OR'+
'("pet"OR"positron emission tomography")OR'+
'("eeg"OR"electroencephalography")OR'+
'("meg"OR"magnetoencephalography")OR'+
'("ecog"OR"electrocorticography")OR'+
'("lfp"OR"local field potential")OR'+
'("erp"OR"event related potential")OR'+
'("single unit"OR"single-unit"OR"single neuron")OR'+
'("calcium imaging")")').
138 terms remained after thresholding at 500 hits.
As suggested by reviewers, we further included a "general neuroscience" database that was not exclusively techniques, using ("neural"OR"neuroscience") as base phrase.

## Data Analysis

Term-Frequency Term-frequency for each cognitive term were calculated as a fraction by dividing the number of hits a term generated by the total results returned for the base phrase alone (for PubMed databases) or the total number of abstracts (for CogSci database). To visualize differences in term usage, we take the term-frequency difference between pairs of databases and find the terms with the highest absolute difference.

Hierarchical Clustering We use the SciPy hierarchical clustering module (scipy.cluster.hierarchy) to cluster terms based on their normalized co-occurrence matrix, where each row is divided by the diagonal of that row (co-occurrence with self). Dendrograms are generated and leaves are cut (colored) to generate $\sim N / 4$ clusters, where $N$ is the total number of terms in tree.

## Results

In summary, we find that:

1) there are discrepancies between prevalent terms discovered in the CogSci database and the PubMed Neuro database, with the former leaning towards more theoretical constructs, and the latter, experimentally tangible;
2) hierarchical clustering reveals reasonable yet novel groupings of cognitive terms that are undocumented in the Cognitive Atlas.

## Term-Frequency Across Databases

First, we address the question: do cognitive scientists and neuroscientists study the same underlying processes? Table

1 presents the top 20 most frequent cognitive terms in each database.

Table 1: Proportion of term occurrence for the top 20 terms in each database. Green boxes denote terms unique to that database, while red boxes denote terms unique to Neuro.

| CogSci |  | PM Cog |  | PM Neuro |  | PM Neuro Meth |  |
| :--- | :--- | :--- | :--- | :--- | :--- | :--- | :--- |
| learning | 0.257 | memory | 0.201 | activation | 0.114 | activation | 0.11 |
| search | 0.228 | risk | 0.131 | learning | 0.071 | detection | 0.068 |
| action | 0.218 | attention | 0.108 | memory | 0.065 | memory | 0.06 |
| language | 0.185 | learning | 0.104 | loss | 0.054 | risk | 0.059 |
| logic | 0.151 | association | 0.081 | action | 0.053 | attention | 0.052 |
| knowledge | 0.128 | anxiety | 0.066 | inhibition | 0.052 | monitoring | 0.048 |
| concept | 0.126 | stress | 0.059 | attention | 0.044 | sleep | 0.043 |
| memory | 0.122 | loss | 0.054 | risk | 0.041 | association | 0.041 |
| context | 0.116 | activation | 0.053 | perception | 0.038 | movement | 0.036 |
| decision | 0.098 | knowledge | 0.052 | detection | 0.037 | loss | 0.034 |
| attention | 0.091 | language | 0.051 | knowledge | 0.036 | action | 0.031 |
| reasoning | 0.081 | context | 0.046 | association | 0.034 | learning | 0.03 |
| judgment | 0.081 | working | 0.044 | context | 0.034 | perception | 0.029 |
| focus | 0.079 | focus | 0.04 | stress | 0.033 | inhibition | 0.029 |
| lying <br> inference | 0.074 | perception | 0.04 | movement | 0.032 | knowledge | 0.028 |
| perception | 0.072 | recognition | 0.039 | mood | 0.038 | recognition | 0.032 | focus $\quad 0.027$.

First, we note the general trend that CogSci proceedings are much more likely to contain one of several popular terms, with 3 terms appearing in more than $20 \%$ of the abstracts and 9 terms in more than $10 \%$. In contrast, only one word in the PMNeuro database is contained in more than $10 \%$ of the abstracts ("activation"), which may be artificially inflated due to usages of the word in contexts not describing cognitive activation (e.g., fMRI activation). This suggests that the terms we deem to describe "cognitive processes" do indeed see more usage in the cognitive science community.

On an individual term level, several striking patterns prevail. First, "learning" appears in about $25 \%$ of CogSci abstracts, but only $10 \%$ in PMCog, $7 \%$ in PMNeu, and $3 \%$ in PMNeuMeth. This reveals that the concept of "learning" is a rather popular theoretical construct, while being harder to study empirically via neuroimaging. Additionally, "search", "language", and "logic" all appear in more than $15 \%$ of CogSci abstracts, but do not crack the $5 \%$ mark in PMNeuro, further suggesting the difficulty or reluctance in studying these theoretically important but empirically illdefined concepts in a neuroscientific context.

On the other hand, "attention", "perception", and "movement" occur in all 4 databases with relatively low but similar proportions. This is unsurprising, as physical processes are much more easily studied in neuroscientific experiments.

Figure 1: Term frequency results for each database. Note that $y$-axis is in log scale.

We saw from Table 1 that term usage distribution for the most frequent terms are not the same across the 4 databases. Figure 1 plots these distributions for the top 250 terms used. We see that CogSci proceedings are not very diverse in terms of their topics of investigation, as the more common terms are much more represented in the abstracts. This may be due to the small number of CogSci abstracts available, compared to around 100 times more results returned from PubMed searches. However, PMCogs is less drastic but follows a similar trend, suggesting that cognitive science as a whole refers to these cognitive terms much more frequently than neuroscience.

Figure 2. Terms used most differently between Cognitive Science (CogSci, left, PMCogs, right) and Neuroscience.

Finally, we find terms with the biggest usage proportion difference between cognitive science and neuroscience. These results recapitulate the top terms we see in Table 1, where an overwhelming proportion of high-level, conceptual terms are overrepresented in the 2 cognitive datasets. Overall, these analyses demonstrates that, while cognitive terms are adopted more frequently in CogSci
abstracts than the general body of literature in PubMed, many of the processes that are focused on in the CogSci community has not seen as much empirical investigation in the neuroscience community.

## Hierarchical Clustering

Having shown a difference in the frequency of cognitive term usage between cognitive science and neuroscience, we turn to the term co-occurrence data to generate ontologies. Here, we can address the question of, in addition to being used with differing frequencies, whether the terms are used in different ways in relation to each other, which suggests a difference in term "meaning". Figure 3 shows dendrograms generated from the CogSci database and PMNeuMeth database. The length of the colored lines (starting from the right) when they merge reflect the similiarity of the the merged terms: the shorter the lines, the more similar they are. As such, pairs of terms like "acuity" and "visual acuity", or "memory" and "working memory" are merged very early on due to the overlap in words, which is a limitation of the text-mining method employed.

Barring these overlapping terms, very reasonable clusters emerge at the mid-level. For example, at the lower end of the CogSci tree exists a language group (red \& green) and a learning group (teal). Interestingly, "learning" and "generalization" are very closely tied. Moving up a few clusters, a reasoning cluster emerges (black), including "reasoning", "inference", "induction", and "rule". Similar clusters existing in the PMNeu tree, where the top clusters reflect all forms of perception, then attention, transitioning to speech processing, and finally to language understanding. "Theory of mind" is grouped with "empathy" and "social cognition", while "discrimination" is grouped with "categorization" and "judgement".

Due to the difference in term prevalence between these two databases, some clusters exclusive to one or the other appear. "Logic", "analogy", and "schema" exist as one cluster in the CogSci database, while "anxiety", "fear" and "extinction" emerge as a cluster in the PMNeu database. These clusters clearly reflect the theoretical vs. experimental nature of works published in these two fields. Furthermore, "learning" in CogSci, as mentioned above, talks about a high-level, mental process (tied to "category learning"), while it is linked to "skill", "navigation", and "expertise" in neuroscience. Overall, these examples qualitatively demonstrate that an automated mining and clustering process can tease out: 1) similarity of cognitive terms by grouping them within clusters, and 2) contextualized meaning of terms by grouping them into different clusters specific to cognitive science or neuroscience.
Finally, in keeping with our original goal, we examine whether clusters discovered with our automated process can be used to supplement information in the Cognitive Atlas. Figure 4 demonstrates one example concept: "learning". We observe that the only populated relationship is "are kinds of", in which more specific types of learning are listed. However, the ontological mapping does not capture
categorically similar terms described above, such as "generalization" or "categorization". Other examples of missed relationships are more nuanced. For example, under "addiction", the Cognitive Atlas currently includes "reward processing" as a part of addiction (also discovered in our clustering). However, it does not mention "anticipation" and "impulsivity", both of which are key factors in the continuation of addictive behavior. Hence, we conclude that automated clustering of related concepts can greatly aid in the curation of an extensive cognitive ontology.

Figure 4: "learning" and "addiction" as curated by Cognitive Atlas, supplemented by clusters generated automatically (from Fig. 3).

## Discussion

## Summary

In this study, we created a text-mining and clustering pipeline that aims to automate the process of aggregating information from existing literature to create an ontological structure for cognitive processes. We searched for cognitive keywords curated by the Cognitive Atlas, and analyzed databases created by scraping the proceedings to the Annual Cognitive Science meeting, as well as PubMed articles, containing these keywords. We find a prevalent usage of these terms in all the databases, particularly so in the CogSci abstracts. The frequency of term usages differ between CogSci abstracts and PubMed neuroscience articles, likely reflecting the methodological preferences in each field. Hierarchical clustering on pairwise term co-occurrence data group terms relating to each other, demonstrating practicality in serving as a hypothesis-generating procedure to further populate manually-maintained ontologies, such as the Cognitive Atlas.

Figure 3: hierarchical clustering results for CogSci and PubMed Neuro Method database.

## Implications for Cognitive Science

The current work presents two main contributions. First, the tool itself is completely open-sourced and depends on publicly available databases. Domain-specific researchers can utilize this tool to find common associations to their process of choice, such as addiction. This will be especially useful for beginner researchers, like undergraduate and early graduate students, to quickly situate their topic in the broader context. Furthermore, on a larger scale, this tool can serve as a complementary approach to hand-curated ontologies, saving experts time from manually filling in blanks. One point worth noting is that our work does not attempt to build the ontological structure of cognitive processes as it exists in our minds, similar to ideas suggested by Newell's universal theory of cognition (UTC). Rather, it is a meta-analysis of how cognitive scientists decide to investigate the latent structure of our cognitive processes through their work, with no claims on whether or how this ontological structure actually exists.

Second, the theoretical contribution of this work is that it points to the discrepancy between how cognitive science and neuroscience study cognition. One simple explanation is that neuroscience only partially overlaps with cognitive science, as genetic, molecular, and cellular investigations often do not relate to cognitive phenomena. This is clearly true, however, given that the PubMed Neuro Method database is built specifically with keywords relating to animal neuroimaging techniques, this is unlikely to be the explanation here. Furthermore, the gap similarly exists between PubMed Cognitive and PubMed Neuro databases, so it is not simply a difference in the source of data. Thus, this gap raises the alarming possibility, as one reviewer pointed out, that theories in cognitive science are not testable in the realm of neuroscience, and/or that neuroscience is simply not interested in or ready for the grand theories of cognition.

## Limitations \& Future Work

While the algorithm returns reasonable and novel results, a few methodological and data-collection limitations must be raised. First, in building the databases, CogSci abstract were collected only up to the annual meeting in 2010, as further archives were unavailable. In contrast, PubMed searches return all hits dating back 30 or more years. As such, it is possible that trends observed in the term-frequency analysis may be due to a temporary peak in interest in certain areas of research, such as "learning". This can be easily ameliorated, however, by rebuilding the PubMed databases while constraining the included search years. In fact, we can analyze different decades (or other periods of time) to see how ontological structure develops over time.

Second, due to the scraping method applied, terms with overlapping words, such as "memory" and "procedural memory" will co-occur with much higher frequency, possibly leading to inflated inferred relationships. Since
terms with overlapping words are very likely to have a superset-subset relationship, the over-interpretation of relationship is unlikely to create false positives. However, the artificial increase in co-occurrence may lead clustering to exclude related but now suppressed terms, leading to false negatives. This may be circumvented by making queries for specific terms, i.e., accessing specific rows in the co-occurrence matrix, and ranking related words in their rate of co-occurrence. Hierarchical clustering is simply one method to visualize the co-occurrence data, and many others may be applied on the same dataset to further tease out latent structures, such as Multi-Dimensional Scaling.

Lastly, the co-occurrence matrix is built on the assumption of a bag-of-words model, i.e., word-order and semantic relations don't matter, simply their shared presence in a document. This may lead to spurious linkages, if a document contained a phrase like "attention is not a type of memory." This is likely to be rare, and ultimately, still useful knowledge, as it implies that at some point these terms were wrongfully linked. This last point, however, raises a larger, philosophical question: can automated text mining of existing literature get at the ontology of cognitive science, and if so, is that the same ontology that exists in our minds? We may never know the answer to the latter, but the former is certainly an issue worth investigating. Regardless of whether or not the structure can be recovered from the model presented here, the knowledge structure clearly exists within the minds of practicing cognitive scientists. As such, we may leverage other sources of information, such as citation links, to trace out the ontology, which ultimately just represents a consolidation of knowledge across the broad, interdisciplinary study of cognition.

# "If It Matters, I Can Explain It": Social Desirability of Knowledge Increases the Illusion of Explanatory Depth 

Christian Gaviria (cdgaviriam@unal.edu.co)<br>Javier Corredor (jacorredora@unal.edu.co)<br>Zadkiel Zuluaga-Rendón (zzuluagar@unal.edu.co)<br>Department of Psychology, Universidad Nacional de Colombia<br>Cr. 30 \# 45-03, Ed. 202 Of. 219, Bogotá, 111321. Colombia

#### Abstract

This paper explores whether social desirability affects the illusion of explanatory depth (IEOD) by comparing the magnitude of this illusion in topics with different levels of social desirability within several domains. This question was chosen because prior literature shows that social expectations about how much a person should know about a certain topic affect the magnitude of the IOED. Previous research shows also that social desirability has an effect on a similar illusion related to argumentation, and that the IOED is affected by the way a person thinks knowledge is distributed in his or her social group. In order to do so, 184 participants were assigned randomly to three knowledge domains (history, economics, and devices) and in each domain they rated their understanding of a high-desirability and a low-desirability topic following a standard IOED procedure. Results show that social desirability has an effect on the IOED magnitude and that overestimation of understanding varies among domains. Particularly, participants tend to overestimate their understanding of high desirability topics only. This effect was stronger in the historical domain.

Keywords: Illusion of explanatory depth; social desirability of knowledge; feeling of knowing; metacognition; motivated cognition.

## Introduction

There is extensive evidence that people are often overconfident regarding the quality and accuracy of their knowledge (Moore \& Healy, 2008; Zell \& Krizan, 2014). This metacognitive bias has been consistently found in the context of tasks as diverse as recalling memorized information (e.g., Koriat, Lichtenstein, \& Fischhoff, 1980), solving general-knowledge questions (e.g., Atir, Rosenzweig \& Dunning, 2015), evaluating text comprehension (e.g., Jaeger \& Wiley, 2015), and making consumer decisions (e.g., Alba \& Hutchinson, 2000).

The discrepancy between what people think they know and what they really know seems to be more conspicuous in certain kinds of knowledge. Thus, Rozenblit and Keil (2002) found that college students are prone to overestimate their ability to explain the mechanisms of devices or natural processes, but not their understanding of facts, narratives or procedures. This "Illusion of Explanatory Depth" (IOED), have been robustly documented in recent years, both in experts and non-experts (Lawson, 2006; Fisher \& Keil, 2015) as in young children (Mills \& Keil, 2004). The IOED
has also been found in both physical (Lawson, 2006; Fernbach, Sloman, St. Louis \& Shube, 2013; Fisher \& Keil, 2015) and social mechanisms (Alter, Oppenheimer \& Zemla, 2010; Fernbach, Rogers, Fox \& Sloman, 2013). These previous works have focused on demonstrating how pervasive is the IOED in different domains of knowledge and on searching for conceptual properties of objects/topics associated to different degrees of this phenomenon. However, when people evaluate how much they know about a particular topic, it is still possible they do not just keep in mind what they do know, but also the representation of what they should know. This representation can be inferred explicitly or implicitly from contextual and motivational cues, such as the perceived social desirability of knowledge. In the following sections, we review some empirical results from research both on IOED and metamemory that are consistent with this interpretation.

## IOED and Social Desirability of Knowledge

Fisher and Keil (2015) investigate whether expertise in a given domain of knowledge is associated to a more accurate self-evaluation of the understanding of objects and processes. In order to do so, they distinguish between passive and formal expertise; passive expertise refers to knowledge coming from the "exposure through life experience and the position one occupies in a society or culture" (p.1251; e.g., specific knowledge or skills culturally associated to gender or age), whereas formal expertise is the final outcome of systematic, continued and deliberate training in a specific domain with definite milestones (e.g., academic degrees). Fisher and Keil found that participants with less formal expertise (e.g., with no college major) overestimated more their understanding of topics related to their passive expertise than they did regarding their understanding of other topics. This difference was not replicated in the group with more formal expertise. In this group, participants overestimated their understanding of topics related to their area of formal expertise more than of other topics. These results suggest that people tend to overestimate their ability to explain topics related to their area of expertise. In the case of people with formal education, it happens with topics related to their formal expertise; in the case of people with no formal training, it happens with topics related to their passive one. In both cases, a critical factor affecting the IOED magnitude
seems to be the participants' beliefs about how much they should know about certain topics because of his or her type of expertise, regardless of how that knowledge was acquired.

In the same vein, Fisher and Keil (2014) asked their participants to write their arguments supporting their position about controversial topics. Before and after this task, they were asked to evaluate how well they could support their own positions. Additionally, participants judged how important the topics were for them. Using an experimental paradigm quite similar to that of the IOED research, they found evidence of an "Illusion of Argumentative Justification" (IAJ): participants' ratings of their ability to support their point of view decreased after writing their arguments. Importantly, caring for each topic was positively associated with both previous and posterior evaluations of the ability to rationally justify their own position, and this pattern was not replicated when arguments were rated by a different group of participants. In short, IAJ seems to be stronger in topics that matter to participants.

In apparent contradiction with these more recent findings, Rozenblit and Keil (2002, study 11) reported that perceived social desirability of explanations was not associated with the magnitude of overconfidence in any domain of knowledge (facts, procedures, narratives, or explanations). They even claim that "if anything, high desirability may cause people to more carefully assess their self-knowledge in a domain and, therefore, be more accurate." (p. 547). However, at least one important difference between Rozenblit and Keil (2002) and Fisher and Keil (2014) studies can account for this discrepancy: whereas Rozenblit and Keil compare differences in overconfidence between kinds of knowledge (e.g., facts, procedures, narratives, and explanations), Fisher and Keil contrast the IAJ magnitude between topics with different degrees of personal significance, within a same kind of knowledge (e.g., arguments). From a methodological point of view, comparing between kinds of knowledge could be not the optimal strategy to establish whether social desirability and IOED are related, as far as the latter is a phenomenon essentially linked to explanations. In this context, comparing the IOED magnitude between more or less socially desirable topics or explanatory domains might be more informative than contrasting the effect of social desirability between explanations and other kinds of knowledge (e.g., arguments). Exploring this alternative is the main purpose of this study.

The influence of social cues in the process of knowledge self-assessment is not an exclusive finding of the IOED paradigm. In the next section, we review some evidence from metamemory research suggesting the inferential nature of such process, and identifying a number of contextual factors affecting perceptions about how likely some specific content is to be recalled from memory.

## Social Desirability and the Feeling of Knowing

The research on metacognitive judgments in memory tasks has inquired about the sources of information people use to infer whether a particular content can be learned or recalled. Specifically, the "feeling of knowing" (FOK) has been extensively investigated. In general, this feeling is experienced by an individual when he or she thinks to have certain items stored in memory and the ability to recall or recognize them in the future, even when they cannot do it at the present (Hart, 1965).
In order to elucidate the metacognitive mechanism underlying to FOK, researchers have explored factors associated to the accuracy of these judgments. Consistently, it has been found that FOK is not the output of a unique mechanism. Instead, diverse factors can affect the metacognitive processes driving to it, depending on both recovery timing and task restrictions (for review, see Thomas, Lee \& Hughes, 2016). For example, whereas perceived familiarity with items can increase the FOK before the recall phase, related information accessibility has a major role when recalling is not successful (Koriat \& Levy-Sadot, 2001). These findings support the hypothesis that the FOK mechanism is not an encapsulated directaccess module (Hart, 1965), but the result from multiple inferential processes, working with information derived from cues previously or simultaneously generated along with the recall process (Thomas et al., 2016).
Supporting this hypothesis, Costermans, Lories and Ansay, (1992, exp. 2) explore several cues related to the magnitude of FOK judgments. In particular, they find that confidence is a better predictor of answers accuracy than FOK. Interestingly, both question familiarity and the estimated amount of people knowing the correct answer were positively associated with the FOK magnitude. In the same vein, De Carvalho and Yuzawa (2001) report that the FOK magnitude in college students with low levels of metacognitive ability increases when they are provided with information about fictitious students having high performances in a similar task and, correspondingly, diminishes it when these fictitious performances were presented as low. These results are compatible with the Self Consistency Model of Subjective Confidence (SCM; Koriat, 2012), which postulates that correlation between confidence and accuracy in FOK judgments is positive when people agree on the correct answer. In contrast, the confidenceaccuracy correlation is negative when there is a similar level of consensus about an answer that is ultimately wrong. Once again, these results confirm that FOK is not directly computed, but inferred from internal cues such as familiarity, processing fluency, and the perceived distribution of knowledge in the population.
Although the effect of social desirability of knowing the correct answer has not been directly tested on the FOK paradigm, there are reasons to think it might well be an informative cue about how likely a content in memory is to be recalled (Gruneberg, Monks \& Sykes, 1977). In a related area of research, Soderstrom and McCabe (2011) found that
college students judge that they will be more able to learn items whose successful recall is better rewarded in the experimental setting. In the same vein, the predicted grades of college students in a course exam are biased by their desired level of performance (Serra \& Demarree, 2016).

On the other hand, though experimental paradigms of FOK differ from IOED in that they had used pieces of nonexplanatory knowledge (e.g., historical events, dates, names, places, etc.), this fact does not rule out the possibility that both IOED and FOK engage analogous or common metacognitive mechanisms. If that is the case, factors related to the FOK magnitude might be responsible of differences in the IOED magnitude between topics and domains. Examining the influence of inferential cues such as social desirability on the IOED will allow us to identify the conditions that lead to the overestimation of the explanatory knowledge about a certain topic. In turn, this information would be useful in creating cognitive strategies to help people to re-calibrate their understanding and monitoring their own learning processes of specific contents in more accurate and effective ways (Dunlosky \& Thiede, 2013). In this context, the aim of this study is to determine whether social desirability of knowledge is used by participants as an informative cue when they are assessing their understanding of mechanisms in different domains of explanatory knowledge.

## Method

The experiment has two goals: First, we intend to establish whether social desirability of knowledge about a specific topic predicts the IOED magnitude. Second, we want to know whether the relationship between IOED magnitude and social desirability differs among explanatory domains (e.g., historical, economic, and devices).

## Participants

In this study participated one hundred and eighty-four students from a large research university (88 women) attending different undergraduate programs, with ages ranging from 18 to 42 years $(M=20.7, S D=2.04)$. Most of them received academic extra-credit for their participation in this study.

## Design

A mixed experimental design, $3 \times 2 \times 2$, was used, with explanatory domain (historical, economic and devices) as the between-subjects factor, and social desirability of topics (high and low), and pre-post measures as within-subjects factors. The dependent variable was the IOED magnitude, measured as the rating of understanding of each topic.

## Materials and Procedure

The same procedure used by Rozenblit and Keil (2002, study 11) was used to select high and low desirability topics for each domain. In a preliminary study, one hundred and ninety-four participants (117 women) evaluated the
perceived social desirability of knowledge about 21 topics (seven in each domain). Specifically, they reported how embarrassed they would feel if they did not have a good understanding on each topic in a 7-point scale, ranging from 1 ("If someone asked me to explain this topic and I had a poor understanding of that item, I would not feel embarrassed at all") to 7 ("If someone asked me to explain this topic and I had a poor understanding of that item, I would feel very embarrassed"). Six items -the two topics showing greater difference in the desirability scale within each domain- were selected for the main study (see Table $1)$.

Table 1: Means of social desirability of each topic in the preliminary study

| Domain | Topic | M | SE | 95\% CI |  |
| :---: | :---: | :---: | :---: | :---: | :---: |
|  |  |  |  | Lower bound | Upper bound |
| Historical | Long duration of the Colombian armed conflict | $5.02^{\text {a }}$ | . 135 | 4.76 | 5.29 |
|  | Creation of the FARC-EP guerilla | $4.58{ }^{\text {b }}$ | . 132 | 4.32 | 4.84 |
| Economic | Why inflation rises in Colombia | $4.37{ }^{\text {b }}$ | . 133 | 4.11 | 4.63 |
|  | How the stock market works | $3.65{ }^{\text {c }}$ | . 128 | 3.39 | 3.90 |
| Devices | How a fishing rod works | $3.40^{\text {c }}$ | . 151 | 3.10 | 3.70 |
|  | How a jet engine works | $2.43{ }^{\text {d }}$ | . 130 | 2.18 | 2.69 |

Note: $M=$ mean; $S E=$ standard error; CI = Confidence interval; Means marked with different letters differed significantly from each other $(p<.01)$

In an isolated and noise-free room, participants did the experimental task at their own pace in individual cubicles. For task presentation and response recording, the Qualtrics web-based survey software was used. During the session, it was verified that participants did not check other websites. After registering their demographic information, participants completed an instructional manipulation check (Oppenheimer, Meyvis \& Davidenko, 2009) to ensure the careful reading of the instructions. The following phases were aligned with the IOED experimental paradigm: initially, participants evaluated their knowledge about twelve topics (six of which were not part of the design), using a 7 -point scale, with 1 meaning "vague or poor understanding" and 7 "detailed and fine-grained
understanding". The instructions to use this rating scale were adapted from Rozenblit and Keil (2002) and Fernbach, Rogers, et al. (2013). Next, participants were randomly assigned to one of the three domains (historical, economic, and devices), and they were asked to explain in a step-bystep way the causal mechanism of one of the object/topic in this domain (explanation phase). In particular, they were provided with the following instruction:
"We want to know your explanation of some topics. The aim of this explanation is to show clearly how each step causes the next one, placing them in a sequence from the emergence of the causes until the moment when the phenomenon occurs. In other words, try to tell a story as
complete as you can (with no plot holes) that might be understood by anyone."
When the explanation was completed, participants evaluated again their understanding of the object/topic they had previously explained (post-evaluation phase). The sequence explanation-post evaluation was then repeated for the second object/topic. The presentation order of high and low desirability topics within each domain was randomly assigned.

## Results

A mixed ANOVA was conducted as the main analysis, with judgment timing (pre and post explanation) and perceived social desirability of knowledge on the topic (high and low) as within-subject factors, and both domain of knowledge and presentation order as the between-subjects factors. The dependent variable was the rating in the 7-point understanding scale.

Replicating the IOED phenomenon, a main effect of evaluation time was found. Ratings of understanding before the elaboration of explanations $(M=3.42, S E=.105)$ were higher than those produced after explanations ( $M=2.81$, $S E=.10), F(1,178)=52.43, p<.001, \eta_{\mathrm{p}}^{2}=.23$. Additionally, there was a significant interaction between judgment timing and domain of knowledge, $F(2,178)=$ 3.33, $p<.05, \eta_{p}^{2}=.03$. Post hoc analysis (Tukey's HSD) revealed that the decrease of understanding ratings was higher for the historical domain, $p<.01$ (see Table 2).

Additionally, social desirability of knowledge interacted with judgment timing, $F(2,178)=56.27, p<.001, \eta_{\mathrm{p}}^{2}=.24$. In particular, it was found a decrease on understanding ratings between judgments before and after the elaboration of explanations, only for high desirability topics (see Figure 1).

It was also found a marginally significant three-way interaction between judgment timing, social desirability and domain of knowledge, $F(2,178)=3.06, p=.049, \eta_{\mathrm{p}}^{2}=.03$. Specifically, the reduction of understanding after generating explanations in low social desirability topics is slightly greater in the historical domain (why FARC-EP guerrilla was created), than both in devices (how a jet engine works) and economic topics (how stock markets work; see Figures 2 and 3).

Table 2: Means of understanding in each domain of knowledge by judgment timing.

| Domain | Time | $M(S E)$ | $95 \%$ CI |  |
| :---: | :---: | :---: | :---: | :---: |
|  |  |  | Lower <br> bound | Upper <br> bound |
| Historical | Pre | $4.20(.182)^{* *}$ | 3.84 | 4.56 |
|  | Post | $3.35(.171)^{* *}$ | 3.01 | 3.68 |
| Economic | Pre | $2.90(.182)$ | 2.54 | 3.26 |
|  | Post | $2.26(.171)$ | 1.92 | 2.59 |
| Devices | Pre | $3.16(.185)$ | 2.79 | 3.52 |
|  | Post | $2.83(.174)$ | 2.48 | 3.17 |
| $* * p<.01$ |  |  |  |  |

Figure 1. Means of understanding in high and low social desirability topics by judgment timing. Bars represent 95\% confidence intervals.

Figure 2. Means of understanding in each domain on high social desirability topics) by judgment timing. Bars represent $95 \%$ confidence intervals.

Figure 3. Means of understanding in each domain on low social desirability topics by judgment timing. Bars represent 95\% confidence intervals.

Finally, there was a robust and unexpected three-way interaction between judgment timing, social desirability, and topic order, $F(2,178)=31.03, p<.001, \eta_{\mathrm{p}}^{2}=.14$. Particularly, when low social desirability topics were evaluated first, the understanding ratings for the second (high desirability) topic showed a lower IOED ( $M_{\mathrm{pre}}=3.85$, $S E=.186 ; M_{\text {post }}=3.05, S E=.171$ ) than when high desirability topics were evaluated first ( $M_{\mathrm{pre}}=4.35, S E=.187 ; M_{\text {post }}=2.68$, $S E=.172$ )

## Discussion

In the present study, we examined the relationship between IOED magnitude and social desirability of knowledge about specific topics in three different domains. Our results show that people overestimate their knowledge about causal mechanisms related to physical devices, as well as to economic and historical phenomena. Furthermore, the IOED seems to be stronger in the historical domain and that difference might be related to the higher social desirability of this domain.

Within each domain, the IOED was exhibited for the highly desirable but not for the less desirable topics. This finding confirms that perceived social desirability of knowledge is a relevant cue in the processes of knowledge self-assessment, as it is suggested by previous research on metamemory judgments. It is possible however that other factors like familiarity, accessibility or perceived distribution of information about topics play a role moderating the IOED effect. This could explain, for instance, why the initial understanding of unfamiliar and non-accessible topics (like the low desirability topic in the domain of devices) could be underrated rather than overrated. In this vein, future studies should separate the effect of social desirability from that of potential confounds as far as possible. Even if the influence of other informative cues is demonstrated, it would support the idea that the IOED is not only a consequence of the coarseness of intuitive theories (Rozenblit \& Keil, 2002), but also a by-
product of the inferential nature of metacognitive mechanisms. In other words, people overestimate their ability to explain objects and phenomena because they use multiple cues to assess how well they know them (including social desirability of that knowledge), and not only because they confuse their skeletal understanding with full-detailed representations of mechanistic knowledge.

Fernbach, Rogers, et al. (2013) found that the IOED magnitude correlated positively with the moderation of extreme political attitudes on controversial issues. Accordingly, if the social desirability of knowledge about a political issue enhances the related IOED, it is possible that extreme attitudes about more desirable topics to be also more likely to be moderated after trying to explain them. However, if an individual holds an extreme position about a socially relevant topic (e.g., abortion, gay marriage, gun control, etc.) and this position is relevant to his or her identity, previous evidence suggests that he or she will engage in a form of ideologically motivated cognition, making the related attitude more resistant to change (Kahan 2013). Eventually, this motivational bias could affect the metacognitive processes involved on the IOED. Thus, in some cases, social desirability of knowledge and motivated cognition could influence the IOED magnitude in opposed directions, depending on the personal relevance of topics related to extreme political attitudes. Testing empirically this potential interaction would shed light on the motivational mechanisms involved in the self-assessment of explanatory knowledge. This is important not only in theoretical terms, but also in applied situations like the decision making on complex policies in core political moments (e.g., Brexit referendum or Colombia's peace plebiscite).

Finding that highly desirable knowledge about relevant topics is more likely to be overestimated is not encouraging for deliberative democracies. However, our results suggest that asking participants to explain less desirable topics first can make them less willing to re-calibrate their initial ratings of knowledge about highly desirable topics. Further studies manipulating social desirability of topics betweenrather than within-subjects- would be useful to determine whether previous exposure to low IOED magnitudes can improve the accuracy of understanding estimation about socially desirable topics.

Our purpose in this paper is to bring together the FOK and IOED literatures in order to identify social desirability as an inferential cue in the process of understanding selfassessment. Exploring other interactions between cognitive, motivational and pragmatic factors in metacognitive processes can provide us with a more comprehensive picture of how we know that we know. Although social desirability cannot be randomly assigned, this study shows how it relates to the IEOD in natural settings. Separating social desirability from other factors might be impossible in natural settings and non-ecological in experimental ones. To give an extreme example, separating social desirability from social relevance be done if the former depends intrinsically
of the latter. So we consider that the manipulation here exposed is enough for to establish the relationship between both variables. Further experimental research is required to check if the relationship stands in experimental environments.

# Reasoning with Fundamental Rights 

Lupita Estefania Gazzo Castañeda (Estefania.Gazzo@psychol.uni-giessen.de) Antje Stemmler (Antje.Stemmler@psychol.uni-giessen.de) Markus Knauff (Markus.Knauff@psychol.uni-giessen.de)<br>Justus-Liebig University, Experimental Psychology and Cognitive Science, Otto-Behaghel-Str. 10F, 35394 Giessen, Germany

#### Abstract

People often withdraw previously drawn conclusions in light of new information. This defeasible reasoning is also important for law, where judges often have to change their verdicts in light of new evidence. Here we investigate defeasibility in the context of conflicting fundamental rights. When, for instance, law to property conflicts with law to information, can one of these rights be "defeated" by the other? We embedded conflicting fundamental rights in inference tasks (Experiment 1) and in elaborated vignettes (Experiment 2). Results show that people decide between two conflicting fundamental rights in a rational way. Case by case, participants protected that fundamental right whose violation evoked the highest moral outrage (Experiment 1) or whose violation was considered to be more serious (Experiment 2). We discuss the implications of our findings for law theory and psychology.

Keywords: defeasibility, legal reasoning, conditionals

## Introduction

Are humans rational? This question has concerned psychologists and philosophers for a long time. Philosophers have developed norms for rational thinking and psychologists have tested them empirically. In many of these experiments, classical logic was used as a norm for rationality. Participants were confronted with inference tasks, consisting of a conditional and a fact, and asked to indicate what follows necessarily. One example is Modus Ponens (MP):

```
If Ann is hungry (p) then she gets something to eat (q).
Ann is hungry (p).
Ann gets something to eat (q).
```

MP is a valid inference because in classical logic the antecedent $(p)$ is sufficient (but not necessary) for the consequent (q) (e.g., Thompson, 1994; 1995). Yet, many participants made logical errors in such inference tasks, rejecting otherwise valid conclusions. Nowadays, however, it is known that these "errors" are only a consequence of the complexity of human everyday reasoning. In everyday situations, many factors that are irrelevant for classical logic have to be considered and weighted in order to arrive at a reasonable conclusion. For instance, if Ann is on a strict diet, it may be rational to conclude that she will not get something to eat even if she is hungry. Contrary to classical logic, where no additional information can make a conclusion false, everyday reasoning is non-monotonic and defeasible (e.g. Oaksford \& Chater, 1995; 2013; Stenning \& van Lambalgen, 2005).

This phenomenon called defeasibility is also very important in legal reasoning (e.g., Bäcker, 2010; Prakken \&

Sartor, 2004). Judges are often confronted with complex cases, in which they have to arrive at rational verdicts. At first sight, we might thus think that classical deduction is an appropriate norm for legal reasoning. For instance, considering that the penal code says that "If a person kills another human, then the person has to be punished for manslaughter" we can conclude from the fact that a person killed another human that the person has to be punished for manslaughter. However, in many cases there are exculpatory circumstances that make it rational to reject this conclusion. There are different exculpatory circumstances defined in penal code, such as self-defense, necessity or psychological disorders. In light of those circumstances, judges know that the otherwise valid conclusion of punishment has to be defeated in favor of acquittal. But what happens if there are no clear rules on how to reason? Although this might sound counterintuitive for legal contexts, this nonetheless happens in federal constitutional courts, when two fundamental rights are in conflict. Imagine, for instance, that you live in a foreign country and the only way to hear news from your hometown is to mount a parabolic antenna on the facade of your rented flat. The landlady nonetheless prohibits it to you. Your right to receive information thus conflicts with the property law of the landlady. In general terms, all fundamental rights are equally important and have to be granted. So, which fundamental right has to be preferred over the other? Can one fundamental right "defeat" the other?

The aim of this paper is to investigate how people reason with conflicting fundamental rights. For this, we will first discuss the psychological literature on defeasible reasoning and then the law theoretic framework on fundamental rights.

## Withdrawing from valid conclusions

Many factors influence defeasible reasoning. One important factor is background knowledge. Just as shown in the introduction of this paper, when people know circumstances that prevent the consequent to occur although the antecedent is true, they reject otherwise valid conclusions. These circumstances are often called disablers or defeaters. But not only the availability of defeaters is important, also is their amount (e.g., Cummins, 1995; De Neys, Schaeken, \& d'Ydewalle, 2003a), their relative strength (De Neys, Schaeken, \& d'Ydewalle, 2003b), and their frequency of occurrence (Geiger \& Oberauer, 2007). The more defeaters there are, the more associated or salient these defeaters are, and the more often they occur, the more readily a conclusion is withdrawn. However, another important factor are utilities. Bonnefon (2009; Bonnefon \& Hilton, 2004) showed
that when people make inferences about actions, they consider the costs and benefits of this action given the consequences. For instance, when presented with the conditional "If Mary's TV is broken, she will have it fixed" and the fact that "Mary's TV is broken" participants refuse to conclude that Mary will have their TV fixed when presented with the additional information that "If Mary has her TV fixed, she will not be able to pay the electricity bill". The consideration of utilities during reasoning illustrates the closed connections between reasoning and decision making. When people reason in their daily lives, it is not just for the sake of reasoning per se, but to reach a goal - may this goal be something simple like getting a TV fixed or something relevant for society like reaching a legal verdict. Because goals are also relevant in law we expect utilities to play a similarly important role in legal reasoning.

## Legal reasoning

Law is defeasible in several ways (cf. Prakken \& Sartor, 2004): during police investigations when new evidence "defeats" previous insights, during trials when attorneys and prosecutors defeat each other's arguments, and in the application of legal rules in light of exculpatory evidence. The role of utilities in the application of legal rules has been tested by Gazzo Castañeda and Knauff (2016). In several experiments, laypeople and lawyers were confronted with legal conditionals embedded in MP inferences, which were presented together with exculpatory evidence (e.g., "If a person kills another human, then the person should be punished for manslaughter; Bob killed another person; Bob is schizophrenic and had a delusion of an attack against him; Should Bob be punished for manslaughter?"). As expected, lawyers considered exculpatory circumstances as prescribed by the penal code and irrespective of how morally outraging the offence was, deciding not to punish in light of exculpatory circumstances. Laypeople, instead, had difficulties in accepting exculpatory circumstances when the offence was highly morally outraging (e.g., maltreatment of wards), but not if the moral outrage was only low (e.g., illegal gambling). We argued that utilities might be responsible for this moral outrage effect. People can only feel secure in a society where they can be sure that the important rules are respected and offenders punished. The benefit of saving one's own feeling of security is thus weighted more than the costs of punishing somebody erroneously. This overweighing of one's own feeling of security is known from the belief in a just world literature (see Lerner, 1970), where people even tend to blame the victims of offences only to preserve their belief that people get what they deserve and that bad things only happen to bad people. From a utilitarian point of view, the punishment of offenders is thus of high utility - and the higher the moral outrage, the higher this utility is. Is it therefore possible that moral outrage also affects the weighing of fundamental rights?

Fundamental rights are generally coded in the constitution. The most known examples are right to dignity, liberty, freedom of thought and of expression, or right of property.

All of these have to be respected and protected. However, there are instances when two or more fundamental rights are in conflict, such as in the introductory example when the right to information conflicts with right to property. Judges in the federal court are thus faced with the problem that they have to decide which one deserves more importance, although both are theoretically equally important. This weighting of fundamental rights is called balancing and is an important case by case decision with no clear rules on how to decide. That is, cases with the same conflicting fundamental rights can (and should) end up with different verdicts due to case-specific details. Because of these missing rules, some law theorists argue that balancing cannot be rational (e.g., Habermas, 1992). Alexy (2003), however, argues that balancing can be rational by comparing for every single case the detriment of one fundamental right $i$ with the importance of satisfying the other fundamental right $j$. This is done by the so-called weight formula, which computes the ratio between the case-specific weights $\mathrm{I}_{\mathrm{i}}$ and $\mathrm{I}_{\mathrm{j}}\left(\mathrm{G}_{\mathrm{ij}}=\mathrm{I}_{\mathrm{i}} /\right.$ $\mathrm{I}_{\mathrm{j}}$ ). The first weight $\mathrm{I}_{\mathrm{i}}$ stands for the violation intensity of fundamental right $i$ by protecting fundamental right $j$, and the second weight $\mathrm{I}_{\mathrm{j}}$ stands for the importance of protecting fundamental right $j$ by violating fundamental right $i$. Applied to our concrete example, this would result in the following two questions: How serious is the invasion of the right to information by prohibiting the installation of the parabolic antenna? How important is it to protect the right to property by prohibiting the installation of the parabolic antenna? Already Darley showed in several experiments that the perceived seriousness or severity of offences is highly correlated by moral outrage (e.g., Alter, Kernochan, \& Darley, 2007; Carlsmith, Darley, \& Robinson, 2002; Darley, Carlsmith, \& Robinson, 2000). Therefore, we also expect that the case-specific weights of fundamental rights will depend on moral outrage: If the invasion of fundamental right A is considered more morally outraging than the invasion of fundamental right B , then fundamental right A should be protected over B.

In this paper, we combine the domains of defeasible reasoning from psychology with the concept of balancing from legal theory. In Experiment 1, we embedded two fundamental rights into conditional reasoning tasks and asked participants what should follow. In Experiment 2, we embedded conflicting fundamental rights into longer vignettes and asked participants for the case-specific weights $I_{i}$ and $I_{j}$.

## Experiment 1

## Methods

Participants We tested 40 people ( 21 male) without legal expertise. They were on average 26.62 years old ( $S D=6.93$ ). Material We took 16 real conflicts of fundamental rights from the German constitutional court and embedded them in defeasible inference tasks. Each problem started with a conditional containing one fundamental right A. Next, we presented a concrete situation as second premise in which the fundamental right A was involved, followed by a third
premise in which the fundamental right A is applied to this concrete situation (MP). Then, the second fundamental right B was presented as a defeater that is in conflict with the previous information. Finally, the conclusion was presented as a question asking either for the application of fundamental right A (Example 1) or fundamental right B (Example 2):
If a person's personal security is endangered, then its protection has to be warranted.
Person A's house has to be searched and seized because A is suspected to have death threatened person B.
To protect B this search and seizure can be authorized.
The suspect A has nonetheless right to privacy.
Should the house of suspect A be searched and seized?
If the personality rights are in danger, then their protection has to be warranted.
A celebrity is photographed without permission.
Due to the personality rights, all people's privacy has to be protected.
The press has nonetheless right to freedom of the press.
Should the celebrity be photographed by the press without permission?
Participants gave ratings from 1 (not at all) to 7 (definitely). Therefore, the higher a rating was, the more the participants preferred one fundamental right over the other. We refer to this as "preference rating".

We created two versions of the experiment by changing the order of the fundamental rights A and B (version 1 and 2). If in one version one fundamental right was presented as the conditional and the other as the defeater, then in the other version it was the other way around. The conclusion, however, always asked for the same fundamental right. This allowed us to control for order effects.

To measure moral outrage we conducted a norming study in which participants $(N=34)$ rated on a seven point Likertscale how morally outraged they would feel if the fundamental rights from the inference tasks were violated (e.g., "How outraging do you find it when a celebrity is photographed without permission?"). Because in each conflict situation there were two fundamental rights involved, this resulted in 32 violation ratings, ranging from 2.65 to $6.09 .{ }^{1}$

Procedure and Design The experiment was programmed on Superlab 4.5. Participants were tested individually on a desktop computer and were instructed that no right or wrong answers exist. The instructions included one practice problem. All 16 problems were presented randomly and separated by fixation crosses. The single premises were presented sequentially on separate screens. Participants could switch to the next premise by pressing the space bar. The last premise was always the question about the conclusion. It was

[^338]written in red font and was presented together with the 7 -point-Likert scale. The experiment was thus one factorial with "version" as a between subject variable.

## Results

Comparisons between the two versions of the experiment revealed no differences in preference ratings, $t(38)=1.36$, $p=.181$. That means that regardless of whether a fundamental right was presented as the conditional or as the defeater, this did not affect its evaluation in the conclusion. This allowed us to test the effect of moral outrage on preference ratings. For this, we first compared the two fundamental rights in each problem on the basis of the moral outrage ratings they got in the norming study. We looked at which fundamental right violation got higher moral outrage ratings and should thus be preferred. These predictions were then compared with the actual preference ratings participants gave in the experiment. Mean preference ratings over 4 (i.e., the scale midpoint) were classified as in favor, and ratings below 4 against the fundamental right presented in the conclusion (no mean preference rating $=4$ ). Descriptively, the moral outrage ratings allowed us to correctly predict 11 out of the 16 conflict situations. To corroborate this statistically, we tested the preference ratings of each inference task against 4 with one sample $t$-tests and a Bonferroni adjusted alpha of 0.0031 . Results are in Table 1. Of the 16 comparisons, 6 were not significantly different from 4 , meaning that participants were neither in favor nor against the fundamental right presented in the conclusion. From the remaining 10 problems, however, we were able to predict statistically 8 conflict situations.

Table 1: Predicted and actually preferred fundamental rights. Predictions were based on the moral outrage (MO) ratings from the norming study. Preference ratings of the actually preferred rights were tested against the scale midpoint 4 (Sign., Bonferroni adjusted alpha: 0.0031).

| Item | MO of A | MO of B | Predicted | Preferred | Sign. |
| :---: | :---: | :---: | :---: | :---: | :---: |
| 1 | 3.15 | 5.44 | B | A | $<.001$ |
| 2 | 4.88 | 5.59 | B | A | $<.001$ |
| 3 | 3.88 | 3.32 | A | A | .001 |
| 4 | 3.85 | 4.21 | B | B | .001 |
| 5 | 3.71 | 4.59 | B | A | .147 |
| 6 | 3.29 | 4.71 | B | B | $<.001$ |
| 7 | 5.79 | 4.38 | A | A | $<.001$ |
| 8 | 3.76 | 5.26 | B | A | .008 |
| 9 | 4.41 | 5.06 | B | B | .386 |
| 10 | 3.24 | 5.53 | B | B | $<.001$ |
| 11 | 3.82 | 3.74 | A | A | .103 |
| 12 | 5.76 | 4.06 | A | A | $<.001$ |
| 13 | 5.18 | 5.44 | B | B | .309 |
| 14 | 2.65 | 6.09 | B | B | $<.001$ |
| 15 | 3.39 | 3.26 | A | B | .305 |
| 16 | 5.32 | 5.29 | A | A | $<.001$ |

As an additional measure of the relevance of moral outrage for balancing, we took the moral outrage ratings from the norming study and used these ratings to classify the fundamental rights in each problem as either low (ratings from 2.65 to 3.76 ), medium (from 3.82 to 4.88 ), or high (from 5.06 to 6.09 ) morally laden (the cut offs resulted from the division of our fundamental rights into these three groups).

An analysis of the respective preference ratings showed that when high and medium morally laden fundamental rights were in conflict, participants gave higher preference ratings for conclusions asking for the highly morally laden right ( $M=5.39 ; S D=1.20$ ) than for conclusions asking for the medium morally laden right ( $M=4.46 ; S D=1.36$ ), $t(39)=3.06$, $p=.004$. The same was the case for problems where medium and low morally laden fundamental rights were in conflict: conclusions asking for the medium morally laden right got higher preference ratings ( $M=4.5$; $S D=1.89$ ) than their counterpart $(M=3.25 ; S D=1.01), t(39)=3.72, p=.001$. We also found the same pattern for problems with high and low morally laden fundamental rights, but the difference in preference ratings ( $M=4.15$; $S D=1.09$ vs. $M=3.73$; $S D=1.36$ ) did not reach significance, $t(39)=1.38, p=.176$ (Bonferroni adjusted alphas: 0.0167).

## Discussion

Moral outrage was an important predictor when deciding between two fundamental rights in a defeasible reasoning paradigm. Participants protected more often that fundamental right whose violation provokes the highest moral outrage. A fundamental right was therefore only considered as a defeater if its violation was morally outraging enough.

Our results demonstrate the defeasibility of human reasoning. Even in contexts where we expect people to reason deductively - such as in law - reasoning is often defeasible. In fact, it is difficult to describe balancing through deduction. Deduction would imply that it should be (in principle) possible to enumerate all defeaters beforehand as part of the antecedent (e.g., If right to property is in danger and it does not conflict with right to information, then we have to protect it). Yet, this is not possible for balancing because cases with the same conflicting fundamental rights can end up with different verdicts due to case-specific details. An important task for cognitive psychologists therefore is to understand the cognitive processes behind balancing. Our research is a first step in this direction.

An open question is, however, whether participants are indeed capable to consider these case-specific details during balancing. Is balancing just a theoretical concept from legal theory? Or do people in fact balance and defeat fundamental rights differently depending on case-specific details? We tested this in Experiment 2.

## Experiment 2

In Experiment 2 we used a new experimental paradigm. First, we embedded the conflicting fundamental rights in elaborated vignettes. The vignettes described many casespecific details and were thus more realistic than the inference tasks from Experiment 1. Second, half of our participants were people with legal expertise. This allowed us to investigate balancing in a more realistic "court like" setting.

## Methods

Participants We tested 40 laypeople ( 17 male) and 40 lawyers (already graduated ones and advanced law students; 18
male). On average, laypeople were 24.3 years old ( $S D=4.2$; one missing value) and lawyers 24.8 years old ( $S D=3.1$ ).
Material We constructed our material by summarizing 8 real cases from the German federal constitutional court (i.e., BVerfGE), and embedding these into vignettes. Each vignette contained case-specific details such as the matter of facts, the case history (e.g., accusations, levels of jurisdiction involved), and the parties' arguments in favor or against the different fundamental rights. We selected our cases in such a way that two of them always contained the same conflicting fundamental rights, but received different verdicts from the constitutional court. These final verdicts were, however, not included in the vignettes. We had thus four pairs of cases: two cases of right to information vs. right to property, two cases of personality rights vs. right to freedom of press, two cases of personality rights vs. right to freedom of speech, and two cases of right to bodily integrity vs. the public interest to legal action. The vignettes were 324 to 506 words long and were developed by an advanced law student with the supervision of an experienced legal researcher.

The participants' tasks were (1) to come to a final verdict and (2) to determine the specific weights for $I_{i}$ and $I_{j}$. The question about the final verdict was formulated according to the legal theoretic tradition: "How would you decide? Which interest should resign: [Right A] or [Right B]?" Participants could select between " $[$ Right A] should resign", " $[$ Right B] should resign", and "Both interest deserve equal protection (standoff)". The question about the specific weights was split into two parts: First, participants had to judge the intensity of violation of right $A$ (e.g., "How intense do you think is the violation of T's right to information by prohibiting him to install a parabolic antenna?"). Second, participants had to judge the importance of protecting right $B$ (e.g., "How important is it to protect the right to property of the landlady by prohibiting the installation of the parabolic antenna?"). Participants had to select between "little", "medium", "very".
Procedure and Design The experiment was conducted via paper and pencil. Each vignette was presented on a small booklet containing on the first page the vignette and on the second page the questions about (1) the verdict and (2) the specific weights (in this order). Participants were instructed to imagine they were judges in the constitutional court. Each participant received 4 of the 8 vignettes, one of each pair. The order of the vignettes was randomized. The experiment thus followed a 4(type of conflict) x 2(pair) design, with "pair" as a between subjects variable and the type of conflict as a within subjects variable.

## Results

We first analyzed in how many cases the specific weights predicted the overall verdicts. As a correct prediction we counted (1) cases in which the fundamental right protected in the final verdict was also the one with the highest specific weight, and (2) cases in which participants weighted both rights equally in the questions about the specific weights and selected "standoff" as the verdict. This analysis showed
that correct predictions were significantly above chance: we could predict $71.9 \%$ of the laypeople's, $t(39)=5.31, p<.001$, and $81.9 \%$ of the lawyers' verdicts, $t(39)=8.64, p<.001$.

In a second step, we analyzed whether participants considered the case-specific details. Therefore, we looked at the four pairs of conflicting fundamental rights and compared within each pair how often Right A, Right B, or standoff were selected. We compared the frequency distributions of the three kinds of verdicts with Freeman-Halton tests. Indeed, results showed that in light of different case-specific details, participants gave different verdicts for the same conflicting fundamental rights. Laypeople did so for 2 of the 4 pairs of cases (personality rights vs. freedom of speech: $p=.002$; bodily integrity vs. public interest: $p=.001$ ), and lawyers did so for 3 of the 4 pairs of cases (personality right vs. freedom of speech: $p=.009$; personality rights vs. freedom of press: $p=.002$; bodily integrity vs. public interest: $p<.001$ ). However, only in $38 \%$ (laypeople) and in $55 \%$ (lawyers) of the cases the participants' final verdicts was the same as the actual verdicts from the constitutional court.

## Discussion

Experiment 2 shows that participants often decide between conflicting fundamental rights by considering case-specific details. This supports our main assumption that balancing is defeasible. In our study, participants did not apply some general rule (e.g., right to information deserves more importance than right to property), but decided on a case by case manner whether a specific fundamental right counts as a defeater or not. This defeasibility seems to be wellcaptured by Alexy's (2003) weight formula. An interesting question now is whether the basic idea of this formula is also helpful for understanding defeasibility outside the legal context. Take our initial example of Ann being hungry. Maybe people decide to defeat the conclusion that people eat when they are hungry by comparing the weights of "if hungry then eating" and "if hungry then not eating". Interestingly, this comparison of weights is similar to the concept of conditional probabilities (e.g., Evans \& Over, 2004). Many theories on conditional reasoning argue that defeasibility results from the fact that conditionals are understood as the conditional probability $\mathrm{P}(q \mid p)$, which is computed by dividing $\mathrm{P}(p \& q)$ with $\mathrm{P}(p \& q)+\mathrm{P}(p \& n o t-q)$. That is, similar to the weight formula, the weight (here the probability) of $p$ and $q$ is compared with the one of $p$ and not- $q$. This similarity, we think, deserves more attention from psychology and also from law theory.

Another point that also deserves attention is the mismatch between the final verdicts of our participants (laypeople and lawyers) and the actual verdicts of the constitutional court. On the one hand, participants followed the weight formula. Thus, they weighted the single fundamental rights in a rational way. On the other hand, our results indicate that they used specific weights that differed from those used by the constitutional court. This might be a result of our specific task setting, relatively low test power, the small number of vignettes we used, and the limited ecological validity of our
study. However, another interpretation is that the ethical values and moral principles that drive people's decisions differ from that of our legal system. We think that this is an important research topic at the intersection of cognitive science, social psychology, legal theory, and moral philosophy.

## General Discussion

We used methods from cognitive psychology to investigate the concept of balancing from legal theory. Our results show that people are willing to defeat single fundamental rights if they are in conflict with other fundamental rights. This defeasibility happens in a case-specific manner and not only when conflicting fundamental rights were presented in inference tasks, but also when they were embedded in ecologically more valid vignettes.

Our findings are important for several reasons. First, they show the importance of defeasible reasoning in many areas of real life. Defeasibility is important if we judge how severe violations of fundamental rights are and when we weight the importance of conflicting fundamental rights. Interestingly, however, some law theorists do not consider balancing as defeasible. According to Bäcker (2010), defeasibility describes the capacity to accommodate legally relevant exceptions. Therefore, only "normal" legal rules would be defeasible (e.g., those from penal code), but not fundamental rights. Fundamental rights are legal principles that have to be optimally achieved taking into account all possible circumstances, including other conflicting rights. Therefore, one fundamental right cannot be an exception to another fundamental right (Bäcker, 2010). From a psychological perspective two reasons speak against this view. The first is an empirical: the important aspect of psychological defeasibility is that people change their conclusions in light of new evidence and this certainly happens when one decides against one right in light of another right. The second reason is a theoretical: that one fundamental right cannot be an exception to another one does not speak against the defeasibility of balancing. In fact, the case by case weighting of fundamental rights is precisely what makes balancing defeasible and non-monotonic. Would one fundamental right be considered an "exception" of another, then we could theoretically enumerate it as part of some rule and reason deductively.

Second, our findings also help to understand the psychological variables behind the weight formula. According to Alexy (2003), balancing depends on specific weights, which reflect how serious it is not to protect one right or the other. It is, however, not clear how exactly judges determine this "seriousness". We operationalized this seriousness through moral outrage, which resulted to be a good predictor for the final verdicts. Is it thus possible that judges' balancing of fundamental rights is influenced by the level of moral outrage? The fact that both, moral outrage (Experiment 1) and the specific weights (Experiment 2), were good predictors for the final verdicts suggests this. Certainly, most judges and lawyers will not accept this view and it is indeed too early to come to this conclusion. However, we think it is
worthwhile to further study the relation between balancing and moral outrage. In these studies, the role of associative strength should also be considered. The concept of associative strength was introduced by Quinn and Markovits (1998) and applied to defeaters by De Neys et al. (2003b). According to De Neys and colleagues, a defeater has a highly associative strength if it is represented in memory as a good reason to prevent $q$ although $p$ is true. This could be also applied to balancing. A participant will probably only defeat a fundamental right $A$ by another fundamental right $B$, if $B$ is highly associated in one's memory as a reason to prevent A. For instance, one would defeat right to privacy by right to personal security, if personal security is represented in one's memory as more important than the right to privacy. The only problem with this approach is, however, that it is not clear whether associative strength captures all the casespecific details necessary for balancing. As already described, according to law theory, cases with the same conflicting fundamental rights do not have to end up with the same verdicts. Whether these case-specific circumstances that are decisive for balancing - are represented in our memory to influence their associative strength requires further investigation. Maybe the associative strength provides some general, case independent, overall weight to balancing, whereas moral outrage is responsible to tune the specific weights in accordance to the case-specific details.

Finally, our studies also show that paradigms from cognitive psychology are useful to investigate questions from other fields. Conditional inference tasks were originally introduced to test people's capacity to reason according to classical logic. In our study, however, we showed that inference tasks are also useful to test accounts from legal theory. We think that this is true for many other areas as well. For instance, inference tasks can also be helpful to study moral reasoning, where - similar to balancing - people also have often to decide between two conflicting principles (e.g., telling the truth or lying to not hurt someone's feelings).

#### Abstract

One of the hallmarks of human natural language (NL) interaction is the ability for people to balance a variety of social and communicative goals when choosing how to realize their speech actions. These goals can include pragmatic criteria such as correctness, informativeness, and brevity (i.e., Gricean conversational maxims) or social factors such as politeness. However, there currently does not exist a general algorithmic method to explicitly modulate language generated by artificial agents based on an arbitrary number of pragmatic and social criteria. We propose a novel method to accomplish this task, in which rankings of candidate utterances by different pragmatic or social criteria are fused by use of a voting algorithm. We then give a proof-of-concept demonstration of the application of this method in the context of directive generation for human-robot interaction.

Keywords: Human-Robot Interaction; Pragmatics; Natural Language Generation; Politeness

## Introduction

One of the key strengths of humans as social agents is the ability to adapt our language to the communicative norms and needs of the present situation. When giving directives and making requests, we know when it is appropriate to be terse and direct (e.g., "Move out, double-time!"), and when it is appropriate to be polite and circumspect (e.g., "Would you mind passing the salt, please?"). In all our natural language (NL) interactions, we are faced not only with the complex problem of what to say, but also how to say it. Much of this complexity originates from the fact that the intended meaning of utterances in different situational contexts often differs with the literal meaning. For example, asking a waiter, "Can I have a steak?" is not a literal query as to one's physical ability to possess a particular menu item, but rather a means to convey an order.

Dialogue interaction for artificial agents is often viewed from a plan-oriented standpoint, in which the key planoperators are speech actions used to achieve some high-level set of task goals. The precise way in which these speech actions are realized (in so far as it does not affect the efficacy of the speech act) is often of secondary concern. As NLenabled agents become more prevalent in society, and as their manufacturers increasingly market these devices as "social" agents ${ }^{1}$, the disparity between the state-of-the-art in compu-

[^339]tational NL systems and the richness of human-generated language will become increasingly apparent. As such, the ability for an NL-enabled agent to consider and modulate their generated language in human-like ways will become correspondingly more relevant and important.

There is a sizable literature that draws inspiration from pragmatics and socio-linguistics in order to address specific subproblems in natural language generation (NLG) at the subsentential, sentential, and discourse levels. For example, there has been extensive work in operationalizing Gricean pragmatic criteria (Grice, 1975) at the subsentential level, specifically in the area of referring expression (RE) generation (Dale \& Reiter, 1995; Krahmer \& Van Deemter, 2012), in which considerations of correctness, informativeness, and brevity are addressed. There also exists a small body of work that seeks to modulate NLG at the sentential level (Briggs \& Scheutz, 2013; Gupta, Walker, \& Romano, 2007; Miller, Wu, \& Funk, 2008). These approaches seek to operationalize the notion of face-threat from politeness theory, and adjust the behavior of an agent accordingly.

Much of the previous work at the intersection of pragmatics, socio-linguistics, and NLG focuses on tackling specific subproblems in NLG or on modulating language based on a small set of criteria, such as politeness, e.g., Gupta et al. (2007). Yet, in order to generate more human-like language, a much more general framework is necessary. Below we propose some features that such a framework should possess:

1. The method of NLG modulation should be able to explicitly consider an extensible number of pragmatic and sociolinguistic criteria.
2. The method of NLG modulation should be adaptable such that the current situational context may affect the relative importance of communicative criteria.
3. The method of weighing communicative criteria should be agnostic to the choice of the underlying semantic representations used by the system.

At present, there exists no framework that meets all of these criteria. Much of the work in RE generation implicitly considers pragmatic criteria in the design of its algorithms (i.e., RE generation algorithms often search in order of shortest to
longest solution and terminate when a sufficiently informative solution is found (Bohnet \& Dale, 2005)), but does not provide an extensible framework for pragmatic and sociolinguistic modulation. Work such as Briggs and Scheutz (2013) is extensible, but it sorts potential utterances according to a fixed preference ordering of communicative goals, and its adaptability is limited. The work in Bayesian cognitive models of pragmatics (Goodman \& Stuhlmüller, 2013) can be extended to account for social communicative criteria, but it is tightly coupled to semantic representations and small domains amenable to Bayesian computational algorithms. Finally, there are promising approaches which meet some of the requirements, but they are limited to specific domains such as tutoring (e.g., Moore, Porayska-Pomsta, Varges, and Zinn (2004); Nye, Graesser, and Hu (2014)), and do not offer general solutions outside of that context.

In the following section, we present an approach that possesses all of the above desired features. We focus, in this paper, on the problem of modulating generated language at the sentential level, though we hope to apply similar techniques to NLG problems at subsentential and discourse levels. We first begin by examining various communicative goals that NL-enabled agents may need to consider. Next, we present a novel method of balancing these communicative criteria based on techniques from social choice theory (specifically, voting algorithms). Finally, we demonstrate our approach in the context of a human-robot interaction (HRI) scenario, and discuss directions for future work.

## Utterance Selection

In this section we describe an utterance selection algorithm designed to achieve the sort of linguistic modulation we have proposed. In Figure 1 we outline the key components to this approach, which bridges, within the context of an NLG architecture, the output of a dialogue planning component (responsible for selecting an appropriate sequence of speech actions to achieve some agent goal) and the input of an NLG surface realizer component, which is responsible for translating some symbolic linguistic representation into text to be displayed or to be output via text-to-speech. In many architectures, this connection is direct. However, as we have previously addressed, there are multiple ways of realizing speech actions. To effectively consider them, we need the following components:

- A component that factors situational context to produce multiple potential candidate utterance realizations for a given speech action. Examples of NLG pipelines that include such a component are Briggs and Scheutz (2013) and Gupta et al. (2007).
- A set of pragmatic or social criteria $\mathbf{P}$, each with a corresponding utility function $U_{\rho}(\rho \in \mathbf{P})$, that generates a weak preference order over candidate utterances ( $\Upsilon$ ). These criteria include correctness (Maxim of Quality), informativeness (Maxim of Quantity), directness and brevity (Maxim of Manner), and politeness.

Figure 1: Diagram outlining an architecture for flexible NLG that is modulated by an extensible number of pragmatic criteria. The dotted line represents the architectural components we focus in detail on in this paper.

- A component that factors in the agent's beliefs about the current situational context, current goals, and potentially any "personality" model given to the agent in order to produce a set of weights for each pragmatic criterion: $\mathbf{W}=$ $\left\{W_{1}, \ldots, W_{|\mathbf{P}|}\right\}$, where $W_{\rho} \in \mathbb{N}$ denotes the current strength of criteria $\rho$.
- A component that merges the rankings of candidate utterances $\Upsilon$ produced by the pragmatic criteria evaluations $\left(U_{1}, \ldots, U_{|\mathbf{P}|}\right)$ in accordance with the weights generated by the communicative norm reasoner.

In order to merge the rankings of candidate utterances, we used the Schulze voting method (Schulze, 2011), where each ordering produced by $U_{\rho}$ was counted $W_{\rho}$ times. This voting method is a ranked single-winner election system from social choice theory, which is used by many organizations to select a candidate that maintains voters' individual preferences. While this approach has not been previously applied to the domain of computational pragmatics, we find that it offers a robust, computationally-tractable solution to the problem of balancing communicative goals in natural language generation. In the following sections, we present a proof of concept demonstration of our framework, and show how it can be used to generate socially-appropriate directives in the context of human-robot interaction.

Table 1: Utterance selections for various communicative criteria priority orderings

| Relative Criteria Weightings | Utterance Selected | Utterance Output |
| :--- | :--- | :--- |
| Directness $>$ Brevity $>$ Politeness | Instruct $(R, \beta, \operatorname{do}(\beta$, plug_in $(R)),\{ \})$ | "Plug me in" |
| Directness $>$ Politeness = Brevity | Instruct $(R, \beta, \operatorname{do}(\beta$, plug_in $(R)),\{$ please $\})$ | "Plug me in"//"Plug me in, please" |
| Brevity $>$ Politeness $>$ Directness | AskYN $(R, \beta$, capableOf $(\beta$, plug_in $(R)),\{ \})$ | "Could you plug me in?" |
| Politeness $>$ Brevity $>$ Directness | AskYN $(R, \beta$, capableOf $(\beta$, plug_in $(R)),\{$ please $\})$ | "Could you plug me in, please?" |
| Directness = Politeness = Brevity | Instruct $(R, \beta$, do $(\beta$, plug_in $(R)),\{ \})$ | "Plug me in"/"Plug me in, please" |
| Politeness $>$ Directness = Brevity | AskYN $(R, \beta$, capableOf $(\beta$, plug_in $(R)),\{$ please $\})$ | "Could you plug me in, please?" |

## Demonstration: Directive Generation

In order to demonstrate the generality of this framework, we describe how our proposed framework has been integrated with the NL pipeline in a cognitive, robotic architecture, DIARC (Schermerhorn, Kramer, Middendorff, \& Scheutz, 2006). There has been growing interest in the field of HRI in the ways in which robots could phrase requests for assistance from human interaction partners with respect to politeness and other social norms (Gupta et al., 2007; Srinivasan \& Takayama, 2016; Strait, Canning, \& Scheutz, 2014; Torrey, Fussell, \& Kiesler, 2013). Below we present how our framework can be used to address this challenge.

## Framework Configuration

In DIARC, utterances are represented in the following form:

$$
v=\text { UtteranceType }(\alpha, \beta, X, M)
$$

where UtteranceType denotes the speech act classification, $\alpha$ denotes the speaker, $\beta$ denotes the addressee, $X$ denotes an initial semantic analysis, while $M$ denotes a set of sentential modifiers (e.g., "please"). The pragmatic reasoning component in the architecture associates an utterance $v$ in context $C$ with a set of implications:

$$
v_{C}:=\left\langle\mathbf{B}_{\text {lit }}, \mathbf{B}_{\text {int }}, \theta\right\rangle
$$

Each rule associates a particular utterance form $v$ in context $C$ with a tuple containing the set of beliefs $\mathbf{B}_{\text {int }}$ to be inferred based on the intended meaning of the utterance, the set of beliefs to be inferred based on the literal meaning of the utterance $\mathbf{B}_{\text {lit }}$, as well as the degree $\theta$ to which the utterance can be considered a face-threatening act (i.e., a threat to a person's self-image or autonomy) in context $C$ (Brown \& Levinson, 1987).

We define the criterion of correctness as:

$$
U_{\text {correct }}\left(v_{C}, \beta\right)=-\left|\left\{x: x \in \mathbf{B}_{\text {int }}\left(v_{C}\right) \wedge \beta \nvdash x\right\}\right|
$$

where $\beta$ consists of the agent's current set of beliefs. Therefore, utterances that imply more facts unsupported by the agent's beliefs are considered less correct than those that imply fewer unsupported facts. We define the criterion of informativeness as:

$$
U_{\text {inform }}\left(v_{C}\right)=\left|\mathbf{B}_{\text {int }}\left(v_{C}\right)\right|
$$

such that utterances that imply more facts are considered more informative than those that imply fewer facts. We define the criterion of directness as:

$$
U_{\text {direct }}\left(v_{C}\right)= \begin{cases}1 & \mathbf{B}_{\mathbf{l i t}}=\mathbf{B}_{\mathbf{i n t}} \\ 0 & \mathbf{B}_{\mathbf{l i t}} \neq \mathbf{B}_{\mathbf{i n t}}\end{cases}
$$

such that utterances in which the literal and intended meanings are the same are considered more direct than those in which they differ. We define the criterion of politeness as:

$$
U_{\text {polite }}\left(v_{C}\right)=-\theta\left(v_{C}\right)
$$

such that utterances in which the associated face-threat value $(\theta)$ are lower are considered more polite than those in which in it is higher. Finally, we define the criterion of modifierbrevity such that:

$$
U_{m-b r e v i t y}\left(v_{C}\right)=-|M|
$$

utterances with fewer sentential modifiers are considered briefer than those with more sentential modifiers ${ }^{2}$.

## Example Scenario

In this section, we present a proof-of-concept demonstration of the pragmatic modulation framework as applied to a directive formulation problem. Consider a scenario in which an NL-enabled robot is low on charge and needs a human to plug it in (want (bob, plug_in(self))). This will require a directive to be formulated and communicated to the human in order to accomplish the end goal of being plugged in. We consider four main directive formulation strategies in this scenario, realized in the following pragmatic rules in the architecture's dialogue component ${ }^{3}$ :

$$
\begin{align*}
& \operatorname{Instruct}(\alpha, \beta, X, M):= \\
& \quad\langle\{\operatorname{want}(\alpha, \operatorname{bel}(\beta, \operatorname{want}(\alpha, X)))\}, \\
& \left.\quad\{\operatorname{want}(\alpha, \operatorname{bel}(\beta, \operatorname{want}(\alpha, X)))\}, \theta_{\text {instruct }}\right\rangle \tag{1}
\end{align*}
$$

represents a literal directive from $\alpha$ to $\beta$. In the case of no politeness softeners, $M=\emptyset$, where in the case of softeners,

[^340]

Figure 2: Ratings of social context dimensions from behavioral data. Error bars represent SEM.
$M=\{$ please $\}$. In contrast, an indirect request can be represented by:

$$
\begin{align*}
& \text { AskYN }(\alpha, \beta, \operatorname{capableO} f(\beta, X), M):= \\
& \quad\langle\{\text { want }(\alpha, \text { informif }(\beta, \alpha, \operatorname{capableOf}(\beta, X)))\}, \\
& \left.\quad\{\operatorname{want}(\alpha, \operatorname{bel}(\beta, \text { want }(\alpha, X)))\}, \theta_{\text {AskYN }}\right\rangle \tag{2}
\end{align*}
$$

which represents the query "Can you $X$ ?" It is literally a query about one's capability, but can be interpreted as an indirect request. In the case of no politeness softeners, $M=\emptyset$, where in the case of softeners, $M=\{$ please $\}$. The relative face-threat values for each strategy are: $\theta_{\text {AskYN-p }}<\theta_{\text {AskYN }}<$ $\theta_{\text {instruct }-p}<\theta_{\text {instruct }}$, where " p " indicates the presence of politeness softeners.

Table 1 contains the utterance forms selected by the voting algorithm given the relative weights of the communicative goals of directness, politeness, and brevity. Correctness and informativeness were weighted above these criteria, but for the purposes of this scenario were irrelevant (as all candidate utterances were equally correct and informative). Our framework allows for socially-appropriate directive generation, as the various directive strategies, including: Direct - "Plug me in", Direct with softener - "Plug me in, please", Indirect "Could you plug me in?", and Indirect with softener - "Could you plug me in please?" were generated in different potential contexts. For example, if directness is the top priority (e.g., in a task-oriented environment) then a direct utterance will be selected. However, if politeness is required (e.g., in casual conversation or a service-robot scenario) then a more indirect utterance will be selected. The results of the demonstration show how our framework can be integrated in a dialogue system in order to produce robust socially-sensitive natural language utterances in a variety of contexts.

## Setting the Pragmatic Criteria Weightings

Next, we conducted an empirical investigation to establish an initial set of weights for the model (see 'Pragmatic Criteria Weightings' component in Figure 1) that is consistent

Figure 3: Ratings of pragmatic criteria from behavioral data. Error bars represent SEM.
with human judgments. To this end. we conducted a crowd sourcing study on Amazon Mechanical Turk in which people were shown hypothetical human-robot interactions and asked to rate various features of the interactions. A total of 42 people participated in the study - 23 of the participants were male, 17 were female, and 2 did not specify a gender. The average age was 35.9. All participants had US zip codes and received $\$ 1$ for their participation. The study was approved by the Tufts Institutional Review Board and all participants gave informed consent. In the study, participants were shown a text description of four scenarios ${ }^{4}$ and were asked to rate various social context dimensions (potential for harm, time pressure, interlocuter authority, and formality) and pragmatic criteria (directness, politeness, brevity) associated with the robot's speech in each scenario on a sliding scale from 0 (Strongly Disagree) to 100 (Strongly Agree).

Analyses of the data were carried out in order to establish a mapping between the pragmatic criteria, weightings, and utterance selection. First, the results for social context dimensions (see Figure 2) showed that each scenario had a distinct feature profile. Consequently, people expected the robot to adopt a different set of pragmatic criteria in each scenario (see Figure 3). The link between these contextual dimensions and the corresponding pragmatic criteria is important for determining the model weights in new contexts, but this will require future investigations that address the problem directly (see Discussion section). For the present work, we focus on using people's ratings for the pragmatic criteria to set the initial weights of our model. In order to rank these weights, we conducted a repeated measures ANOVA (with Bonferroni

[^341]Table 2: Candidate utterance types with corresponding directives from Scenario \#2

| Utterance Type | Robot Directive |
| :--- | :--- |
| $\left(u_{1}\right)$ Direct | "Plug me in." |
| $\left(u_{2}\right)$ Direct with softener | "Plug me in, please" |
| $\left(u_{3}\right)$ Indirect statement | "I would like you to plug me in. |
| $\left(u_{4}\right)$ Indirect statement with softener | "I would like you to plug me in, please." |
| $\left(u_{5}\right)$ Indirect question | "Could you plug me in?" |
| $\left(u_{6}\right)$ Indirect question with softener | "Could you plug me in, please?"" |

correction) to tease out the ordering of the pragmatic criteria for each scenario. In scenario $1(F(2,82)=18.237, p<$ .001 ), post-hoc tests revealed that people expected the robot to be more direct $(89 \%)$ vs polite $(71 \%, p<.005)$ and brief ( $62 \%, p<.005$ ). There was no significant difference between politeness and brevity in this scenario ( $p=.309$ ). This corresponds to criteria weightings of Direct $>$ Polite $=$ Brief, which would result in a tie in the selected utterance: "Hand me the red pills"/"Hand me the red pills, please" (see Table $1)$. In scenario $2(F(2,82)=4.470, p<.05)$, post-hoc tests revealed that people expected the robot to be slightly more direct ( $87 \%$ ) vs polite ( $74 \%, p<.05$ ). However, there was no significant difference between directness and brevity in this scenario ( $p=.092$ ) or between politeness and brevity ( $p=.673$ ). This corresponds to criteria weightings of Direct = Polite $=$ Brief, and a tie in the selected utterance: "Plug me in"/"Plug me in, please". In scenario $3(F(2,82)=44.334$, $p<.001$ ), post-hoc tests revealed that people expected the robot to be more polite ( $92 \%$ ) vs direct ( $58 \%, p<.001$ ) and brief $(56 \%, p<.001)$. There was no significant difference between directness and brevity in this scenario ( $p=1.00$ ). This corresponds to criteria weightings of Polite $>$ Direct $=$ Brief, and a selected utterance of "Could you hand me your coat, please". Finally, in scenario $4(F(2,82)=32.004, p<$ $.001)$, post-hoc tests revealed that people expected the robot to be more direct ( $85 \%$ ) vs polite $(42 \%, p<.001)$ and brief ( $77 \%, p<.005$ ). People also expected the robot to be more brief vs polite ( $p<.001$ ). This corresponds to criteria weightings of Direct $>$ Brief $>$ Polite, and a selected utterance of "Move out of the way". The utterance output corresponding to each of these criteria weightings is listed in Table 1, and was selected from a list of 6 possible utterance types (see Table 2). Overall, these empirical results serve as a starting point by which to set the weights of our model for sociallyappropriate utterance selection. Extensions of this approach as well as suggestions for future work are discussed in the Discussion below.

## Discussion

In the previous section, we demonstrated how the application of our novel, pragmatically-sensitive framework can result in richer, more human-like modulation of NL. The method of explicit operationalization of pragmatic and socio-linguistic criteria into functions that can produce preference orderings over candidate NLG representations holds advantages over many of the pre-existing approaches. For example, the merg-
ing of preference orders produced by utility functions rather than the direct merging of utility values avoids tricky questions about the direct quantitative comparisons of different pragmatic and socio-linguistic criteria ${ }^{5}$. Additionally, the explicit operationalization of criteria allows for more extensibility and flexibility compared to algorithms in which communicative criteria are factored in implicitly. Nonetheless, this extensibility and flexibility leads to a variety of challenges for future work.

## Computing and Learning Criteria Weights

While we used an empirical approach to initially set the weights for utterance selection, there still exists the normative challenge of determining what the most appropriate orderings/weightings of pragmatic and social goals are in any given communicative context. We allude to possible sources of information that could be used to compute these weights in Figure 1. These include the current beliefs of the agent about the situational context, the agent's goals (task-goals and social-goals), and potentially even models of personality (Mairesse \& Walker, 2011) or culture (Endrass \& André, 2014) that a designer may wish to imbue in the agent (e.g., a social robot configured to be impolite for entertainment purposes). The dynamics of how weights change within a single interaction and context are also a matter for future investigation. For example, a robot could become more polite if it detects that its interlocutor is distressed. The appropriate solution for this component would be entirely dependent on the particular interaction purpose, context, and desired effect. We view the present work as the first necessary step to opening up this rich area of future research.

We envision the process of computing criteria weights as a two-step process. First, various observable or inferable social context factors are evaluated in the given interaction scenario. These contextual features may include factors such as those in Figure 2. These in turn govern the weights that modulate utterance selection. The mapping between social context features and communicative criteria weights could potentially be learned in the following ways. Explicit feedback: the human interactant could provide explicit negative or positive feedback about the agent's recently-produced utterance with respect to a particular communicative criterion (e.g., "That was rude!" would indicate that weights for politeness should be increased in the present context). More subtle cues from facial expression, body language, or affect could also be used to modulate politeness, as in Moore et al. (2004). Passive observation: in a given interaction context, the agent could observe the utterances generated by other agents. An assumption of appropriateness could be made, in which case hypotheses for the possible criteria weights that the agent utilized in the present scenario could be abduced. These hypotheses can be used by the agent itself as constraints that in turn govern its own utterance selection in similar social contexts.

[^342]
## Improved Operationalization of Criteria

Because our proposed framework relies on explicit operationalization of communicative criteria in order to rank candidate utterances, adapting and refining these operationalizations to new criteria, semantic representations, and NLG architectures will be an ongoing task. Adaptation will likely be fairly straightforward for criteria such as correctness, but other pragmatic and socio-linguistic criteria are more complex and leave room for future work. In particular, within DIARC the operationalizations of politeness and brevity can be improved and expanded. As alluded to earlier, brevity will require architectural integration with the lower-level NLG components such as the surface realizer and text-to-speech in order to calculate metrics for lexical and auditory brevity. This will be especially important when the spoken tempo of utterances can be manipulated (one can imagine a speed vs. intelligibility trade-off). Politeness is another criterion ripe for refinement. For example, though we modeled a scenario in which positive face (agent standing) was potentially threatened, a general framework to detect and evaluate threats to positive face is still needed (Briggs \& Scheutz, 2014).

## Conclusion

It is important that socially-embedded artificial agents generate speech in human-like ways in order for interaction with such agents to be truly natural. To this end, we have introduced and demonstrated a general method for modulating utterance selection based on an arbitrary number of social and pragmatic criteria. Our approach possesses an important set of novel features, including extensibility to additional sociolinguistic criteria, adaptability to changing situational context, and agnosticism with respect to underlying semantic representations. In a proof of concept demonstration, we showed how our approach can be integrated with a cognitive robotic architecture in order to generate flexible, socially-appropriate directives in a variety of contexts. Future work will be needed to extend the operationalization of the communicative criteria and devise mechanisms to learn the weights of the model through natural interaction. Overall, the present work moves us a step closer towards the goal of artificial agents that can communicate in the kinds of robust and socially-sensitive ways found in human language.

#### Abstract

This paper examines a process of solving different types of counterfactual arithmetic problems (problems contradicted a visual experience, an experience of temperature, encyclopedic knowledge, etc.) in comparison with their 'real' counterparts by different types of subjects (e.g., educated in math and educated in humanities). As a result, a two-stage model of solving arithmetic problems is outlined in the paper.

Keywords: situated cognition; counterfactual reasoning; arithmetical problem; two-stage model; four-level-cognitive-development theory.

## Introduction

This research has been carried out at the junction of two sets of problems. The first one is concerned with counterfactual reasoning ${ }^{1}$. This issue has been discussed intensively in recent decades (e.g., Pearl 2000; Fauconnier \& Turner 2002, p. 17-59; Hiddleston 2005; de Vega et al. 2007; de Vega 2008; Ferguson \& Sanford 2008; de Vega \& Uritta 2011; Rips \& Edwards 2013), but some aspects thereof have not been touched so far. 'Situated cognition' is a blanket term for the second set (e.g., Clancey 1997; Kirshner \& Whitson 1997; Watson \& Winbourne 2007; Robbins \& Aydede 2009). This paper examines the role of situated cognition in counterfactual reasoning. A distinguished work of A. Luria (1976) was a starting point for that. When investigating cognitive skills of dekchans of Central Asia in $1930^{\text {th }}$ he encountered a curious phenomenon. His subjects were not able to solve counterfactual problems, whereas they solved quite easily similar problems consistent with their everyday life. Importantly, trying to solve counterfactual problems subjects addressed their day-to-day experience. Some striking examples thereof are given in Luria's monograph (1976, p. 131):

[^343]
## A 'conditional' problem that conflicts with actual experience is given:

[Exp.] Suppose it were to take six hours to get from here to Fergana on foot and a bicycle was twice as slow?
[Sub.] Then a bicycle would get there in three hours!
Solution on a level corresponding to practical reality.
[Exp.] No, a teacher gave this problem as an exercise - suppose that the bicycle were twice as slow.
[Sub.] If the cyclist makes good time, he will get to Fergana in two and a half or three hours. According to your problem, though, if the bicycle brakes down on the way, he'll arrive later, of course. If there's a breakdown, he'll be two or three hours late.
From the perspective of cultural psychology (Vygotsky, Luria, Cole, Tulviste, etc.), this and similar facts are usually interpreted as a difference between 'situational' thinking and 'abstract' thinking. The subjects of Luria's investigation were people of so-called 'sympractical' culture, in which 'situational' thinking based on day-today experience is supposed to be the only way of reasoning (Cole \& Scribner 1974, p. 160-168, 178-179; Luria 1976; Tulviste 1991). In that, Luria's dekchans endeavored to reinterpret abstract problems as stories from their everyday life.

Indeed, people of modern industrial cultures can solve counterfactual problems; meanwhile, situated cognition is an important part of their everyday life, and, therefore, it may influence their way and speed of solving counterfactual problems. The overall objective of our research was to test some obstacles they may encounter in this process.

It is worth noting that there are two basic models of counterfactual reasoning in contemporary cognitive science (Pearl 2000; Hiddlesston 2005; Rips \& Edwards 2013). The first model is called 'pruning theory'. From this perspective, when modeling counterfactual situation, subject changes the only element (in particular, in famed If Clinton were the Titanic, the iceberg would sink

Clinton replaces iceberg), all others being the same. The second model is named 'minimal network theory'. In its scope, a change of one element entails a number of changes in elements close to this one. Importantly, both models look formal and do not distinguish between situated cognition and abstract knowledge.

A preliminary hypothesis of this research was as follows. Given some discrepancies between situated cognition and a counterfactual situation in arithmetic problems, people of modern industrial cultures face a number of difficulties when solving counterfactuals. These difficulties would engender an extended period of time needed for solving counterfactual problem in comparison with 'real' one and also more errors in that. Perhaps, the most intriguing issue in this scope is a particular way of how situated cognition is involved in the process of solving. There are two basic options. From the first perspective, situated cognition is actual for the whole period of solving; from the second perspective, it is at work only in the first stage, in which an abstract model of the task is built, whereas in the second stage only formal operations are processed. If the first option is true, difficulties caused by a counterfactual situation can be drawn forth at any moment of reasoning; if the second option works, they are present early in stage, and then there is no difference, other things being equal, in solving counterfactual and 'real' problems.

One of the ways to test these options is to compare mean $\Delta \mathbf{t}_{\text {cr }}$ (the difference between the time needed to solve a counterfactual problem and the time needed to solve its 'real' equivalent) for people who solve problems faster (aka 'experts') and slower (aka 'amateurs'). 'Experts' superiority over 'amateurs' may be a result of more developed computational skills (factor $a$ ), of higher speed of transformation of a task into a system of abstract symbols (factor $b$ ), and of a combination of these factors. If mean $\Delta \mathbf{t}_{\mathbf{c r}}$ for 'experts' is less than for 'amateurs', the factor $b$ is important; if the difference between mean $\Delta \mathbf{t}_{\mathrm{cr}}$ is not significant, the factor $a$ dominates.

The lack of difference between mean $\Delta \mathbf{t}_{\mathrm{cr}}$ can be also an argument for the two-stage model with the following interpretation: in the first stage there is no difference between 'experts' and 'amateurs', the process in this stage is determined by situated cognition; in the second stage situated cognition is out of work, subjects only perform computational operations with formal objects. Importantly, it does not exactly mean that perception is also out of work in the second stage; it may also mean that in this stage perception works in quite a specific way, distant from day-to-day experience.

Another intriguing issue is a correlation between mean $\Delta \mathbf{t}_{\mathrm{cr}}$ and a type of problem. Counterfactual situation can be concerned with various perceptive channels (vision, hearing, taste, etc.) as well as with some theoretical knowledge. To find out which channel causes maximum $\Delta \mathbf{t}_{\mathrm{cr}}$ is useful to clarify the structure of basic elements of situated cognition. The priority of perceptual channels over encyclopedic knowledge was our working hypothesis in this case (e.g., Zacks 2015, p. 95-107).

The framework of the experiments to carry out was determined by a problem field represented above.

## Experiment 1

## Method

Subjects. A total of 25 students of Moscow high schools, $15-16$-year-old were the subjects of Experiment 1. We argued for this choice by fewer discrepancies in solving arithmetical problems for students than it would be for adult participants.
Material. The subjects were suggested to solve 16 simple arithmetical problems divided into 8 groups: a) problems which contradict a social experience, and their 'real' counterparts (e.g., A 24-page notebook costs 20 roubles more than a 96-page notebook. What is the price of the 24-page notebook if the price of 96-page notebook is 10 roubles?, and A 96-page notebook costs 20 roubles more than a 24-page notebook. What is the price of 96-page notebook if the price of 24-page notebook is 10 roubles?); b) problems which contradict a visual experience, and their 'real' counterparts (e.g., A cyclist moves 10 times faster than a car driver. Please, work out the speed of the car if the speed of the cyclist is $80 \mathrm{~km} / \mathrm{h}$; and A cyclist moves 10 times slower than a car driver. Please, work out the speed of the car if the speed of the cyclist is $8 \mathrm{~km} / \mathrm{h}$ ); c) problems which contradict hearing, and their 'real' counterparts (e.g., In normal conditions, a shout covers a distance of 10 metres; this is 40 metres less than the distance covered by a whisper. Please work out the distance that a whisper covers, and In normal conditions, a shout covers a distance of 50 metres; this is 40 metres more than the distance covered by a whisper Please work out the distance that a whisper covers); d) problems which contradict an experience of temperature, and their 'real' counterparts; e) problems which contradict an experience of taste, and their 'real' counterparts; f) problems which contradict laws of biology, and their 'real' counterparts (e.g., A father is 20 years younger than his son. How old is the son if the father is now 17 years old?; and A mother is 20 years older than her daughter. How old is the daughter if the mother is now 37 years old?); g) problems which contradict encyclopedic knowledge, and their 'real' counterparts; h) problems which contradict an experience of weight, and their 'real' counterparts. Each problem was printed on a special card.
Procedure. Each subject worked out the problems individually. Each subject solved firstly 16 counterfactual problems, randomly given to him/her (2 from each group), and then, a month after, 16 their 'real' counterparts. We endeavored, as seen, to minimize any text difference in each pair of problems in order to avoid 'noise interference'. Before the main procedure the subjects solved two control problems to make sure that they had no difficulties in that. Time from receiving a card to reporting the answer was measured for each problem.

The data was processed as follows. Firstly, $\Delta \mathbf{t}_{\mathrm{cr}}$ was counted for each pair of problems. Then, a total of positive and negative $\Delta \mathbf{t}_{\mathbf{c r}}$ was calculated, and the significance of the difference between positive and negative $\Delta \mathbf{t}_{\mathrm{cr}}$ alongside with the significance of the difference between a total of 'counterfactual' errors and that of 'real' errors was estimated with Pearson's chisquared test. After that, for more detailed analysis
comparative data for all pairs of groups of problems were processed with one-way ANOVA.

## Results \& Discussion

The results of Experiment 1 provided strong evidence for supporting the hypothesis that subjects will encounter more obstacles when solving counterfactual problems than real ones: only $5 \Delta \mathbf{t}_{\mathrm{cr}}$ from 400 had a negative value ( $\chi^{2}(1)=380.25 ; p<0.0001$ ).

Some complementary evidence for supporting general hypothesis was also provided by the analysis of the errors: a total of 34 for counterfactual problems; a total of 10 for 'real' ones $\left(\chi^{2}(1)=380.25 ; p<0.01\right)$.

Mean $\Delta \mathbf{t}_{\mathbf{c r}}$ and standard deviation for each group of problems are presented in Table 1.

Table 1: Mean $\Delta \mathbf{t t}_{\mathbf{c r}}$ for the groups of problems (sec.)

| a) | b) | c) | d) |
| :---: | :---: | :---: | :---: |
| $8.12 \pm 5.89$ | $11.95 \pm 15.66$ | $10.62 \pm 6.04$ | $8.32 \pm 10.93$ |
| e) | f) | g) | h) |
| $10.30 \pm 12.62$ | $6.30 \pm 2.95$ | $6.15 \pm 5.25$ | $8.39 \pm 12.70$ |

The first remarkable result in this table is a gross standard deviation engendered by a big dispersion of results for different participants. The minimal standard deviation holds for the groups f), g), a), and c). This may be connected with a computational complexity of a particular problem: in particular, other things being equal, multiplication leads to higher dispersion than addition; multiplication by eight - to higher dispersion than multiplication by two, etc.

Because of high dispersion, there is no significant difference in $\Delta \mathbf{t}_{\mathrm{cr}}$ for almost all pairs. The only exception is pairs (c, f) and (c, g) (p<0.01). However, this information is also useful as an argument for the hypothesis of the perceptual channels priority over encyclopedic knowledge: problems contradictory with hearing need more time to comprehend the task than problems contradictory with biological laws and encyclopedic knowledge.

By and large, the results of Experiment 1 gave clear evidence to support the basic hypothesis of more difficulties in solving counterfactuals than in solving their 'real' counterparts. Meanwhile, they raised a number of significant questions for further research. Firstly, Experiment 1 gave no evidence pro or contra the two-stage-model. The way of how a counterfactual situation matters the process of reasoning needed a fine-grained analysis. Secondly, the hypothesis of the perceptual channels priority over encyclopedic knowledge required a more detailed investigation.

The framework of Experiment 2 was determined by these issues. To examine the two-stage-model by engaging two groups of subjects with different skills of solving arithmetical problems was its objective. In that, students specialized in mathematics (SM) and their peers specialized in humanities (SH) were chosen to participate Experiment 2. As mentioned above, SM were expected to solve both 'real' and counterfactual problems faster than SH. Given that, the comparison of mean $\Delta \mathbf{t}_{\mathrm{cr}}$ for SM and

SH was under discussion. If significant difference between them could be interpreted in different ways and demanded further investigations to draw a more minute description, then the lack of such difference would testify for the two-stage model.

Let us take a more detailed look at this. The influence of a counterfactual situation is obviously concerned with situated cognition. The same $\Delta \mathrm{t}_{\mathrm{cr}}$ show that such influence does not depend on computational skills being an invariant, at least, for a particular age. Then, if situated cognition is actual for the whole process of working out a problem, its equal influence on SM and SH will be represented in equal $\boldsymbol{\varepsilon}$ (the ratio $\Delta \mathbf{t}_{\mathrm{cr}}: \mathbf{t}_{\text {real }}$ ), but not $\Delta \mathbf{t}_{\mathrm{cr}}$. Equal $\Delta \mathbf{t}_{\mathrm{cr}}$ is an argument for the two-stage model.

## Experiment 2

## Method

Subjects. A total of 40 students of Moscow high schools, 15-16-year-old - 20 SM students and 20 SH students were the subjects of Experiment 2. None of them participated Experiment 1.
Material. The subjects were suggested to solve ten arithmetical problems: five problems contradicting a visual experience (type b) and five problems contradicting encyclopedic knowledge (type g). The problems suggested were the same as the problems of this type in Experiment 1.
Procedure. It was the same as that of Experiment 1.
The data was processed in a following way. Firstly, similar to Experiment 1, Pearson's chi-squared test was applied to estimate the significance of the difference between positive and negative $\Delta \mathbf{t}_{\text {cr }}$ alongside with the significance of the difference between a total of 'counterfactual' errors and that of 'real' errors. After that, a correlation between a group of subjects (SM and SH ) and $\mathbf{t}_{\text {real }}, \mathbf{t}_{\mathbf{c}}, \Delta \mathbf{t}_{\mathrm{cr}}$ was checked with one-way ANOVA Finally, one-way ANOVA was used to check a correlation between $\Delta \mathrm{t}_{\mathrm{cr}}$ and the type of problem (type b vs. type g).

## Results

In accordance with Experiment 1, both SM and SH needed more time to solve counterfactual problems in comparison with their 'real' counterparts ( $\mathrm{p}<0.0001$ )

As predicted, SM solved both 'real' and counterfactual problems faster than SH ( $\mathrm{p}<0.001$ ).

The difference between $\Delta \mathbf{t}_{\text {crSm }}$ and $\Delta \mathbf{t}_{\text {crSH }}$ was not significant. In Table 2 mean $\Delta \mathbf{t}_{\text {crSm }}, \Delta \mathbf{t}_{\text {crSH }}$ and standard deviation are presented for each problem (problems 1-5 are concerned with visual experience, problems 6-10 with encyclopedic knowledge).

Table 2: Mean $\Delta \mathbf{t}_{\mathbf{c r S M}}, \Delta \mathbf{t}_{\mathbf{c r S H}}, \mathbf{P}$ for each problem

| № | $\Delta \mathbf{t}_{\text {crsm }}$, sec. | $\Delta \mathbf{t}_{\text {crSH, }}$, sec. | $\mathbf{P}$ |
| :---: | :---: | :---: | :---: |
| 1 | $5.9 \pm 5.9$ | $11.2 \pm 10.0$ | $\mathbf{0 , 0 3 7}$ |
| 2 | $4.5 \pm 4.0$ | $4.2 \pm 9.6$ | 0,883 |
| 3 | $3.8 \pm 4.0$ | $5.8 \pm 7.5$ | 0,521 |
| 4 | $7.8 \pm 6.2$ | $3.5 \pm 3.2$ | $\mathbf{0 , 0 1 0}$ |
| 5 | $5.2 \pm 5.1$ | $8.1 \pm 7.2$ | 0,123 |

| 6 | $4.6 \pm 3.3$ | $7.0 \pm 7.3$ | 0,197 |
| :---: | :---: | :---: | :---: |
| 7 | $4.7 \pm 3.6$ | $4.6 \pm 7.5$ | 0,970 |
| 8 | $4.6 \pm 2.5$ | $5.4 \pm 2.6$ | 0,319 |
| 9 | $4.8 \pm 4.8$ | $4.5 \pm 7.3$ | 0,782 |
| 10 | $4.5 \pm 3.7$ | $4.6 \pm 4.1$ | 0,951 |

As seen, only the results for problem 1 and problem 4 are more or less significant; at that, for problem 1 $\Delta \mathbf{t}_{\text {crSM }}<\Delta \mathrm{t}_{\text {crSH }}$ and for problem $4 \Delta \mathrm{t}_{\text {crSM }}>\Delta \mathrm{t}_{\text {crSH }}$.

Mean $\Delta \mathbf{t}_{\mathbf{c r}}$ for problems contradicting a visual experience (№ 1-5) is more than that for problems contradicting encyclopedic knowledge (№ 6-10)( $\Delta \mathbf{t}_{\text {cr1- }}$ ${ }_{5}=6.24 \pm 7.07 ; \Delta \mathrm{t}_{\text {cr6-10 }}=4.91 \pm 5.42 ; \mathrm{p}=0.046$ ).

## Discussion

The results of Experiment 2 provide some evidence to support the two-stage-model. A higher level of computational skills entailing a higher speed to work out a problem does not lead to less $\Delta \mathbf{t}_{\mathrm{cr}}$. As noticed above, constant $\Delta \mathbf{t}_{\text {cr }}$ is evidence of the same - at least, for the groups of subjects involved in the experiment - stage of the process. This stage is likely to be connected with the constructing a formal model of the problem, put another way, with the transforming a particular situation into the system of abstract symbols. Situated cognition dominates in this stage, whereas the next stage is concerned with computational operations with such system.

The results of Experiment 2 also support the hypothesis of the priority of perceptual channels over encyclopedic knowledge. The subjects face more difficulties in the situation contradicting their visual experience than in the situation contradicting their encyclopedic knowledge. These data are consistent with some observations in different fields, e.g., with the decisive role of perception in categorization (this idea is represented by the concept of basic level category; see, e.g., Rosch 1978; Lakoff 1987).

As mentioned, subjects of Experiment 1 and Experiment 2 were 15-16-year-old students. Such a choice was determined by a higher level of homogeneity in computational skills for that group in comparison with adults. Nevertheless, in order to verify the results on another age group, Experiment 3 was carried out.

## Experiment 3

## Method

Subjects. A total of 20 high-educated adults (age 35-60; mean age -48 ), half with education in math and physics (EM), and half with education in humanities (EH) were subjects of Experiment 3.
Material and procedure coincided with that of Experiment 2.

## Results and discussion

As it was hypothesized, dispersion for adults was much more significant than for students, because of notable
difference in practice. Nevertheless, the main results of Experiment 1 and Experiment 2 were confirmed.

Subjects solved counterfactual problems longer than 'real' ones $\left(\chi^{2}(1)=26.27 ; p<0.0001\right.$ for $E M ; \chi^{2}(1)=7.19$; $\mathrm{p}<0.01$ for EH ).

Although EM subjects solved the problems of both types faster than EH ones ( $\mathrm{p}<0.005$ ) the difference between $\Delta \mathbf{t}_{\mathbf{S M}}$ and $\Delta \mathbf{t}_{\mathbf{S H}}$ was not significant ( $\mathrm{p}=0.33$ ).

## General discussion

Returning to the issues represented in the introduction it is worth stressing again that the obstacles which Luria's dekchans faced when working out counterfactual problems also characterize people of modern industrial societies in similar situation. These obstacles are not as crucial, however, they lead to longer time needed to solve counterfactual problem in comparison with their 'real' counterparts as well as to more solving errors. These results are consistent with some data from other research fields. Thus, works by Frumkina and colleagues (see Frumkina \& Mikheev 1996 as a summary) gave clear evidence that 'complex thinking', which is, according to Vygotsky, a feature of preschool-age children and people of hunter-gatherer cultures, can also characterize people of modern industrial culture in some situations (e.g., in classification tasks). The only difference is that modern people can change their mind and shift from complex thinking to more abstract cognitive models after some clarifications of an experimenter.

In order to generalize these and similar observations, it is worth addressing the four-level-cognitivedevelopment theory (Glebkin 2015, Glebkin 2015a). This theory singles out four basic cognitive levels, which hold also a framework for cultural-historical typology: Level A characterizes great apes; Level B - prehistoric culture and hunter-gatherer culture; Level C - early theoretical cultures; Level D - Modernity in Europe and modern industrial cultures. Importantly, these levels build on each other, but do not interchange with each other; modern people, guided by circumstances, can operate on all levels. In particular, a majority of everyday skills (swimming, navigation in space, etc.) demand Level A and Level B; Level C is actual for, e.g., working out problems of school geometry; Level D - for abstract algebraic operations. By and large, conceptual systems on Level C operate with objects of natural/social world and their direct representations (historical events, social and political actions, natural objects, etc.). Unlike that, systems on level D operate with abstract objects which have no direct connections with natural/social world (e.g., non-Euclidean geometry, quantum field theory, etc.).

From this perspective the two-stage-model of working out arithmetic problems, developed in this paper, might be interpreted as a shift from Level C, basic in the first stage, to Level D dominating in the second stage. It means that humans can change cognitive levels not only by changing problems but also when solving the same problem.

Finally, it is worth noting that a two-stage model was also suggested by Maruyama et al. (2012) to account for a process of performing nested calculations (e.g. $8+(5-(3$
$+1)$ ) ). Both an analysis of eye-movements of subjects and magneto-encephalography data give some evidence for that. This means that such a model may work not only for arithmetical problems but also for other types of problems in mathematics.

#### Abstract

This work focuses on an issue situated at the intersection of two domains: the oral mode of communication vs. the written mode of communication, and language acquisition. The backbone of this research is a conjecture that, for some age groups (babies, toddlers and preschool-aged children), to explore the acquisition of discourse as a whole (including gestures, facial expressions, prosody, pauses and discursive markers, etc.) is more appropriate than explore the acquisition of language exclusively. "The Pear Film" experimental line underpins the method of this research. The database comprises 74 'pear stories' of Moscow preschool-aged children and high school students. Three parameters of the discourse are of interest for the authors: a logical structure and a coherence of the narrative; gestures and spontaneous movements lost any communicative meaning; discourse words and pauses.

Keywords: multimodal communication, discourse, language acquisition, narrative, pear stories.

## Introduction

The study of spoken language in contrast with its written form has been one of the most intriguing issues in cognitive science over recent decades. At the beginning of the paper it is worthwhile to outline the key points which underpin this avenue of research (Tannen 1982; Chafe 1985; Chafe \& Tannen 1987; Miller \& Weinert 1998; Holie \& Adger 1998; Li \& Hombert 2002; Linell 2005; Tomasello 2008; Fais et al. 2012).

Since its emergence as an independent branch of science, linguistics by default has been based on the structure of written language as a paradigm for language in general. This has deep roots in the backstory of linguistics. Although for the Ancient Greeks and the Ancient Romans speech and argument were important elements of both politics and everyday life, theoretical approaches to language developed by Plato and, especially, by Aristotle bore on written language. This held true, without any alternatives, in the philosophy of the Middle Ages. Linguistic views of patristics and, then, scholasticism were almost exclusively concerned with literacy. Afterwards, the ancient and medieval tradition strongly influenced early modern scholars in their view of
language (Pascal, Descartes, Leibniz, Wilkins, etc.). As a result, some models of language as a formal system of symbols were developed which, in turn, inspired modern linguists to develop formal theories of language (Chomsky's works include abundant quotations from Descartes (Chomsky 1966, 2006), NSM theory by Wierzbicka and Goddard is, more or less, a replica of Leibniz's language of thought (Wierzbicka 1972, 1980, 1996), etc.). All these theories are based, as a matter of fact, on the framework of written language, even if their authors claim the opposite.

Although the view of language represented in the previous paragraph is likely to be a common place for linguists, this is anything but the truth. Importantly, unlike written language, spoken language is an element of multimodal communication, and it is absolutely senseless to explore spoken language beyond its links with other elements (gestures, facial expressions, prosody, pauses and discursive markers, etc.). Therefore, the only way to account for the framework and functions of spoken language in different communicative situations is to tackle the structure of discourse as a whole.

Such a change of perspective helps, in particular, to shed new light on the question of the origin of language. Thus, Tomasello (e.g., 2008) and colleagues take the social nature of humans as a basis for the research framework. For them, the demands of social nature cause a growth of both intensity and complexity of social communication which, in turn, leads to emergence of more complicated tools to perform that. These tools include gestures, prosody and, then, meaningful combinations of sounds as a part of multimodal communication.

This approach also changes standard views of the problem of language acquisition. Babies, toddlers and preschool-aged children acquire not exclusively language, but rather different types of discourse in which language is an extremely important but not the only element. Language acquisition goes for them in line with gesture acquisition, prosody acquisition, mimicry acquisition, etc.

This provides a theoretical framework of our research, whereas its experimental framework is based on "The Pear Film" research line. It is reasonable to outline
the milestones of "The Pear Film" story before proceeding to the structure and the results of the experiment.
"The Pear Film" is a six-minute movie made by Wallace Chafe and his colleagues in 1975. The film includes actions, pictures and sounds, but no words. In that, it deploys the same chain of events for all viewers. Therefore, a comparison of "the Pear Film" retellings, i.e. 'pear stories', by people of different cultures and languages can provide the researcher with important data of how language and culture influence a way people conceptualize a stream of events. Since 1975 a lot of investigations have been carried out to compare retelling strategies for people of different cultures (Du Bois 1980; Tannen 1980; Orero 2008; Matzur \& Mickievicz 2012; Blackwell 2015), for people with intellectual disability (Cummings 2015, 59-63); some investigations have explored peculiarities of referential choice in retellings (Downing 1980; Clancy 1980), work of consciousness in narration (Chafe 1980; Bernardo 1980), a structure of multimodal discourse (Fon et al. 2011; Kibrik et al. 2015).

As mentioned, a structure of multimodal discourse is also the main object of interest for the authors of this paper. In general, we follow the model developed by Kibrik and colleagues (2015), but we are interested in a process dynamics rather than a static picture.

Let us proceed directly to the research presented in this paper. The 'pear stories' of Moscow preschool-aged children in comparison with similar stories of high school students were in the focus of our interest in this research. In other words, we addressed a particular type of multimodal discourse in order to explore the process of discourse acquisition by focusing on a logical structure and a coherence of the narrative, gestures and spontaneous movements lost any communicative meaning, discourse words and pauses. Before dealing this issue at hand, some clarifications are needed.

Firstly, the discourse of the pear film retellings is not an informal situation for subjects, especially, for kids. Indeed, in natural contexts kids communicate and, in particular, retell stories in different way. At the same time, this situation is not completely unnatural for them. This is a type of a public talk they encounter in kindergartens, at schools and some other public places. They acquire this as they acquire many other types of multimodal communication. So, despite obvious restrictions, this kind of discourse can provide important data on the way of acquiring particular elements of multimodal communication by preschool and early school-age children.

In order to monitor quality of acquiring particular discourse skills, a sample for comparison is needed. Adults are expected to be such sample; however, the work with 14-16 year old students shows that they are as skillful in "The Pear Film" retellings as adults are. In that, because of some practical reasons a group of such students was taken as a control group for our research.

In our analysis we focused on three discourse elements which need more precise description.
A. A logical structure and a coherence of the narrative. There are a lot of works investigating the narrative development in preschool age children which use a wide range of criteria to check this process (Peterson
\& McCabe 1983; Stein \& Albro 1997; Sedov 2004; Nicoladis et al. 2009; Laurent et al. 2015; Levy \& McNeill 2015). A commonly used parameters to check narrative development are as follows: the length of story in words; the number of different words used to tell the story; a total of scenes in retellings; presence of basic semantic components of the story (beginning, setting and ending) (Nicoladis et al. 2009; Laurent et al. 2015). However, these characteristics seem to provide only a coarse-grained picture of the process failing to verify how subjects represent a logical structure of the narrative, i.e. causal links connecting the events within it. A more precise model to evaluate exactly this factor was elaborated in Sedov 2004. In order to check to what extent subjects represent a logical structure of stories they retell, the author examines such variables as the frequency of deictic words in the retellings, the frequency of anaphoric repetitions, the frequency of introductory model words, referential models the subjects apply, the appearance of retrospective and perspective views in the retellings, etc.

Taking into account these and similar works, in our research we focused on the following characteristics: the total number of words exploited in retelling, discounting selfrepetitions and false starts (TW); a total of scenes presented in retelling (TS); a total of errors in action description standardized on 100 words (FA) (e.g., 'guys picked up pears' instead of 'the boy hands pears to one of the guys'); a total of errors in object description standardized on 100 words (FO) (e.g., 'apples' instead of 'pears'); a total of incorrect description of causal chain of events and sub-events standardized on 100 words (FC) (e.g., ambiguous reference, missing connections within an event and between events); a total of interpretations (TI) (e.g., 'stole a basket of pears' instead of 'picked up a basket of pears'); a total of dependent words standardized on 100 words (TD) (such as 'who', 'which', 'because', etc.).
B. Gestures and spontaneous movements lost any communicative meaning. As mentioned, a number of works has been published over recent years to explore various aspects of correlation between gesture development and spoken language development in narratives of preschool age children (Nicoladis et al. 2009; Laurent et al. 2015; Levy \& McNeill 2015). Meanwhile, in our knowledge there are no works focusing on spontaneous movements lost any communicative meaning. Of great importance is the fact that kids, when retelling the story, perform a lot of unconscious movements which do not address their interlocutors. These movements are not gestures in the strict sense; the only function of such movements is to help kids in their reasoning and speaking. This is no metaphor to say that kids not only think with their brains and speak with their tongues, but they also think and speak with their bodies. Some evidence of this can be also found in students' and adults' retellings, but in this case such movements are presented in a restricted mode.

Again, in our knowledge this is a novel research domain which demands, first of all, a correct typology of spontaneous movements. A version of this is suggested below. Another important task is to measure the difference
in spontaneous movements of preschool age kids and that of high school students. This procedure is also presented below in the description of experimental method.
C. Discourse words and pauses. An important aspect of language acquisition is also, so to speak, smoothness of speech. Adults avoid pauses in communication and use different strategies to fill them (stretching out first and last sounds of the word, use of discourse words and single sounds, etc.). At the same time, kids are not embarrassed by gaps in communication. Their speech, at least, in this particular type of discourse, is, as it were, ragged. In the experiment we measured this difference. Also we compared a number of and a mean length of EDU (elementary discourse units) for the two groups of participants.

## Experiment

## Method

Subjects. 50 5-7 year old children ( $22 \mathrm{~m}, 28 \mathrm{f}$ ) attending Moscow kindergartens $(\mathrm{CH})$, and 24 ( $10 \mathrm{~m}, 14 \mathrm{f}$ ) 14-16 year old Moscow high school students (S). All subjects were monolingual.
Material. "The Pear Film" by Wallace Chafe ( 6 min 32 sec ).
Procedure. Each subject was processed individually. At the beginning the subjects were asked for watching the film closely in order to retell it as precisely as they can. Then they watched the film and after a minute retold it to some people who have not seen this film before. For kindergarten kids it was their kindergarten teacher, for students - their peers. At the same time, in order to check how the choice of addressee may influence the results, five students were asked to retell the story to the school principal in her office. When retelling, all subjects were sitting on high chairs for recording not only hand movements but also leg movements.

The retellings were filmed by a hidden camera for CH subjects and overtly for S subjects. Because of some technical problems only 37 from 50 CH video-retellings fitted for further examination (at the same time, all CH tape recordings were made properly).

Then the data were processed with ELAN to examine gestures and spontaneous movements. Also the retellings were recorded with unite-based discourse transcription system.

In order to work out TS we asked 10 independent participants to divide the film into episodes, and premised on their choice singled out eight basic scenes which formed the narrative framework.

## Results

A. The results for narrative skills are presented in Table 1 and Table 2.

Table 1. Mean TW, TS, TI, EC for CH and S

|  | TW | TS | TI | TD |
| :---: | :---: | :---: | :---: | :---: |
| $\mathbf{C H}$ | $88.2 \pm 45.9$ | $5.3 \pm 1.6$ | $1.5 \pm 1.0$ | $1.0 \pm 1.2$ |
| $\mathbf{S}$ | $298.6 \pm 138.2$ | $7.8 \pm 0.7$ | $4.7 \pm 1.9$ | $2.4 \pm 1.1$ |

Table 2. Mean FA, FO, FC for CH and S

|  | FA | FO | FC |
| :---: | :---: | :---: | :---: |
| $\mathbf{C H}$ | $1.9 \pm 2.1$ | $1.5 \pm 2.2$ | $2.0 \pm 2.2$ |
| $\mathbf{S}$ | $0.1 \pm 0.4$ | $0.1 \pm 0.3$ | $0 \pm 0.2$ |

All these results are statistically significant ( $\mathrm{p}<0.001$ ).

Concerning five students retelling the pear story to the school principal, there were no significant difference between them and other students in the scope of this experiment. Retellings in the principal office were likely to be less detailed and more formal, but in comparison with CH subjects these discrepancies were not important.

The quantitative data can be complemented by some qualitative analysis. Let us begin with TW. As this can be seen from Table 1, the mean length of the narrative is over three times more for the students than for the preschoolaged children. It means that the CH subjects lose a lot of content when describing any episode. Importantly, they only point at actions not focusing on appearance, clothes, scenery, etc. In turn, S subjects provided more or less detailed description of the picker, and also briefly characterized appearance of other characters.

FO values are consistent with this observation. In contrast with S subjects, CH subjects confused not only pears and apples, but also, and much more often, they confused age ('man' instead of 'boy') and gender ('boy' and even 'man' instead of 'girl') of the characters.

TS, FA and FC values points to notable difficulties in representing causal chain of the narrative. TS values show that two, in average, basic scenes get lost in 'pear stories' of preschool-aged children. This means that the story is often broken up into independent fragments which are linked with the conjunction 'then'. To be more precise, a majority of CH subjects missed the episode with a goat, which does not 'work' later on in the film (only 8 subjects from 50 remembered this), many of them missed also the girl on a bike approaching the boy, and sometimes the final scene was missed as well. Also, almost in all stories of CH subjects there were some ambiguities in reference because their use of pronouns sometimes did not allow determine a subject correctly.

Data for EC are consistent with that point. S subjects often used dependent words (mainly, 'who', 'which', but also 'when', 'where', 'what', 'why', etc.) in order to clarify reference. If there are some objects with the same nomination (e.g., 'boy'), exploiting of such constructions is useful tool for reference clarification. Meanwhile, CH participants can hardly use this tool.

Let us proceed to exploring some correlations within CH group. First of all, there is a positive correlation between the age of participants (AP) and TW, TI, TD and a negative correlation between the age of participants and FA, FO, FC. However, only the correlation between AP and TW; AP and FO are significant $(\mathrm{r}(\mathrm{AP}, \mathrm{TW})=0.35$, $\mathrm{r}(\mathrm{AP}, \mathrm{FO})=-0.27, \mathrm{p}<0.05 ; \mathrm{r}(\mathrm{AP}, \mathrm{TI})=0.14, \mathrm{r}(\mathrm{AP}, \mathrm{TD})=$ $0.23, \mathrm{r}(\mathrm{AP}, \mathrm{FA})=-0.25, \mathrm{r}(\mathrm{AP}, \mathrm{FC})=-0.13)$.

In the meantime, there is a significant positive correlation between TW and TI, TW and TD, and also a significant negative correlation between TW and FA, TW and FC, TW and FO (r(TW, FA) $=-0.44, r(T W, F C)=-$ $0.46, \mathrm{p}<0.01 ; \mathrm{r}(\mathrm{TW}, \mathrm{TI})=0,34, \mathrm{r}(\mathrm{TW}, \mathrm{TD})=0.33, \mathrm{r}(\mathrm{TW}$, $\mathrm{FO})=-0,29, \mathrm{p}<0.05)$. This gives some evidence for the point that all narrative skills represented by the variables of the subset A develop consistently.

In order to complete the spectrum of problems CH subjects encountered it is worth noting that ten of them $(20 \%)$ were not able to retell the pear film on their own, and the experimenters were made to help them with leading questions.
B. As mentioned, spontaneous movements were in focus of our interests. We singled out three general types of body movements according to body parts which provide them: hand movements (HM), leg movements (LM), torso movements (TM). Also for hands and legs we distinguished implicit movements (e.g., slight finger movements) and explicit movements (e.g., open movements of the whole hand). So, we used five combinations: IHM, EHM, ILM, ELM, TM. We measured the total time of each kind of movement in ratio to the time of the whole story presented in percent. The results are expressed in Table 3.

Table 3. Mean IHM, EHM, ILM, ELM, TM for CH and S

|  | IHM | EHM | ILM |
| :---: | :---: | :---: | :---: |
| $\mathbf{C H}$ | $31.9 \pm 22.2$ | $5.5 \pm 10.1$ | $7.0 \pm 11.6$ |
| $\mathbf{S}$ | $20.0 \pm 21.4$ | $0.2 \pm 0.8$ | $4.6 \pm 9.6$ |
|  | $\mathbf{E L M}$ | $\mathbf{T M}$ | $\mathbf{\Sigma}$ |
| $\mathbf{C H}$ | $6.9 \pm 16.9$ | $15.7 \pm 17.3$ | $65.8 \pm 18.2$ |
| $\mathbf{S}$ | 0 | $0.6 \pm 1.1$ | $24.5 \pm 21.1$ |

As can be seen from Table 3, there is a significant difference in performing spontaneous movements during the retelling between CH and S groups (the use of oneway ANOVA to compare $\boldsymbol{\Sigma}$ for these groups gives $\mathrm{p}<0.001$ ). CH subjects perform such movements during over a half-time period of the retelling, and over a quartertime period of the retelling the movements are explicit. The spectrum of their movements is really wide: kids put their hands under the legs, fidget in their seats, lift their legs up to their mouths, etc. All this almost totally disappear in retellings of $S$ subjects. The only spontaneous movements they perform are implicit hand movements
such as to finger over and, to some extent, implicit leg movements. Other types of movements are extremely rare.

Importantly, there is no significant correlation between $\Sigma$ (the sum of IHM, EHM, ILM, ELM, TM) and TW for CH subjects ( $\mathrm{r}=-0.14$ ). This can be interpreted as some evidence against the conjecture that narrative skills and body experience in discourse develop coherently.

The picture of gestures for CH and S groups is strictly opposite. Only 8 from $50(16 \%) \mathrm{CH}$ subjects exploited gestures as a more or less important tool in communication. At the same time, almost all $S$ subjects resorted to the permanent use of gestures during their retellings. The total time of gesture performance in ratio to the time of the whole story presented in percent is $2.4 \pm 5.2$ for $C H$ subjects and $68.5 \pm 23.7$ for $S$ subjects ( $p<0.001$ ).

Addressing again $S$ subjects who retold the pear story to the school principal, it is worthwhile to note that they performed less gestures and more spontaneous movements than their peers but this difference cannot change the picture drawn above.
C. The last group of parameters we worked out is concerned with discourse words, pauses and an EDU length. We measured the total number of discourse words in ratio to TW (DW, \%), the total length of pauses in ratio to the time of the whole story (LP, \%) ${ }^{1}$, and a mean EDU length (EDUL, words). The data are presented in Table 4.

Table 4. Mean DW, LP, EDUL for CH and S

|  | DW | LP | EDUL |
| :---: | :---: | :---: | :---: |
| $\mathbf{C H}$ | $3.0 \pm 2.0$ | $38.2 \pm 11.2$ | $3.2 \pm 0.5$ |
| $\mathbf{S}$ | $4.1 \pm 3.1$ | $25.3 \pm 10.4$ | $4.2 \pm 0.6$ |

These data give clear evidence that CH subjects in comparison with $S$ ones are less skillful in filling pauses in communication ( $\mathrm{p}<0.001$ ). Also it is worthwhile to point at more extensive EDU for S subjects ( $\mathrm{p}<0.001$ ). The difference between DW for CH subjects and S subjects is not significant.

Importantly, there is significant positive correlation between TW and DW for CH subjects ( r (TW, DW) = $0,32, \mathrm{p}<0.05$ ). Meanwhile, the correlation between TW and LP and between TW and EDUL is not significant ( r $($ TW, LP $)=-0,23 ; r($ TW, EDUL $)=-0,02)$.

## Discussion

The results of the experiment support the basic hypothesis of significant obstacles which preschool-aged children encounter when acquiring the discourse of retelling story in formal situation. In the experiment three basic components of this discourse were examined: a logical structure and a coherence of the narrative; gestures and spontaneous movements lost any communicative meaning; and EDU, discourse words and pauses. In all these components CH subjects experienced more or less serious difficulties in comparison with a control group presented by high school students. Furthermore, the

[^344]experiment provided some evidence that these components are acquired coherently, that is, the progress in one component correlates with positive shifts in others.

It is worth classifying the problems CH subjects face and cognitive skills behind these problems. Two basic domains can be picked out in "The Pear Film" retelling discourse. The first one is concerned with the 'content' of the discourse (to make sense of the story and to present this correctly in speech), the second one - with 'right' mode of communicative behavior. Cognitive skills behind the first domain can be also divided into two parts. The first part is based on situated cognition. A lack of practical knowledge entails increasing FO value which characterizes flaws in recognizing particular objects (as mentioned, kids confused pears with apples, goat with caw, girl with boy, boy with man, etc.) The second set of problems points at an inability to figure out a causal chain of events and to represent this chain in the retelling. In consistency with Sedov's (2004) results our data show that a majority of CH subjects in their retellings get plunged into the stream of events, and they are unable to change the perspective and to look at the story from the bird's eye view. This also determines their view of an addressee. They usually take for granted that an addressee is also familiar with all details of the story and he can easily reconstruct those following restrained comments of a storyteller. TS, TI, FA, and FC values characterize this issue.

CH subjects have also obvious problems with the use of language. "The Pear Film" retelling as a kind of discourse is close to writing, and writing skills are widely used by S subjects in their retellings. More or less consciously, they rest on texts studied at school as a paradigm for 'pear stories' they make up. CH subjects have no such experience. An influence of literacy on their retellings is trifling, if it is at all. As a result, their language is extremely poor, with minimum of extended and subordinate constructions. TC value is responsible for this set of factors.

The 'communicative' domain of the discourse is characterized by values of variables which constitute subsets B and C. In particular, LHM, EHM, LLM, ELM, and TM values point at a flaw in discourse competence connected with some lack of body control in communication.

Although three sets of factors presented above address different cognitive domains and function more or less independently, there is some coherence in their development (e.g., significant positive correlation between TW and DW give some evidence for such coherence).

Also LHM, EHM, LLM, ELM, TM data need more detailed commentary. This sounds nowadays as a common point that body movements in discourse have nothing but communicative function. Nevertheless, this is not so for kids. Again, the behavior of CH subjects gives robust evidence that they not only think with their brains and speak with their tongues, but they also think and speak with their bodies. The spontaneous movements which they perform intensively during the retelling are not directed to their interlocutors, but these movements do rather produce, as it were, 'nutrient medium' for the process of speaking. Their speech is a vivid and striking illustration
of theoretical postulates of embodiment theory (Barsalou 1999; Krois 2007; Barsalou 2010).

Finally, we venture to make a conjecture in this scope. The comparison of communicative models of CH and S subjects indicates a substantial shift from spontaneous movements to gestures. This shift is likely to be consistent with Vygotsky's (1986) theory of inner speech. According to Vygotsky, cognitive development in ontogeny is concerned with the transition from egocentric speech to inner speech which cognitive function is to mediate between speech and thought. From this perspective, inner speech is interpreted as interiorization of egocentric speech. Similarly, implicit spontaneous movements can be treated as interiorization of explicit spontaneous movements. Such interiorization comes to the end in thought which includes words and movements in a 'converted' mode similarly to how synthesis includes thesis and antithesis in Hegel's philosophy. On the opposite stage, thought deploys into a communicative utterance directed to an addressee and formed by words, gestures, prosody and other elements of multimodal communication. In this scope, gestures not just accompany words in communication, but rather they are equally meaningful element of communicative behavior.

Another possible domain to apply the results of our research is the theory of origin of language developed by Tomasello and colleagues. As mentioned, they point at gestures as at an important predecessor of vocal communication, but they do not take into account spontaneous movements. A precise analysis of spontaneous movements of children and great apes might shed new light on this issue.

#### Abstract

Zoonoses (diseases that enter the human population via animal contact) are a major global health concern. Because of how zoonoses emerge, understanding human reasoning about the risk factors associated with animal contact is central to combating their spread. However, little is known about the factors that influence perception of these risks. We present an inductive account of zoonosis risk perception, suggesting that it is influenced by beliefs about the range of animals that are able to transmit diseases to each other. In Study 1, we find that participants who endorse higher likelihoods of cross-species disease transmission have stronger intention to report animal bites. In Study 2, adapting real world descriptions of Ebola virus from the WHO and CDC, we find that communications conveying a broader range of animals as susceptible to a disease increase intentions to report animal bites and decrease perceived safety of wild game meat. These findings suggest that cognitive factors may be harnessed to modulate zoonosis risk perception and combat emerging infectious diseases.

Keywords: Induction; categorization; risk perception; public health; premise number; premise diversity

## Introduction

Emerging infectious diseases are a major economic and public health concern. A majority of such diseases are of zoonotic origin (i.e. come from animals, Jones et al., 2008), with drivers including animal bites, consumption of wild game meat, and contact with livestock (Daszak, Cunningham, \& Hyatt, 2000). Human-animal interaction is central to all these drivers, but little is known about how people reason about potential risks in such scenarios (Janes, Corbett, Jones, \& Trostle, 2012). Similarly, research on cognitive factors is largely absent from public health initiatives targeting zoonoses, including interdisciplinary approaches such as One Health (Heymann \& Dar, 2014). The present work aims to bridge this gap by examining cognitive principles that influence zoonosis risk perception and how they can be harnessed to shape communications regarding disease transmission risk.

The literature on zoonoses lacks extensive research on the role of human reasoning, though several recent studies have examined factors that determine whether people will eat wild game meat (Kamins et al., 2015) and report adverse animal contact, such as bites, to a health professional. One particularly suggestive study (Bingham, Budke, \& Slater, 2010) found that survey respondents were more likely to report dog bites if they knew that bats could transmit rabies to humans. At first glance, this seems surprising - people's inferences about the risk associated with one species appear to be influenced by their knowledge of a completely different species.

The finding that knowlege about one animal can affect beliefs about other animals may be partly accounted for by two principles from the literature on inductive reasoning, namely premise number and premise diversity (Hayes, Heit, \& Swendsen, 2010; Osherson, Smith, Wilkie, Lopez, \& Shafir, 1990). According to the premise number principle, people are more confident in inferences that apply to a large number of category members (Li, Cao, Li, Li, \& Deak, 2009; McDonald, Samuels, \& Rispoli, 1996), where for example a property known to hold for both lions and giraffes will be more likely to hold for rabbits as well. According to the premise diversity principle, people find inferences sound to the extent that they hold for a wider range of category members (Heit \& Feeney, 2005; Lopez, 1995), where for example a property known to hold for lions and giraffes is more likely to generalize to rabbits, compared to one that holds for lions and tigers. In terms of zoonosis risk perception, knowing that both dogs and bats can transmit rabies may increase perceptions of human risk because they are often viewed as very different members of the mammal category.

Although premise number and diversity are plausibly related to the previous observations surrounding bite reporting
intentions, research on inductive reasoning has not been extended to many concrete domains such as work on risk perception in health or real-world decision making about health behaviors. Similarly, while people's judgments regarding contagion have been studied in social and health psychology research (Nemeroff, 1995), these studies have focused on affective and cultural factors as opposed to underlying cognitive processes such as inductive reasoning.

In the present work, we test two specific hypotheses from our theory that inductive reasoning principles influence zoonosis risk perception. First, consistent with the aforementioned rabies study, individual differences in perceived risk from animal contact should be associated with individual differences in beliefs about interspecies disease transmission. Second, perceptions of risk to humans should increase as a result of being presented with communcations depicting transmissibility amongst a wider range of species.

## Study 1

The goal of Study 1 was to examine whether perceived disease risk (measured by intentions to report animal bites) is associated with beliefs about interspecies disease transmission likelihood. Based on the premise number principle, we hypothesized that individuals who endorse stronger likelihoods of disease transmission between a number of different animal species would be more likely to perceive human risks from animal bites. To test this hypothesis, we conducted a survey measuring intentions to report bites from common mammals and birds along with judgments of interspecies disease transmission likelihood for a ficticious novel disease.

Method. Participants were 289 adults ( $55 \%$ men; mean age $=33.6, S D=10.2$ ) who completed an online survey and were recruited through the Mechanical Turk crowdsourcing platform. The survey was available to Mechanical Turk workers in the following countries where English is the primary language: USA, Australia, Canada, Great Britain, Ireland, New Zealand, and the Bahamas. The majority of participants had undergraduate (48.8\%) or advanced degrees (8.7\%). The sample was predominantly White (80.6\%), with $5.9 \%$ Asian, $3.8 \%$ Black, $6.9 \%$ Hispanic, $1 \%$ Native American or Alaska Native, and $1.7 \%$ other ethnicities. A majority of the sample ( $73.4 \%$ ) reported currently owning a pet. Participants were compensated $\$ 2$ for participation in the survey. Informed consent was obtained from all individual participants in the study, no participants were excluded from the survey results, and all protocols were approved by the Texas Tech University IRB.

Design. The study materials consisted of an electronic survey containing sections on demographics, bite reporting intentions, and species-to-species disease transmission beliefs. Demographics questions included sex, sexual orientation, ethnicity, education level, parents' education level, language(s) spoken, and pet ownership.

In the bite reporting section, participants were asked to judge their likelihod of reporting bites from various target animals to a health professional (of any type). Participants judged likelihood of reporting for each animal using a slider that could be adjusted in units of 1 from $0-100$ and also contained descriptive labels ranging from "Very Unlikely" to "Very Likely". Mammal and bird reporting were presented in a random order on separate screens. Mammals included dogs, skunks, monkeys, bats, and squirrels. Birds included grackles, swans, robins, blue jays, and peacocks.

The species-to-species disease transmission beliefs section employed the same sliding scales as the bite reporting section, but participants were asked to rate the likelihood of betweenanimal disease transmission for a hypothetical new disease. Each question took the following form:

Scientists discover that a new disease can infect the liver tissue of [premise animal]. How likely is it that this disease can infect the following animals?

The conclusion animals were listed on separate lines, each with their own response slider. Premise animals included bats, dogs, skunks, monkeys, grackles, blue jays, swans, and peacocks. Conclusion animals included bats, dogs, skunks, monkeys, squirrels, grackles, robins, blue jays, swans, and peacocks. Fewer premise animals were used so that less time would be required to complete the survey and to reduce participant attrition. Animals only appeared as conclusion categories when they were not the premise. Premises were presented in a random order on separate screens.

Results. Intentions to report bites were highly reliable within person (mammals: Cronbach's $\alpha=0.86$; birds $\alpha=$ 0.95 ), as were judgments of interspecies disease transmission likelihood (mammal-to-mammal: $\alpha=0.96$, bird-to-bird: $\alpha$ $=0.97$; between birds and mammals: $\alpha=0.99$ ). Nonetheless, linear mixed effects models revealed that intentions to report bites varied considerably between different species [Mammals: $F(4,1152)=111.1, p<.001, \eta_{p}{ }^{2}=0.28$; Birds: $\left.F(4,1152)=35.23, p<.001, \eta_{p}^{2}=.11\right]$ and ratings of interspecies disease transmission likelihood varied between the different premise types [mammal-to-mammal, bird-tobird, between birds and mammals; $F(2,576)=356.3, p<$ $\left..001, \eta_{p}{ }^{2}=0.55\right]$. Intentions to report bites were stronger for mammals than for birds $[t(288)=27.06, p<.001, d=$ 1.59; Figure 1A], and diseases were rated as more likely to be transmissible within mammals or birds than between them [mammal-to-mammal vs. between birds and mammals, $t(288)=18.77, p<.001, d=1.10$; bird-to-bird vs. between birds and mammals, $t(288)=23.42, p<.001, d=1.38]$. Consistent with previous work suggesting bats are viewed as similar to both mammals and birds (Davis et al., 2013), bats were rated as more likely than other mammalsto share diseases with birds $[t(288)=7.03, p<.001, d=0.41]$.

Figure 1: (A) Intentions to report animal bites. (B) Association between intentions to report mammal bites and mammal-to-mammal disease transmission ratings. (C) Association between intentions to report bird bites and between bird and mammal disease transmission ratings. Error bars reflect 95\% within-subject confidence intervals.

In support of our primary hypotheses, we found that individual differences in endorsement of bird-to-bird and mammal-to-mammal disease transmission were both positively associated with individual differences in intentions to report mammal bites [Mammal-to-mammal: Kendall's $\tau=$ $.147, p<.001$ (Figure 1B); Bird-to-bird, $\tau=.140, p<.001$; Between birds and mammals: $\tau=.009$ (Pearson's r of .21 , .21 and .009 respectively)].

Consistent with the premise number principle, endorsing greater odds of interspecies disease transmission was associated with stronger intentions to report mammal bites. For bird bites, only ratings of disease transmission between birds and mammals were associated with reporting intentions [Mammal-to-mammal $\tau=.043$, Bird-to-bird $\tau=.077$, Between birds and mammals $\tau=.219, p<.001$ (Pearson's $r$ of
$.04, .05$, and .26 respectively) (Figure 1C)]. Coupled with weaker intentions to report bird bites overall, these results suggest that people may only judge birds as risky to the extent that they believe birds and mammals can share diseases.

Discussion. Study 1's results suggest that inductive reasoning principles may underlie people's perceptions of zoonosis risk. Although the correlations are between a small and medium correlation given Cohen's (1992) criteria, they are within those expected between general health attitudes and behaviors (Azien \& Timko, 1986; Glasman \& Albarracin, 2006). However, because the results are correlational, it is difficult to infer the causal direction between the beliefs about interspecies disease transmission risk and bite reporting. It is possible that both are influenced by a common underlying factor, such as beliefs about contagion (Haidt, McCaluey, \& Rozin, 1994) or risk attitudes (Dohmen et al., 2011). Moreover, because the results examine individual differences, it is not clear from Study 1 whether such inductive reasoning principles could be harnessed to influence people's beliefs about the risks associated with animal contact.

## Study 2

The goal of Study 2 was to test whether it is possible to influence people's perceptions of zoonosis risk through framing communications to portray a greater number of animals as susceptible to a disease. As a case study, real-world communications about Ebola virus vary in terms of how they describe the range of animals susceptible to the disease. The Centers for Disease Control's factsheet (CDC, 2016) lists contact with fruit bats and nonhuman primates (apes and monkeys) as sources of human Ebola infection. Contrastingly, the World Health Organization's factsheet (WHO, 2016) lists a much wider range of animals: chimpanzees, gorillas, fruit bats, monkeys, forest antelope, and porcupines.

According to the premise diversity principle, the WHO's factsheet should lead to stronger perceptions of Ebola risk from animal conact because it lists a broader range of animals as sources of human Ebola infection. To test this hypothesis, in Study 2 we gave particpants two different communications about Ebola derived from the CDC and WHO factsheets (tailored to control all other differences in wording).

Method. Participants were 152 adults recruited from Mechanical Turk in the same manner as for Study 1. Sample demographics were comparable to those in Study 1; additionally $94.7 \%$ of the sample in Study 2 reported eating meat. No participants were excluded from the results, and all protocols were approved by the Texas Tech University IRB.

Design. The study materials consisted of an electronic survey containing a demographics section, an experimentally manipulated reading prompt about Ebola (derived from CDC and WHO factsheets), an Ebola susceptibility section, a bite reporting intentions section, and a meat safety section.

For the reading prompt, participants were given the following description about Ebola and asked to fill in a blank box by detailing the animals listed in the description:

> The Ebola virus causes an acute, serious illness which is often fatal if untreated. Ebola virus disease (EVD) first appeared in 1976 in 2 simultaneous outbreaks, one in what is now Nzara, South Sudan, and the other in Yambuku, Democratic Republic of Congo. The latter occurred in a village near the Ebola River, from which the disease takes its name. Ebola is introduced into the human population through close contact with the blood, secretions, organs, or other bodily fluids of infected animals such as [animal 1], [animal 2], [animal 3], and [animal 4].

The animals listed in the description were experimentally manipulated between participants. Participants were randomly assigned to read either a CDC-inspired set of animals with lower premise diversity (fruit bats, gorillas, monkeys, and chimpanzees; $\mathrm{n}=81$ ) or a WHO-inspired set with higher premise diversity (fruit bats, monkeys, forest antelope, and porcupines; $\mathrm{n}=70$ ). To verify that these prompts did indeed differ in premise diversity, we had a separate group of participants ( $\mathrm{N}=53$ ) provide pairwise similarity judgments between each of the premise animals. Consistent with our expectations, participants judged the CDC prompt animals to be significantly more similar (i.e. less diverse, $\mathrm{t}(52)=14.56, \mathrm{p}$; .001).

Next participants completed the Ebola susceptibility questionnaire. For each question, participants were asked "How likely is it that [animal] can get Ebola?" ( $1=$ Very Unlikely, 7 = Very Likely). Animals included both mammals and birds: bats, monkeys, zebras, meerkats, anteaters, giraffes, gazelles, storks, flamingos, cranes, vultures, and parrots.

Next participants completed the bite reporting questionnaire. Participants were told to "imagine that you are on safari and get bitten by an animal, but the bite just barely breaks the skin" when considering whether they would report a bite to a health professional. Each question asked them to rate ( $1=$ Very Unlikely, 7 = Very Likely), "how likely would you be to report being bitten by a [animal]?"

Last, participants completed the meat safety questionnaire. Participants were asked to rate ( $1=$ Very Unsafe, $7=$ Very Safe), "how safe you think it is for people in general to eat meat from each animal" and to "consider only immediate health risks from disease transmission."

Results. The results were consistent with predictions based on the premise diversity principle. Participants in the WHO (diverse) wording condition rated individual mammals as more susceptible to Ebola $[t(150)=3.70, p<.001, d=$ 0.6 ; Figure 2A], were more likely to report mammal bites $[t(150)=2.85, p=.005, d=.46$; Figure 2B], and perceived mammal meat as less safe $[t(150)=2.66, p=.009, d=.434$; Fiture 2C].

The WHO (diverse) wording condition also increased perception of birds' susceptibility to Ebola $[t(150)=2.06, p=$ $.040, d=0.33$ ] but did not significantly increase intentions to report bird bites $[t(150)=1.10, d=0.18]$ or lower perceptions of meat safety $[t(150)=1.28, d=0.21]$.

We additionally used linear regression to test whether the effect of wording condition on bite reporting and perceptions of meat safety was mediated by its effect on Ebola susceptibility ratings. First, we found that Ebola susceptibility was significantly associated with bite reporting and meat safety perceptions for both mammals and birds, even after taking into account the effect of wording condition [Mammal bites: standardized $b=0.47 ; t(149)=6.40 ; p<.001$; Mammal meat: standardized $b=-0.43 ; t(149)=5.67, p<.001$; Bird bites: standardized $b=0.51 ; t(149)=7.32, p<.001$; Bird meat: standardized $b=-0.45 ; t(149)=6.01, p<.001]$. Next, we found that including Ebola susceptibility in the regression model with the effect of wording condition made the effect of condition non-significant for all models [Mammal bites: $b=0.18, t(149)=1.20$; Mammal meat: $b=$ $-.18, t(149)=-1.16$; Bird bites: $b=.009 ; t(149)=0.063$; Bird meat: $b=-0.06 ; t(149)=0.43]$, suggesting that the effects of condition on meat safety and bite reporting were fully mediated by the effect of the different wordings on participants' perceptions of Ebola susceptibility. Finally, using a bootstrapping procedure (Preacher \& Hayes, 2008), we found that the indirect pathways between wording condition and the bite reporting and meat safety ratings were significant for both birds and mammals.

## General Discussion

Results from both studies indicate an important role that cognitive research can play in combating emerging zoonoses. Although rarely studied in the public health literature, humans' inferences about risk are central to their interactions with potential disease vectors. We found that cognitive principles related to premise number and diversity impact perceptions of zoonotic disease transmission risk and associated health behaviors. To the extent that people believe it is possible for many diverse species to transmit diseases to one another, they become more wary of their own risk of infection.

An experiment based on CDC and WHO Ebola factsheets further revealed that individuals' inductive reasoning strategies can be harnessed to make communications about disease risk more effective. Through the use of cognitive framing strategies, it may be possible to reduce adverse contact with animals and increase rapid reporting of potential disease exposure. Such approaches may be particularly effective for rural communities that are difficult to reach with other interventions. These results have the potential to contribute goals of identifying low-cost strategies for reducing emerging disease risk before outbreaks occur (Heymann \& Dar, 2014).

To our knowledge, the present results are the first to suggest that inductive reasoning processes studied in cognitive psychology also influence health behaviors. With such connections established, future studies on disease transmission risk perception would benefit from even stronger connections with cognitive research. One question is how people judge risks from different species. Here we focused on person-level characteristics that relate to perceived risk of animal contact

Figure 2: Effect of communication wording on (A) Perceived susceptibility of animals to Ebola, (B) Intentions to report animal bites, and (C) Perceived meat safety. Error bars reflect $95 \%$ within-subject confidence intervals.
(bites and game meat), averaging over differences between species. However, not all animals are associated with the same zoonosis risk, and it will be important to understand how to tailor communications to impact species selectively. For example, bats have a very strong association to emerging zoonosis (Calisher, Childs, Field, Holmes, \& Schountz, 2006), and it may be useful to tailor messages to focus on bats specifically. Although bats were associated with high levels of intended bite reporting and were perceived as being unsafe to eat, participants also may have underestimated the risks bats pose to other animals - indeed, participants rated disease transmission risk between bats and other mammals as lower than for more typical mammals. Because wildlifelivestock interactions are a major driver of emerging zoonosis (Jones et al., 2008), this finding suggests that people may underestimate the risk of keeping livestock near bat habitats.

One limiation of our second study is that much of the sample is not at high risk for Ebola virus. However, because zoonoses are common within the countries surveyed and can be transmitted via many different interactions with animals all of our participants were at some risk of zoonosis exposure. Still, future research should examine whether risk level or other variables may moderate the effect of inductive reasoning principles on risk perception. We anticipate that people's personal experience with zoonosis, as opposed to pure risk level per se, may strengthen the relationship between beliefs and health intentions. Indeed, in the broader attitudes and public health literatures, many associations between attitudes and behaviors are rather weak in the general population, but are much stronger in groups with direct experience (Fazio \& Zanna, 1978; Glasman \& Albarracin, 2006). Thus while
many people in these studies do not have direct experience with Ebola virus, we would expect attitudes and health intentions to be even stronger in those who do.

The present research is primarily aimed at building interdisciplinary connections between public health research (particularly inerdisciplinary efforts such as One Health) and cognitive psychology. Still, the current results may have implications for basic psychological research on contagion and induction as well. The law of contagion is a prominent social psychology construct that describes people's tendencies to believe that negative (and positive) properties, including diseases and social ills, can be transmitted to objects or people through mere contact (e.g. Rozin and Royzman (2001)). Current theories of sympathetic magical thinking often make distinctions between the law of contagion and the law of similarity, a separate construct that describes the belief that objects that share surface features also share deeper common essences (e.g., leading to disgust with fudge shaped like dog feces, and beliefs that voodoo dolls can affect the person they resemble; Rozin, Markwith, and Ross (1990)).

The present results suggest that the laws of contagion and similarity may not be fully separate, and similarity-based effects may influence perceptions of contagion. Indeed, theories suggest that inductive reasoning principles like premise number and diversity can increase generalization of properties (such as disease susceptibility) via similarity relationships between known and novel/unknown examples. For example, the diverse prompts in our second experiment may have increased perceptions of Ebola susceptibility by increasing the likelihood that the unknown examples would match the known examples in some respect. A major question in
cognitive psychology is how different respects in which items can be similar (Medin, Goldstone, \& Gentner, 1993) impact generalization of novel/unknown properties. Although our data does not distinguish between different candidate theories for similarity-based transfer of contagion, the results are suggestive that beliefs about contagion can be transferred via such similarity relationships.

In conclusion, emerging diseases from animals pose a substantial public health concern, yet little is known about how people judge risks associated with different drivers of zoonosis. The present studies illustrate that basic cognitive principles related to inductive reasoning not only impact individuals' perceptions of disease risk and associated health behaviors, but also can be harnessed for tailoring messages to properly convey risks associated with emerging diseases.

# High-Performing Readers Underestimate Their Text Comprehension: Artifact or Psychological Reality? 

Stefanie Golke (stefanie.golke@ezw.uni-freiburg.de)<br>Department of Educational Science, University of Freiburg<br>Rempartstr. 11, 79098 Freiburg, Germany

Jörg Wittwer (joerg.wittwer@ezw.uni-freiburg.de)<br>Department of Educational Science, University of Freiburg<br>Rempartstr. 11, 79098 Freiburg, Germany

#### Abstract

We focused on the controversy whether high-performing readers consistently underestimate their comprehension or are prone to detrimental overestimations as much as less skilled readers are. Therefore, we conducted an experiment ( $N=105$ university students) to investigate judgment bias as a function of reading skill and text difficulty in terms of text cohesion. Results showed that the easy text produced underestimation of comprehension, whereas the hard text led to overestimation. Furthermore, readers with higher reading skills were less prone to overestimate their comprehension of a hard text than less skilled readers. However, we also found that more skilled readers showed lower sensitivity in discriminating between correct and incorrect answers than less skilled readers. Overall, our results do not support the idea that high-performing readers consistently underestimate their text comprehension. Findings are discussed with respect to readers' awareness of different text-based judgment cues and their (beliefs about their) reading skill.

Keywords: judgment bias; metacognitive sensitivity; text difficulty; reading skill; high-performing readers

## Introduction

Successful learning from text requires readers to accurately judge their text comprehension because false judgments (e.g., overestimation) can hamper the learning process. It is well acknowledged that readers in general are prone to overestimations, whereas particularly high-performing readers (i.e., readers who achieve high scores on a text comprehension test) might more likely underestimate their comprehension (de Bruin et al., 2016; Dunlosky \& Rawson, 2012). However, the methodology used to unveil underestimation by high-performing readers is not fully undisputed. Therefore, it remains unclear whether highperforming readers' underestimation is psychological reality or rather an artifact. We present an experiment that was conducted to advance our understanding about how highperforming readers judge their text comprehension.

## Comprehension Judgments and the Learning Process

Learning from text involves constructing a mental representation of the information provided in a text and retrieving the learned information at a later time. The learning process heavily depends on a reader's metacognitive ability
to monitor comprehension (i.e., metacomprehension), which is mirrored in the correspondence between a reader's comprehension judgment and actual performance on a comprehension test (Wiley, Griffin, \& Thiede, 2005).

Comprehension judgments can occur at different times in the learning process. Accordingly, research uses different types of comprehension judgments (Griffin, Jee, \& Wiley, 2009). The first type is the prospective judgment of comprehension that readers make after reading a text to predict how well they will perform on yet unknown test questions about the text. Furthermore, when readers complete test questions, they can use information about their (perceived) performance in answering the test questions to evaluate their comprehension. Thus, the second type of comprehension judgments is readers' confidence in their retrieved answers on single test questions (i.e., response confidence). The third type is the retrospective judgment of comprehension that refers to a whole set of test questions (i.e., how many of the test questions were answered correctly). The three types of judgment are assumed to reflect (slightly) different aspects of metacomprehension but complement each other (Schraw et al., 2014).

When readers make comprehension judgments, they normally use available cues (Koriat, 1997). These cues can arise from the learning material (e.g., text difficulty), a reader's (self-perceived) skills and resources (e.g., prior knowledge, reading ability) and a reader's experiences when reading the text or answering test questions. All types of cues can be useful for precise judgments when they are valid indicators of the required level of comprehension.

To support learning, judgments of comprehension need to be precise because they influence readers' subsequent learning activities. Imprecise judgments, especially overestimations, have a detrimental effect on learning (Dunlosky \& Rawson, 2012). For example, overestimation means that readers do not realize that their comprehension of text is worse than they think. Therefore, they might abstain from engaging in remedial activities. In contrast, underestimation might be less problematic for learning but it can hamper learners in allocating their learning time appropriately.

## Controversy Over High-Performing Readers' Underestimation

Numerous studies have shown that readers typically provide imprecise judgments. Most readers overestimate their comprehension of text and are overconfident in the correctness of their retrieved information when answering test questions about the text (Dunlosky \& Rawson, 2012; Maki et al., 2005).

However, concerning high-performing readers, it is sometimes reported that they tend to underestimate their comprehension (de Bruin et al., 2016; Zabrucky, 2010). This underestimation is often interpreted as a result of specific metacognitive or cognitive processes. For example, high performers are assumed to not give very high judgments of their comprehension to avoid being perceived as arrogant or to have negatively skewed misperceptions of their abilities, both resulting in underestimation (Zabrucky, 2010).

A completely different explanation of this phenomenon refers to a statistical bias of the measure used to unveil overestimation and underestimation (i.e., judgment bias) that becomes relevant when readers' level of performance is determined by their performance in the experimental comprehension test. More specifically, judgment bias uses the signed difference between a reader's prospective or retrospective judgment of comprehension and his/her actual performance on a comprehension test. Therefore, the reader's judgment bias is constrained by his/her performance (Griffin et al., 2009; see also Kruger \& Dunning, 1999). That is, readers who achieve the maximum or a very high performance score on a comprehension test (i.e., highperforming readers) are much more likely to show underestimation than readers with lower performance scores. Conversely, readers who have a very low performance score are much more likely to overestimate their comprehension. Furthermore, if the performance-level of readers is determined by their performance on the comprehension test - that is also part of the measure of judgment bias - both measures are statistically dependent on each other and normally show high negative correlations (i.e., higher performance on the comprehension test is associated with lower/more negative scores of judgment bias). Thus, the finding that high-performing readers underestimate their comprehension could also be a statistical artifact and, hence, might not reflect their actual ability to judge comprehension. To disentangle the effect of the level of comprehension on judgment bias, it seems useful to investigate judgment bias as a function of both readers' general reading skill and test/text difficulty.

## The Effect of Text Difficulty and Reading Skill

Maki et al. (2005) investigated judgment bias (i.e., overestimation or underestimation) as a function of text difficulty - determined by the readability of the texts - and students' general reading skill. Their findings did not support the view that high performers generally underestimate their
comprehension. Instead, for difficult texts (i.e., lower readability), it was found that high-ability readers were precise when making prospective judgments. Only when making postdictions, they underestimated their comprehension but so did medium-ability readers as well. Conversely, for easier texts (i.e., higher readability but still in the range between difficult and standard texts), all readers provided overoptimistic predictions of comprehension but precise postdictions.

This latter finding on easier texts is intriguing with regard to Schraw and Roedel's (1994) study that determined difficulty by the mean item difficulty of the test questions. They found that readers were overconfident on their answers in response to difficult and moderately difficult items but precise on items with low difficulty. Because high-ability readers in Maki and colleagues' study (2005) solved about $70 \%$ of the test items on the easier text, these test items were of low difficulty for them. Hence, their postdiction judgments were precise. But why did the (high-ability) readers overestimate their comprehension when making prospective judgments on the easier text? It appears as if the higher readability of the text might have induced readers - at any level of reading ability - to be overoptimistic. This interpretation is supported by findings from Weaver and Bryant (1995) who revealed that predictions of comprehension are not highly correlated to actual performance for texts with high or low readability.

Thus, previous studies showed that high-performing readers do not consistently underestimate their comprehension. Therefore, these studies provide useful hints about the controversy on high-performing readers. However, at the same time, the studies only provide information about the effects of item difficulty (Schraw \& Roedel, 1994) or text difficulty in terms of readability (Maki et al., 2005; Weaver \& Bryant, 1995). Readability that depends on, for example, word length, number of words per sentence, or passive/active structure is a salient text-based cue and a more distal indicator of the difficulty of the text content than, for example, text cohesion. With regard to theories on text comprehension (see e.g., Wiley et al., 2005), varying text difficulty in terms of readability might not discriminate well enough between readers with different levels of reading proficiency. Hence, it would be interesting to focus on cohesion as a different indicator of text difficulty and investigate judgment bias as a function of this text feature and reading skill.

## The Present Study

We examined the precision of comprehension judgments as a function of text difficulty and reading skill. In contrast to previous studies, we determined text difficulty in terms of text cohesion. To assess judgment bias, we used the signed difference between a reader's prospective or retrospective judgment of comprehension and his/her actual performance on a comprehension test. Moreover, we assessed readers'
metacognitive sensitivity and response bias as additional indicators of metacomprehension.

As main effects of text difficulty on performance, we expected that the easy text resulted in higher performance on the test questions than the hard text. Regarding the effect of text difficulty on judgment bias, we based our hypotheses on findings about item difficulty instead of texts' readability. Therefore, given the statistical dependence of performance level and judgment bias, we hypothesized that the easy text would lead to significant underestimation whereas the hard text should result in significant overestimation. Hence, using a within contrast, the easy text should result in a lower bias score of prospective and retrospective judgments than the hard text. Furthermore, we investigated in an exploratory way how reading skill was linked to readers' judgment bias for the easy text compared with the hard text. To do so, we computed multiple linear regressions that included reading skill and prior knowledge as relevant predictors of prospective judgment bias for the easy text and the hard text. In case of the retrospective judgment bias, we also used readers' metacognitive sensitivity and response bias that are based on readers' response confidence for the test questions as additional predictors. With regard to the relationship of reading skill with metacognitive sensitivity and response bias, we inspected their correlations with each other.

## Method

## Design

The experiment followed a two-factorial design with reading skill as a metric between-subjects factor and text difficulty as the within-subjects factor with two levels: one text with lower text difficulty (easy text) and one text with higher text difficulty (hard text) in terms of cohesive relations within the text (see also Materials). The order of the texts was counterbalanced across all participants.

As dependent variables, we assessed: 1) text comprehension (i.e., number of correctly answered questions about the text), 2) the bias of prospective and retrospective judgments, 3) metacognitive sensitivity, and 4) response bias. Furthermore, we assessed participants' prior knowledge about the topics of the text materials.

## Participants

Participants were 105 university students from educational science. They had a mean age of $22.78(S D=4.95)$ years and $82 \%$ of them were female.

## Materials

Table 1 displays the main characteristics of both texts. Given the scope of this study, we selected texts that represented different levels of text difficulty in terms of cohesion. Cohesion refers to the extent to which relations between ideas in a text are made explicit by using, for example, textual features such as causal, temporal, or additive connectives. We
determined cohesion by the proportion of sentences that contained a cohesive device on how the sentence is connected to previous ones. As displayed in Table 1, the cohesion score for the hard text was considerably lower than the score for the easy text. Thus, the hard text required readers to engage more deeply in comprehending the text compared with the easy text. Apart from cohesion, the texts were equivalent with respect to other characteristics including surface cues, such as readability or text length, as well as the domain of the texts (i.e., biology, see Table 1).

We used six open-ended comprehension questions for each text. The questions tapped information explicitly stated in the text.

Table 1: Characteristics of the texts.

| Characteristic | Easy text | Hard text |
| :--- | :---: | :---: |
| Topic | Reproduction | Immunology |
| No. of words | 380 | 397 |
| No. of sentences | 25 | 30 |
| Flesch-Index | 46 | 41 |
| Cohesion | 0.67 | 0.38 |

Note. ${ }^{\text {a }}$ Texts with a Flesch-Index (i.e., flesch reading ease score) between 30 and 50 reflect difficult texts in terms of readability that are typically used in higher education.

## Instruments and Measures

Prospective and Retrospective Judgments Participants indicated how many of the six text comprehension questions they think they would answer correctly (= prospective judgment) or had answered correctly (= retrospective judgment; value between 0 and 6).
Judgment Bias We used the signed difference between a reader's prospective or retrospective judgment of comprehension and the actual performance on the text comprehension test. Hence, the bias score could range between -6 (i.e., maximum underestimation) and +6 (i.e., maximum overestimation).
Response Confidence For each question, participants indicated how confident they were that their answer was correct (Likert scale from $1=$ very uncertain to 7 = very certain).
Metacognitive Sensitivity ( $\boldsymbol{d}^{\prime}$ ) Sensitivity reflects the ability of readers to distinguish between correct and incorrect responses on test questions. It uses readers' performance on single test questions and their response confidence on these test questions. We determined metacognitive sensitivity via $d^{\prime}$ that is based on signal detection theory (see Fleming \& Lau, 2014; Schraw et al., 2014) using the hit rate (i.e., number of questions that a reader answered correctly and rated as correct, divided by the total number of correctly answered questions) and the false alarm rate (i.e., number of questions that a reader did not answer correctly but rated as correct, divided by the total number of incorrect answers). The measure of $d^{\prime}$ is the difference between the standardized hit
rate and the standardized false alarm rate. A value of zero means that the reader could not discriminate between correct and incorrect responses, a positive value (i.e., higher hit rate than false alarm rate) reflects good sensitivity, and a negative value (i.e., higher false alarm rate than hit rate) suggests that the reader considered rather a false answer as correct than a correct answer.
Response Bias (c) The response bias $c$ is based on the sensitivity measure $d^{\prime}[c=-0.5$ * (standardized hit rate + standardized false alarm rate)]. The response bias represents the tendency of a reader to accept false alarms $(c<0)$ or to be cautious when giving confidence judgments on single test questions in order to avoid false alarms ( $c>0$ ).
Reading Skill We used a subtest of a computer-based German reading comprehension test for adults (ELVES; Richter \& van Holt, 2005). The subtest assessed higher-order processes of text comprehension.
Prior Knowledge There was a total of 12 open-ended questions that assessed readers' prior knowledge on immunology and reproduction. These questions were not identical to the text comprehension questions.

## Procedure

At the beginning, participants answered the prior knowledge test and proceeded with the reading comprehension test ELVES. After that, participants read the first experimental text and then judged their comprehension by predicting how many of the six text comprehension questions they think they would answer correctly. After the judgment, they answered the comprehension questions and rated their response confidence for each question. After answering all comprehension questions, participants made a retrospective comprehension judgment by indicating how many of the six questions they thought they had answered correctly. Subsequently, participants proceeded with the second experimental text in the same manner as they did for the first one.

## Results

To test the hypotheses regarding the main effect of text difficulty on performance and judgment bias, we performed (paired) $t$-tests (for descriptive statistics, see Table 2). In line with our hypotheses, we found that the easy text resulted in higher performance on the text comprehension questions, $t(104)=13.73, p<.001$, Cohens $d=1.49$ (large effect), than the hard text. Moreover, the mean scores of prospective and retrospective judgment bias for both texts (see Table 2) were significantly different from zero (i.e., the value of perfect judgment), all $p$ 's $<.004$. Thus, the easy text resulted in significant underestimation for both prospective and retrospective judgments. In contrast, the hard text resulted in significant overestimation for both types of judgment. A paired $t$-test confirmed that the easy text resulted in lower bias scores of prospective judgments, $t(104)=-12.96, p<.001$, Cohens $d=-1.42$ (large effect), and lower bias scores of
retrospective judgments, $t(104)=-6.13, p<.001$, Cohens $d=$ -0.68 (medium effect), than the hard text.

Furthermore, we performed multiple linear regressions to examine our research question regarding the relationship of reading skill with judgment bias for the easy and the hard text. For each type of judgment bias (i.e., prospective vs. retrospective bias), we computed separate multiple regressions for the easy and the hard text. Predictors were entered in one step.

Table 2: Means (and standard deviations) for dependent variables as a function of text difficulty.

| Dependent variable | Easy text | Hard text |
| :--- | :---: | :---: |
| Text comprehension | $4.90(1.31)$ | $2.99(1.25)$ |
| Prospective judgment <br> bias | $-0.79(1.42)$ | $1.21(1.40)$ |
| Retrospective judgment <br> bias | $-0.35(1.18)$ | $0.49(1.29)$ |

Regarding prospective judgment bias, we included prior knowledge on the topic of the text and reading skill as predictors. The results (see Table 3) showed that neither prior knowledge nor reading skill were statistically relevant predictors of prospective judgment bias for the easy text. However, for the hard text, reading skill was a statistically significant negative predictor of prospective judgment bias. That is, participants with higher reading skills were less likely to overestimate their comprehension of the hard text. However, as descriptive statistics revealed (see Table 2), we cannot conclude that these participants generally showed underestimation because only $12 \%$ of the total sample underestimated their comprehension of the hard text when making prospective judgments.

Table 3: Predictors of prospective judgment bias for easy and hard text.

| Predictor | $b$ | $S E b$ | $t(101)$ | $p$ |
| :--- | ---: | :---: | :---: | :---: |
| Easy text |  |  |  |  |
| Constant | -0.39 | 0.53 | -0.74 | .462 |
| Reading skill | -0.02 | 0.03 | -0.65 | .516 |
| Prior <br> knowledge | 0.00 | 0.01 | -0.32 | .749 |
| Hard text |  |  |  |  |
| Constant | 2.43 | 0.49 | 4.96 | $<.001$ |
| Reading skill <br> Prior <br> knowledge <br> -0.08 | 0.03 | -2.83 | .006 |  |

Note. For easy text: $R^{2}=.01, F(2,102)=0.32, p=.730$. For hard text: $R^{2}=.08, F(2,102)=4.16, p=.018$.

Moreover, regarding retrospective judgment bias, we included prior knowledge, reading skill as well as
metacognitive sensitivity and response bias as predictors. The multiple regression analyses revealed (see Table 4) that metacognitive sensitivity and response bias significantly predicted the retrospective judgment bias for the easy text. That is, the better a reader discriminated between correct and incorrect responses and the more the readers avoided false alarms in the confidence rating, the less likely this reader was to overestimate comprehension when making retrospective judgments on questions about an easy text. This result was also found for the hard text. Additionally, reading skill also predicted retrospective judgment bias for the hard text.

Table 4: Predictors of retrospective judgment bias for easy and hard text.

| Predictor | $b$ | $S E b$ | $t(99)$ | $p$ |
| :--- | ---: | ---: | ---: | :---: |
| Easy text |  |  |  |  |
| Constant | -0.02 | 0.41 | -0.05 | .958 |
| Reading skill | -0.03 | 0.02 | -1.30 | .222 |
| Prior knowledge | 0.00 | 0.01 | 0.31 | .761 |
| Sensitivity | -0.24 | 0.08 | -2.96 | .004 |
| Response bias | -0.59 | 0.14 | -4.13 | $<.001$ |
| Hard text |  |  |  |  |
| Constant | 1.51 | 0.46 | 3.30 | .001 |
| Reading skill | -0.06 | 0.02 | -2.34 | .022 |
| Prior knowledge | 0.00 | 0.01 | -0.48 | .632 |
| Sensitivity | -0.16 | 0.09 | -1.78 | .078 |
| Response bias | -0.78 | 0.16 | -5.04 | $<.001$ |

Note. For easy text: $R^{2}=.22, F(4,104)=6.83, p<.001$. For hard text: $R^{2}=.23, F(4,99)=7.30, p<.001$.

Furthermore, we explored the relationship of reading skill with metacognitive sensitivity and response bias, respectively. As displayed in Table 5, we found that participants with higher reading skills were less cautious (measure of response bias, $c$ ) when giving confidence ratings on the comprehension questions about the easy text. In addition, they were less able to discriminate between correct and incorrect answers (measure of metacognitive sensitivity, $d^{\prime}$ ) in response to questions about the hard text. Given the magnitude of the correlation coefficients, these relations are small effects. However, it appears that more-skilled readers were metacognitively less aware and, therefore, more overconfident when answering the test questions.

Table 5: Pearson's $r$ correlations between reading skill, sensitivity ( $d^{\prime}$ ), and response bias (c) for easy and hard text.

|  | Easy text |  | Hard text |  |
| :---: | :---: | :---: | :---: | :---: |
| Measure | $d^{\prime}$ | $c$ | $d^{\prime}$ | $c$ |
| Reading skill | .10 | $-.22^{*}$ | $-.27^{* *}$ | -.16 |

Note. ${ }^{*} p<.05 .{ }^{* *} p<.01$.

To sum up, we found that reading skill was a relevant predictor of prospective and retrospective judgment bias in case of the hard text, but not in the case of the easy text. Hence, participants with higher reading skills were less likely to overestimate their comprehension of the hard text. Moreover, we found that response bias and sensitivity influenced retrospective judgment bias for the easy and the hard text. Thus, the better participants discriminated between correct and incorrect answers or the more cautious they were when rating their answers as correct, the less likely they made overoptimistic retrospective judgments. In addition, we found that sensitivity and response bias were more negative for readers with higher reading skills, although these effects were rather small.

## Discussion

This study aimed to shed further light on the question whether high-performing readers adhere to judgment processes that lead them to consistently underestimate their comprehension across materials with different levels of difficulty. The results of our study do not support this assumption. Instead, our results suggest that readers with higher reading skills are better calibrated because they are less prone to overestimate their comprehension of a hard text compared with readers with lower reading skills. Kwon and Linderholm (2014) also found this relationship for texts with standard readability.

The finding that participants with higher reading skills were better calibrated supports the notion that higher reading skills include better monitoring during reading. Readers who actively monitor their text comprehension obtain a more comprehensive mental model of the text and are therefore more precise at judging their comprehension (Wiley et al., 2005). Furthermore, although a relationship between reading skill and judgment bias is evident, the magnitude of the relationship we found in our study is rather small. This indicates that other characteristics of the reader are also or even more relevant for judgment bias, for example, the selfperceived reading skill (Kwon \& Linderholm, 2014).

In contrast to the hard text, there was no relationship between reading skill and judgment bias on the easy text. This finding can be explained by the low difficulty of the test questions. Therefore, general reading skill was not predictive of test performance on the easy text and, thus, reading skill was not related to judgment bias on the easy text.

Another important finding in our study were the negative relations of reading skill with metacognitive sensitivity and response bias. This finding suggests that readers with higher reading skills may be metacognitively unaware when responding to the type of test questions we used in the present study. Therefore, despite their good calibration with respect to the hard text, participants with higher reading skills showed a flawed discrimination performance. To explain this lower discrimination, it can be speculated that their beliefs about their reading skill tempted high-ability readers to
proceed less mindfully with the test questions and, thus, to be overconfident on their answers.

This interpretation does not necessarily contradict the findings on the positive influence of reading skill and the negative impact of sensitivity and response bias on retrospective judgment bias because the strength of these relations was rather small. Moreover, it can be assumed that other factors influence judgment bias as well. Therefore, the seemingly contradicting relations between reading skill, discrimination performance, and retrospective judgment bias might simply indicate complex interactions between readers' characteristics and judgment processes that still need to be further uncovered (Schraw et al., 2014).

The findings of this study also contribute to the understanding of the effects of text-based cues on judgment bias. In our study, the easy text (i.e., higher cohesion) resulted in underestimation. Given that performance on test questions about the easy text was rather high, this underestimation was very likely to occur due to probabilistic assumptions (Schraw \& Roedel, 1994). Likewise, the observed overestimation on the test questions about the hard texts was also expected. In contrast, the easy text (i.e., higher readability) in Maki and colleagues' (2005) study resulted in overestimation of prospective judgments for all readers. Only when readability of texts was low, readers, except for weak readers, adjusted their comprehension judgments. Thus, we can conclude that texts that are easy to read - and, therefore, often preferred in instructional contexts because they increase performance are more likely to seduce readers to be overoptimistic. Conversely, high text cohesion does not seem to have such an effect on metacognitive judgment. Therefore, readers, including high-ability readers, are apparently unaware of the low validity of good text readability as a cue to judge their comprehension. With respect to readers' sensitivity for text cohesion, we aim to analyze our data in more depth addressing possible anchor effects based on the withinsubjects design and also examine the role of reading skill in this regard.

## Acknowledgments

This study is based on data collected by Nadine Bianchi, Nina Krämer, and Andreas Leiprecht as part of their unpublished Bachelor theses.

#### Abstract

Attention plays a fundamental role in higher-level cognition. In this paper we develop a computational model for how auditory spatial attention is distributed in space. Our model builds on the assumption that attentional bias has bottom-up and top-down components. We represent each component and their synthesis as a map, associating a level of attentional bias to locations in space. The maps and their interaction are modeled using an artificial intelligence approach based on constraints. We describe the behavioral task we have designed to measure the attentional bias and discuss the results. We then test different hypotheses on the shape and interaction modalities of the maps in terms of how well they fit our behavioral data. The findings showed that combining top-down and bottom-up spatial attention gradients that differ in their spatial properties produced the best fit to behavioral data, and suggested several novel mechanisms for future testing.

Keywords: auditory attention; computational modeling; saliency map; constraints.

## Cognitive engineering problems and attention

Humans evolved in a dynamic environment of shifting opportunities and threats. Consequently, we are wellequipped to organize and frequently change goals and priorities to effectively deal with events in the natural and social worlds. High-level cognitive attributes, such as intelligence, creativity, and imagination presumably evolved to capitalize on these dynamics to promote survival (Flinn, Geary, \& Ward, 2005). A key aspect of higher-level cognition is attention. An important role for attention-like selection in information processing may not be limited to human cognition. For example, Helgason and colleagues proposed that attention is an essential element for systems to exhibit generalized intelligence, regardless of whether it is a biological or artificial intelligence system (Helgason, Thorisson, Garrett, \& Nivel, 2014).

In this article we broadly consider attention as a flexible means of enhancing specific aspects of information processing, as determined by factors such as the current goal (top-down) or stimulus characteristics important to the organism (such as unexpected loud sounds)(Chun, Golomb, \& Turk-Browne, 2011). This flexibility is assumed to be implemented by specific cognitive processing routines that were selected during the course of human evolution (Cosmides \& Tooby, 2013). Differences between sensory modalities in terms of how the adequate stimulus and receptor transduction relate to the kinds of information that can be detected in the environment is one factor relevant to the design of attentional processes. Consequently, in at least some respects attentional processing may sharply differ between sensory modalities.

We focus on the auditory system, and consider implications of the idea that the auditory system has a comparative advantage over other modalities in the ability to panoramically monitor the environment. Hearing provides an early warning system (Scharf, 1998) that allows organisms to prepare for, or evade, threats and to capitalize on prey or mating opportunities. This "3-D sphere" of spatial sensitivity for hearing is unique among sensory modalities because it can detect environmental events that are at a distance from the body (cf. somatosensation, gustation, to some degree olfaction) and out of sight (vision).

## Stability-flexibility dilemma and attentional systems

Most attention models consider attention that is directed by a conscious choice ("top-down" or "voluntary") to differ in important ways from attention that is involuntarily "captured" by an event in the world that has a salient property (Petersen \& Posner, 2012). Salience can be due to physical properties, such as a loud sound, or by having personal meaning such as one's name (Moray, 1959) or taboo words (Arnell, Killman, \& Fijavz, 2007),
and other aspects that may depend on the situation (Gygi \& Shafiro, 2011). The distinction between top-down and bottom-up attentional functions is both useful and
meaningful, even though top-down and bottom-up attentional processes are highly interactive (Folk, Remington, \& Johnston, 1992).

One of the defining features of the top-down aspect of attention is that it is limited. Either by design, such as matching the limitations in the number of actions that can be done at one time, or by overload from having too much information to be processed at one time, or both, voluntary attention is limited (Allport, 1989; Posner, 1978). Spatial attention has been intensively studied, in part, because it vividly illustrates limitations in attentional capacity. The limited capacity of spatial attention can be expressed as a spatial gradient relative to an attended location (reviewed in (Cave, 2013). The classic way to consider this gradient is that it reflects decreased investment of attentional resources with greater distance from an attentional focus, and the extent of the gradient can be adjusted based on the current task (Eriksen \& St. James, 1986).

The fundamental problem with including top-down and bottom-up attention in one general attention system that distributes attentional resources across space is that attention cannot be simultaneously both focused and diffuse. This kind of trade-off has been termed the "stability-flexibility dilemma (Liljenström, 2003), the "shielding-shifting dilemma" (Thomas Goschke \& Bolte, 2014), and a trade-off between organization and flexibility (Baars, 1997). The problem is compounded by not knowing when something will happen outside of the attentional focus that is critical for survival, thus preventing an anticipatory shift by top-down attention. Both top-down and bottom-up attention have clear survival value, but limited attention capacity implies tradeoffs between resources devoted to top-down vs. bottom-up attention functions. Similar issues concerning cognitive trade-offs have been explored in the context of cognitive control and task switching (Goschke, 2000), automatic vs. controlled processing (Schneider \& Chein, 2003), various dual process models of cognition (Evans, 2008), long-term knowledge (Caramazza \& Shelton, 1998), and memory systems (Sherry \& Schacter, 1987).

## Methods and computational modeling

The present study addresses the stability-flexibility dilemma posed by needing attention to be both focused on a task while also monitoring the environment for potential threats or opportunities by modeling auditory spatial attention bias as the net result of two attention modules and their output (Figure 1). Our aim is to develop a rigorous quantitative theory of auditory spatial attention. One module, called the "goal map" is devoted to top-down attention necessary to perform the current task. The other module, termed the "saliency map", is specialized to monitor, in parallel, the environment and, when needed, engage bottom-up orienting that overrides current attentional focus based on top-down processes. We combine novel parametric behavioral measures to map-out auditory attention over space with a computational model to explain how specific top-down and
bottom-up mechanisms jointly determine the shape of auditory spatial attention gradients.

Top-down goals

Figure 1. Proposed attentional model architecture.
Relative to existing models of auditory attention, the current model is designed to help understand somewhat higher levels of cognitive processing. Others have modeled perceptual features and how they are combined to generate a saliency map. There is overlap with our model at the level of saliency map. Prior work computes perceptual features such as stimulus location, frequency, intensity, and saliency as an output that is computed from a raw sensory input (Coensel \& Botteldooren, 2010; Kayser, Petkov, Lippert, \& Logothetis, 2005). Instead, we start with perceptual features as a given input and model how top-down and bottom-up modules interact in the context of working memory. Note also that the choice of modeling auditory spatial attention in the frontal plane has the benefit of needing to explain attentional bias in only one-dimension (the azimuth plane at a constant distance from center of head), which simplifies modeling. In contrast, visual studies of saliency maps use two-dimensional models (Kalinli \& Narayanan, 2007).

Model design The model is designed using constraints, a very general and powerful artificial intelligence framework for problem modeling and solving. (Rossi, Van Beek, \& Walsh, 2006). Constraints lie at the core of many successful applications in several domains such as scheduling, planning, vehicle routing, configuration, networks, and bioinformatics. The basic idea in constraint-based modeling is that the user states the constraints and a general-purpose constraint solver is used to solve them. Constraint solvers take a real-world problem, represented in terms of decision variables and constraints, and find, if it exists, an assignment to all the variables that satisfies all the constraints. A constraint concerns a subset of variables and defines which simultaneous assignments to those variables are allowed. Solutions are found by searching the solution space either systematically, as with backtracking or branch and bound algorithms, or use forms of local search which may be incomplete, that is, there is no guarantee they will return a solution. Systematic methods often interleave search and inference, where inference consists of propagating the information contained in one constraint to other constraints via shared variables. Constraints have been used before in the context of human cognition for example to model skilled behavior (Howes, Vera, Lewis, \& McCurdy, 2004). Recently an implementation of the cognitive architecture ACT-R
based on constraint handling rules, which are a closely related to constraints, has been proposed in (Gall \& Frühwirth, 2014). To the best of our knowledge, this is the first time constraints are employed at this level of cognitive modeling and in the context of attention.

The model makes several assumptions regarding proactive and reactive control. According to Braver's dual mechanisms framework (Braver, 2012), proactive control generates a sustained attentional bias in accordance with task goals, such as focusing on a pianist about to begin their recital. Reactive control, as the name suggests, is attentional orienting in response to a stimulus, such as if the pianist plays their first chord and everybody realizes that the piano is out of tune. In our model the goal map is the mechanism for proactive control. The spatial focus of the goal map can also be redirected in response to stimuli, and so could have a role in reactive control too. In contrast, the saliency map codes for reactive control. The relation between the saliency map and proactive control is only indirect. The focus of the saliency map is designed to be away from the goal map focus, thus any proactive shifts in the goal map focus will consequently lead to a similar shift in the saliency map focus.

Task and data to be modeled Young adult subjects ( $\mathrm{n}=42$ ) listened to 25 and 75 Hz amplitude modulated white noise, and responded with left/right hand (counterbalanced across subjects). Virtual stimuli were delivered via headphones to one of 5 locations in the frontal horizontal plane ( $\mathrm{L} \rightarrow \mathrm{R}$ locations: $-90^{\circ},-45^{\circ}, 0^{\circ},+45^{\circ},+90^{\circ} ; 2.4 \mathrm{sec}$ SOA). In each 6 min block subjects attended to a standard location (either $90^{\circ}, 0^{\circ}$, or $+90^{\circ}$ ). Most stimuli were given at the standard location ( $\mathrm{p}=.84$ ), with occasional shifts to the other 4 locations ( $\mathrm{p}=.04 / \mathrm{location}$ ). Analysis of variance (ANOVA) was used to examine reaction time as a function of standard condition (3) and stimulus location (5). Data were collapsed across AM rates (ns). We note that the following model is designed from general principles based on the attention and working memory literature, but the actual modeling here is very specific to our task. This is common in other areas such models of canonical visual search tasks. Future work will expand this model to include other tasks and situations.

The model Behavioral results were modeled using a constraint-based representation made up of three components: goal map, saliency map, and priority map. The maps represent the attentional bias across the horizontal frontal plane $\left(-90^{\circ}\right.$ to $+90^{\circ}$ ) (see heat-map in Figure 2, topleft). The priority map is the weighted sum of the goal and saliency maps and represents the total attentional bias at each degree location. Operationally, attention bias in the priority map relates to reaction time by equation 1 :

Eq. 1 Attentional bias $=(2,000$-reaction time $) /(2,000)$
The " 2,000 " value was chosen as an upper limit on reaction times to be analyzed (both in ms), and included nearly every correct trial in every subject. The units of attention bias are
arbitrary, but index reaction time with a range of between approximately 0.90 , which corresponds to a an extremely fast reaction time of 200 ms , to 0.0 , which indicates a $2,000 \mathrm{~ms}$ reaction time. Thus, larger attention bias values in the priority map reflect short reaction times and efficient processing, and longer reaction times have smaller values.

Figure 2: Variables and constraints that represent the interactions between the three maps in the model.

Each map is represented by a collection of variables, one for each 2-degree (the minimum distinguishable by a human ear) location in the range $\left\{-90^{\circ}, \ldots,+90^{\circ}\right\}$, and a set of constraints over the variables. Figure 2 (left) shows a portion of the constraint graph of the model where nodes correspond to variables and edges to constraints. These constraints limit the simultaneous assignments of the constrained variables as indicated in the equations below, where $V_{G}{ }^{i}, V_{S}{ }^{i}$, and $V_{P}{ }^{i}$ represent the $i$-th variables of the goal, saliency and priority maps. The constraints defining each map involve the variable corresponding to the attended location $(A)$ and the variables corresponding to a location. The variables associated with the goal map (blue nodes in Figure 2) are constrained to represent a standard Gaussian distribution with its peak at level $G_{G}$ and located at the attended location A. An example of one such distribution is shown in Figure 2 right above the set nodes representing the goal map variables. Each node represents the 2 degree portion of the x -axis right above it and the associated attentional bias value (y-axis) is the value assigned to the variable corresponding to the node. Similarly, for the saliency (where the distribution is shown below the nodes) and the priority map. Note that parameter $d_{G}$ is the standard deviation of the Gaussian and is used to model a symmetrical decrease in top-down attentional resources away from the goal location. Likewise, the variables corresponding to the saliency map have values compatible with an inverted Gaussian distribution with peak level $-G_{S}$ at attended location A and standard deviation $d_{S}$ representing a symmetrical increase in bottom-up attention away from the attended location. Finally, each priority map's variable takes as value the weighted sum of the values of the corresponding goal map and saliency map variables. The
graph at the bottom-right of Figure 2, shows an example of a goal map bias (green), saliency map bias (blue) and the associated priority map (purple). Weights $\alpha$ and $\beta$, are used to model the magnitude of contribution of, respectively, the goal and saliency maps to the priority map.

$$
\begin{gathered}
\text { Goal Map: }\left(A=a, V_{G}^{i}=G_{G} e^{\frac{-|a-i|^{2}}{2 d_{G}^{2}}}\right) \\
\text { Saliency Map: }\left(A=a, V_{S}^{i}=G_{S}-G_{S} e^{\frac{-|a-i|^{2}}{2 d_{G}^{2}}}\right) \\
\text { Priority Map: }\left(V_{G}^{i}=u, V_{S}^{i}=v, V_{P}^{i}=\alpha u+\beta v\right)
\end{gathered}
$$

We note that the constraint based model allows an easy extension to a 2D or 3D bias distribution. This can be achieved in two ways: either by increasing the number of variables (e.g. for the planar case a set for each concentric hemisphere), or by increasing the complexity of the domain values, e.g. 2D bias distributions over 2 degree sectors.

## Results

We first describe and discuss the results of the behavioral experiment in the previous section, and then the results of applying our computational model to the behavioral data. The goal map and saliency map each had two parameters for fitting: attention bias and standard deviation.

## Behavioral results

Reaction time curves for angular shifts had an inverted-u shape at all 3 standard locations ( $p$ 's $<.01$ )(Figure 3). Attending to the right ( $+90^{\circ}$ standard) had an attenuated inverted-u curve vs. $-90^{\circ}$ and $0^{\circ}$ standards ( $\mathrm{p}<.01$ ). Results show comparable reaction time increases to the nearest shift location for the $0^{\circ}$ and $-90^{\circ}$ standards, and then decreases in reaction time at the most distant locations. For the $+90^{\circ}$ standard there was a more gradual increase and decrease in reaction time across shift locations. Accuracy was high for all stimulus locations and conditions (> 94\%) and will not be analyzed here.

Figure 3. Behavioral results showing mean reaction times for standard locations at the far left $\left(-90^{\circ}\right)$, midline $\left(0^{\circ}\right)$, and far right $\left(+90^{\circ}\right)$ locations. A) Reaction time as a function of location for the three standard locations. B) Normalized reaction times plotted relative to the standard location, here denoted by " 0 ".

## Computational modeling results

Stochastic local search was used to find parameter values for $d_{S}, d_{G}, G_{S}$ and $G_{G}$, that minimize the root-mean-square (rms) error between the priority map and behavioral data. Bootstrapping methods were used to compare model fit as the parameters for the goal and saliency maps varied. There were 100 runs for each standard location to assess the consistency of results. On each run half of the subjects ( $\mathrm{n}=21$ ) were randomly selected to train the model. The model was then tested for fit using root-mean square error on the grand average of the remaining subjects ( $n=21$ ).

Comparison of two vs. three-component models Having attention bias centered on the standard location and decreasing with distance was modeled with only the goal map having input to the priority map. This two-component model had a poor fit to the reaction time data, with rms values nearly 100x worse than models with both goal and saliency map inputs to the priority map (Figure 4). Models with both topdown (goal map) and bottom-up (saliency map) spatial attention bias fit the data well, with rms values ranging from 0.0040 to 0.0035 for left or right standard locations $\left( \pm 90^{\circ}\right)$ and 0.0011 and 0.0012 for the $0^{\circ}$ standard. The fits at each standard location were all significantly different from each other ( p 's $<.001$ ). By contrast, rms values with only the goal map in the model were 0.3137 ( (-90 ${ }^{\circ}$ standard), $0.3060\left(+90^{\circ}\right.$ standard), and 0.1191 ( $0^{\circ}$ standard). We note that a model based only on the saliency map was not tested as it would have not been able to model the increased bias at the attended location. The results clearly show that a simple attention gradient that decreases with distance from the attended standard location (goal map only) is unable to account for the behavioral data. Models with both goal and saliency maps provided a good fit to the behavioral results. It is unclear why

Figure 4. Model fit with only the goal map (GM) representing top-down attention bias vs. the addition of a bottom-up component (saliency map, SM). Models examined whether goal and saliency maps had either equal influence on the priority map ("GM \& SM) or their levels were included as a parameter in the model ("free levels"). Model fit was measured using root-mean-square error (rms).
the fit for the $0^{\circ}$ standard is even better than the $\pm 90^{\circ}$ standards, but this may relate to the truncated range of locations on either side $\left( \pm 90^{\circ}\right)$.

Standard deviation parameters The range of spatial attention bias for the goal and saliency maps was quantified with separate standard deviation parameters (Figure 5). When only the goal map was included in the model the best fits had standard deviations of $\sim 100^{\circ}$, which produced a gradual decrease of attentional bias from the standard location. As shown above, only including the goal map produced a poor fit to the behavioral data. In all models with goal and saliency maps the standard deviations had, large, progressive reductions from standard locations on the left, to midline, and to the right ( $\mathrm{p}<.001$ ). This pattern was evident for both the goal and saliency map SD parameters. Analysis of both fixed and free bias models showed main effects of map type, with significantly larger SD values in the saliency map (p's $<.001$ ). There were interactions between standard location and map type, indicating that the difference between the SD of goal and saliency maps varied among standard locations ( p 's $<.001$ ).

Figure 5. Standard deviation (SD) parameters in the models with goal map (GM) and saliency map (SM) components. Standard deviation units are in degrees.

Attention bias level Lastly, we tested a model where the attention bias levels from the goal and saliency maps to the priority map were free to vary. The findings from when bias parameters were added to the model are shown in Figure 6 for each standard location. For the $\pm 90^{\circ}$ standards the goal map had a significantly greater bias than the saliency map, indicating a greater influence over the priority map outcomes. This was most evident for the $-90^{\circ}$ standard, which had little variability among modeling runs ( $\mathrm{p}<.001$ ). In contrast, for the $0^{\circ}$ standard there was substantial variability over modeling runs, and there was no significant difference between goal and saliency map bias.

Note that the range of attentional bias levels in the goal and saliency maps is much larger than the priority map (data not shown). This is the result of the model solutions having SD

Figure 6. Attention bias level results in the free level models. Bias indicates the overall level of inputs from the goal and saliency maps to the priority map. Greater bias indicates more influence over the priority map values.
parameter values that were both narrow enough to individually have bias levels near asymptote within the degree range tested. The model sums the contributions of goal and saliency maps to generate the priority map, which in turn is proportional to reaction time. The goal and saliency curves over space overlapped such that when one map had low bias the other had a large amount of bias. This additive approach in combination with moderate SD ranges forces many locations to have large differences between goal and saliency map values while retaining a much smaller range of priority map values. For perspective, the range of biases of between . 76-. 70 corresponds to reaction times between 480600 ms .

## Discussion and conclusions

In this paper we have studied spatial attention of the auditory system from a behavioral and computational modeling point of view. The main findings were that a traditional top-down attention gradient could not account for the behavioral data, but a model with two gradients corresponding to top-down and bottom-up bias worked well. The model is based on structuring the overall allocation of attentional bias as the sum of bottom-up and a top-down components. We have presented behavioral results aimed at describing the effect of the overall attentional bias and we have provided an experimental evaluation of different model hypothesis in terms of how well they fit the data. There was a pronounced left-right asymmetry in the reaction time profiles as a function of location that was accounted for by progressive reductions in the SD parameters of goal and saliency maps. The results support our approach which constitutes, to the best our knowledge, the first computational model that integrates top-down and bottom-up auditory spatial attention processes.

# Recruitment of the motor system in the perception of handwritten and typed characters 

Chelsea L. Gordon (cgordon7@ucmerced.edu)<br>University of California at Merced, Department of Cognitive Science, 5200 North Lake Road, Merced, CA, 95343<br>Ramesh Balasubramaniam (ramesh@ucmerced.edu)<br>University of California at Merced, Department of Cognitive Science, 5200 North Lake Road, Merced, CA, 95343

#### Abstract

Many different functional roles have been ascribed to the motor system due to its prevalent recruitment in perceptual and cognitive tasks other than motor production. We discuss findings that suggest the motor system might take on multiple roles that vary with context and the brain networks involved. Using single-pulse TMS, we measured the corticospinal excitability of the FDI muscle in primary motor cortex as participants viewed words that were either typed or handwritten. We observed consistent facilitation of corticospinal excitability during reading of handwritten text. Although we observed facilitation in corticospinal excitability during the presentation of typed text, this effect decreased with repetitive presentations of stimuli. We suggest that the facilitation during presentation of typed words is a case of action simulation, and that the diminishing facilitation in the case of typed stimuli is representative of sensory prediction by the motor system. These findings suggest that we should consider multiple roles for motor recruitment during the observation of visual stimuli, taking context into consideration.

Keywords: Action observation, motor involvement in reading, sensorimotor prediction.

## Introduction

The motor system is involved in a large number of cognitive and perceptual domains, including action observation, perception of object affordances, speech perception, language and metaphor, and social cognition. There are many theories aimed at explaining this widespread use of the motor system. We will introduce some of these theories here and work supporting each of them. Then we provide an alternative hypothesis: that there is no one particular role for the motor system in perception and cognition, but that it plays many roles decided, in part, by situational context.

Outside of its role in moving the body, the most common and widely posited role of the motor system is in observation-execution mapping. A network which includes several motor regions of the brain is responsible for mapping observed actions onto one's own motor system, which is said to underlie action understanding. The neurological underpinnings of this system rely on particular neurons in motor cortex, called mirror neurons, that fire during both observation and performance of a motor act in macaque monkeys and in humans. (Rizzolatti et al. 1988, di Pellegrino
et al., 1992; Gallese et al., 1996; Mukamel et al., 2010). Umiltà et al. (2001) found that some subset of mirror neurons fire during the final part of an observed action, even if that final part of the action is occluded from view, suggesting that mirror neurons code the goal-related execution of an action. This also suggests that mirror neurons respond to action-related situations where determining the actor and situation involves more inference, suggesting a role in deeper understanding of action. Kohler and colleagues (2002), recording from single neurons in monkey premotor cortex, found that some of the same neurons that fire during observed action will also fire when monkeys are only hearing the auditory information from the action (i.e., the cracking of a peanut). Again, this involves inference to the presence of the actor without visual recognition.

Motor activation during action observation is also called motor resonance (Iacoboni, 1999), due to its timedependent and effector-specific nature. It is said that the motor system of the observer "resonates" with that of the actor, allowing the observer to use their own body to understand the action being performed. Gangitano, Mottaghy, and Pascual-Leone (2001) applied transcranial magnetic stimulation (TMS) to record motor-evoked potentials (MEPs) from the first dorsal interosseus (FDI) muscle on the right hand during the observation of a cyclic hand movement. They found that at the time when the FDI muscle of the observed hand was most contracted, MEPs in the observer were highest, and when the muscle was least contracted, MEPs were lowest. Thus, the motor resonance occurring in the observer is timelocked with specific muscle activity in the observed agent.
A related theory of motor system involvement is that of overt action simulation (Barsalou, 2009; Gallese and Lakoff, 2005). This is related to the above mentioned position and not mutually exclusive, as observationexecution matching could involve low-level simulation of an actor. Simulation theories, however, posit explicit ongoing simulation underlying perceptual and cognitive processes as a sort of online enactment, particularly for understanding semantics of action language. In other words, linguistic phrases such as "the boy caught the ball" are understood by low level simulation of the action in the
sentence. Numerous studies have shown that action language activates the motor system.
In an fMRI experiment, Hauk, Johnsrude, and Pulvermuller (2004) found that when participants read action words related to the arm, leg, or face, the corresponding regions of the motor somatotopy were active. Oliveri et al. (2004), using single pulse TMS, found that motor cortex activation increased for both action nouns and action verbs when compared to activation during non-action words. Candidi and colleagues (2010) found that verbs conjugated in the future tense induce higher corticospinal excitability than verbs conjugated in the past. Finally, Yang and Shu (2016) performed a meta-analysis on a large number of fMRI experiments where subjects were listening to literal action sentences, fictive motion sentences, metaphorical action sentences, and idioms, and found increased activation in motor regions during metaphorical action sentences. This activation is thought to contribute to understanding and mapping metaphors onto their concrete reference. Simulation theories are often associated with embodied cognition, proposing that we use our brains and bodies to ground conceptual and abstract content in sensorimotor systems.

The third theory we discuss is sensory prediction. In this case what is being coded for in the motor system is sensorimotor prediction, or continuous online prediction of the very next state of the stimulus. A predictive role for the motor system is suggested in Clark's (2015) theory of "embodied prediction", in which motor activation during action observation would entail prediction of the upcoming sensory signal based on the current sensory information. In this case, motor cortex would be active during the observation of a grasping action, because the observer's brain would be actively predicting the very next movement via motor regions. Thus, a predictive role can account for the findings from the action-observation network literature. Wilson and Knoblich (2005) outline a version of the perceptual prediction role of motor areas that uses what they call perceptual emulators. An emulator is a mental simulation that models the external world. The emulator continues updating the model online, and the output from this emulator can be compared to the actual state of the external world to verify that expectations are being met. Emulators running in the motor system would internalize a model of the biomechanics of the human body, allowing observers to model the movements of an observed agent as they unfold in time. Importantly, these emulators are running one step ahead of sensory input, predicting the upcoming external state before it happens and then comparing real to modeled state afterward.

If the motor system uses these emulators, it should also be able to model predictable sensory information that isn't human-made, such as rhythmic waves or the bouncing of a ball, by internalizing a model for the observed system. Supporting research comes from Schubotz (2007), whose work suggests that even observation of movements coming
from non-animate entities recruits the motor system. In a number of fMRI experiments, they find that particular types of perceptual prediction tasks involving such things as pitch identification, spatial or object-related identification tasks activates premotor areas in a somatotopic way, similar to effector-related observation/execution tasks. For instance, object-related tasks recruited regions of premotor cortex that share activation in hand-related execution and observation tasks. As there isn't a common repertoire to humans and rolling waves, these findings could not be explained under the motor resonance account.

We propose that the role of the motor system varies depending on context. For instance, during the perception of action language, the motor system might serve to provide the motor component of covert simulation that occurs in the embodied processing of language. During the observation of very well practiced movements by an outside actor, the motor system may serve the purpose of driving motor resonance in the observer to quickly map the actions to the observer's body and understand the action. Finally, during perceptual processing of non-human movements, the motor system might serve to assist in perceptual processing by way of predictive emulator models.
One potential way of differentiating between prediction and simulation is by observing how the modulation of the motor system changes over repetitive viewing of stimuli. If the observer is simulating the observed action, then we should see a steady facilitation of MEPs across repetitions of a stimulus, indicating simulation at each occurrence. If motor system facilitation is due to predictive processes, however, might expect a different pattern of modulation. Because less error correction takes place as a stimulus becomes more predictable, we can predict that the neural populations underlying the predictive processes will be less active for more predictable sensory stimuli. Thus, we should see a decrease in corticospinal excitability over multiple repetitions of a stimulus, as it becomes more predictable and leads to lower error correction..
In this experiment we look at corticospinal excitability using single-pulse transcranial magnetic stimulation (TMS) during the perception of written language to examine the extent of motor involvement in a few variations of the stimuli. Subjects viewed videos of words being written out with a stylus and of words being typed letter by letter. Previous analyses in our lab have shown that observation of handwriting leads to motor simulation, while observation of typed words does not. We proposed that this is because while it is apparent that the handwritten text are human created, this is less apparent for text created on a keyboard. We repeat all stimuli four times over the course of the experiment. We predicted that MEPs in the handwritten stimuli trials would show an even facilitation across all presentations of the stimuli, because simulation should be consistent no matter how predictable it is. We hypothesized that the MEPs in the typed stimuli trials would show initial facilitation, which would lessen as the stimuli are repeated
and there is less prediction error. This would be expected because the first presentations of the stimuli, appearing letter by letter, should be difficult to predict, resulting in a large error in perceptual prediction. As stimuli are presented more often, perceptual prediction should become easier and less effort required on the part of error correction.

## Methods

## Participants:

Twenty-four right-handed normal participants (8 males, 16 females, mean age $\sim 19.5$ ) were recruited in this study through UC Merced's SONA research system. All participants passed a safety screen and gave written, informed consent. The experimental procedure was approved by the UC Merced Institutional Review Board. Participants received 2 research credits that can be used for credit in some undergraduate courses.

## TMS and EMG recording:

Corticospinal excitability was measured by the amplitude of motor evoked potentials (MEPs) recorded using electromyography (EMG) on the first dorsal interosseus (FDI) muscle of the right hand. Two small adhesive electrodes $\left(1 \mathrm{~cm}^{\wedge} 2\right)$ were placed over the belly of the recorded muscle and a ground electrode was placed over a bone on the participant's elbow. A bandpass filter (50 $\mathrm{Hz} 1,000 \mathrm{~Hz}$ ) was applied to the EMG signal, which was digitized at $1,000 \mathrm{~Hz}$ for offline analysis. MEPs were elicited by applying single-pulse TMS to the FDI region of the left motor cortex. Pulses were delivered using a Magstim Rapid ${ }^{2}$ with an attached $70-\mathrm{mm}$ figure-of-eight coil positioned over the optimal scalp location with the handle pointing backward at 45 degrees from the midline. The procedure was as follows. Subjects were fitted with a swim cap that was covered by a grid of dots placed $1 \mathrm{~cm}^{2}$ apart. Optimal scalp position was determined by moving the coil by one centimeter intervals until the location eliciting the best MEPs was identified. This location was marked on the swim cap worn by the participant. Resting motor threshold was determined as the percent of machine output that produced 5 out of 10 MEPs of at least $50 \mu \mathrm{~V}$ peak-topeak amplitude. The stimulation intensity during the experiment was set to $120 \%$ of a participant's resting motor threshold. The coil was held steady at the optimal position throughout the experiment. Subjects were instructed to keep their head still and remain relaxed for the duration of the experiment.

## Experimental paradigm:

The visual stimuli consisted of videos of either handwritten or typed words or nonwords appearing letter by letter at a variable typing speed averaging 3-4 letters per second. Words were chosen that did not relate to any actions or manipulable objects, to ensure that our measurement would not be influenced by the effects of semantic processing of
action. We also included 10 baseline trials, which consisted of a single black box for the same duration as the stimuli. We chose to randomize the baseline trials in with the rest of the trials so that the baseline measure would not be biased by a lack of attention that can occur when baseline measures are all recorded pre-experiment. Stimuli included ten linguistic stimuli, which appeared four times in each of the conditions. This resulted in 80 stimuli trials and 10 baseline trials, or a total of 90 trials. Eight seconds passed in between individual trials, and the total experiment length was approximately 12 minutes. We chose to apply stimulation two seconds into the ongoing video, so that as the stimuli were repeated, they were more highly predictable (by the presence of the first few letters) by the time stimulation occurred. Because TMS stimulation would occur two seconds into the video, we ensured that the typed stimuli would display one of the following letters at that time [ $\mathrm{N}, \mathrm{H}$, $\mathrm{U}, \mathrm{M}, \mathrm{J}, \mathrm{I}]$, so that if subjects were simulating the typing in proper typing position, FDI would be the simulated muscle.
The stimuli appeared on a computer screen in front of the participants. Participants were instructed to attend to the stimuli on the screen and were given notice when the experiment was one-third and two-thirds of the way finished to prevent loss of attention.
TMS pulses were delivered 2 seconds after video onset. The interval between trials was 8 seconds, to avoid any cumulative effects of single-pulse TMS. After the experiment, subjects were asked whether they were able to stay attentive during the length of the experiment. Participants who said they were not were excluded from analyses (5 subjects).

## volume volume mjknmw mjknmw

Figure 1: Examples of stimuli used in the experiment. Handwritten stimuli are on the left and typed stimuli on the right. In the experiment, participants saw the stimuli appear as a video as they were written or typed.

## Results

The average raw MEP amplitude for handwritten stimuli was 1.126 mV , with a standard deviation of 1,303 . The average for typed words was 1098 mV , with a standard deviation of 1.295 . Because of the large variations between participants, raw MEP amplitude values were $z$-scored to allow inter-individual comparisons. The resulting z-scores indicate the distance (in standard deviations) that a particular MEP score is from the mean. Figure 2 shows the average $z$ score in each condition. The average $z$-score for handwritten stimuli was .1, while that for typed stimuli was -.06.
A two-way repeated-measures analysis of variance (ANOVA) was computed on the standardized MEPs to test
for significant effects. The considered factors were condition (handwritten or typed) by order (nth time that a stimulus appeared). We observed a significant main effect for condition, with handwritten stimuli producing greater facilitation of MEP amplitude with respect to typed stimuli, $\mathrm{F}(1,23)=7.62, \mathrm{p}<.01$. We also observed a significant interaction effect of condition by order of presentation, $F(3,184)=3.77, p=.05$. In particular, there was a consistent facilitation in MEPs in the handwritten stimuli regardless of how many times the stimulus has been presented. In the typed stimulus condition, however, there was an initial facilitation in the MEP amplitude that decreased with each repetition of the stimuli. This pattern of results confirms our hypothesis of typed stimuli showing an initial facilitation of corticospinal excitability, followed by a decrease in that facilitation. This also confirms our hypothesis that the handwritten words would induce consistent facilitation of corticospinal excitability.

A linear regression of presentation number on baseline zscore was performed in order to evaluate whether the baseline MEPs changed with multiple presentations of the stimuli. The regression came out non-significant $(\mathrm{t}=-1.1$, p $>.3$ ). This indicates that overall MEP amplitudes are not varying as a function of time or number of repetitions to stimuli.

MEPs of Condition by order of presentation

Figure 2: Standardized (Z-scored) MEP amplitudes for each condition. X-axis shows presentation number (nth time a stimulus was presented). Motor evoked potentials in the handwritten condition show consistent facilitation, while those in the typed condition show initial facilitation that decreases with presentation number.

## Discussion

In this experiment we observed a differential pattern of motor facilitation dependent on word reading condition. In particular, the observation of actively handwritten words produced a persistent facilitation in MEP amplitudes. This is consistent with the action observation research, where
subjects view actions produced by others over multiple trials and produce consistent MEP facilitation. When subjects are exposed to actively typed words, however, the pattern of MEP facilitation changes, with repetitive exposure to the stimulus resulting in a decrease in observed corticospinal excitability. In previous work, we hypothesized that typed stimuli might not show simulation because of two reasons. Either the act of typing has weak or no sensorimotor association, or the discrete nature of typed words does not invoke simulation the same as the continuous strokes of handwriting.

Evidently the motor system is doing something different from motor simulation during the observation of words that are actively typed. One potential hypothesis is that corticospinal excitability in the typed condition is influenced by attentiveness. As subjects are repeatedly exposed to words, they might lose interest and thus exhibit lower attention. We included in the experiment a baseline measure appearing randomly throughout, consisting of a solid black box that appears instead of the language stimuli. There were 10 baseline trials used. If corticospinal excitability was picking up on a measure of attention, we should see a predictable decreasing trend in MEP amplitudes across repetitions of the baseline trials as well. No such decreasing trend was observed over the repeated baseline trials. Though we cannot rule out the possibility entirely, this does suggest that there is something happening for the typed stimuli other than decreased attentiveness.

We suggest that the decrease in excitability across repetitions of stimuli is due to sensory prediction by the motor system. When the stimuli are less predictable (i.e., the first presentations), the sensory prediction error is large, resulting in higher motor activation. As the stimuli are repeated and become more predictable, the sensory prediction error becomes lower and we observe less corticospinal excitability in the motor system. This account is consistent with Schubotz's (2007) findings of motor activation during serial prediction tasks and Wilson and Knoblich's (2005) emulator account.
If our theoretical formulation is correct, this implies that the study of motor involvement in perception and cognition should take into account that the motor system is playing multiple processing roles that are network and contextdependent. The action observation based recruitment of the motor system is well established. Strong evidence suggests that this is due to motor resonance that is both effectorspecific and time-dependent. We contend that the role of motor cortex in action-observation is for low-level activation of one's own motor repertoire. Under our account, motor activation during perceptual processing of non-human-created stimuli, reported by Schubotz and colleagues, is not at odds with the resonance account of action observation. The particular information processing role of motor regions does not need to be identical across contexts. The functional network underlying action observation includes bilateral mid-temporal gyrus (MTG) and left
inferior parietal lobule as well as left premotor cortex. (Gazzola, Aziz-Zadeh, \& Keysers, 2006). Other brain regions active during figurative language include the left and right inferior frontal gyrus (IFG), bilateral medial frontal gyri (medFG), left temporal lobe, and amygdala. (Bohrn, Altmann, \& Jacobs, 2012). The function of motor activation in each of these different networks can be defined by its connections and interactions, allowing a motor predictive system or motor simulation system when appropriate.

How would this region have multiple functional roles? Evidence from single-unit recording of neurons in premotor areas suggests that there is a wide variety of neurons that respond to different contexts. For example, during the discovery of mirror neurons, many types of such neurons were identified (Di Pellegrino et al., 1992). Some of these are called "strictly congruent" mirror neurons, which respond to action observation and action execution only to the same exact movement. More common were "broadly congruent" mirror neurons, which respond to action observation and action execution during similar types of movements, encompassing a broader response range. We postulate that the first type is responsible for driving motor resonance-related activation, while the latter type could potentially underlie the sort of sensory prediction we discuss. Finally, a third type of neuron they observed was called a "canonical neuron", which respond to the observation of manipulable objects. Perhaps these neurons could play a role in mental simulation, or affordance processing. These examples are all speculative and not grounded by any evidence in the present work, but they aim to push intuitions toward a fresh perspective. Future work using single-neuron recording would be needed to directly test such hypotheses. At a brain region level, however, we can learn more by observing how activation in local regions changes with repetition of sensory stimuli or changes in stimuli.

Future research that we are currently engaged aims to explore how sensorimotor contingencies are learned by training participants on novel sensory to motor mappings. We will then use these controlled artificial mappings to explore sequential prediction and/or simulation using the motor system.

# A Spiking Independent Accumulator Model for Winner-Take-All Computation 

Jan Gosmann (jgosmann@uwaterloo.ca)<br>Aaron R. Voelker (arvoelke@uwaterloo.ca)<br>Chris Eliasmith (celiasmith@uwaterloo.ca)<br>Centre for Theoretical Neuroscience, University of Waterloo<br>Waterloo, ON, Canada N2L 3G1

#### Abstract

Winner-take-all (WTA) mechanisms are an important component of many cognitive models. For example, they are often used to decide between multiple choices or to selectively direct attention. Here we compare two biologically plausible, spiking neural WTA mechanisms. We first provide a novel spiking implementation of the well-known leaky, competing accumulator (LCA) model, by mapping the dynamics onto a population-level representation. We then propose a two-layer spiking independent accumulator (IA) model, and compare its performance against the LCA network on a variety of WTA benchmarks. Our findings suggest that while the LCA network can rapidly adapt to new winners, the IA network is better suited for stable decision making in the presence of noise.

Keywords: Neural Engineering Framework; Nengo; winner-take-all; decision making; mutual inhibition; neural competition; dynamical systems

## Introduction

Winner-take-all (WTA) networks are mechanisms that select the largest value among a number of inputs. More precisely, given a $D$-dimensional vector corresponding to the non-negative utility of $D$ different choices, the desired output is positive for the dimension with highest utility (i.e., the "winner") and zero for all others. This mechanism is regularly employed as a component of cognitive models involving selective attention (e.g., Itti, Koch, \& Niebur, 1998; Standage, Trappenberg, \& Klein, 2005) and decision making, where the action with the highest utility is selected to drive behaviour (e.g., O’Reilly, 1998).

A large body of literature examines the optimality of WTA mechanisms and their consistency with neurobiological and psychological data (e.g., Bogacz, Brown, Moehlis, Holmes, \& Cohen, 2006; Gold \& Shadlen, 2007; Smith \& Ratcliff, 2004). Here, we investigate the suitability of two different WTA mechanisms in the context of neurally plausible cognitive modelling. In particular, we map each mechanism onto a network of spiking neurons, and then compare them using a set of functional benchmarks that are normative in nature. The first mechanism we consider is an implementation of the leaky, competing accumulator (LCA) model from Usher and McClelland (2001). The LCA model and variants have been widely used, for example in versions of the Temporal Context Model (Sederberg, Howard, \& Kahana, 2008), and in work on the Remote Associates Test models (e.g., Kajic, Gosmann, Stewart, Wennekers, \& Eliasmith, 2017). The second mechanism we consider is the independent accumulator (IA) model that we propose here, which involves a secondary thresholding layer that is recurrently connected to a primary integrating layer.

To implement each model, we use the Neural Engineering Framework (NEF; Eliasmith \& Anderson, 2003) to map the model's dynamics onto populations of spiking neurons. In the remainder of the paper, we provide a short introduction to the NEF, describe our implementation of the two WTA mechanisms, present our benchmarks, and finally discuss some resulting implications for cognitive modelling.

## Methods

## The Neural Engineering Framework

The Neural Engineering Framework (NEF; Eliasmith \& Anderson, 2003) is a method for mapping a cognitive model, described using mathematical equations, onto a spiking neural network. We now describe the aspects of this framework that are relevant to this work, by summarizing its three principles: representation, transformation, and dynamics.

Principle 1: Representation We define the representation of a scalar value $x(t)$ by an encoding and decoding with respect to some population of neurons. The encoding of $x(t)$ into a spike train $a_{i}(t)$ for neuron $i$ is given by:

$$
\begin{equation*}
a_{i}(t)=G_{i}\left[\alpha_{i} e_{i} x(t)+J_{i}^{\mathrm{bias}}\right] \tag{1}
\end{equation*}
$$

where $\alpha_{i}$ is a gain factor, $e_{i}$ is an encoder that determines a neuron's tuning curve, $J_{i}^{\text {bias }}$ a bias current, and $G_{i}[\cdot]$ is the neural nonlinearity. Here, we use spiking, leaky integrate-and-fire (LIF) neurons for $G_{i}[\cdot]$, and set the encoders to one. Decoding weights $d_{i}$ are then used to approximate the represented value $\hat{x}(t)$ from the activity of the population of neurons by:

$$
\begin{equation*}
\hat{x}(t)=\sum_{i} d_{i}\left[\left(a_{i} * h\right)(t)\right] \tag{2}
\end{equation*}
$$

where $h(t)=\tau_{\mathrm{s}}^{-1} \exp \left(-t / \tau_{\mathrm{s}}\right)$ is an exponentially decaying synaptic filter with time-constant $\tau_{\mathrm{s}}$, and $*$ is the convolution operator. The decoding weights are obtained by least-squares optimization of the error $E_{x}=|x-\hat{x}|$. For the transmission of a value from one population to another, the connection weights are given by:

$$
\begin{equation*}
W_{i j}=\alpha_{j} e_{j} d_{i} \tag{3}
\end{equation*}
$$

Principle 2: Transformation By finding alternate decoding weights $d_{i}^{f}$ with the error given by $E_{f(x)}=|f(x)-\hat{x}|$, arbitrary linear and nonlinear functions $f(x)$ can be approximated in the connections between neural populations.

Principle 3: Dynamics Given some desired nonlinear dynamics for the state variable $x(t)$ :

$$
\begin{equation*}
\frac{\partial x}{\partial t}=g(x) \tag{4}
\end{equation*}
$$

we can map these dynamics onto a recurrent transformation, by harnessing the synaptic filter mentioned in Principle 1. In particular, for the exponentially decaying $h(t)$ we may apply Principle 2 to the recurrent transformation $f(x)=\tau_{s} g(x)+x$ to ensure that $x(t)$ obeys Equation 4.

## Leaky, competing accumulator model

Using the principles of the NEF, we have implemented the widely-used leaky, competing accumulator (LCA) model proposed by Usher and McClelland (2001). The dynamics (see Fig. 1a) for each state variable $x_{i}(t), 1 \leq i \leq D$, where $D$ is the number of choices, are given by:

$$
\begin{equation*}
\frac{\partial x_{i}}{\partial t}=\left(\rho_{i}-k x_{i}-\beta \sum_{j \neq i} x_{j}\right) \frac{1}{\tau}, \quad x_{i} \geq 0 \tag{5}
\end{equation*}
$$

where $\rho_{i}$ is each external input, $k$ is the leak rate, $\beta$ the lateral inhibition, and $\tau$ the integration time-constant. This model essentially integrates each input $\rho_{i}$ with a leak term $\left(-k x_{i}\right)$, minus competition from every other variable $\left(\beta \sum_{j \neq i} x_{j}\right)$. Supposing $\rho_{i}>\rho_{j}$ for all $j \neq i$, a WTA mechanism should indicate that $i$ is the winning choice. Setting $k=\beta=1$ will guarantee that the winning state $x_{i}$ converges to the value of the largest input $\rho_{i}$, while each losing state $x_{j}(j \neq i)$ converges to zero. Other choices of $k$ merely alter the effective $\tau$ and the effective gain on the input, while other choices of $\beta$ will produce unwanted behaviours (see supplementary analysis).

We implement Equation 5 with the NEF by using one population of neurons for each $x_{i}$, and applying Principle 3 to each population. By appropriately selecting the gain and bias parameters from Principle 1, we ensure that each state variable is rectified $\left(x_{i} \geq 0\right)$ as required. We believe this implementation is novel as it does not interpret each $x_{i}$ as a distinct neural firing rate, but rather as a population-level representation distributed across any number of spiking neurons. In effect, heterogeneous spike trains are weighted by optimal decoding weights to precisely implement the stated dynamics. This allows us to attain greater biological realism without altering the dynamics prescribed by Equation 5.

## Independent accumulator model

The other WTA mechanism that we investigate is our proposed independent accumulator (IA) model (see Fig. 2). We use the term 'independent' to refer to the fact that there are no direct interactions between each accumulator, unlike in the LCA model which has direct competition between states. To enable a form of competition, we add a second thresholding layer that projects back to self-excite and mutually-inhibit the first layer. We now provide the details of each layer - again implemented using the principles of the NEF.

Figure 1: Example time course of the state variables in the LCA (top) and IA (bottom) networks with three choices $(D=3)$. The vector of inputs is $[0.8,0.7,0.6]$.

The first layer consists of a separate integrator population (i.e., accumulator) for each state variable $x_{i}(t), 1 \leq i \leq D$. The second layer consists of independent, non-recurrent populations that receive input from the first layer in a one-toone fashion. From the second layer, we decode the function $\bar{x}_{i}:=\Theta\left(x_{i}-\vartheta\right)$ where $\Theta$ is the Heaviside function, and $\vartheta=0.8$ is a fixed threshold value that determines how much evidence needs to be accumulated to produce an output. The Heaviside decoded output of layer 2 projects back to layer 1 to add $\bar{x}_{i}-\bar{\beta} \sum_{j \neq i} \bar{x}_{j}$ to the input of $x_{i}$. Since intuitively the largest input will accumulate the fastest, once this reaches the threshold $\vartheta$ it will self-excite and inhibit all other state variables. Fixing $\bar{\beta}=2$ ensures that the losing state variables will

Figure 2: Independent accumulator (IA) network. Neural populations are denoted by circles labelled with their represented state variable. Arrows denote excitatory connections, while lines ending in circles denote inhibitory connections. The second layer computes $\bar{x}_{i}:=\Theta\left(x_{i}-\vartheta\right)$.
go to zero (see supplementary analysis). This is summarized more precisely by the following dynamics (see Fig. 1b):

$$
\begin{equation*}
\frac{\partial x_{i}}{\partial t}=\rho_{i} \frac{1}{\tau_{1}}+\left(\bar{x}_{i}-\bar{\beta} \sum_{j \neq i} \bar{x}_{j}\right) \frac{1}{\tau_{2}}, \quad x_{i} \geq 0 . \tag{6}
\end{equation*}
$$

Notably, this takes the form of Equation 5 after substituting $\tau=\tau_{1}, k=-\tau_{1} / \tau_{2}$, and $\beta=\bar{\beta} \tau_{1} / \tau_{2}$, with the only remaining difference being the Heaviside nonlinearity applied to the state feedback. Thus, in contrast to the continual competition occurring in the LCA model, the threshold $\vartheta$ is a free parameter that controls how much evidence needs to be integrated before enabling any competition between states. Instead of directly manipulating $\vartheta$, we opt to change $\tau_{1}$, which has a comparable effect due to the leak-free integration.

Note that the decoded output from layer 2 of the IA network has higher variance than the LCA network (Fig. 1), but the separation of the output for different choices is more relevant than the variance in interpreting the output.

## Benchmarks

To test and compare the two WTA mechanisms we provide an input of $\rho_{i}=u-s\left(1-\delta_{1 i}\right)+\eta_{i}$, where $u$ is the magnitude of the largest input, $s>0$ is the target separation relative to all other inputs, $\delta$ is the Kronecker delta, and $\eta_{i}$ is Gaussian (white) noise with standard deviation $\sigma$. Thus, without loss of generality, the first state variable receives the largest input $u$ plus noise, and all other state variables receive a noisy input that is smaller by $s$. It is important to note that $u$ not only determines the size of the largest input, but also the general baseline of inputs. Since all of the runner-ups have equal magnitude, this represents the most difficult scenario for the networks, where all potential choices must be considered. As $s \rightarrow 0$ the problem also becomes more difficult because the utilities of the choices are closer together. We use $u=1$ unless indicated otherwise, and set the number of choices to $D=10$. Furthermore, we increment the noise variance to highlight successes and failures as the task becomes increasingly difficult with more noise. This allows us to determine which functions are performed robustly by each network. In both WTA models we use 200 neurons per choice. In the IA network this is split into 150 neurons for each layer 1 population and 50 neurons for each layer 2 population. All remaining network parameters are summarized in Table 1.

To evaluate the two mechanisms on the previously defined input, we use a number of separate metrics. First, we determine whether the model is able to form a clear decision within one second. To be counted as 'clear', at least one output must remain above 0.15 across the time interval $(1 \mathrm{~s}, 2 \mathrm{~s}$ ] while all other outputs remain below this threshold. This lower bound of 0.15 was chosen to ensure that noise on a zero output is not mistaken for a non-zero output. Note that this metric requires that the decision does not change throughout the time interval. This does not take into account whether the winning output actually corresponds to the largest input. However, for

Table 1: Summary of parameter values.

| LCA time-constant | $\tau=0.1 \mathrm{~s}$ |
| :--- | :--- |
| LCA recurrency parameters | $k=\beta=1$ |
| IA accumulation time-constant | $\tau_{1}=0.1 \mathrm{~s}, 0.5 \mathrm{~s}$ |
| IA feedback time-constant | $\tau_{2}=0.1 \mathrm{~s}$ |
| IA threshold | $\vartheta=0.8$ |
| IA recurrency parameters | $\bar{\beta}=2$ |
| Recurrent synaptic time-constant | $\tau_{\mathrm{s}}=0.1 \mathrm{~s}$ |
| Feed-forward synaptic time-constant | $\tau_{\mathrm{s}}=0.005 \mathrm{~s}$ |
| Output decoding synaptic time-constant | $\tau_{\mathrm{s}}=0.01 \mathrm{~s}$ |

some models it is more desirable to produce a clear incorrect decision than an unstable incorrect decision. In other situations, though, the correctness of the decision may be of higher importance. Thus, we consider a trial 'correct' if the model forms a clear decision, and the largest output corresponds to the true largest input. Measurement of correct trials forms our second benchmark.

We use two additional benchmarks on the set of all trials with a clear decision. First, it is important to consider the speed at which the network can make decisions. We therefore define the 'decision time' as the length of time it takes to fulfil the conditions of a clear decision. Second, the correctness metric only considers the final averaged output during a time interval. It is possible for a network to produce transient outputs before the final decision is reached. In the context of a larger model, this can become a problem because the transient output might be prematurely interpreted as a decision. Thus, we define it as the 'highest output of a losing choice' during the whole simulation.

## Results

We find that the ability to form a clear decision of the LCA network decreases with more noise and less target separation (see Fig. 3). Also, the magnitude of the inputs has an important influence. For a small inputs with $u=0.2$ the winner will mostly not exceed the 0.15 threshold with noise present. The best performance is achieved with medium inputs with $u=0.6$. Higher inputs make it more likely that runner-ups will exceed the 0.15 threshold, especially with a small target separation. In contrast to the LCA network, the IA network manages to form a clear decision in every trial (not explicitly shown in Figure 3, but all data points fall on the grey line).

Interestingly, for all clear decisions the correct winner was determined by the LCA network. Thus, a plot of correct trials looks identical to Figure 3, with slightly different error bars. While always reaching a clear decision, the decisions of the IA network are not always correct. Overall, the IA performance tends to be worse than the LCA performance for a high input magnitude, but better for smaller inputs (Fig. 4a, b). We can greatly improve the IA performance by increasing $\tau_{1}$ to 0.5 s which slows down the integration of evidence (Fig. 4c). This improves the IA performance to be above the LCA performance for high baselines, but it will also increase the de-

Figure 3: Fraction of trials with a clear decision for the LCA network (which also exactly matches the fraction of correct trials). Each plot shows data for a different input magnitude $u$. Error bars denote bootstrapped $95 \%$ confidence intervals. The grey horizontal line indicates the optimum, which coincides with the performance of the IA network.
cisions times of the IA network. For a low baseline with $u=0.2$, it makes the IA network unable to decide within the allocated time frame, but given more time it would still reach a decision.

As shown in Fig. 5a, the time required to reach a decision in the LCA network depends mostly on the size of inputs and target separation. We averaged over the different noise conditions because the noise influence on the timing was minor. In the IA network the largest input is the most important factor (dashed vs. solid lines in Fig. 5b). Depending on this magnitude, the network can either be faster or slower than the LCA network, but it will need more time given a value of $\tau_{1}$ that achieves the same fraction of correct responses as the LCA network. There is also a slight influence of target separation and input noise, with an interaction of these two parameters (solid lines in Fig. 5).

Finally, looking at the transient responses indicates that both models might produce outputs of losing choices. For the LCA network the magnitude of the transient response mainly increases with the amount of noise (Fig. 6a). For the IA network, transient outputs are smaller in noisy conditions, but can be higher than for the LCA network in less noisy conditions with small target separations. The magnitude of such transient responses is reduced by adjusting $\tau_{1}$ to 0.5 , at the cost of a slower decision.

## Discussion

We have shown that neither network performs better on all benchmarks, but rather each is better suited for different purposes. For instance, the LCA network can determine the correct winner more quickly, and, given that a conclusive decision was made, it always selects the correct winner. However, under noisy conditions it may fail to produce a clear output at all, and thus not make a decision. This can be problematic for cognitive models that must form a clear decision (even when it may be incorrect). The IA network might not be able to identify the correct winner as quickly or as reliably (depending on the choice of $\tau_{1}$ ), but given enough time it will eventu-
ally arrive at a decision and produce a clear output. This is a direct consequence of the thresholding on the state feedback, which prevents competition from occurring until a sufficient amount of evidence has accumulated. This also enables the IA network to react to small inputs. In addition, the IA network is easily extendible to allow dynamic control of the decision speed, by supplying an external bias to layer 2 to adjust the $\vartheta$ threshold.

The LCA network is especially well-suited for situations where a decision needs to be continuously adjusted. The dynamics constantly push the winning state variable to the magnitude of the largest input, while adapting to input changes along a time-scale of $\tau$. This makes it quick to respond to changes in the input for smaller $\tau$, but leads to randomly switching outputs due to noise.

In contrast, the IA network is better suited for situations where a discrete sequence of decisions is required. After selecting a winner, the model's decision will persist due to selfexcitation, even in the absence of input. Thus, after making a decision, it is necessary to reset the model by inhibiting the winning accumulator. This limits how quickly successive decisions can be made and reduces the ability to react to changing inputs. However, once a decision is made, the network provides a stable output. For example, we intend to use the IA network in a model of free recall to output a sequence of WTA responses. In this case, the model requires stable recall in the presence of noise, even if each response may not be the "true" winner.

Both models might produce a transient response that may be interpreted as a decision, which can make the detection of decisions problematic. This is of special relevance when incorporating the networks into larger cognitive models. For the LCA network, the transient behaviour is inherent to its design; there will always be an initial rise of all state variables (that receive input) before the mutual inhibition grows strong enough to push them back to zero. In the IA network, however, such transient responses may be avoided by choosing appropriate $\tau_{1}$ and $\vartheta$. It should be noted that other recur-

Figure 4: Fraction of correct trials for the IA network. Each plot shows data for a different combination of input magnitude $u$ and integration time-constant $\tau_{1}$. Error bars denote bootstrapped $95 \%$ confidence intervals. The grey horizontal line indicates the optimum.

Figure 5: (Left) Mean decision times for the LCA network. Shown data is averaged across all noise levels, since noise had minimal effect on decision times. (Right) Mean decision times for the IA network with input magnitude $u=0.2$ (solid) and $u=1$ (dashed). Error bars denote bootstrapped $95 \%$ confidence intervals.
rently connected readout mechanisms have been proposed for the two choice case that produce bursting outputs somewhat comparable to the IA network (Lo \& Wang, 2006). However, the evidence integration in the Lo and Wang (2006) model uses competition via pooled inhibition, making it more similar to the LCA then the IA network.

We have not yet investigated the agreement of these mechanisms with neurobiological and behavioural data, although this has been done before for other WTA networks (Gold \& Shadlen, 2007; Smith \& Ratcliff, 2004). The implementation in spiking neurons, however, provides some basic biological plausibility and more readily permits comparisons with neural data. In particular, the IA network predicts that the firing rates for neurons in the first layer will rise up to a threshold, and that neurons in the second layer will not become active or inhibit the first layer until reaching this threshold. Neurons in the macaque lateral intraparietal area exhibit a similar step response (Latimer, Yates, Meister, Huk, \& Pillow, 2015). In contrast, the LCA network predicts that the firing of any neurons will proportionately inhibit all other neurons that do not represent the same state. With regard to behavioural data, different effects for decision times are predicted as the number
of choices increases: for the LCA network decisions become slower due to the mutual interaction, but for the IA network decisions will take less time because only a single accumulator needs to exceed the threshold. Nevertheless, evidence for one network does not exclude the possibility that the other network is employed for different tasks or by different brain areas. Relatedly, it might be more plausible to distribute the representation of all state variables over a single population of neurons. This is directly supported by the NEF, but we chose to leave this to future work to keep the current analysis free from potential interactions of the state variables introduced by such a distributed representation.

We also did not look at at the influence of the number of dimensions $D$ in detail. For higher $D$, we see reduced accuracy overall since each additional choice has a baseline chance to win due to noise. Nevertheless, the results that we discuss here are qualitatively similar.

One critique of non-leaky accumulator models is that their ability to discriminate the largest input increases indefinitely with time (Usher \& McClelland, 2001) and that there is no sensible stopping criterion. However, this assumes that the time to reach a decision has no cost. If time-to-decision has a

Figure 6: Transient response (highest output of losing choices) for the LCA and IA network. Error bars denote bootstrapped 95\% confidence intervals. The grey horizontal lines show the optimum.
cost, then it will at some point exceed the gain achieved from making a correct decision. Furthermore, this argument assumes integration with perfect accuracy. But, with networks built using the NEF, the representation of each state variable has limited precision, and so an ideal trade-off must be found.

To conclude, we investigated two spiking neural networks computing a winner-take-all function based on the leaky, competing accumulator model and a novel two-layer independent accumulator model. While both perform the same basic tasks, they fail in different ways as each task scales in difficulty via increased noise or less separation between choices. From a modelling perspective, this makes each network more useful for different situations. The LCA model is better for continuous updating of decisions, whereas the IA network is better suited for more discrete decisions in the presence of noise. It is left to future work to investigate whether these two distinct mechanisms can be identified from either behavioural or neurophysiological data.

#### Abstract

In science and philosophy, there is still no general agreement on what 'consciousness' is. But how do normal people (with no education in psychology or philosophy) use the term in their everyday life? What is the folk understanding of the word "conscious"? We conducted an online study on how the general public uses the word "consciousness" in their daily life. Participants ( $\mathrm{n}=445$ ) answered the question "What is consciousness?" in four different formats: they (1) generated free definitions in their own words, (2) generated many synonyms, (3) generated one synonym, or (4) selected one alternative description in a multiple choice task. The most frequent words were: alertness, clarity, I-sensation, knowledge, perception, reflecting, and thinking. The word perception was provided most often across all formats. There was also a high correlation between all response formats. We discuss these findings and their implications for the scientific study of consciousness.

# Pragmatic aspects of spatial language acquisition and use across languages 

Myrto Grigoroglou (Mgrigor@Udel.Edu)<br>Department of Linguistics and Cognitive Science, University of Delaware<br>125 East Main Street, Newark, DE 19716 USA

#### Abstract

Across languages, back is produced earlier and more frequently than front. This asymmetry has been attributed either to a conceptual/semantic asymmetry in the early meanings of these locatives (with back being more basic than front; conceptual immaturity account) or to the fact that Back configurations are inherently more 'noteworthy' than Front configurations (pragmatic account). Here, we tested the two accounts. In Study 1, children and adult speakers of English and Greek described Front/Back motion events. In Study 2, adult speakers of 10 additional languages described the same events. Despite cross-linguistic differences, speakers of all age and language groups typically used more Back than Front adpositions; furthermore, they often encoded Back information in occlusion verbs (e.g. hide) but no such verbs were available for Front. Thus, the front/back asymmetry is not due to children's conceptual immaturity but should be linked to pragmatic factors that also shape adult spatial language production cross-linguistically.

Keywords: front; back; motion events; spatial cognition; language production; pragmatics; theories of acquisition

## Introduction

It is widely recognized that children acquire spatial locatives in a consistent order cross-linguistically (e.g., E. Clark, 1980; E. Clark, 1977; Johnston \& Slobin, 1979; Parisi \& Antinucci, 1970). In many cases, patterns of language use in children, especially when these emerge cross-linguistically, have been argued to point to shared (possibly universal) conceptual asymmetries in underlying representations (Bowerman, 1996). For instance, the early emergence of prepositions such as in and on has been considered to reflect the early development of the notions of containment and support (Johnston \& Slobin, 1979; Piaget \& Inhelder, 1967).

However, it remains unclear whether patterns of spatial language use in children can be attributed merely to conceptual factors. For instance, unlike their positive counterparts in and on, 'negative' containment and support prepositions such as out and off are used extremely infrequently by children to mark locations, although, in principle, both 'positive' and 'negative' prepositions should present the same level of conceptual difficulty for the learner (compare The egg is in the cage vs. The egg is out of the cage; Papafragou, Viau, \& Landau, 2013). By contrast, a pragmatic explanation seems more adequate to account for these facts: 'negative' prepositions are used less frequently because their
informational contribution is low (they do not specify where something is) unless they can be interpreted as indicating a change of location (The bird is out of the cage is more felicitous than The egg is out of the cage; ibid.). Even though it is often acknowledged that both conceptual and pragmatic factors shape the way spatial language is used and acquired (e.g., E. Clark, 1973; Levinson \& Wilkins, 2006), the exact contribution of each factor remains open. The objective of the current study is to contribute to this debate.

## Case study: the acquisition of front and back

The acquisition of the locatives front and back presents a particularly good domain to explore the division of labor between pragmatic and conceptual explanations of spatial language acquisition and use. A number of studies have shown that, across different languages, the locative back is produced earlier and appears more frequently in children's speech than the locative front (Johnston, 1984; Johnston \& Slobin, 1979; Kubena, 1968). Some researchers have suggested that this asymmetry should be attributed to the conceptual immaturity underlying children's early representations of the relations front and back. According to this view, although the adult meanings of front/back are geometric and semantically symmetrical ("first/second in-line-of-sight"), children's early meanings are immature, function-based and asymmetrical: front means "visible" and back means "occluded". This conceptual/semantic asymmetry in the early meanings of Front and Back results in the asymmetric acquisition of the locatives (Johnston, 1984; Johnston \& Slobin, 1979).

Other researchers have argued that the asymmetry in the acquisition of front and back should be attributed to the pragmatics of these spatial expressions (Hill \& Vandeloise, 1991; Tanz, 1980). On this view, occlusion and visibility characterize typical Back and Front configurations, with occlusion (the functional corollary of Back) being, typically, more informative than visibility (the functional corollary of Front). Thus, children use back more frequently than front because the communicative need to mark that an object is occluded is (in most cases) more pressing than the need to mark that an object is visible.

The two explanations converge on the view that children should encode Back more frequently than Front but, crucially, they differ on whether adults should also exhibit a
similar asymmetry. If the asymmetry is due to early, immature meanings for the prepositions front and back (i.e., visibility and occlusion), as posited by the conceptual immaturity account, adults, having mature spatial semantics, should use the two terms equally frequently. By contrast, if the front/back asymmetry is driven by the inherent 'noteworthiness' of occlusion, as proposed by the pragmatic account, adults-just like children-might also exhibit the asymmetry.

Furthermore, the two accounts share the assumption that the meanings of the prepositions front and back involve the notions of visibility and occlusion, but they disagree on whether adults should entertain such meanings. On the conceptual immaturity account, adults (unlike children) should not have a bias to mark occlusion (as opposed to visibility) with expressions beyond front and back (e.g., with verbs such as hide, etc.) because such function-based representations should characterize only the early immature child semantics. By contrast, on the pragmatic account, adults-just like children-might also show a bias to mark occlusion.

## Current study

In the current study we test the predictions of the conceptual immaturity and pragmatic explanations. In Study 1, we elicit descriptions of Front/Back motion events from children and adult speakers of two typologically distinct languages (English and Greek). In Study 2, adult speakers of 10 additional languages describe the same events.

To evaluate the predictions of the conceptual immaturity and pragmatic explanations we compare Front/Back motion descriptions in both children and adults. Although previous research, surprisingly, did not include adults, adult data, especially if they represent a wide cross-linguistic sample, are crucial for validating theories of spatial language acquisition and use.

Furthermore, we look at elicited descriptions of motion paths. Unlike prior work on locative front/back, the choice of motion paths allows us to compare not only the use of 'front' and 'back' adpositions (prepositions and postpositions) across the languages in our sample but also the use of functional information (occlusion/visibility) encoded in verbs (see Landau \& Jackendoff, 1993; Miller \& JohnsonLaird, 1976; Talmy, 1983, on the role of spatial verbs). To ensure cross-linguistic validity, we include both satelliteframed languages that tend to encode motion paths in particles/non-verb elements, and verb-framed languages that tend to encode motion path information in the verb (Talmy, 1985). In study 1, we compare English (a satellite-framed language) to Greek (a verb-framed language). In study 2, our language sample contains an equal number of verb-framed and satellite-framed languages. For completeness in path descriptions, each Front or Back path has a goal variant (e.g., figure moving in front of/ behind the reference object) and a source variant (e.g., figure moving from front of/ from behind the reference object). In the case of Back paths, figures undergo a dynamic change of state from visibility to
occlusion (for goals) or vice versa (for sources). In the case of Front paths, figures undergo a change of location without a change of visibility (e.g., when figure X moves to/from front of $\mathrm{Y}, \mathrm{X}$ moves along a trajectory while being continuously visible).

## Study 1

## Methods

Participants Participants were 40 native English speakers and 40 native Greek speakers. They fell into two age groups (Children, Adults) with 20 participants in each age group for each language. The English-speaking children were recruited at daycares in Newark, DE and ranged between the ages of $3 ; 8$ and $5 ; 5(\mathrm{M}=4 ; 6)$. The English-speaking adults were undergraduate students at the University of Delaware and received course credit for their participation. The Greekspeaking children were recruited at daycares in Evia, Greece and ranged between the ages of $3 ; 9$ and $5 ; 3(M=4 ; 6)$. The Greek-speaking adults were University students or young professionals and were recruited in Evia and Athens, Greece.

Materials The stimuli consisted of a total of 48 dynamic motion events presented in Microsoft PowerPoint. Each event consisted of a Figure, which was always the same soccer ball, and a Reference object, which was selected from a set of simple, abstract 3D objects. We chose to use very simple schematic stimuli to elicit only or mainly path information (even from speakers of a language such as English which regularly encodes manner of motion).

The motion events depicted a total of eight different spatial relations, each with a source and a goal version. This battery was part of a larger project investigating cross-linguistic descriptions of motion paths. In the present study, we focus on Front (IN FRONT OF/FROM IN FRONT OF) and Back (BACK/FROM BACK). Stimuli depicting the Back relation always involved occlusion but stimuli depicting the Front relation never did (see Fig.1).

Figure 1: Schematic examples of test events. In FRONT/FROM FRONT scenes, the ball is always visible but in BACK/FROM BACK scenes it is occluded at the endpoint (goal scenes) or the beginning (source scenes) of the event.

The remaining relations were Containment (IN/OUT OF), Cover (UNDER/FROM UNDER), Support (ONTO/OFF OF), Contact (TO/FROM), Vertical Proximity (TOWARDS THE SIDE OF/AWAY FROM THE SIDE OF), and Horizontal Proximity (TOWARDS THE TOP OF/AWAY FROM THE TOP OF).

Six events were shown for each relation ( 3 exemplars, each with a goal and a source version). The source and goal versions of the same exemplar were identical except for the color of the Reference object and the direction of the motion path. The motion events lasted for three seconds and then the end state of the event remained on the screen until a key was pressed.

Procedure The adult participants were told that they would see a series of motion events involving a ball and another "toy." After viewing each event, the participants had to describe, in their native language, what the ball did in each event. Events remained on the screen until a key was pressed. The adult participants performed one practice trial.
Children were told that they were going to play a game where animals play with balls and "toys." They were then shown a screen with all Reference objects, and were told to call them all "toys." In order to help children maintain attention, a slide with a small cartoon animal in one of the bottom corners was presented before each motion event. The children's attention was drawn to the animal by the experimenter saying "Look at the (animal)! Let's see what the (animal)'s ball will do!". The motion clip was then played and remained on the screen; then the experimenter asked the child to describe what the animal's ball did. The children completed at least three practice trials before beginning the experiment.

Coding Each linguistic description for the Front and Back relations was first coded for the presence of a target preposition that had to correspond to the type of scene (goal/source). For Front (goal scenes), the target prepositions were in front of/to front of in English and brosta apo/brosta sto 'in front of' in Greek. For Front (source scenes), target prepositions included from (in) front (of) in English and (apo) brosta (apo) '(from) front (of)' in Greek. For Back (goal scenes), the target prepositions included behind, to back/in back in English and piso (apo)/apo piso 'behind' in Greek. For Back (source scenes), the target prepositions included from behind in English and apo piso (apo) 'from behind (of)' in Greek.

The linguistic descriptions were also coded for the presence of spatial expressions of visibility or occlusion. For the Front relation, there were no expressions encoding visibility. This fact is highly significant, and we return to it in the Results section. For the Back relation, we coded predominantly appearance/disappearance verbs that encoded occlusion (or, more accurately, a change of state from or to occlusion): disappear and hide (goal scenes), appear, emerge (source scenes) in English, and hanome 'disappear', krivome 'hide' (goal scenes) and emfanizome 'appear', apokaliptome 'reveal oneself' (source scenes) in Greek.

Finally, all linguistic descriptions of Front and Back relations were coded in terms of the total target spatial information they contained (i.e., target preposition or occlusion expression). This was done because there was often overlap in the use of target prepositions and other expressions to describe an event (e.g., in Greek I bala krivete piso apo to pehnidi 'the ball is hiding behind the toy'), so analyzing each separately might not accurately represent the way Front and Back relations are linguistically represented.

## Results and discussion

In three separate analyses, we test the competing predictions of the conceptual immaturity and the pragmatic account in terms of (a) the use of front/back prepositions, (b) the use of a broader set of visibility/occlusion expressions, (c) the use of the devices in (a) and (b) combined.

## Use of front vs. back prepositions

Beginning with prepositions, we performed a mixed $2 \times 2 \times 2$ ANOVA with Relation (Front, Back) as a within subjects factor, Age (children, adults) and Language (English, Greek) as between subjects factors, and the proportion of target prepositions as the dependent variable. The analysis yielded a significant main effect of Relation $(F(1,76)=11.29, p=$ $.001, \eta^{2}=.13$ ): participants, overall, mentioned Back prepositions more frequently than Front prepositions ( $\mathrm{M}_{\mathrm{F}}=$ $\left..35, \mathrm{M}_{\mathrm{B}}=.45\right)$. The analysis also yielded a main effect of Age $\left(F(1,76)=70.65, p<.001, \eta^{2}=.48\right)$ : unsurprisingly, adults used more prepositions than children ( $\mathrm{M}_{\mathrm{CH}}=.17, \mathrm{M}_{\mathrm{AD}}=.65$ ). Finally, the analysis returned a marginally significant effect of Language $\left(F(2,76)=3.55, p=.063, \eta^{2}=.05\right)$ in the expected direction: English speakers exhibited a small tendency to use more target prepositions than Greek speakers $\left(\mathrm{M}_{\mathrm{ENG}}=.50, \mathrm{M}_{\mathrm{GR}}=.29\right)$. The ANOVA did not show any other effects or interactions.

## Use of visibility vs. occlusion terms

We moved beyond front/back prepositions in the two languages under study to consider a broader set of expressions encoding visibility for Front and occlusion for Back relations. As already mentioned, across ages and languages, there was a great variety of expressions encoding occlusion in Back scenes in the present dataset, but no expressions encoding visibility in Front scenes. We, thus, analyzed only expressions marking occlusion (since visibility was not encoded). A two-way factorial ANOVA, with the proportion of occlusion expressions as the dependent variable and Age and Language as factors, returned a main effect of Language $\left(F(1,76)=10.51, p=.002, \eta^{2}=.12\right)$ : because the occlusion expressions were mainly verbs, Greek speakers used occlusion expressions more frequently than English speakers $\left(\mathrm{M}_{\mathrm{ENG}}=.38, \mathrm{M}_{\mathrm{GR}}=.60\right)$. Crucially, the ANOVA did not yield an effect of Age $(F(2,76)=0.87, p=.769$, n.s. $)$ : adults used occlusion expressions as frequently as children.

## Use of total Front vs. Back information

Finally, to explore the predictions of the conceptual immaturity and pragmatic accounts at a more comprehensive level of spatial encoding, we analyzed the proportion use of total spatial information (target prepositions and occlusion expressions) to mark Front and Back relations. We conducted a mixed $2 \times 2 \times 2$ ANOVA with Relation (Front, Back) as a within subjects factor, Language (English, Greek) and Age (children, adults) as between subjects factors, and the proportion of total spatial information as the dependent variable (see Fig.2). Results yielded a significant main effect of Relation $\left(F(1,76)=137.42, p<.001, \eta^{2}=.64\right)$ and a main effect of Age $\left(F(1,76)=52.19, p<.001, \eta^{2}=.41\right)$, qualified by an Age by Relation interaction $(F(1,76)=11.53, p=.001$, $\eta^{2}=.13$ ). T-tests within each relation revealed that the interaction was due to the fact that although adults used a higher amount of spatial information for both the Front and Back relations than children ( $p \mathrm{~s}<.001$ ), this difference was smaller for the Back relation $\left(\mathrm{M}_{\text {FRONT_DIFF }}=.47 \mathrm{vs}\right.$. $\mathrm{M}_{\text {BACK_DIFF }}=.22$ ). Importantly for present purposes, spatial information was used more frequently to encode Back compared to Front relations by both age groups (children: $t(39)=-10.33, p<.001$; adults: $t(39)=-6.22, p<.001)$.

Total spatial information

Figure 5: Proportion of total spatial information given by English and Greek speakers for the Front and Back relations. Error bars represent standard error.

Overall, these results show that both children and adults encode Back information more frequently than Front information at the three levels of spatial encoding. The analysis of Front and Back prepositions showed an asymmetry in the use of 'front'- and 'back'-denoting prepositions in both age and language groups. Furthermore, the asymmetry generalized to a broader range of occlusion/visibility expressions: Back scenes often elicited expressions encoding the change to or from occlusion (e.g., verbs denoting appearance/disappearance), and these expressions were used equally frequently by adults and children. By contrast, Front scenes did not elicit any expressions encoding visibility in any age or language group. Finally, an examination of the total spatial information offered in Front and Back paths confirmed the conclusion that
asymmetries in encoding the two types of path are largely informational: both children and adult speakers of English and Greek marked Back paths more frequently than Front paths. These findings are in accordance with the pragmatic hypothesis, which allows for the asymmetry to be present in various age groups and at any level of spatial encoding.

## Study 2

In Study 2, we tested 14 native speakers of 10 languages (Cantonese, Dhivehi, German, Javanese, Korean, Pashto, Malay, Spanish, Swahili, Turkish) on a paradigm almost identical to that in Study 1. We included both satellite-framed languages that, like English, tend to encode motion paths in particles/non-verb elements, and verb-framed languages that, like Greek, tend to encode motion path information in the verb (Talmy, 1985). Our new sample was split almost evenly between these two language types (Spanish, Turkish, Korean, and Swahili are verb-framed, German, Cantonese, and Javanese are satellite-framed, and Dhivehi, Malay, and Pashto are of unknown type).

## Methods

Participants Native speakers of 9 languages (Cantonese, Dhivehi, German, Korean, Malay, Pashto, Spanish, Swahili, Turkish) were recruited from the graduate student population of the University of Delaware. All students were proficient in English as well as their native language and had spent on average 5 years in the US. Data from one additional language (Javanese) were collected at a site abroad (Jakarta, Indonesia); see Table 1 for all 10 languages and language families. One to two informants from each language were tested. The average age of the informants was 26 years. Participants received a $\$ 10$ gift certificate as compensation for their participation.

Table 1: Languages sampled in the cross-linguistic survey (with number of participating speakers), language families, countries of origin and typological classification in the motion domain

| Language | Language Family | Country | Motion Typology |
| :---: | :---: | :---: | :---: |
| Cantonese $(\mathrm{n}=1)$ | Sino-Tibetan | China | S-Framed |
| Dhivehi ( $\mathrm{n}=1$ ) | Indo-Aryan/IndoEuropean | Maldives | Unclassified |
| German ( $\mathrm{n}=2$ ) | Indo-European | Germany | S-Framed |
| Indonesian/ <br> Malay ( $\mathrm{n}=2$ ) | Austronesian | Malaysia | Unclassified |
| Javanese $(\mathrm{n}=1)$ | Austronesian | Central Java | S-Framed |
| Korean $(\mathrm{n}=1)$ | Altaic | Korea | V-Framed |
| Pashto $(\mathrm{n}=1)$ | Indo-Iranian/IndoEuropean | Pakistan | Unclassified |
| Spanish ( $\mathrm{n}=2$ ) | Indo-European | Mexico, Columbia | V-Framed |
| Swahili $(\mathrm{n}=1)$ | Niger-Congo | Tanzania | V-Framed |
| Turkish $(\mathrm{n}=2)$ | Altaic | Turkey | V-Framed |

Materials The same motion events as in Study 1 were used but with one additional event for each relation (shown in both a source and goal version) for a total of 64 stimuli.

Procedure The procedure was the same as in Study 1 except that participants entered the descriptions of the events in a spreadsheet using their native language. These descriptions were glossed at a later stage by the participants and coded by the experimenters. Further interviews with participants were held to resolve any coding questions.

## Results

To compare the two contrasting predictions of the conceptual immaturity and pragmatic accounts, we recorded how frequently 'front' and 'back' adpositions (prepositions and postpositions) and visibility and occlusion expressions were used in Front and Back scenes cross-linguistically, averaging across informants of the same language (see Table 2). Beginning with adpositions, numerical data showed that in 6 out of 10 languages (German, Javanese, Korean, Malay, Spanish, and Turkish) 'back'-denoting adpositions were mentioned more frequently than 'front'-denoting adpositions, while in 3 languages (Dhivehi, Pashto, and Swahili) both types of adpositions were mentioned equally frequently. The opposite pattern was exhibited in the remaining language (Cantonese).

We also inspected the proportion of expressions indicating visibility (in the context of Front scenes) and occlusion (in the context of Back scenes). This inspection revealed that there were no visibility expressions for Front in any of the languages surveyed but occlusion expressions for Back occurred in 8 of the 10 languages in the sample (e.g., verbs with meanings such as 'hide', 'appear'/‘disappear' etc.).

Table 2: Percentage of adpositions and expressions of visibility and occlusion used for the FRONT and BACK relations across languages

| Language | FRONT <br> Adpositions | BACK <br> Adpositions | Visibility <br> Expressions | Occlusion <br> Expressions |
| :--- | :---: | :---: | :---: | :---: |
| Cantonese <br> $(\mathrm{n}=1)$ | 62.5 | 50 | 0 | 0 |
| Dhivehi <br> $(\mathrm{n}=1)$ | 100 | 100 | 0 | 50 |
| German <br> (n=2) | 75 | 100 | 0 | 0 |
| Javanese <br> $(\mathrm{n}=1)$ | 0 | 50 | 0 | 37.5 |
| Korean <br> (n=1) | 12.5 | 100 | 0 | 100 |
| Malay <br> $(\mathrm{n}=2)$ | 25 | 100 | 0 | 12.5 |
| Pashto <br> (n=1) | 100 | 100 | 0 | 100 |
| Spanish <br> $(\mathrm{n}=2)$ | 87.5 | 100 | 0 | 100 |
| Swahili <br> $(\mathrm{n}=1)$ | 100 | 100 | 0 | 12.5 |
| Turkish <br> $(\mathrm{n}=2)$ | 87.5 | 100 | 0 | 62.5 |

Overall, the present cross-linguistic data largely replicated the key findings from Study 1. Adult speakers of 9 different languages (with the exception of the Cantonese speaker) used 'back'-denoting adpositions and/or occlusion expressions more frequently than 'front'-denoting adpositions. Similarly to the English and Greek data, there were no expressions denoting visibility for Front scenes in any of the languages in this wider cross-linguistic dataset. Despite the limitations of working with such low numbers of informants, this set of data presents suggestive evidence that our developmental conclusions from Study 1 generalize across languages.

## General discussion

Previous research shows that the acquisition of spatial language follows a stable, potentially universal, crosslinguistic timetable. However, the precise factors involved are not always clear. The acquisition of the locatives front and back is a case in point. Across languages, the locative back is produced earlier and is more frequent than the locative front. This asymmetry has been attributed either to a conceptual/semantic asymmetry in the early meanings of these locatives (with back being more basic than front; conceptual immaturity account) or to the fact that Back configurations are inherently more 'noteworthy' than Front configurations (pragmatic account). The present study put these two accounts to test.

Results showed that, in Study 1, both children and adult speakers of English and Greek typically used more Back than Front prepositions. Furthermore, speakers of all age and language groups often encoded Back information in occlusion verbs (e.g. hide) but no such verbs were available for Front. Study 2 provides suggestive evidence that the English and Greek developmental findings extend to a wider cross-linguistic sample of adult speakers of 10 additional languages. Taken together, these data support the predictions of the pragmatic hypothesis over those of the conceptual immaturity hypothesis.

Why do speakers prefer to encode Back over Front? On a pragmatic account that treats spatial language production as a form of communication governed by broadly Gricean (1975) or post-Gricean (Herskovits, 1985; Levinson, 2000; Sperber \& Wilson, 1985/1995) pragmatics, speakers need to mark occlusion (or the change to/from occlusion in our dynamic stimuli) so that the location (or path) of the Figure can be identified correctly by a hearer, even if the hearer has no visual access to the scene. By contrast, visibility for Front (or no change of visibility in our stimuli) is a default situation that speakers are less likely to mark. In our stimuli, speakers used many other alternatives instead of 'front' (e.g., 'beside', 'near', 'to/from the middle of'). It is possible that the bias favoring Back might be supported by non-linguistic factors relating to how occlusion is represented (e.g., see Hespos, Gredebäck, von Hofsten, \& Spelke, 2009; Spelke \& von Hofsten, 2001).

The present results have intriguing implications about the nature of spatial language acquisition and use. According to traditional theories of linguistic and cognitive development,
the order in which children acquire spatial locatives (and other non-spatial vocabulary) is considered as an index of conceptual growth (e.g., see E. Clark, 1973; Bowerman, 1996; Huttenlocher, Smiley, \& Charney, 1983; Johnston \& Slobin, 1979). Our results raise the possibility that pragmatic pressures, which are active in adult communicators as well, can also shape the way spatial language is acquired and used. Furthermore, our findings suggest that pragmatic factors may also yield cross-linguistically stable, and potentially universal, patterns of spatial language use. Interestingly, the pragmatic preference to encode Back over Front may also affect the shape of cross-linguistic spatial semantic systems. In an extensive cross-linguistic report, Levinson and Wilkins (2006) state that, if a language has a 'front'-denoting locative it will necessarily have a 'back'-denoting locative but the reverse pattern does not occur. The way pragmatic considerations interact with conceptual and other factors to shape spatial language acquisition and use crosslinguistically is a rich avenue for future research.

## Acknowledgement

We wish to thank Gaby Hermon and Tom Conners for help with the Javanese data. This material is based upon work supported by the National Science Foundation under grant no. 1632849. M.J. is now with Community Research Partners in Columbus, Ohio.

#### Abstract

Magicians often rely on misdirection to fool their audience. A common way to achieve this is for the magician to provide a plausible and intuitive (but false) account of how an effect is performed in order to prevent spectators from uncovering the truth. We hypothesized that analytical thinkers would be more likely than intuitive thinkers to seek alternative explanations when observing a mental magic effect because generating a coherent explanation requires analytical thought. We found that while intuitive thinkers often espoused explanations for a magic trick similar to one provided by the magician, analytical thinkers tended to generate new explanations that echoed rational principles and relied on physical mechanisms (rather than mental capabilities). This difference was not predicted by differences in numeracy skills or need for cognition.

Keywords: cognitive style, misdirection, CRT, dual process theory of reasoning.

## Introduction

Renewing a research program as old as scientific psychology itself (Binet, 1894; Triplett, 1900), in the last decade a new research program has emerged that uses illusionism and magical effects to investigate how the mind works (Kuhn, Amlani, \& Rensink, 2008; Kuhn \& Land, 2006; Kuhn, Olson \& Raz, 2016; Macknik, MartinezConde, \& Blakeslee, 2010; Rensink \& Kuhn, 2015). Such efforts have mainly focused on the roles of perception, attention, and visual cognition, though a limited number of studies have examined the relationship between higher-level cognition and illusionism (Danek et al., 2014; Olson et al., 2015; Subbotsky, 2010). Nonetheless, there may be a deep connection between cognitive styles of thinking and the way in which people explain a magical effect.

Ekroll and Wagemans (2016) wrote "[illusionists'] ultimate aim is to design miracles, not mere illusions. That is, the magician's first question is how they can create the illusion of impossibility. Relatedly, the magician's second question is how they can make sure that nobody is able to figure out how it was done. That is, they are essentially aiming to construct a problem that is as difficult to solve as possible, given the fundamental principles of human
problem solving" (p. 486). These goals are mainly addressed by using misdirection: the act of manipulating the spectator's attention away from the actual cause of a magic effect (Kuhn et al., 2014). From a psychological point of view, misdirection can be achieved through the manipulation of variables related to at least three different processes: perception, memory and reasoning.

Kuhn et al. (2014) describe the role of perception and memory in detail, but the authors pointed out that misdirection of reasoning and beliefs is loosely defined and harder to describe. However, virtually all areas of illusionism employ techniques based on the dual process theory of thought (Evans \& Over, 1996; Sloman, 1996; Stanovich \& West, 2000) distinction between analytical (i.e., a slow and effortful form of deliberative thought) versus intuitive (i.e., a fast and effortless form of associative thought) thinking. When a magician interacts directly with a spectator, their actions, dialogue, and other aspects of the performance are aimed at prompting fast, effortless, associative, and nearly-automatic responses. For example, in the classic force, a spectator is asked to pick a card. The choice appears to be at the discretion of the spectator; however, the magician has actually chosen a predetermined card that he "forces" the spectator to pick. The force is obtained by placing the chosen card directly in the hand of the spectator in a way that seems as if it were a random choice. The timing and the naturalness of the magician's movements are crucial factors in getting the participant to "choose" the predetermined card. From a psychological point of view, the success of the force depends on triggering an intuitive-based response-that the participant actually has a choice-and crucially, avoiding an analytical response that could lead the participant to choose a different card (such as one located at the extremities of the fan of cards). The renowned card magic conjuror Roberto Giobbi suggests a series of verbal and non-verbal techniques that stimulate a quick and automatic response (Giobbi, 1995). For example, make a person feel comfortable and then abruptly ask for a card. When this happens in front of an audience, the person may feel pressured to comply quickly or risk embarrassment in front of the public for not having completed such a simple assignment.

Mental magic attempts to create the illusion of impossibility by simulating supernatural mental abilities (e.g., telepathy, clairvoyance, psychokinesis, mediumship, and so on) and, as opposed to more traditional magic areas (such as card magic), sleight-of-hand or object manipulation skills cannot be taken into account as a possible explanation. More recently, given the cultural and educational changes in Western society, supernatural-based explanations have become unrealistic for a general audience-although intuitive thinkers are more likely to hold supernatural (Bouvet \& Bonnefon, 2015) and paranormal (Pennycook et al., 2012) beliefs. Instead, the mental magic effects are explained in terms of natural skills, such as the ability to reliably read non-verbal signals, body language and subliminal manipulation of others behaviors by means of psychological suggestion. Even if such abilities are not $100 \%$ reliable and in many cases are not sufficient for explaining the observed effect, people generally accept that mental magic is due to highly trained psychological skills. Mentalists will adopt many subtle techniques in order to promote the default, most intuitive or automatic explanation and to avoid promoting alternative explanations. Analytical thinking could help the observer to contemplate alternative hypotheses (such as the use of physical devices or the presence of an accomplice) as well as the weaknesses of the assumed explanation based on the highly developed psychological ability of the mentalist (such as the unreliability of method).

Because magicians rely on intuitive explanations to sell the illusion, individuals prone to analytical thinking may be less susceptible to these tricks. Can individual differences in cognitive style predict the explanations given to a mental magic performance? Adopting a common methodology adopted from the dual process theory literature (Gronchi et al. 2016; Zemla, Steiner, \& Sloman, 2016), it is possible to investigate the relation between cognitive style (predisposition to adopt analytical vs intuitive thinking) with the explanation given to a mental magic effect. We seek to establish whether analytical thinking affects the explanations produced by spectators of a magic trick. We predict that observers adopting an analytical cognitive style are more able to inhibit the default, mental power-based explanation suggested by the mentalist.

## Experiment

We investigated whether an individual's cognitive style affects judgments about a mental magic effect. Participants watched a video where an expert mentalist performed a prediction effect (predicts a purported "free" choice made by the spectator), and were then prompted to explain the effect they just witnessed. In addition, participants made several judgements, such as whether it was easy to generate an explanation, whether they were surprised by the outcome of the effect, and whether they enjoyed the trick. On a separate day, participants completed an extended version of the cognitive reflection test (CRT; Frederick, 2005) used to measure the cognitive style and other related measures.

## Method

Participants 335 freshmen college students (71 male, 29 unknown) enrolled in the Psychology major of the University of Florence were recruited for course credit. The sample mean age (in years) was $19.5(\mathrm{sd}=2.3)$, range $18-46$ (29 of unknown age).

Materials and procedure Participants completed a Mental Magic Task and four other questionnaires: an extended version of the CRT questionnaire, the Need for Cognition (NFC) questionnaire, an abbreviated Numeracy Scale, and three questions about Science Interest. All materials were presented to participants in Italian and are translated here for the reader.

On day 1 of the experiment, participants completed an extended version of the CRT questionnaire (Toplak, West \& Stanovich, 2014; Zemla, Steiner, \& Sloman, 2016). The CRT scale is comprised of questions that have a wrong but intuitive answer in addition to a correct answer that requires analytical thinking. For example, one question states: In a lake, there is a patch of lily pads. Every day, the patch doubles in size. If it takes 48 days for the patch to cover the entire lake, how long would it take for the patch to cover half of the lake? The default, intuitive response is 24 days (if 48 days is the time necessary to cover the entire lake, half of 48 should be intuitively the time necessary for covering half the surface). However, if the responder inhibits such response, it is relatively easy to see that every day the patch doubles in size, so on the $47^{\text {th }}$ day the lake was half covered and on the $48^{\text {th }}$ the lily pads will cover the entire surface. So, the inhibition of the most obvious response allows to adopt a deliberation-based form of thinking. The number of correct answers on the CRT measures the degree to which participants engage in analytical thinking and inhibit intuitive responses. Participants completed the 7 -item CRT scale in an open-ended format (except for the last item which was a multiple choice question).

On the same day, participants also completed three multiple choice questions about Science Interest inspired by the Science Curiosity Scale (Landrum et al., 2016): 1) Which of the following do you most like to read? Possible answers: fiction, science, sports, politics, history, other. 2) Let's suppose that it's necessary to take a mandatory class (which will not influence your grade; only attendance is necessary). Which of the following topic would you like to take? Possible answers: Contemporary history, Creative writing, Physics and Astronomy, Cinema and Arts. 3) Let's suppose that you are travelling for business in an abroad city that you have already visited and known. You have a free afternoon and you have time to do only one of the following activities (free and equally near to your hotel): Possible answers: Visiting the science museum, visiting the contemporary art museum, watching a show in a square, relaxing in a park, stay in the hotel to rest. Thus, for each question, there was an answer indicating interest toward science. The scale is intended to avoid socially desirable
responses that may be elicited from other science interest scales.

On day 4, participants completed a six-item numeracy scale (Weller et al., 2013) that evaluates one's competence in solving numerical problems (i.e., basic numerical operations, percentages). Given that CRT also measures numerical abilities as well as of inhibition of the intuitive response, we included the Numeracy Scale in order to exclude the possibility that an effect is due to numeracy and not cognitive style. On the same day, participants also completed the Need for Cognition scale (NFC; Cacioppo \& Petty, 1982). The NFC measures the tendency to enjoy and engage in challenging cognitive activities. Indeed, some people have little motivation and tend to avoid effortful cognitive activities whereas other individuals consistently seek opportunities to engage such kind of tasks.

On day 8, participants watched a video about a mentalist's performance. The mentalist is talking with a spectator about free will and the possibility of predicting others' behavior. The mentalist then shows a chessboard with the pieces in the starting position and asks the spectator to choose one of the pieces. The spectator, following the mentalist's directions, announces the chosen piece (a white bishop) and places it in the middle of the chessboard. The mentalist takes the chosen piece in his hands and begins to speculate about the factors that could have influenced the participant's choice: Did the white bishop have a particular significance? Was that particular bishop closer to the spectator compared to other bishops? Finally, the mentalist declares that he knew in advance that the spectator would take that particular piece and then invites the spectator to take another piece. The video ends with the revelation that every other piece besides the white bishop is stuck to the chessboard, so it would appear impossible that the participant could have chosen any other piece. Participants observed the video in a group, but they were also able to re-watch it using a smartphone or tablet. After watching the video, participants were individually asked to provide an explanation for the effect they just saw in an open-ended format. In addition, they answered each of the following questions on a 5-point Likert scale (from "not at all" to "extremely" for questions 1,2 and 4 and from "strongly disagree" to "strongly agree" for questions $3,5,6,7): 1$ ) How much did you enjoy the effect you just saw? 2) How much did it surprise you? 3) I tried to predict what the magician would do before he did it 4) How confident are you in your explanation? 5) It is easy to think of many alternative explanations for this effect 6) I would like to know how the effect actually works 7) I would like to see other magic effects.

## Data Analysis

For each participant, four scores were computed: a CRT score (the number of correct analytical responses out of 7), an NFC score, and a science interest score (giving 1 point for each answer related to science), and a numeracy score. The open format question ("How do you explain the effect you just saw?"), was coded using two different criteria. The
first criterion was based on physical explanation vs mental explanation. Physical explanations often contained reference to a physical device, such as glue or a magnet, but also include trivial solutions such as collusion between the mentalist and the spectator. Mental explanations were based on the possibility of behavior conditioning, the power of gestures, and the possibility of genuinely predicting in advance the spectator's choice (including supernatural powers). A third "other" category included no response, incomplete responses, and explanations not suitable to be categorized in previous terms (such as "I don't know"/"no idea").

A second criterion coded explanations as rational or irrational. Rational explanations included all the physical explanations that are actually feasible in practice, but also included statistical-based reasoning such as the possibility of predicting behavior with high probability on the basis of modal choices (obtained from experience). Irrational explanations were the same as the mental explanations excluding interpretations based on the statistical properties of people's choices (by means of previous empirical observations). Since all reported physical explanations were feasible ways of obtaining the effect, no physical explanations were coded as irrational. Again, an "other" category was included for coding no response, incomplete responses or other explanations not suitably categorized in previous terms. Two independent judges coded each explanation according to the two criteria. A third, independent judge broke any ties ( 5 out of 335 for the first criterion and 22 out of 335 for the second criterion).

## Results

Explanations of the magic effect With regard to the physical/mental dichotomy, the most common explanation (about 70\%) was a mental explanation based on the belief that the magician could systematically influence other people choices, such as "the mentalist implicitly and secretly conditioned the choice of the spectator." In several cases, participants added details such as "with gestures", "with his voice", "with his gaze", "with his mind", "with his movements," and so on. Only $13 \%$ of participants explained the effect in terms of a physical device (e.g., a special, delayed-effect glue; a magnet-based mechanism) or with a trivial solution (the spectator is an accomplice). The remaining $17 \%$ of responses were classified as "other".

With regard to the rational/irrational dichotomy, all of the physical explanations were included in the rational category and the majority of the mental explanations were categorized as "irrational". However, some of the mental explanations were included in the "rational" category. These were explanations based on the belief of influencing other's choice by subtle psychological techniques together with some rational considerations. For example: "The mentalist did a lot of trials before with other people to look for the most chosen piece. When facing the spectator, the mentalist someway suggested with his gaze to take the most likely piece. I think the mentalist has been very lucky." or "The
mentalist knows which piece is generally chosen most often. He exploited such knowledge together with his ability to influence spectator choice. Maybe he was not certain of the final result, but it was the most likely result." According to the rational/irrational dichotomy, the rational explanations were about $20 \%$ and the irrational explanations were about $63 \%$. The remaining $17 \%$ were classified as "other".

Explanations types and analytical style We evaluated whether CRT scores were correlated with the type of explanation produced (Figures 1 and 2). As predicted, those who generated a physical explanation (compared to a mental explanation) tended to have higher CRT scores, $t(70.1)=$ $12.89, p<.001$. Likewise, participants who wrote a rational explanation had higher CRT scores compared to those who wrote an irrational explanation $t(105.7)=13.61, p<.001$.

Figure 1: Participants who generated physical explanations typically had higher CRT scores (more analytical).

Figure 2: Participants who generated rational explanations typically had higher CRT scores (more analytical).

Explanations types and Numeracy Scale Unlike CRT, numeracy scores did not predict the explanation type that
participants generated. Participants who generated physical compared to mental explanations did not differ in numeracy, $t(34.2)=.33, p=.74$, nor did participants who generated rational compared to irrational explanations, $t(73.9)=.27, p$ $=.79$. This rules out the possibility that the observed CRTrelated differences can be due to disparity in numerical ability.

Explanations types and Need for Cognition There were no differences in the NFC score between those who generated physical and mental explanations, $t(33.2)=.11, p$ $=.91$, or between those who generated rational/irrational explanations, $t(80.8)=1.26, p=.21$. This rules out the possibility that the observed CRT-related differences can be due to different inclination towards effortful cognitive activities.

Explanations types, science interest and analytical style Participants that wrote a physical explanation had a greater score in Science Interest compared to those that wrote a mental explanation, $t(55.3)=2.65, p=.011$. Similarly, participants who wrote a rational explanation had a greater interest in science, $t(94.97)=2.36, p=.021$. Science Interest was also significantly correlated with the CRT, $\mathrm{r}=$ $.35, p<.001$.

Explanation types and correlations among the questions of the Mental Magic task We expected that the way in which participants explained the effect would influence their response and enjoyment of the effect. However, we found that the type of explanation produced did not predict enjoyment of the effect, the surprise experienced, the attempt to predict the effect, the confidence in the explanation given, the ease of thinking of different explanations, the desire to know how it works, or the desire to see a new effect (all $p>.1$ ). Similar results were obtained for the rational/irrational dichotomy. However the questions about the Mental Magic effect were correlated among themselves (Figure 3). Having enjoyed the effect correlated with all other variables in the mental magic task except the confidence of the given explanation. The degree of surprise was highly correlated with enjoyment of the trick ( $\mathrm{r}=.45$ ), the desire to know how the trick was performed $(\mathrm{r}=.33)$ and desire to see new magic effects ( $\mathrm{r}=.34$ ). Attempts to predict the mentalist's actions during the effect was weakly correlated with the ease of generating an alternative explanation after the effect $(r=.07)$, the desire to know how the trick was performed ( $\mathrm{r}=.14$ ), and desire to see new magic ( $\mathrm{r}=.12$ ). The highest correlation was between the desire to know how the trick was performed and the desire to see new magic $(r=.65)$. All correlations reported above were significant with $p<.05$, uncorrected for multiple comparisons.

Figure 3: Correlations among the enjoyment of the effect (enjoyment), the surprise experienced (surprise), the attempt to predict the effect (prediction), the confidence in the explanation given (confidence), the easiness of thinking of alternative explanations (ease of explanation), the desire to know how it was performed (know the trick) and the desire to see a new effect (new). Correlations with CRT, NFC,
Numeracy skills and Science Interest are also reported.
Analytical style and Mental Magic task questions The CRT was marginally correlated with the interest in seeing new magic ( $\mathrm{r}=.10, p=.08$ ), significantly correlated with attempts to predict how the trick was done $(\mathrm{r}=.11, p=$ .004 ), and significantly correlated with enjoyment of the mental effect ( $\mathrm{r}=.14, p=.01$ ).

NFC and Mental Magic task questions Similarly to CRT, Need for Cognition was correlated with the interest in seeing new magic ( $\mathrm{r}=.21, p=.01$ ), attempts to predict the next move of the mentalist ( $\mathrm{r}=.21, p=.01$ ), and with the enjoyment of the mental effect ( $\mathrm{r}=.18, p=.04$ ). The NFC was also marginally correlated with the interest in how the trick was performed ( $\mathrm{r}=.15, p=.07$ ).

Science Interest and Mental Magic task questions Science Interest was significantly correlated with attempts to predict the actions of the mentalist $(\mathrm{r}=.12, p=.029)$.

## Discussion

We found that analytical thinking predicts the way people explain a mental magic effect: intuitive thinkers were more inclined to explain a mental magic effect in the same terms suggested by the mentalist (e.g., conditioning the spectator's choice or advanced psychological ability), whereas analytical thinkers were more likely to explain the observed
effect by referring to a physical device or trivial tricks (such as collusion, i.e., a previous agreement between the mentalist and the spectator). The same pattern also held when "rational" considerations were taken into account in the categorization of the explanations: analytical thinkers were more inclined to seek an alternative explanation and reject an irrational explanation offered by the mentalist. We also found that these same differences in explanation type were predicted by interest in science, perhaps due to an aversion towards non-scientific (irrational) explanations. Moreover, we observed that such differences between analytical and intuitive thinkers were not due to related constructs such as numeracy skills or need for cognition

Although the explanation that a participant offered did not affect the way they perceived the trick (i.e., it was not correlated with any of the mental magic task questions), analytical style did predict differences. Analytical thinkers were more likely to predict the next step of the performance, suggesting that they were trying to go deeper into the effect not only at the end of the performance but also during the trick itself. This deeper level of engagement may be the reason why analytical thinkers also enjoyed the magic effect more, and expressed more interest in seeing new magic. We also found that being an analytical thinker was associated with an interest in science.

A limit of the present study is its reliance on correlational data. We are planning to further investigate this topic by manipulating the cognitive style to verify whether inducing analytical thinking will prompt participants to generate alternative rational explanations. Moreover, it is important to note that the sample was composed of Italian freshmen psychology students in their first days of college: commonly, those students have high expectations about the capabilities of psychology, including the skills that mentalist's performance suggests. This may explain the bias to provide mental explanations in our sample, although it does not explain the main effect of analytical thinking on explanation type. Another critical aspect is that we employed a single performance that was either interpretable in terms of advanced psychological skills and in physicaldevice terms in a relatively easy way. In other kinds of performances, it could be more difficult to think of rational/physical device-based explanations.

This work represents a first-step in the psychological investigation of magical effects in cognitive terms going beyond the more common perception and attention-based perspectives. The already existent but still limited literature about high-level cognition and magic may greatly benefit from our understanding of reasoning-based misdirection in terms of dual process theory of thought. In particular, such benefits can go in two opposite directions: psychological studies on cognitive styles (and dual process theory) may employ mental magic effects and magician's misdirection techniques to create unique and innovative experimental settings and, at the same time, conjurors may rely on the dual process theory of thought to improve their performance.

## Acknowledgments

Many thanks to Stefania Righi and Fiorenza Giganti for judging the open format questions. We are also in debt with Rachele Massini (who was also the third judge), Giacomo Fini, Daniele Lari, and Eleonora Falciani for collecting data. This work has been motivated also by fruitful discussions during La Corte dei Miracoli - House of Magic meetings.

#### Abstract

An experiment aiming to assess the use of stopping rules in information acquisition was performed. Participants were requested to make a decision in 24 financial scenarios with the possibility of buying information pieces. Behavioral and EEG data were recorded for analysis. Results showed that participants followed Bayesian calculations in order to determine a stop on information acquisition and decide. Moreover, the information acquisition strategies were consistent with prospect theory, in which participants will weigh information pieces differently and seek more or less information given different manipulations in scenario probability and consequences. EEG data suggest Slow Cortical Potentials at fronto-central electrodes.

Keywords: decision making; information acquisition; EEG; slow cortical potential.

## Introduction

As Taghavifard, Damghani and Moghaddam (2009) discuss, it is only possible to know the risks inherent in a decision if the individual has a relatively small degree of uncertainty. One way to diminish levels of uncertainty is by reducing residual uncertainty (Courtney, Kirkland \& Viguerie, 1997) through information acquisition. To acquire information is to search both internally and externally for elements that can affect the decision process. In their daily lives individuals receive a considerable amount of information through various modalities. Auditory, visual, tactile, emotional stimuli can be sources of new information. Each piece of information has some importance toward deciding either by improving the quality and quantity of information or by impairing an individual's ability to decide given that the amount of information is so great that the performance will be deteriorated (Di Caprio, Santos-Arteaga, \& Tavana, 2014). When information reveals itself and is processed by the decision maker, we find a transition from a situation of uncertainty to a situation of risk. In other words, the
decision maker now knows enough information about the problem so that he is able subjectively infer a probability for each outcome (Di Caprio et al., 2014).

Pretz, Naples, and Sternberg (2003) discuss the role of experts and the fact that too much information can actually impair the decision process. They propose that when an expert (a person that possesses a great deal of knowledge, acquired by experience and information gathering) in chess plays with slightly different rules, his performance might actually be worse than that of a player that is new to chess and plays the same modified game as the expert. This suggests that when an otherwise static environment becomes dynamic, a difficulty in deciding might appear. Too much information may be suboptimal for a decision maker (Di Caprio et al., 2014), whereas not enough information will prevent him from calculating risks properly and brings the decision process to one of most uncertainty (Taghavifard, Damghani \& Moghaddam, 2009). On the other hand, Frey, Hertwig and Rieskamp (2014) propose that there is no way to determine when the right amount of information is reached and no further acquisition needs to be done, at least in decisions from experience, although they also say that there may be benefits in small samples and frugal search. The question that remains is: how does a decision maker knows that he/she acquired enough information to go through with the process?

Many researchers are investigating the subject of information acquisition and how and when individuals stop searching for new information and proceed to decide. Gigerenzer (2000) proposes a fast and frugal way to decide in environments where both time and knowledge are restricted. By searching past information and knowledge in order to recognize elements regarding the decision and cues about those elements, the Take the Best (TTB) heuristic searches for the best cue in order to make a choice. In the experiments by Gigerenzer (2000), when people where
asked which of two German cities was the most populated, individuals would most likely use TTB in order to decide. Even so, the individual might seek other cues about each city from memory (i.e., perhaps if he saw the city on the news). According to the subjective validity of the cues, the one with the highest ranking is considered the best and thus appropriate for a decision. Little information search and acquisition are performed. Stern, Gonzalez, Welsh, and Taylor (2010) conducted and experiment in which individuals were presented with two decks with varying proportions of red and blue cards. Four draws of cards were made and at each draw the individual would have to state from which deck the card had been drawn from. Each draw represented acquiring a new piece information about the decision. After all four draws the individual would have to make a final decision between the decks or they could decline to choose. It is clear that each new information presented changed or reaffirmed the decision made by the individual. When conflicting information was presented (two draws were red cards and two were blue) individuals mostly declined to choose, inferring a $50 \%$ chance to each deck. When all draws were the same color, by the third draw individuals were already $100 \%$ confident from which deck the draws were made. This experiment poses that information acquisition can update individual beliefs about the outcome and that searching for information might improve the decision making process by incrementing it with a better view about the problem at hand.

Fifić and Buckmann (2013) probed the use of stopping rules by individuals. Stopping rules might determine the moment where the decision maker stops, or should stop, searching for information and actually decide. The authors reviewed some options of stopping rules that might require higher or lower cognitive demands. The first one is the socalled optimal stopping rule for evidence accumulation. It is based on Bayesian inference and implies that there should be an optimal number of pieces of information that need to be acquired. In their example the optimal stopping rule is 3 . This number represents that the individual will search for positive $(+1)$ and negative (-1) pieces of information and will only stop searching when the sum of the search reaches either +3 or -3 , in which case the individual will choose the option represented by the positive or negative sum, in their example to proceed or not with a risky cancer treatment. There is criticism regarding this rule, in order to calculate the optimal number there is a need to have a perfect knowledge of the situation and enough calculating skills to solve it through Bayesian probability (Fifić \& Buckmann, 2013). This option requires great amounts of time, knowledge and cognitive effort. In most cases in the real world there are limited amounts of each available to the decision maker. They then propose a stopping rule selection theory based on bounded rationality.

Two rules are suggested that do not depend on high amounts of knowledge about the environment and the situation. The first one is the fixed sample size. This rule entails that the decision maker will determine a sample size
before the beginning of the information search process, for example five. The individual will then search for information and will make the choice based on the valence that appears the most (positive or negative). The other rule is called runs stopping rule. In this case the decision maker will begin the search for information without determining a fixed sample. She will stop searching when a streak of either positive or negative pieces of information is found, three consecutive positive opinions for example.
The stopping rule selection theory proposes that each individual might use different stopping rules given time and cognitive efforts available (Fifić \& Buckmann, 2013). That is because there is no evidence that one single stopping rule can account for all responses from individuals. According to Fifić and Buckmann (2013) each individual will search a decision operative space in which the rules and values are stored. Given a decision situation the individual will then retrieve a stopping rule - a process that the authors call castnet retrieval. Much like fishing, each individual will select a space and a net size to cast and retrieve a stopping rule that will be applied. What is considered in order to cast a net in the decision operative space is the level of uncertainty with the environment, time frame, cognitive demand, and accuracy expectancy (Fifić \& Buckmann, 2013). After the stopping rule is selected, the individual will then proceed to collect information and finally decide.
Cognitive demand and the search for a stopping rule might reflect high levels of task engagement. That is, the individual is fully focused on solving the problem and anticipates the outcomes of the decision given each new information. This situation represents higher use of brain resources, especially in frontal areas. Few studies focus their analysis on pre-stimulus ERPs, especially when decision making is concerned. Böckner, Bass, Kenemans and Verbaten (2001) studied one form of Slow Cortical Potential (SCP). They found a Stimulus-Preceding Negativity at fronto-central electrodes in fear-induced trials. Oswald and Sailer (2013) found fronto-central SCPs before and after response in a temporal discounting task.

Other elements also influence the information acquisition process. Frey, Hertwig and Rieskamp (2014) found that both a facial expression of fear or the subjective feeling of fear may cause an individual to search more information. Söllner, Bröder, Glöckner and Betsch (2014) discovered that when intruding incompatible information appears, individuals trained in the TTB heuristic would not stop searching for information when they were supposed to if following TTB. Individuals rather adapted their information search, choice and confidence judgment processes to the content of such intruding information. It is widely recognized that the amount of information available and acquired by each individual will augment complexity levels in the decision situation, much like what happened with the intruding information.

## Methods

The objective of this study was to probe, based on the models of Fifić and Buckmann (2013), Stern et al. (2010) and Söllner et al. (2014), the use of stopping rules in the information acquisition and evidence accumulation processes and its electrophysiological correlates. A financial decision task was devised so that the use of stopping rules could be measured by the amount of information acquired by the individuals in each of the scenarios. As with real world decisions, scenarios were presented with varying levels of risk, uncertainty and consequences. During the task, EEG was continuously recorded to investigate correlates of information acquisition and decision behavior processes. A total of 47 (mean age: 18.89, SD: 1.68, 33 females) undergraduates from the University of Michigan Pysch Pool participated. Data was collected from 50 participants, however 3 were discarded because of poor electrode readings interfering with the EEG data. This study was approved by the University of Michigan's Institutional Review Board.

## Financial decision task

Each participant was presented with all 24 financial decision scenarios. The scenarios were presented written in a single paragraph. In all scenarios participants would have to choose whether to accept or reject the proposed situation, but they could also choose not to decide at all (a procrastination behavior). For every scenario there were 20 information pieces (or advices) that a participant may or may not buy in order to help them decide. Participants were instructed to press the "I" key on the keyboard whenever they wanted to buy information in a scenario. All information was presented in a crescent and pseudorandom order. The order of information appearance was made to resemble the stopping rules tested by Fifić and Buckmann (2013). Each new information was presented using simply the words "positive" or "negative", thus diminishing the probability of bias. The words mean a positive or negative opinion about accepting or rejecting the proposition in the scenario. Each information had a price ( $\$ 1$ for the first 10 pieces and $\$ 2$ for the other 10 ). There was a fixed fictional amount of $\$ 480$ available to any participant to complete the experiment - this amount was created specifically to refrain participants from always buying all 20 pieces of information. They were instructed not to use all the money available.

Each scenario showed a situation involving aspects of financial decisions such as investments, purchases, asset management, losses, etc. After reading the description of the situation, participants could obtain (buy) information regarding that scenario. Even if not buying any information, participants would be required to make a decision for each scenario. They could decide to buy/invest/pay (Positive), not to buy/invest/pay (Negative) or to not decide at the moment (Procrastination). After a decision, there was no feedback on the success of it, and the next scenario was presented. Participants did not receive any instructions regarding a
maximum period of time to decide at each scenario. They were free to use as much time as they wanted to read the scenario description, seek information and make a decision. The 24 scenarios were divided as such: 1) 12 scenarios with stated probabilities (risk scenario) in the description, composed of 3 scenarios with low negative consequences, 3 with high negative consequences, 3 with low positive consequences and 3 with high positive consequences; 2) 12 scenarios with unstated probabilities (uncertainty scenario) in the description, composed of 3 scenarios with low negative consequences, 3 with high negative consequences, 3 with low positive consequences and 3 with high positive consequences.
One example of a stated probability, low positive consequence scenario is: "You are thinking about buying a bicycle. There is a model that is $35 \%$ better than the alternative. You don't know what the average maintenance costs might be. You must decide if you: buy the bicycle, don't buy the bicycle or rather not decide now.", as shown in Figure 1. The stated probability is the $35 \%$ chance depicted, low consequence is due to the amount ( $35 \%$ is considered a low chance), positive consequence is the referred chance of being better than the alternative. Scenarios differ in the presence or not of the stated probability, consequences and valences of consequences. That means that the example above might be presented in another form, representing an unstated probability, high negative consequence scenario, like: "... There is a model that is much worse than the alternative ". Phrasings of probabilities and consequences were randomized. That means that the object of the scenario would be the same (bicycle, student loan, car fixing, etc.), but the probabilities (stated or not), and consequences (high or low and positive or negative) were randomized across participants for any given object.
EEG data was recorded through Acknowledge 4.4 software using an ABM B-Alert X10, with a 9 channel setup (Fz, F3, F4, Cz, C3, C4, Pz, P3 and P4) using linked mastoid as reference. Data was collected at a sampling rate of 256 Hz . Electrode scalp impedances were kept below 5 $\mathrm{k} \Omega$. Behavioral data and stimulus presentation was made via PST E-Prime Professional 2.0. The data was analyzed using ERPLab (Lopez-Calderon \& Luck, 2014). Data went through moving window artifact detection and filtered for both low and high pass $(0.1 \mathrm{~Hz}$ and 30 Hz , respectively). ERP epoch was from -2000 ms before the decision was made and 200 ms after the decision was made, giving the possibility of observing variations that occurred in a window of time before the actual decision. The use of this epoch is justified given that the information acquisition process is over before the decision is actually made, so in order to analyze event related potentials of stopping rules it is necessary to observe what happens before the decision. Target electrodes were located at fronto-central sites in order to search for SCPs (Oswald \& Sailer, 2013). Mean voltage over a specific time epoch was used to analyze the data.

Figure 1: Example of a scenario.

## Results

In order to determine the use of stopping rules and strategies for information acquisition we focus our analyses on two measures: information quantity (QTY) and balance (BAL). Information quantity is the mean amount of information pieces that each individual bought during each scenario. The balance is, just as Fifić and Buckmann (2013) proposed, one of the stopping rules, the Bayesian calculation of the valences for each information bought. That is, if an information is positive, then the value considered is +1 , if an information is negative, then the value considered is -1 . At the end of a given scenario, for example, if the pieces of information acquired were 3 positives and 2 negatives (independent of order of appearance), the balance will be +1 . The conditions compared to the two measures were: decision (positive, negative and procrastination), probability (risk and uncertainty), and the combination of consequences (high or low) and valence of consequences (positive or negative) in risky and uncertainty.

## Information acquisition

Of the total of possible scenarios, $40.63 \%$ were decided without any kind of information acquisition, thus without the use of stopping rules. This behavior might emerge given the objects of the scenarios at hand. In order to better control the conditions, the objects of decision (car, bicycle, motorcycle purchase, student financial aid, home and car repair, investments) were less complicated. That might have made the decisions easier based on each individual set of preferences. However, there is no data to back this hypothesis. Next, there were $44.88 \%$ of the scenarios that were decided using 1 through 5 information pieces. The $14.50 \%$ of cases left used 6 through 20 information pieces.

## Decision

Regarding the decisions available for the participants, the mean information quantity gathered when a decision was positive is 4.11 , when a decision was negative also 4.11 and when participants decided to procrastinate the mean quantity was 5.04. That shows that, despite the fact that participants had up to 20 information pieces available they sought only a small amount. Also it shows that the procrastination behavior was observed with more acquisition of information. On the other hand, when the balance is considered, a positive decision was made with a mean balance of +1.13 , negative decisions -0.73 and
procrastination decisions -0.05 . That means that the information acquisition stopping point behavior is more influenced by the so called balance of the valences, regardless of the quantity of information acquired. A oneway ANOVA was conducted to test for differences between each decision. The test revealed that there is a difference between the decisions both for QTY and BAL, $\mathrm{F}(2,1146)=189.9, \mathrm{p}<0.001$ and $\mathrm{F}(2,1149)=6.35, \mathrm{p}<0.01$, respectively. Post-hoc analysis using Tukey HSD test revealed significant differences between all interactions: positive-negative $\quad(\mathrm{p}=0.001)$, negative-procrastination ( $\mathrm{p}<0.001$ ) and positive-procrastination ( $\mathrm{p}<0.001$ ) for the BAL measure and only negative-procrastination ( $\mathrm{p}<0.05$ ) and positive-negative ( $\mathrm{p}<0.05$ ) for the QTY measure.

## Probability

Analyzing only if the scenario presented risk or uncertainty, the only significant difference was observed in the BAL measure, $\mathrm{F}(1,1150)=4.75, \mathrm{p}<0.05$. The mean BAL for risk scenario was 0.031 . For uncertainty scenario the mean BAL was 0.262 . As for the QTY measure the mean value for the risk scenario was 4.263 and 4.100 for the uncertainty scenario.

## Combining the conditions

The conditions were not presented isolated to the participants. Combining the conditions yielded 8 possible scenarios, as it was previously explained, that were randomly presented three times each for the participants. If all conditions are analyzed there is a significant difference for the BAL measure $(\mathrm{F}(7,1128)=8.090, \mathrm{p}<0.001)$. A post hoc Tukey HSD test revealed significant differences between several of the possible combinations. However, two differences between conditions are of particular interest. The first one is between scenarios with uncertainty, low positive consequence $(\mathrm{M}=0.118)$ and scenarios with uncertainty, low negative consequence ( $\mathrm{M}=0.326$ ), with $\mathrm{p}<0.001$. The second one is between scenarios with risk, high positive consequences $(\mathrm{M}=0.007)$ and scenarios with risk, high negative consequences ( $\mathrm{M}=0.181$ ) with $\mathrm{p}<0.001$.

## EEG

EEG analysis focused on risky and uncertain scenarios and both of the combined conditions highlighted previously. As was discussed earlier SCP might emerge in a situation where there might be prolonged use of cognitive control and resources in fronto-medial electrodes (Oswald \& Sailer, 2013). As it was seen, BAL has significant differences in risky and uncertain scenarios and also in scenarios with different valences and consequences. That might point to the fact that prior to a decision individuals may exert more thought and allocate more cognitive resources to decide given the conditions presented.
The comparison between risky and uncertain conditions showed SCP negativity for the uncertain condition and a positivity for the risky condition in F4 between -950 ms and
-500 ms , with statistically significant difference $(\mathrm{F}(1,98)=5.847, \mathrm{p}<0.05)$ as shown in figure 2 .

Figure 2: SCPs in risk x uncertain condition in F4. Black line represents uncertain condition, red line risk condition. The ellipsis shows the point of the significant difference. Y axis represents micro voltages, X axis represents the epoch in milliseconds.

As for the comparison between risky and uncertain scenarios in a low consequence condition, we found a SCP negativity for the uncertain condition and a positivity for the risky condition in Fz and F4 between -1290 ms and -490 ms , with statistically significant differences for both electrodes $(F(1,98)=3.631, \quad \mathrm{p}=0.05$ and $\mathrm{F}(1,98)=4.720$, $\mathrm{p}<0.05$, respectively) as shown in figure 3 .

Figure 3: SCPs in risk $x$ uncertain, low consequence condition. Top part represents Fz electrode. The bottom panel depicts voltages in the F4 electrode. Black line is uncertain condition, red line is risk condition. The ellipsis shows the point of the significant difference. $Y$ axis represents micro voltages, X axis represents the epoch in milliseconds.

When high consequences are observed, there is a marginal statistical significance between a SCP positivity in risky conditions and a negativity in uncertain conditions in F4 between -920 ms and $-500 \mathrm{~ms}(\mathrm{~F}(1,98)=3.517, \mathrm{p}=0.06)$ as shown in figure 4.

Figure 4: SCPs in risk x uncertain, high consequence condition in F4. Black line represents uncertain condition, red line risk condition. The ellipsis shows the point of the significant difference. Y axis represents micro voltages, X axis represents the epoch in milliseconds.

## Discussion

Behavioral data suggests that the balance of acquired information (BAL), according to Bayesian calculations (Fifić \& Buckmann, 2013), is a preferred stopping rule. EEG data supports this conclusion given the fact that where BAL represented significant differences, there was the emergence of SCPs. According to Oswald and Sailer (2013), the SCPs are task-related and the negativity might mean conflict processing and the usage of cognitive resources to resolve such conflicts. Even though there was also a significant difference for the quantity of information bought and the decisions, consciously or not participants behave according to Bayesian calculation in order to determine the end of the information acquisition process.
This holds up even if the conditions are considered (combined or isolated). This means that the participants will take into account the valences of the information pieces acquired and when they reach a particular threshold (depending on the scenario characteristics), the decision is made. That becomes clearer when the threshold is approximately +1 for a positive decision, approximately -1 for a negative decision and approximately zero for a procrastination decision. The procrastination decisions show that even though there are more pieces of information acquired, participants often would feel more uncertain and would rather skip the decision. This means that that particular scenario and the set of information acquired would not diminish the residual uncertainty acknowledged by the participant, thus making it harder to assess which decision is better given the probabilities and consequences.

Uncertain scenarios needed less QTY and a higher BAL in order to reach a decision than risk scenarios. The appearance of the SCP negativity for uncertain scenarios can reflect a higher conflict in this condition given that, even though participants seek less information, they need higher valences to resolve the conflict. This conflict may arise due to the difficulty to assign a value to the unstated probability described in the scenarios. As in Stern et al. (2010) each new information can change the subjective probability that the participant assigns to the outcome. These changes can require more BAL and result in more use of cognitive resources in order to decide.

When conditions were combined, especially the two highlighted previously, the same effect is also present. In uncertain low negative consequence conditions there is the need for more BAL and there is also a SCP negativity although with higher amplitude than the one described on the last paragraph. This, according to Oswald and Sailer (2013), mean that there is an expanded cognitive effort in resolving the conflict that the valences and the condition might imply.

Lastly, in high negative consequence conditions, risky scenarios need more BAL, however, in high consequence conditions the SCP negativity is seen for uncertain scenarios. We hypothesize that the lack of stated probability in a high consequence scenario might mean that the information has a higher weight for the participants and therefore there is no need to allocate as much cognitive effort as with risky conditions. In this case, a stated probability might introduce some level of ambiguity given that the risk is apparent and the consequences can be large.

## Conclusion

We developed an experiment aiming to observe different strategies, or stopping rules, that individuals might use in order to cease information acquisition and make a decision in a given scenario. Departing from the stopping rules proposed by Fifić and Buckmann (2013), we manipulated scenarios in order to show or not show probabilities, high or low consequences and positive or negative consequences. The data suggests that individuals do not actually follow a particular stopping rule, rather they tend to use, consciously or not, Bayesian calculations in order to consider all the information that was bought in a scenario, when considering the decisions participants made. Moreover we found SCP waves for different conditions in the experiment. That can mean that for those conditions there was an expanded allocation of cognitive resources in order to solve conflicts that emerged from the information acquisition and the scenario description. Those manipulations showed that the information acquisition behavior resembled prospect theory (Tversky \& Kahneman, 1992) in that different levels of risk or uncertainty combined with high/low and positive/negative consequences will directly affect the quantity of information bought and the weight that the information will have in order for a participant to feel satisfied and proceed to a decision.

This was an exploratory experiment in order to study the moments leading to a decision in an information acquisition task. Further studies should focus on confirming the behavior and electrophysiological correlates of each condition separately. Also, there is an opportunity for the use of integrated psychophysiological measures in order to confirm task engagement and cognitive effort in those conditions (ECG and eyetracking, for example)

#### Abstract

Young children use informal strategies to solve arithmetic word problems. The Situation Strategy First (SSF) framework claims that these strategies prevail even after instruction. The present study was conducted with second grade students in order to investigate the persistence of intuitive, situationbased strategies, on word problems that do not involve dynamic temporal changes. This is challenging for the SSF framework, since the lack of this dimension might bypass intuitive strategies. The results revealed that intuitive strategies persist, are valid for these types of problems, and impact the problems' difficulty. Indeed problems that require the application of arithmetic principles remain hard, even though they have been practiced at school. These findings provide complementary evidence to how mental calculation strategies articulate with arithmetic word problem solving and call for the extension of the $S S F$ framework.

Keywords:arithmetic word problems; problem solving; informal strategies; solution strategies; education.

## Introduction

Even before instruction young children can solve arithmetic word problems by usinginformal strategies (Verschaffel\& De Corte, 1997). These informal strategies reflect the situation described in the problem and preclude the flexible application of mathematical principles like commutativity, inversion or distributivity (Verschaffel \& De Corte, 1997).During the early years of elementary school, children improve their numerical competencies and acquire certain mathematical principles, which could lead us to expect that newly acquired arithmetic competencies would take place over the informal strategies.

Indeed, numerous mental calculation strategies that schooled children develop to solve problems when presented in their arithmetic expression (e.g.'8-5=') have been documented (e.g. Carpenter, Ansell, Franke, Fennema, \& Weisbeck, 1993; Torbeyns, De Smedt, Ghesquière, \& Verschaffel, 2009). They are mainly determined by the arithmetic operation that provides the solution. For subtraction problems, the principal distinction bears between direct subtraction strategies in which the subtrahend is straightforwardly taken away from the minuend (e.g. in which '42-39 =' is solved by '42-39'), and indirect addition strategies in which the calculation consists in finding how much needs to be added to the minuend to reach the subtrahend (e.g. in which ' $42-39=$ ' is solved by '39 + . = 42'). In both of these strategies, the arithmetic
operation that is used is subtraction, it is just the arithmetic format that is different (Campbell, 2008). In order to describe how students use the two strategies, Peters, DeSmedt, Torbeyns, Ghesquière, and Verschaffel (2013) provided empirical support for their Switch model. According to this model, students solve two-digit subtraction problems by switching between direct subtraction and indirect addition depending on the combination of the magnitude of the subtrahend and the numerical distance between the subtrahend and the minuend.

Brissiaud and Sander (2010) investigated how these mental calculation strategies articulate with the informal strategies students use on arithmetic word problem solving. They proposed a Situation Strategy First (SSF) framework which posits that the initial representation of a problem activates asituation-based strategy, both before and after instruction. Only when this strategy is not efficientthe representation of the problem may be modified and a set of arithmetic principles may be applied in order to provide an adequate solution in a more efficient way. In their experiments, each problem was presented to second and third grade students in two versions. The first version could be efficiently solved by mentally simulating the actions described in the problem - situation strategy problems ( $\mathbf{S i}$ problems). For example:
I. Luc is playing with his 42 marbles at recess. During the recess, he loses 3 marbles. How many marbles does Luc have now? [42-3= .]
Problem I is an Si-problem because simulating the action of losing 3 marbles through mentally counting down from 42 is easy to perform( 41 (1), 40 (2), 39 (3)). Thus, a situation-based solving strategy, modeling the described situation - the Si-strategy - is efficient.

For each Si-problem, a Mental Arithmetic counterpart was introduced (MA-problem). MA-problems are problems for which mental simulation is too costly to attain the result - thus for which the Si-strategy is not efficient. On the contrary, the use and application of arithmetic knowledge is efficient and makes the problem easy (MA-strategy). For example:
II. Luc is playing with his 42 marbles at recess. During the recess, he loses 39 marbles. How many marbles does
Luc have now? [42-39 = .]
The solution to problem II cannot be efficiently obtained by using the same procedure as for the first one; mentally simulating the action by counting down 39 marbles would be too costly. However the mental subtraction $42-39$ is
easy when the complement principle is mastered and leads to counting up from 39 to 42 .

The findings revealed that even after instruction, the Si problems remained systematically and significantly easier than the corresponding MA-problems. Furthermore, a higher use of informal strategies was observed on Siproblems, while arithmetic principles were almost exclusively used on MA-problems. For instance, when students succeeded to solve an Si-problem such as Problem I, they exclusively used a direct subtraction strategy, which is the Si-strategy in this case. However, when they succeeded to solve an MA-problem such as Problem II, even though Si-strategies were (scarcely)observed, they were solved to a greater extent by MA-strategies, such as looking for a missing addend in the previous example (' $39+$. $=$ 42'). This was never observed for Si-problems: no child tried to solve a problem such as Problem I by the missing addend' $3+$. $=42$ '.

Indeed, the arithmetic computations of both Si - and MAstrategies on subtraction problems are executed by the aforementioned mental computation strategies. The Switch model could accurately account for how the various arithmetic characteristics of the problems tested so far by the $S S F$ framework yield a clear computational advantage for one strategy over another. However, the Switch model does not provide an explanation for why students fail to apply arithmetic principles, such as it is observed through the significantly lower success rates on MA-problems. Indeed, even though the Switch model accurately describes the numerical conditions that require a switch between direct subtraction and indirect addition, it does not account for the mental re-representation needed in order to make this switch when a presented strategy cannot be easily performed in the same format as the one it is presented in.

We propose that the attainment of a mental rerepresentation would reflect an underlying conceptual metaphor that guides the interpretation and application of arithmetic principles. Conceptual metaphors are based on everyday human experience. The underlying mathematical ideas are constructed through cognitive mechanisms called fictive motion, which refer to the conception of static entities in dynamic terms (Lakoff \& Núñez, 2001). One of the main representations of arithmetic is object collection (Lakoff \& Núñez, 2001). The most widespread conceptual metaphor of subtraction that can be drawn from itis "taking away" (Fischbein, 1989; Lakoff and Núñez, 2001). Alternatively, arithmetic can be considered as motion along a path (Lakoff \& Núñez, 2001). The conceptual metaphor of subtraction that can be drawn from this conception is subtraction as a measuring stick (Lakoff \& Núñez, 2001), or as "determining the difference" (Selter, Prediger, Nührenbörger \& Hußmann, 2012). As Selter and collaborators (2012) pointed out, the "taking away" model might be more widespread, however seeing subtraction
solely as "taking away" is too one-sided, and both models are required in order to be flexible in mental arithmetic.

We consider that the failure to apply arithmetic principles on MA-problems is due to a restrictive representation of arithmetic, an intuitive representation(such as the "taking away" model), which entails a limited interpretation of the arithmetic situation embedded in the problem statement. Such an extension of the SSF framework would also challenge the most commonly used classification of arithmetic word problems introduced by Riley, Greeno and Heller (1983). Their classification determines the difficulty of a problem based on the semantic category it belongs to, while the $S S F$ framework puts emphasis on situation-based strategies and proposes thatthe efficiency of such strategies would be also a determining factor of difficulty.

Yet, all the subtraction problems that were tested by Brissiaud and Sander (2010) belonged to one same category of subtraction problems from Riley, Greeno and Heller's (1983) classification - change problems. These problems are dynamic in nature and describe an action with a temporal dimension,soliciting a mental simulation. However, the other problem categories do not involve this temporal dimension. They have been identified as more difficult than change problems, especially "compare" problems, in which a comparison between two quantities is involved and the question bears on the difference or on one of the compared quantities. It therefore remains an open issue if the mental simulation advocated by the $S S F$ framework is still relevant for problems that do not unfold along a temporal dimension.

Indeed, if the mental simulation of the problem was not solicited, then we could expect that the distinction between Si- and MA-problems among these categories would lose its relevance. It therefore remains an open issue if the mental simulation advocated by the SSF framework is still relevant for problems that do not unfold along a temporal dimension. If it would be demonstrated that the efficiency of the mental simulation influences a problem's difficulty even when it does not develop along a temporal timeline, it would warrant a broader view of Si -strategies and provide a new criterion for the assessment of problem difficulty, not based only on the semantic category, but also on the efficiency of the Si- strategy.

## Aim of the study

The purpose of the study was to demonstrate that the mental simulation of the arithmetic relations is not a mere consequence of a dynamic semantics of the problem, but an intrinsic property of arithmetic problem solving. Firstly, we conducted a longitudinal study in order to test the distinction between Si - and MA-problems in contexts less favorable for a mental simulation. Secondly, we conducted individual verbal reports in order to gather confirmatory evidence of situation-based strategies for Si-problems and a switch to non-situation-based strategies for MA-problems.

Table 1: Example of the problems for the number set (31, 27, 4) presented with different contexts

| Problem categories |  | Si problems | MA problems |
| :---: | :---: | :---: | :---: |
| Comparison problems | $\mathrm{D}[\mathrm{b}+.=\mathrm{a}]$ | There are 27 roses and 31 daisies in the bouquet. How many daisies are there more than roses in the bouquet? | There are 4 roses and 31 daisies in the bouquet. How many daisies are there more than roses in the bouquet? |
|  | $\mathrm{D}[\mathrm{a}-.=\mathrm{b}]$ | There are 31 oranges and 27 pears in the basket. How many pears are there less than oranges in the basket? | There are 31 oranges and 4 pears in the basket. How many pears are there less than oranges in the basket? |
|  | $C\left[b+b^{\prime}=.\right]$ $C[a-b=$. | James has 27 marbles. Steve has 4 marbles more than James. How many marbles does Steve have? <br> Anna has 31 euros. Susan has 4 euros less than Anna. How many euros does Susan have? | James has 4 marbles. Steve has 27 marbles more than James. How many marbles does Steve have? <br> Anna has 31 euros. Susan has 27 euros less than Anna. How many euros does Susan have? |
| Equalizingproblem S | $\mathrm{E}[\mathrm{b}+.=\mathrm{a}]$ | There are 27 oranges and 31 pears in the basket. How many oranges should we add to have as many oranges as we do pears? | There are 4 oranges and 31 pears in the basket. How many oranges should we add to have as many oranges as we do pears? |
|  | $\mathrm{E}[\mathrm{a}-.=\mathrm{b}]$ | There are 31 roses and 27 daisies in the bouquet. How many roses should we take away in order to have as many roses as we do daisies? | There are 31 roses and 4 daisies in the bouquet. How many roses should we take away in order to have as many roses as we do daisies? |
| Combine problems | $\mathrm{S}[\mathrm{b}+.=\mathrm{a}]$ | Mary has 27 euros in her piggybank and she has euros in her pocket. In total, Mary has 31 euros. How many euros does Mary have in her pocket? | Mary has 4 euros in her piggybank and she has euros in her pocket. In total, Mary has 31 euros. How many euros does Mary have in her pocket? |
|  | $S\left[b+b^{\prime}=.\right]$ | There are 27 blue marbles and 4 red marbles in Marc's bag. How many marbles are there in Marc's bag? | There are 4 blue marbles and 27 red marbles in Marc's bag. How many marbles are there in Marc's bag? |

## Experiment 1

## Method

## Participants

269 second grade students from 13 classes in 7 schools from working-class neighborhoods participated in the study. The average age of the children in January, when the first test was passed, was 7.62 years ( $s d=0.32,138$ girls).

## Material

There were 8 addition and subtraction problem types belonging to 3 major categories:

- compare problems: difference $\operatorname{set}(\mathrm{D}[\mathrm{b}+\ldots=\mathrm{a}$, $\mathrm{D}[\mathrm{a}-\mathrm{F}=\mathrm{b}])$ and compared set $\left(\mathrm{C}\left[\mathrm{b}+\mathrm{b}^{\prime}=.\right], \mathrm{C}[\mathrm{a}-\right.$ $\mathrm{b}=$.$] ),$
- equalizing problems $(\mathrm{E}[\mathrm{b}+.=\mathrm{a}], \mathrm{E}[\mathrm{a}-.=\mathrm{b}])$,
- combine problems $\left(\mathrm{S}[\mathrm{b}+.=\mathrm{a}], \mathrm{S}\left[\mathrm{b}+\mathrm{b}^{\prime}=.\right]\right)$.

The subtraction problems involved two numbers, $a$ and $b$ $(a>b)$. The numerical values for $a$ were either 42, 41, 33 or 31 , while in order to differentiate between Si - and MAproblems the values for $b$ were either kept small ( 3 or 4) or were close to $a(39,38,29$ or 27). To create Si-problems the small value of $b$ was used for the $\mathrm{C}[\mathrm{a}-\mathrm{b}=$.$] , while the b$
value close to $a$ was used for $\mathrm{D}[\mathrm{b}+\ldots=\mathrm{a}], \mathrm{D}[\mathrm{a}-.=\mathrm{b}]$,
 $\mathrm{S}\left[\mathrm{b}-\mathrm{b}^{\prime}=\right.$. ]. To create MA-problems the opposite $b$ value was respectively used for each problem, since it would make the Si-strategy costly.

Addition problems $\mathrm{S}\left[\mathrm{b}+\mathrm{b}^{\prime}=\right.$. ] and $\mathrm{C}\left[\mathrm{b}+\mathrm{b}^{\prime}=\right.$. $]$ involved two numbers, $b$ and $b^{\prime}$. Both numbers had the same characteristics as $b$ for subtraction problems, while the unknown value was equivalent to $a$. To create Si-problems the $b$ value close to $a$ was presented first, while the small $b$ value ( $b^{\prime}$ ) was presented second. To create MA-problems they were presented in the opposite order.

Thus the numbers involved in the data and the solution are $(31,27,4),(33,29,4),(41,38,3)$, and $(42,39,3)$.

Note that the number size was not the determining factor in the Si vs. MA-problem distinction. In the Si - versions one problem had the $b$ value close to $a$, while others had small $b$ values ${ }^{1}$. Also the second experiment was conducted to support this, by directly investigating students' strategy use.

[^345]Four different contexts were used for the wording of the problems: marbles, euros, flowers and fruits.

Table 1 provides examples of each problem category.

## Design

Children solved a total of 8 problems created by combining the 8 problems categories in either their Si - or MA- version. Each student therefore solved 4 Si-problems and 4-MA-problems. To control for the impact of position, numerical sets and context, 8 different problem sets were created. Another 8 problem sets were 'mirror' sets in which the Si-version of one problem would be presented in its MA counterpart, while the MA-problem would be presented in its Si-counterpart. Thus, 16 groups of problem sets were created altogether and counterbalanced across classrooms.

## Procedure

The experiment was composed of two sessions. The first conducted in January and the second one, strictly identical to the first one, 6 months later, in June. It was administered in the students' classrooms. Each child received an 8 pages booklet. There was a square in the middle of each page in which they wrote their answer. Each problem was read aloud twice to the whole classroom and children had one minute to write down the number that was the solution.

## Scoring

The solutions provided by the children were scored with 1 point when the numerical answer was exact, or within the range of plus or minus one of the exact value, in order to take into account mistakes in counting procedures. Any other answer received 0 points. The average of the sum of the scores on Si- and MA-problems was used as the dependent variable and analyses on these scores were carried out.

## Results

A first analysis was conducted in order to compare children's average success rates on Si - and MA-problems at the beginning of the year, followed by a second set of analyses in order to compare the success rates on the problems at the end of the school year. A third analysis bore on the progression over the year.

Repeated measure ANOVAs, with the 'Si- versus MAproblems' variable (further referred to as Problem type)as within-participant independent variables, were conducted for each session. The analyses of the scores obtained in January showed a highly significant main effect of Problem type on performance $\quad(F(1, \quad 268)=98.39, \quad p<$ $0.001, \eta^{2}=0.11$ ).Table2displays the average success rates. Indeed the Si-problems had a $19.57 \%$ higher success rate than MA-problems.

In June, there was a significant difference in performance between the two times of testing on Si-problems $(F(1,268)=$ 86.39, $\quad p<.001, \quad \eta^{2}=0.06$ ) and on MA-problems $\left(F(1,268)=36.58, p<.001, \eta^{2}=0.05\right)$. Yet, in accordance with our hypotheses, the results still revealed a highly significant main effect of Problem type on performance in June $\left(F(1,268)=119.57, p<.001, \eta^{2}=0.13\right)$.As displayed in Table2, the Si-problems had a $24.38 \%$ higher success rate than MAproblems in June (experiment 2).

Table 2: Average success rates

| Averagesuccess rate | January | June |
| :---: | :---: | :---: |
| Si-problems | $47.86 \%$ | $64.53 \%$ |
| MA-problems | $28.25 \%$ | $40.15 \%$ |

Indeed, after performing a repeated measure ANOVA with the Problem type and the times of testing as withinparticipant independent variables, the results confirmed that there was a significant main effect of Problem type $\left(F(1,268)=171.64, p<.001, \eta^{2}=0.12\right)$ and a main effect of the Time of testing $\left(F(1,268)=106.19, p<.001, \eta^{2}=0.05\right)$, but most importantly there was no interaction between the two variables $\left(F(1,268)=3.51, \quad p>.1, \quad \eta^{2}=0.001\right)$. Thus, as hypothesized, despite the progress made on each problem type throughout the year, the gap in performance persisted between Si - and MA-problems.

In order to test the hypotheses problem per problem, univariate ANOVAs, with the Problem type variable, were conducted for each of the eight problem categories and showed that almost all of the Si-problems were significantly easier than the corresponding MA-problems both in January and in June: $\mathrm{D}[\mathrm{a}-.=\mathrm{b}], \mathrm{C}\left[\mathrm{b}+\mathrm{b}^{\prime}=.\right], \mathrm{C}[\mathrm{a}-\mathrm{b}=],. \mathrm{E}[\mathrm{b}+$. $=\mathrm{a}], \mathrm{E}[\mathrm{a}-.=\mathrm{b}]$ and $\mathrm{S}[\mathrm{b}+.=\mathrm{a}](3.843<F(1,267)<72.501$, $p<.01,0.01<\eta^{2}<0.20$. The $\mathrm{D}[\mathrm{b}+.=\mathrm{a}]$ seemed to be particularly hard in January when no difference was observed $\left(F(1,267)=0.23, p>.1, \eta^{2}=0.001\right)(27.6 \%$ success rate on Si - and $25 \%$ on MA-problems), but the Si- versus MA-distinction was valid at the end of the year $\left(F(1,267)=15.63, p<.001, \eta^{2}=0.06\right)(47 \%$ success rate on $\mathrm{Si}-$ and $24 \%$ on MA-problems). The single exception for which no difference was observed on either time of testing was the combine superset problem $\mathrm{S}\left[\mathrm{b}+\mathrm{b}^{\prime}=\right.$. ] (January $\mathrm{F}(1,267)=2.69, p>.1, \eta^{2}=0.01$, June $F(1,267)=1.223, p>.1$, $\eta^{2}=0.005$ ), for which a difference was observed in the expected direction but not confirmed by the test ( $75 \%$ and $83 \%$ success rate on Si-problems and $66 \%$ and $77 \%$ on MAproblems, in January and June respectively).

## Discussion

The results revealed that the distinction between Si - and MA-problems remain relevant for subtraction and addition word problems that do not evolve along a temporal timeline. Our study shows that indeed, problems efficiently solved by direct modeling strategies remain easier for students even after they acquired more advanced skills in mathematics at the end of the year. The progression between the two sessions did not obliterate the distinction between Si -and MA-problems. The similar progression on Si - and MA- problems might be explained by the advances children made in computational execution of the calculations, or regarding their general comprehension skills.

A second experiment was conducted in order to provide confirmatory evidence that the difference in difficulty between Si - and MA-problems actually results from the preferential use of Si-strategies when they are efficient and for the lack in the application of arithmetic principles when this strategy is inefficient.

Table 3 : solving strategies for each problem category (with an example of the number set (31, 27, 4))

| Problem category | Si-problems |  |  |  | MA-problems |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |

## Experiment 2

We collected additional information concerning the strategies children actually use when solving Si- and MAproblems. We asked them to solve problems and then to describe their solving strategy aloud. We predicted that the solution strategies which directly model the problem would be predominant for Si-problems but that alternative strategies would emerge for MA-problems.

## Method

## Participants

42 Grade 2 students from 4 classes in2 different schools from working-class neighborhoods participated in the study. The test occurred in June and the average age of the children on the test was 7.93 years ( $\mathrm{sd}=0.26,23$ girls). None of the participants participated in the previous experiment.

## Material \& Design

The same material and design was used as in the first experiment.

Concerning the evaluated strategies, if we take the $\mathrm{D}[\mathrm{a}-$. $=b]$ problem as an example, the Si- strategy used to solve it is to start from the largest presented quantity (31) and to double-count downwards until the second quantity is reached: in the Si-problem this would not be costly. The students would describe their solving process as starting
from 31 and counting down30(1), 29(2), 28(3), 27(4), bearing the answer 4 , and noted by the experimenter as 31-. $=27$.Yet using the same Si-strategy of double-counting downward in the MA-problem to get from 31 to 4 is a costly procedure. When students would use this strategy they would describe the same solving process: starting at 31 and counting down30 (1), 29(2), 28(3), ... 5(26), 4(27), bearing the answer 27 and noted by the experimenter as $31-.=4$.

Nevertheless, when applying arithmetic knowledge we can easily know that taking away 4 from 31 provides the correct numerical answer to this MA-problem. One of the possible descriptions of the students' solving process would be to start from 31 and take away 4 , with the result no longer being the number of times they counted down, but the number they reached. This Non-Si-,mental arithmetic strategy (MA-strategy) would be noted as '31-4 = .'.

## Procedure

The procedure was identical to the first experiment, except that the test was conducted individually in the school library and that after writing down the numerical answer, the student was asked to explain aloud how he or she found the solution. The possible strategies were established beforehand and there was no ambiguity in their coding. The strategies that the students reported were classified according to table 3 into Si-strategies when the strategy directly modeled the wording of the problem, or into Non-

Si-strategies when the strategy that the student described did not directly model the problem.

## Scoring

For both Si- and MA-problems, we computed a score of Si-strategies (Si-score) and Non-Si-strategies (Non-Siscore). If a pupil provided a correct answer and explained a strategy, the nature of this strategy was assessed and contributed 1 point to either the Si -strategy score or the Non-Si-strategy score of the problem type. No points were attributed if a student did not provide a correct response and/or did not describe any strategy after providing the correct answer (only $7.5 \%$ of the correct responses were not accompanied by a strategy description). Given that children solved 4 problems of each type, the scores ranged from 0 to 4.

## Results

The experiment replicated the previous findings, confirming that Si-problems were easier for children than MA-problems. The success rates were $67.2 \%$ and $41.5 \%$ respectively, and the variance analysis revealed that this difference was significant $\left(F(1,41)=17.86, p<.001, \eta^{2}=0.13\right)$.

Table 3 shows strategy use for each problem category and the disparities between the two kinds of strategies, among students that provided the right numerical solution and described a strategy.

We further performed two variance analyses using the Si strategy score and the Non-Si-strategy score as the dependent variables, and Problem type as the within factor variable. The average scores are presented in table 4.As expected, both differences were significant. Si-strategies were used significantly more on Si-problems $(F(1,38)=79.1$, $\left.p<.001, \eta^{2}=.5\right)$, as well as Non-Si-strategies on MAproblems $\left(F(1,38)=20.06, p<.001, \eta^{2}=.2\right)$.

Table 4 : Si- and Non-Si-score for solving strategies

| Problem type | Si-score | Non-Si-score |
| :---: | :---: | :---: |
| Si-problem | 2.05 | 0.31 |
| MA-problem | 0.26 | 1.13 |

## Discussion

The variance analyses confirmed that solution strategies which directly model the situation were predominant for Si problems and that solution strategies which required arithmetic knowledge were predominant for MA-problems. These findings suggest that the selected strategy drives the difference in performance on top of the problem category or factors such as mental calculation competences.

## General Discussion and Conclusion

The experiments conducted in the present study account for the spontaneous and intuitive modeling of the situation described in arithmetic word problems, which leads to a primary use of situation strategies and the application of arithmetic principles only when the first one is too costly. The significant difference that was observed between Siand MA-problems fits with the previous findings on change problems (Brissiaud \& Sander, 2010), and confirms that this
problem distinction is not specific to problems that evolve along a temporal timeline. These findings complement the traditional classification of arithmetic word problems according to which problem difficulty depends mostly on the problem category. They also provide evidence that situation strategies are not only tied to the semantic wording of a problem, but could be a fundamental property solicited by arithmetic problems.

## Acknowledgments

This study was supported by the "Fonds d'expérimentation pour la jeunesse" through the funding grant ACE_HAP_10for the project "ACE-ArithmEcole".

We thank the teachers and classes who participated in the the study, Adeline Lucchesi for her help with data collection and Sébastien Puma for his helpful comments.

# Age differences in language comprehension during driving: Recovery from prediction errors is more effortful for older adults 

Katja Häuser (khaeuser@coli.uni-saarland.de)<br>Saarland University<br>Campus C7.4<br>66123 Saarbrücken<br>Germany<br>Vera Demberg (vera@coli.uni-saarland.de)<br>Saarland University<br>Campus C7.4<br>66123 Saarbrücken<br>Germany<br>Jutta Kray (j.kray@mx.uni-saarland.de)<br>Saarland University<br>Campus A1.3, 66123 Saarbrücken<br>Germany

#### Abstract

Prior research yielded conflicting findings regarding whether older adults show a greater processing cost than younger adults when encountering unpredicted semantic material during language processing. Here, we investigated whether age-related differences in recovery from prediction error are influenced by increased demands on working memory. We used a dual task design: a primary sentence comprehension task in which semantic predictions were fulfilled or violated, and a concurrent driving task, thought to limit working memory resources in resolving prediction errors. In the dual task, older participants showed an increase in comprehension accuracy for sentences with semantic violations, while demonstrating a decrease in driving accuracy. Thus, when working memory resources were limited, older adults focused exclusively on the language task and neglected the driving task. This could be related to an age-related increase in generating semantic predictions, or to a general inability among older adults to divide attention between two cognitively demanding tasks.

Keywords: aging, semantic expectancy, dual tasking, attention allocation

## Introduction

Prediction of upcoming linguistic material is pervasive during language comprehension. Recent theories hold that expectations at higher levels of processing (e.g., syntactic, contextual) generate hypotheses and facilitate low-level processing, for example in word recognition (Kuperberg \& Jaeger, 2016).

Frequently, however, people encounter unpredicted linguistic content and must recover from unexpected events that violate their expectations. Indeed, research has shown that this recovery phase often involves a processing cost. For example, Federmeier and Kutas (1999) analyzed the N400 EEG component (for review, see Kutas \& Federmeier, 2000) to index comprehension difficulties when participants were reading unexpected sentence continuations. Sentences contained either an expected word, an unexpected word from the same semantic category, or an unexpected word from a different semantic category (e.g., They wanted to make the hotel look more like a tropical resort. So along the driveway, they planted rows of palms (expected) / pines (unexpected same category) / tulips (unexpected different category)). According to the results, the N400 was reduced for expected and semantically related words, indicating that processing of predicted (palms) and semantically related words (pines) was facilitated. In contrast, for semantically unexpected words (tulips) the N400 amplitude was high, suggesting comprehension difficulties among participants when predictions based on context were violated.

However, an unanswered question is whether older adults (65 years or older) use context to anticipate upcoming content during language processing in a similar fashion as younger adults do. Some studies have shown that older adults are more disturbed by unpredicted semantic material than younger adults, which suggests that older adults may rely more heavily on prediction making during language processing (DeLong, Groppe, Urbach, \& Kutas, 2012; DeDe, 2014; Rayner, 2006; Borges \& Coco, 2015). For example, Borges and Coco (2015) investigated age differences in visual object detection by using a priming paradigm in which prime and search scene were either
congruent (e.g., kitchen-kitchen) or not (e.g., bathroomkitchen). In addition, visual target objects (e.g., bread basket) were presented in a semantically consistent condition (e.g., on a restaurant table) or in an inconsistent condition (e.g., on a pool table). According to the results, older adults were less successful at detecting target objects when prime and search scene were semantically congruent, but the target was inconsistent with the search scene. The authors concluded that older adults rely more heavily on contextual expectations than younger adults by generating very specific predictions based on consistent information. Consequently, they showed a greater processing cost when expectations based on context and new information are inconsistent.

Other studies, in contrast, have shown that older adults generally appear less likely than younger adults to use context and engage in pre-activating information during sentence processing (e.g., Federmeier \& Kutas, 2005; Federmeier, Kutas, \& Schul, 2010). For example, Federmeier and Kutas (2005) compared younger and older adults' N400 amplitude for sentence-final words in highly and weakly constraining contexts (e.g., highly constraining: No one at the reunion recognized Dan because he had grown a beard; weakly constraining: At the children's park next to the beach she saw a man with a beard). Even though both age groups showed a similar N 400 for weakly constraining sentences, the older adults' brain response for strongly constraining sentences was delayed and diminished in shape. The authors concluded that older adults were unable to make use of the richer information available from strongly constraining contexts to guide semantic processing; possibly because age-related declines in working memory prevented older adults from quickly constructing and updating an ongoing message-level representation while at the same time processing new input (see Huettig \& Janse, 2016, for a similar account).

Given Federmeier and Kutas' (2005) implication of working-memory capacity, the goal of the present study was to examine whether age-related changes in predictive processing are influenced by increasing demands on working memory. We used a dual-task paradigm with a primary language comprehension task and secondary driving task, thought to limit cognitive resources that participants can expend to resolving semantic prediction errors. To our knowledge, only one previous study has investigated how aging affects dual-task performance during language processing and driving, and that particular study found an age effect that was limited in scope.

Becic et al. (2010) investigated story-retelling ability in younger and older adults while participants were engaged in a secondary driving task. According to the results, younger adults achieved high accuracy in both story retelling and driving, suggesting high capacity in this participant group to divide attention between the language and the driving task. For older adults, no reliable effects emerged in the primary analysis. However, there was a trend in the data (revealed by post-hoc tests), which suggested that better driving (less
variability in velocity and lane keeping) was associated with worse retelling. In other words, older adults who drove better also performed more poorly in the language task. Since the group of older adults showed worse story-retelling ability overall, it seemed that older adults primarily focused on getting the driving task right, while neglecting the language task. The authors suggested that, due to agerelated declines in working-memory capacity, older adults may be more likely to protect their driving by giving up on the story retelling task. However, the Becic et al. (2010) study remains somewhat mute with respect to age differences in predictive processing (the primary focus of the present study), since this question was not specifically addressed by that paper.

In the present study, we sought to adress age-related differences in recovery from prediction error more directly, by presenting stimuli in a low- vs. high-surprisal condition (e.g., Since Petra didn't have anything to wear for the barbeque, she bought a dress (low surprisal) in a nearby shop; vs. Since Petra didn't have anything to drink for the barbeque, she bought a dress (high surprisal) in a nearby shop). High-surprisal sentences were thought to induce a strong cognitive conflict since the second clause violated semantic predictions based on contextual information provided by the first clause (i.e., drink-dress).

Based on prior research on semantic surprisal in younger adults (DeLong, Troyer, \& Kutas, 2014; Kutas \& Federmeier, 2000), we predicted that younger adults should be sensitive to violations of semantic expectancies (probably indexed by lower accuracy for high-surprisal sentences in the language comprehension task). In addition, we expected stable performance in this participant group regardless of whether sentences were processed in the single or dual task, indicating high capacity in younger adults to divide attention even under conditions of high linguistic load (cf. Becic et al., 2010).

In contrast, for older adults our predictions were less clear based on previous research. If, on the one hand, older adults generate more specific predictions during language processing, we expected to find large processing costs in response to high-surprisal sentences, in particular under dual-task conditions, when less cognitive resources are available to resolve the semantically unexpected event. If, on the other hand, older adults are less efficient at generating predictions, we expected only minimal processing costs for high-surprisal sentences, with only small differences between single and dual-task condition.

## Method

## Participants

Thirty-six older adults (mean age $=72$ yrs; 18 female) from the Saarbrücken community participated for compensation. The control group consisted of 34 younger adults (mean age $=23 ; 20$ female), mostly students at UdS. All participants were native speakers of German, reported no hearing problems and had normal or corrected-to-normal vision.

## Procedure

We investigated age-related differences in recovery from prediction errors while participants were engaged in a single and dual task. The dual task consisted of a language comprehension and continuous driving task. The single task consisted of the driving or language task only. Overall, the experiment consisted of six major blocks - two dual-task blocks for simultaneous language comprehension and driving, two single-task blocks for single driving, and two single task blocks for language comprehension.

Language Task. The language comprehension task consisted of a sentence verification task for 192 spoken sentences, half of them presented in a low-surprisal condition (low processing effort) and high-surprisal condition (high processing effort). Each sentence was constructed of two clauses, with the verb of the first clause providing a semantic context and the noun of the second clause either matching (low-surprisal condition) or violating this semantic context (high-surprisal condition), for example, Since Petra didn't have anything to wear (low surprisal) / drink (high surprisal) for the barbecue, she bought a dress in a nearby shop. Participants were instructed to carefully listen to the sentences, which were presented to them over speakers, and asked to judge whether each sentence was meaningful and correct by verbally answering "Yes" or "No", while the researcher recorded their responses. In order to minimize prosodic differences among items, all sentences were synthesized prior to the experiment using MARY TTS (Schröder, Charfuelan, Pammi, \& Turk, 2008) and pauses manipulated so that the duration of the disambiguating word (dress) was always identical. To avoid stereotyped responses, we also presented 72 filler items in a low- and high-surprisal condition, involving syntactic violations. All items were randomized using a Latin Square randomization, with surprisal (highlow) as blocking factor, to ensure that each participant encountered each experimental item in only one of its experimental conditions.

Driving Task. We used the Continuous Tracking and Reaction Task (ConTRe Task; Mahr, Feld, Moniri \& Math, 2012), a highly controlled driving task which measures rapid changes in steering deviation from a target. As such, the ConTRe task allows for continuous and very finegrained measurement of online changes in task performance over time (e.g., Becic, Dell, Bock, et al., 2010; Demberg, Sayeed, Mahr, \& Müller, 2013). Participants were seated in front of a steering wheel and saw a 3D road on a screen, with two vertical color bars moving laterally across the screen at a continuous speed. Participants were instructed that they could control one of the bars (the blue one) by turning the steering wheel whereas the other bar (the yellow one) was controlled by the computer. Their task was to continuously track the yellow bar so as to keep the distance between the two bars minimal at all times. Participants' driving performance was assessed by measuring their
steering deviation (indicated in meters) when processing low- and high-surprisal sentences.

## Results

We constructed separate linear mixed effects models for response accuracy and steering deviation, as implemented in the lme4 library (Bates \& Sarkar, 2007) in R (R Development Core Team, 2013). Fixed effects for response accuracy were sentence type (low surprisal vs. high surprisal), task condition (single vs. dual), and age group (younger vs. older). Fixed effects for steering deviation were sentence type and age group. Since raw steering deviation was coded in positive and negative values, indicating left- and right-sided deviations, we squared its values to obtain a final measure. For the LMER model for steering deviation, $p$-values were approximated from the model coefficients using the normal distribution (see Barr, Levy, Scheepers, \& Tily 2013). Categorical predictors were sum coded. All models contained participants and items as crossed random effects, and random slope adjustments for subjects and items. In the event that a model failed to converge, we simplified the random slope structure progressively until convergence was achieved (for guidelines, see Barr et al., 2013). Higher-order interactions involving the factor age group were followed up with planned model splits between younger and older adults.

## Response accuracy

The model for response accuracy showed a significant interaction between sentence type and age group, as well as a significant interaction between sentence type and task condition (see Table 2). To locate the source of these interactions, we computed two follow-up models in which items were split by age group. Thus, we computed one model for younger adults, and another model for older adults.

The model for the younger adults showed nothing but a significant main effect of sentence type ( $b=-0.62, S E=$ $\left.0.14, t=-4.29, p<.001^{* * *}\right)$, indicating that, regardless of task condition, younger adults responded less accurately to high-surprisal than low-surprisal sentences (see Figure 1, left panel). In contrast, the model for the older adults showed a significant interaction between sentence type and task condition ( $b=-0.86, S E=025, t=-3.4, p<.001 * * *$ ). An inspection of the plot for this interaction (see Figure 1, right panel) suggested that older adults responded equally accurately to high- than low-surprisal sentences in the single task condition, but showed a selective increase in response accuracy for high-surprisal sentences in the dual-task condition. These observations were confirmed by additional follow-up models, in which we split items by task condition: As predicted, only the model for the dual-task condition showed a significant main effect of sentence type ( $b=0.77$, $S E=0.18, t=4.28, p<.001 * * *)$, indicating an increase in response accuracy for high-surprisal sentences.

Thus, the data for response accuracy showed two main things of interest: First, younger adults responded less
accurately to high-surprisal sentences, regardless of task condition, indicating stable performance in this participant group even when working-memory load was high (i.e. the dual-task condition). Older adults, in contrast, responded more accurately to high-surprisal sentences in the dual-task condition, indicating that they selectively focused on resolving the semantic conflict in these items (cf. Becic et al., 2010), presumably by giving up driving. To support this view, we now turn to the driving performance in both age groups.

Figure 1: Response accuracy ( $\pm$ SEM) in younger and older adults, depending on task condition and sentence type.

## Steering deviation

The model for squared steering deviations showed a significant interaction between sentence type and age group (see Table 2). The plot of this interaction (see Figure 2) suggested that younger adults showed stable driving
performance regardless of whether sentences were highly surprising or not, whereas older adults demonstrated higher steering deviations when high-surprisal sentences were presented. To confirm these observations, we again computed follow-up models in which we split items by age group. As expected, only the model for older adults showed a main effect of sentence type $(b=0.24, S E=0.06, t=4.05$, $p<.001^{* * *}$; younger adults: $b=-0.02, S E=0.03, t=-0.70$, $p>.05)$.

Thus, the analysis of the driving data supported our hypothesis based on the response data. First, younger adults showed constant steering deviations regardless of semantic violations, suggesting that even under conditions of high linguistic load, they maintained high driving acuity. Older adults, in contrast, demonstrated greater steering deviations in response to high-surprisal sentences, suggesting increased effort to recover from semantic violations.

In sum, whereas younger adults maintained a stable pattern of performance even under conditions of high linguistic load, older adults devoted all attentional resources to resolving semantic violations, while neglecting the driving task.

Figure 2: Steering deviations in the dual task ( $\pm$ SEM) for younger and older adults, depending on sentence type.

## Discussion

Prior research has yielded conflicting findings with respect to predictive processing in aging. Some studies have shown that older adults are impaired at using context to generate predictions about upcoming content during language comprehension. Other studies have indicated that older adults form strong and semantically specific predictions during language processing, resulting in effortful recovery when such predictions are violated.

In this study, we investigated age-related differences in recovery from prediction error under conditions of increased working-memory load. By using a secondary driving task, we limited working-memory resources participants could devote to resolving prediction errors. To manipulate prediction error, we presented sentences in a high- and lowsurprisal condition. In high-surprisal sentences, participants were expected to experience integration difficulties when encountering unpredicted semantic content. Low-surprisal sentences, in contrast, were thought to induce only minimal processing effort.

Two key findings emerged. First, even though younger adults were sensitive to violations of semantic predictions overall (indicated by lower response accuracy for highsurprisal sentences), they maintained a stable behavioral pattern in both response accuracy and driving performance. Thus, younger adults were able to resolve the semantic violation in high-surprisal sentences without experiencing trade-off effects between primary and secondary task. This suggests high working-memory capacity in this participant group to split attention even under conditions of maximal linguistic load. Second, we found that older adults allocated all processing resources towards resolving the unexpected sentence continuation in high-surprisal sentences. This increased their response accuracy in the sentence verification task, but it came at the expense of driving accuracy: When high-surprisal sentences were presented, older adults demonstrated a strong increase in steering deviation.

Thus, our results are more in line with studies suggesting that older adults form strong predictions during language processing, and that violations of these predictions induce maximal processing effort to resolve the prediction error. Unlike younger adults, however, older adults may not have sufficient working-memory capacity to integrate semantically unexpected material into an unfolding sentence context and to additionally perform a secondary task without a substantial drop in task performance.

A second interpretation of our results is that older adults are inable to successfully divide attention between two cognitively demanding tasks. Thus, they might globally
shift attentional resources towards one cognitive goal when multiple tasks have to be performed at the same time. This interpretation is in line with prior research suggesting that older adults can relevel their task priorities in a case-by-case manner that follows principles of selective optimization, by taking into account the subjective difficulty of each task and choosing the one which is most likely to garner success (see Li, Baltes, Staudinger, \& Lindenberger, 1999; Miles \& Stine-Morrow, 2004; Stine-Morrow, Miller \& Hertzog, 2006). Here, older adults might have adopted a strategy of selective performance optimization, by neglecting the high demands in the bar-tracking task and focusing exclusively on the sentence verification task. Overall, the language task may have seemed more likely to yield success, given older adults' increased verbal knowledge and linguistic capacity (Glisky, 2007).

Finally, a somewhat open question is to what extent our data have real-life implications on older adults' car driving security. On the one hand, our results are supported by prior studies using simulated but also naturalistic driving scenarios, suggesting that driving ability suffers most under conditions of high working-memory load (Cantin, Lavallière, Simoneau, et al., 2009; Strayer, Cooper, Turrill, et al., 2013), and that older adults are more likely to adapt to such situations by selectively focusing their attention on one task and disregarding the other (Becic et al., 2010). In addition, there is evidence from research on car driving safety (Strayer et al., 2013) indicating that behavioral results obtained in simulated driving environments are largely identical to real-life driving.

On the other hand, car driving involves a range of cognitive-behavioral demands the bar tracking task in the present study was lacking, for example reactions to road signs or traffic lights, overtaking maneuvers and lane changes, or braking for other cars. In fact, the contrast between the present results and those obtained by an earlier study using a similar dual-task paradigm (Becic et al., 2010), shows that differences in design might impact the results to a large extent. According to the results of Becic et al. (2010), older adults showed a reversed pattern of task prioritizing than observed here, by focusing exclusively on the driving task and neglecting the language task. However, the experimental set-up in Becic et al. (2010) was more naturalistic than the one in the present study, since that study used an actual car dummy and a wrap-around projection screen that displayed realistic images of road situations and naturalistic driving scenarios. This set-up might have induced a more realistic feeling of car driving, where accidents can actually be fatal. The older adults in that study might have employed a task solving strategy that followed the rule of safety-first, by focusing their attention on the task which seemed most dangerous to them. In contrast, poor performance in the bar tracking task in the present study had no such real-life implications, possibly rendering this task somewhat negligible to older adults.

In sum, our data support studies arguing that recovery from prediction errors is more effortful for older adults, and
that older adults allocate attentional resources differently from younger adults when task demands are high, by prioritizing one cognitive goal over others. We discussed two possible causes for these age-related differences, i.e. older adults' increased rate of forming semantic predictions based on context, and/or impaired working-memory resources normally associated with aging. Future work in our lab will further investigate these possibilities by also exploring the pupillary response as a measure of cognitive load, and by taking into account individual differences in executive functions.

#### Abstract

Variance of the outcomes associated with an option often provides a measure of the riskiness of that option. Hence, it is important for organisms are able to detect any sudden changes in outcome variance. In Experiment 1, we presented people with graphs of share price time series or water level time series. In half the graphs, variance (financial or flooding risk) changed at some point. People were better at detecting increases than decreases in risk - maybe because it is more important to detect increases in danger than decreases in it. However, in Experiment 2, people were still better at detecting increases than decreases in variance even when those changes did not reflect altered levels of risk. Our findings may reflect the fact that the actual change in variance exceeds the change needed to identify a regime change in variance by a larger amount for upward than for downward changes.

Keywords: volatility; variance; risk; change detection; judgment

## Introduction

In many domains, variance of outcomes associated with an option is taken as a measure of level of risk of that option. For example, in modern finance theory, level of risk associated with an asset is defined as the standard deviation of the returns on that asset (Jorion, 2006). Similarly, as variability in water levels increases, so does the risk of flooding or drought (Crowell, Coulton, Johnson, Westcott, Bellomo, Edelman, and Hirsh, 2010). Finally, in foraging theory, the risk associated with different food sources is defined in terms of the variance of the energy gains that an animal can derive from those sources (Kacelnik and Bateson, 1996). In all these cases, higher variance in the data is treated as a signal that risk levels are higher.
Most work in these and other domains has been based on the assumption that the riskiness of different options remains constant over time. For example, Diacon and Haseldine (2007), Duxbury and Summers (2004, 2017), Sobolev and Harvey (2016), and Weber, Siebenmorgen and Weber (2005) have used various methods to examine the relation between volatility of financial indicators (e.g., returns) and financial risk perception. However, level of risk can change: variance of outcomes may increase or decrease, often quite suddenly. As far as we are aware, there have been no studies of people's ability to perceive a change in volatility and, hence, to detect onset of a new level of risk.
Here we ask how easily people are able to detect such a change when they are given a graphical record of the
outcomes that have occurred. More specifically, we examine how well people are able to detect a structural break in the variance of a time series and study whether the level of their ability is influenced by whether that variance is framed as representing level of risk.

We varied task frame. In Experiment 1, any structural break in the series signified an increase or decrease in the level of risk over time. Changes in financial trading risk and water flooding risk were of this type. In Experiment 2, any structural break in the series did not represent any change or difference in risk level. Instead, participants needed to detect it because it represented an opportunity rather than a risk. These experiments were used to address two questions.

First, is there any asymmetry in ability to detect increases and decreases in volatility? Second, is any such asymmetry limited to tasks in which changes in volatility should be interpreted as temporal changes in level of risk? It can be argued that it is more important to detect an increase in risk so that protective measures can be adopted. Removing those protective measures when there is a decrease in risk is likely to be less critical.

## Experiment 1

In this first experiment, participants performed the task within a temporal risk frame. They were presented with one of two scenarios: a finance scenario and a flooding scenario.

## Method

Participants One hundred and sixty-five students acted as participants: 59 were assigned to the financial risk scenario and 106 were assigned to the flooding risk scenario.

Stimulus materials Each graphically presented series comprised 50 data points generated uniquely for each participant. They were drawn from a Gaussian distribution with a mean of 500 and a standard deviation of either 5.00 (low volatility) or 15.0 (high volatility). Of the 60 graphs seen by each participant, 15 were of low volatility throughout, 15 were of high volatility throughout, 15 contained a change from low volatility to high volatility, and 15 contained a change from high volatility to low volatility. The 60 graphs were presented in random order. When there was a change in volatility, it occurred between points 11 and 40 inclusive and with equal likelihood. One third of the graphs of each of the four types contained no trend, one third contained a shallow upward trend, and one
third contained a shallow downward one. When there was a trend, the series still started at 500 but was then incremented or decremented by 0.1 on each successive point. Labelling of graphs depended on the task frame.

Procedure In the financial risk scenario, the vertical axis was labelled as 'price' and the horizontal axis as 'hours' (Figure 1). Participants were told that the series represented a record of recent stock prices and told that increased volatility represented increased trading risk. They needed to detect whether a change in risk had occurred because their trading strategy would need to change if it had done.

Figure 1: Example graph from the finance scenario in Experiment 1 showing prices that change every hour for a period of 50 hours and volatility shifting from high to low.

In the flooding risk scenario, the vertical axis was labelled as water depth and the horizontal axis as 'hours'. Participants were told that each graph represented a record of water levels in various locations and that increased volatility represented increased risk of flooding. They needed to detect whether a change in flood risk had occurred in order to implement flood control measures if it had increased or to stand them down if it had decreased.
For each graph, participants first gave a yes/no response to signal whether they had detected a change in the volatility in it. They then estimated the likelihood that their response was correct on a $50-100 \%$ scale.

## Results

Here we report analyses of participants' detection responses using signal detection theory (Macmillan and Creelman, 1991). We extracted measures of sensitivity ( $\mathrm{d}^{\prime}$ ) and response criterion ( $\beta$ ) for a) trials starting with low volatility on the left of the graph that either stayed low or that changed to high volatility and b) trials starting with high volatility on the left that either stayed high or that changed to low volatility. Data were analysed in this way so that we could use the signal detection measures to compare detection of change when the series started with low volatility to that when it started with high volatility. To obtain $\mathrm{d}^{\prime}$ and $\beta$, the z -transformations of the hit rate $(\mathrm{z}(\mathrm{H})$ ) and false alarm rate $(\mathrm{z}(\mathrm{F}))$ were first obtained. Then

$$
\begin{aligned}
& \mathrm{d}^{\prime}=\mathrm{z}(\mathrm{H})-\mathrm{z}(\mathrm{~F}) \\
& \beta=\exp \left(\left(\mathrm{z}(\mathrm{~F})^{2}-\mathrm{z}(\mathrm{H})^{2}\right) / 2\right)
\end{aligned}
$$

The sensitivity measure d' reflects how discriminable signal (change) trials are from noise (no change) trials, with higher values indicating better detection performance. The response criterion measure $\beta$ reflects the relative strength the evidence has to reach in order for the organism to respond that the trial was a change trial, with a value of 1 indicating no response bias, while values below 1 indicating a bias towards responding 'change' (i.e., the evidence for 'no-change' has to be stronger than the evidence for 'change').

As we are interested only in the effect of increasing as compared to decreasing volatility, we collapse the data over the presence and types of trend. Also, note that the signal detection measures are based on both signal (change) and noise (no change) trials, and hence we cannot compare sensitivity and response bias between change and no-change trials.

Table 1: Mean values of sensitivity ( $\mathrm{d}^{\prime}$ ) and response criterion ( $\beta$ ) in the two types of scenario for detection of changes in volatility in graphs that started with low volatility and in those that started with high volatility.

|  | Sensitivity (d') |  | Response criterion $(\beta)$ |  |
| :--- | :--- | :--- | :--- | :--- |
|  | Low | High | Low | High |
|  | Starting <br> Volatility | Starting <br> Volatility | Starting <br> Volatility | Starting |
| Volatility |  |  |  |  |
| Financial <br> risk <br> scenario <br> $(\mathrm{n}=59)$ | .95 | .26 | .22 | .19 |
| Flooding <br> risk | .79 |  |  |  |
| scenario <br> $(\mathrm{n}=106)$ |  |  |  |  |

Mean values of $\mathrm{d}^{\prime}$ and $\beta$ are shown in Table 1. A two-way analysis of variance on $\mathrm{d}^{\prime}$ using starting volatility as a within-participant variable and temporal frame as a between-participant variable revealed a strong main effect of starting volatility $\left(\mathrm{F}(1,163)=43.82 ; \mathrm{p}<.001 ; \eta^{2}=.21\right)$ and some evidence of an interaction between this variable and frame type $\left(\mathrm{F}(1,163)=4.57 ; \mathrm{p}=.034 ; \eta^{2}=.03\right.$ ).

An ANOVA using the same variables on $\beta$ failed to reveal any significant effects.

## Discussion

The experiment showed that people find it easier to detect increases in volatility than decreases in volatility. Given that increases in volatility in the task scenarios corresponded to increases in risk, this result can be interpreted as showing that people are better at detecting increases than decreases in risk. This corresponds to what would be expected from a functional perspective: it is more important to be sensitive to increases in risk (so that protective measures can be
implemented) than to decreases in risk (as removal of protective measures is less urgent). Differences in the size of the effect in the two scenarios may be related to beliefs about the nature of the risks and the ease of managing them in the two cases.
Before committing to this risk-based interpretation of the effects, it is important to ascertain whether they appear when the same graphs are presented within a scenario that does not involve risk.

## Experiment 2

In this experiment, participants were presented with a version of the task in which risk assessment was not involved. Results were then compared to those obtained in the previous experiment.

## Method

Participants A total of 80 new participants drawn from the same pool as before performed a risk-free version of the task.

Procedure Participants were told that the data points represented the contours of a mountain range. The vertical axis represented height in meters and the horizontal one degrees of visual angle. Mountains could be formed of soft rock that had eroded (low variance) or harder rock that had not (high variance). They were told that they needed to detect differences in the contours of the mountains because mineral deposits tended to occur at the interface of hard and soft rocks. Identifying such interfaces would trigger groundbased surveys to confirm the presence of mining opportunities. Thus, a left/right difference in variance was associated with identification of an opportunity rather than a risk.

In all other respects, the experiment was the same as Experiment 1.

## Results

In the same way as before, the $\mathrm{d}^{\prime}$ and $\beta$ values were extracted from the data (Table 2). Then an ANOVA was used to compare the values obtained from the temporal risk scenarios of Experiment 1 with those obtained from the risk-free scenario in the current experiment. Starting volatility (low versus high volatility on the left side of the graph) was a within-participants variable and task frame (risk-free versus temporal risk scenarios) was a betweenparticipants variable.
Again, there was a strong main effect of starting volatility $\left(\mathrm{F}(1,243)=30.00 ; \mathrm{p}<.001 ; \eta^{2}=.11\right)$. However, in this case, though there was an effect of frame type $(F(1,243)=$ $10.34 ; p=.001 ; \eta^{2}=.04$ ), there was no interaction between frame type and starting volatility. Thus, while people were better at detecting differences in volatility in the risk-free scenario, they were better in both types of scenario at detecting changes in volatility from low to high (assuming left-to-right scanning in the risk-free scenario) than at detecting volatility changes from high to low.

As before, an ANOVA using the same variables on $\beta$ failed to reveal any significant effects.

Table 2: Mean values of sensitivity ( $\mathrm{d}^{\prime}$ ) and response criterion ( $\beta$ ) in the two types of scenario for detection of changes in volatility in graphs that started with low volatility and in those that started with high volatility.

|  | ${ }^{2}$ |  | Sensitivity $\left(\mathrm{d}^{\prime}\right)$ |  |
| :--- | :--- | :--- | :--- | :--- |
| Response criterion $(\beta)$ |  |  |  |  |
|  | Low | High | Low | High |
|  | Starting | Starting | Starting | Starting |
|  | Volatility | Volatility | Volatility | Volatility |
| Temporal | .85 | .37 | .15 | .21 |
| risk |  |  |  |  |
| scenario <br> $(\mathrm{n}=165)$ |  |  |  |  |
| Risk-free <br> scenario <br> $(\mathrm{n}=80)$ | 1.01 | .75 | .17 | .24 |

## Discussion

We obtained the same effect reported in Experiment 1 when participants performed the task within a risk-free scenario. Assuming left-to-right attentional scanning of the graphs (Bergen and Lau, 2012; Eviater, 1995; Maas and Russo, 2003), we can say that they were more sensitive to an increase in volatility than to a decrease in volatility. Furthermore, this was true whether or not greater volatility represented greater risk. The asymmetry uncovered in Experiment 1 is of a more general nature than we originally assumed. However, its implications for detection of changes in levels of risk remain.

There was also a main effect of scenario type on $d^{\prime}$ : sensitivity was higher in the risk-free scenario. Focusing on opportunities rather than risks appears to have made the task simpler for participants.

## General discussion

The experiments show that people find it easier to detect an increase than a decrease in the variance of a graphically presented time series. Though changes in risk are realized as changes in variance in many domains, Experiment 2 indicated that increases in variance are easier to detect than decreases in variance even when changes in variance do not correspond to changes in risk level. Here we will outline two possible explanations for our findings: an explanation in terms of the processes needed to detect upward and downward changes in variance and a functional explanation based on the relative importance of upward and downward changes in variance.

## A process-based account

It is possible that our findings arose because increases in variance are statistically easier to detect than decreases in
variance. For example, we could ask whether it is statistically easier to detect the presence of a data point outside a given distribution (an outlier) than to detect the absence of a data point expected within that distribution. Conceivably, more data might be needed to perform the latter detection reliably.

In fact, to detect an increase in variance, it is not sufficient to detect a single anomaly: in normal distributions, we expect one in 22 data points to be more than two standard deviations away from the mean. To detect a change in variance, the presence of unexpected data points outside a reference distribution or the absence of expected data points within that reference distribution must be persistent. In other words, there must be evidence of a regime shift in the variance of the distribution.
There are many different approaches to detecting regime shifts in the mean of time series but relatively few have been developed for detecting shifts in the variance of series. Downton and Katz (1993) developed a non-parametric bootstrap technique to compute confidence intervals for discontinuities in variance. However, their approach requires the series containing the putative regime shift in variance to be compared to a separate reference series known to be characterized by homogeneous variance. We presented our participants with series in which variance did not change but we did not inform them of this constancy for particular series. Thus they had no series that they could treat as a reference series in the manner that Downton and Katz (1993) require.

Rodionov (2004) developed a sequential algorithm for early detection of regime shifts in the mean of series. The advantage of his approach is that it does not require large amounts of data to be accumulated and can automatically detect regime shifts in real time. Later, Rodionov (2005) extended his approach so that it could be used to detect regime changes in variance in short series in real time. These features of his approach render it a suitable one for modeling detection of variance change in our experiments.

The first step is to identify the regime length ( $l$ ). In our task, this value would initially be set to 10 because participants knew there was no shift in the first 10 data points. The next step is to use an F-test to determine the critical variance ratio ( $\mathrm{F}_{\text {crit }}$ ) of two successive regimes that would be statistically significant. For an $l$ value of 10 and a p -value of 0.05 (one-tailed), this ratio is 4 . The variance of the initial $l$ values of the series is then used to estimate the variance of the current regime ( $\mathrm{V}_{\text {cur }}$ ). For the new regime to be statistically different from the current regime, its variance ( $\mathrm{V}_{\text {new }}$ ) should be equal to or greater than the critical variance ( $\mathrm{V}_{\text {crit }}$ ) if the variance is increasing or equal to or less than the critical variance $\left(\mathrm{V}_{\text {crit }}\right)$ if the variance is decreasing, where

$$
\begin{aligned}
& \mathrm{V}_{\text {crit }}=\mathrm{V}_{\text {cur }} \cdot \mathrm{F}_{\text {crit }} \\
& \mathrm{V}_{\text {crit } \downarrow}=\mathrm{V}_{\text {cur }} / \mathrm{F}_{\text {crit } \downarrow}
\end{aligned}
$$

The variance, $\mathrm{V}_{\text {cur }}$, is the sum of squares of $\mathrm{z}_{\mathrm{i}}$, where i spans from the first point of the current regime to $i=t_{\text {cur }}-1$. If, at time $\mathrm{t}_{\text {cur }}$, the current value $\mathrm{z}_{\text {cur }}$ satisfies either $\mathrm{z}^{2}$ cur $>$ $\mathrm{V}_{\text {crit } \uparrow}$ or $\mathrm{z}_{\text {cur }}^{2}<\mathrm{V}_{\text {crit } \downarrow}$, this time is marked as a potential point
where a regime shift in the variance has occurred. Subsequent values ( $\mathrm{z}_{\mathrm{cur}+1}, \mathrm{Z}_{\mathrm{cur}+2} \ldots$ ) are used to verify this hypothesis by using a Residual Sum of Squares Index (RSSI).

$$
R S S I=1 / l \sum_{i=t_{\text {cur }}}^{m}\left(z_{i}^{2}-V_{\text {crit }}\right),
$$

where $\mathrm{m}=\mathrm{t}_{\mathrm{cur}}, \mathrm{t}_{\mathrm{cur}}+1, \ldots, \mathrm{t}_{\mathrm{cur}}+l-1$.
If, at any time during the testing period from $\mathrm{t}_{\text {cur }}$ to $\mathrm{t}_{\mathrm{cur}}+l$ -1 , the index turns negative for the case where $\mathrm{V}_{\text {crit }}=\mathrm{V}_{\text {crit }}$ or positive for the case where $\mathrm{V}_{\text {crit }}=\mathrm{V}_{\text {crit }}$, the hypothesis of a regime shift in variance at time $t_{c u r}$ is rejected and $z_{\text {cur }}$ is included in the current regime. Otherwise, time $t_{\text {cur }}$ is taken as a break point at which a regime shift in variance occurred.

In essence, Rodionov's (2005) approach first detects an anomaly and then goes on to determine whether that anomaly persists over time. A regime shift in variance is identified only when it does. Because his approach is simple and requires little accumulated data, it is appropriate for the statistical detection of regime changes in variance in the type of task that our participants completed.

In our task, the value of the lower variance was 25 and, hence, $\mathrm{V}_{\text {crit }}=25 \times 4=100$. The value of the higher variance (225) exceeded this critical value by a large amount (125). The value of the higher variance was 225 and, hence, $\mathrm{V}_{\text {crit } \downarrow}=225 / 4=56.25$. The value of the lower variance (25) was less than this critical value by only a small amount (31.25). However, the relative difficulty of two comparative judgments does not depend on the size of the absolute difference between the stimuli.

According to Weber's Law, "The stimulus increase which is correctly discriminated in any specified proportion of attempts (except 0 and 100 per cent) is a constant fraction of the stimulus magnitude" (Thurstone, 1959, p. 61). In the case of upward changes in variance, the change in variance that participants had to detect (125) as a proportion of the critical variance (100) was 1.25 . In the case of downward changes in variance, the change in variance that participants had to detect (31.25) as a proportion of the critical variance (56.25) was 0.56 . Hence the task of deciding whether there was evidence of a new variance regime would have been more difficult when the variance decreased from the high to the low value than when it increased from the low to the high value.

In terms of Rodionov's (2005) approach, for each current value, $\mathrm{z}_{\mathrm{cur}}$, it would have been harder to determine whether $\mathrm{z}^{2}$ cur was less than $\mathrm{V}_{\text {crit }}$ than to determine whether it was greater than $\mathrm{V}_{\text {crit }}$. As a result, the initial assessment of whether a potential anomaly had occurred at $t_{\text {cur }}$ would have been harder for a downward than for an upward anomaly. Furthermore, using the RSSI to verify whether the potential anomaly should be confirmed would have been less effective for a downward than for an upward anomaly.

We have outlined this process-based account using the parameters of our experimental task but it could be applied to any task in which comparative judgments of variance are made. Of course, other process-based accounts are possible:
the strategy outlined by Rodionov (2005) is not the only statistical approach to detecting regime change in variance. Indeed, it is possible that no unitary process-based explanation would be appropriate to account for the asymmetry in our data. We may have evolved so that the characteristics of the processes that detect upward and downward changes in variance are different. It is to this possibility that we turn next.

## A functional explanation

A sudden increase in volatility can be regarded as a signal onset and a sudden decrease in volatility as a signal offset. Work in psychophysics indicates that people are better at detecting the onset of a signal than the offset of one (e.g., Ahumuda, Marken, and Sandusky, 1975). This phenomenon can be given a functional interpretation, albeit a more general one than that we proposed when discussing the results of Experiment 1. The onset of a signal is likely to be of greater importance to an organism than the offset of one. Signal onsets (e.g. the appearance of a predator) are more likely to require urgent and rapid action than signal offsets (e.g., the disappearance of a predator).

One objection to this account is that differences in signal importance should be expected to affect response bias ( $\beta$ ) rather than sensitivity ( $\mathrm{d}^{\prime}$ ). If a signal is more important, the response criterion should be shifted to the left to increase the proportion of hits. In other words, there should be no difference in $\mathrm{d}^{\prime}$ values for detecting signal onsets and offsets. Instead, responses should be more biased in favour of saying there is a change when signals start low but may change to high (potential signal onset) than when they start high but may change to low (potential signal offset).
The problem with this approach is that shifting the response criterion to the left will also serve to increase the proportion of false alarms. Responding to these false alarms is likely to be costly. For example, animals reacting to a non-existent predator may lose foraging time and flee into a more dangerous environment. These high costs would tend to force the response criterion rightwards and so counteract the benefit-driven increase in hit rate arising from moving it leftwards. According to this functional account, evolution resolved this dilemma over time by increasing sensitivity to signal onsets. Such a strategy would avoid the increased costs arising from the additional false alarms associated with a laxer response criterion while still assuring the benefits of a high hit rate.

## Implications

Although the phenomenon that we have identified is not specific to identification of changes in risk, it still has implications for risk perception. In finance, sudden changes in series variance occur (Hammoudeh and Li, 2008; Todea and Petrescu, 2012). Although attempts to predict these changes have been made using autoregressive conditional heteroskedasticity ( ARCH ) and generalized autoregressive conditional heteroskedasticity (GARCH) models
(Bollerslev, 1986; Engle, 1982), severe problems in forecasting them remain.

For Mandelbrot (1997), this was not surprising. He argued that bursts of high volatility are inherently unpredictable and emerge naturally as a consequence of the nonlinear processes responsible for generation of financial series. He claimed that these series do not meet the assumptions of modern financial theory (e.g., Markowitz, 1959; Sharpe, 1964; Black and Scholes, 1973) but are, instead, fractal. If he is correct, technical analysts and traders cannot possibly predict sudden volatility changes in financial series. Instead, all they can do is to be alert to the possibility that such changes will occur and then react to them appropriately as soon as possible.

Assuming that sudden volatility changes in financial series are not predictable, how would the asymmetry that we have identified here affect trading behavior? Increases in risk may lead investors to sell winning shares to lock in their profits but to keep losing ones in the hope that high volatility will provide an opportunity of selling them later at a higher price. Decreases in risk should lead to investors keeping their winning shares because nothing untoward will happen but to sell their losing shares because there is no chance of their bringing in a higher price later if they are retained. Easier detection of an increase than a decrease in volatility will lead responses to increases in risk to dominate responses to decreases in risk. In other words, the tendency to sell winning shares but to retain losing ones will dominate. This is the disposition effect (Shefrin and Statman, 1985). While we would not wish to claim that easier detection of increases than decreases in risk is the only driver of the effect, it may be contributory.

In our experiments, we presented time series graphically. We could explain our results by assuming a) that graphs were scanned left to right so that earlier data points were encountered before later ones, and b) that signal onsets are easier to detect than signal offsets. Both these assumptions are supported by existing evidence in the literature.

Consider now the case where the data points are encountered sequentially in real time. We would no longer need to make the first assumption: the earlier points would be encountered before later ones anyway. Hence, given that the second assumption holds, we would expect the asymmetry to be maintained. In other words, our findings could be expected to generalize to situations in which people experience data points successively over a period in real time.

For example, situations in which operators of some system receive readings in this way but assess volatility judgmentally rather than formally may produce a greater tendency to implement measures to protect against increased risk than to remove those measures once the period of increased risk has passed. Such situations could include those associated with natural hazards, such as evacuation decisions in the case of potential volcanic eruptions or hurricanes.

We would not wish to claim that asymmetric tendencies to respond to increases and decreases in risk in such cases
should be characterized as cognitive biases. In line with the functional approach discussed above, they may represent sensible ways of responding to changes in risk levels.

#### Abstract

This study investigated how the expectations of others (i.e., top-down processes) and actual perceived behavior (i.e., bottom-up processes) influence negotiations during humanagent interactions. Participants took part in several sessions of the ultimatum game; we investigated the bargaining strategies directed toward the computer agent. To investigate the influence of top-down and bottom-up processes on performance, we designed an experiment wherein (1) participants expected their partners were humans or agents, and (2) agents used different types of algorithmic behavior. Results revealed that irrational decisions, which are characteristic of human-human interactions, emerged when participants believed their opponents were human and when opponent behaviors were ambiguous. Further, we found participants adopted different bargaining strategies according to their expectations and the agent's specific algorithmic behavior. We discuss interplay of the two types of cognitive processing in human-agent interaction.

Keywords: human-agent interaction; top-down/bottom-up processes; social interaction; ultimatum game

## Introduction

Studies in human-computer interaction have revealed that how people engage with systems depends on how the agents are perceived (Nass, Moon, Fogg, Reeves, \& Dryer, 1995). The human user responds to social cues (Johnson, Veltri, \& Hornik, 2008) and to the apparent level of agency of the system (Blascovich et al., 2002). Studies have focused on how users adaptively interact based on their developing representation of the agent, which can be driven by the use of prior knowledge, such as using heuristics (top-down processing), and which can be modified based on the agent's actual behavior (bottom-up processing) (Hayashi \& Miwa, 2008). However, it is still unclear how the interdependence of these cognitive processes emerges, and it is not fully understood in which situations such interdependence occurs. To investigate these issues, we conducted a human-agent experimental study that involved negotiation in an ultimatum game.

## Two types of cognitive processing in human-agent interaction

Under what circumstances human-like traits such as agency are assigned to computers has been investigated in the fields of human computer interaction and interfaces (Kiesler, Waters, \& Sproull, 1996; McEneaney, 2013; Nass et al., 1995; Johnson et al., 2008; Blascovich et al., 2002). Theoretical studies of human computer interaction (e.g., Nass et al.
(1995)) have noted that people unintentionally respond to technology that exhibits social traits as if it were human, as a way to conserve cognitive resources and maximize response efficiency. HCI studies also suggest that how people perceive computers depends on the social cues that are designed into the system. For example, human facial features (Gong, 2008), embodied gestures (Buisine \& Martin, 2007), and language use (McLaren, DeLeeuw, \& Mayer, 2011) provide for a human-like agent that evokes social responses. However, there is controversy associated with this theory: such automatic responses have been suggested to be aberrant behaviors that result from situational inattention or inappropriate overgeneralization (McEneaney, 2013).
Recent studies in human-agent interaction (HAI) have pointed out the importance of top-down and bottom-up cognitive processing (Miwa \& Terai, 2006). Top-down processing is based on the socialized knowledge of others, i.e., interpersonal schemas or stereotypes (Fisk \& Taylor, 1991). Such processing is essential for developing representations of others in the initial stage of interaction, and can be used as supplemental information when representations are difficult to develop based on other's behaviors. However, the representation of others may change over time due to their ongoing behavior and the context in which the interaction occurs (Hayashi \& Miwa, 2008). Such behavior-based processes are examples of bottom-up processing.

It is important to note that in interpersonal communication between humans, people flexibly use both types of cognitive processing to economically process information when developing representations of others and deciding upon a response. However, few studies have investigated the relationship between the two types of processing in HAI, and it is unclear how such processing plays a role in interactions. Accordingly, in this study we used the Ultimatum Game (UG), a bargaining game that is commonly used in behavioral economics (Guth \& Tietz, 1990), to investigate how the combination of expectations and actual behavior influences cognitive processing during decision making.

## Influence of top-down and bottom-up processing in an ultimatum game

The ultimatum game is often used to investigate behaviors that are not self-regarding, such as choice inequity and reciprocity (Yamagishi et al., 2009). This game is played by two
players a proposer and a responder. Typically, one individual actively participates at any given time (i.e., it is a turntaking game).

First, the proposer receives a sum of money from the experimenter and then makes a proposal concerning how to share the money with the responder. The responder is given two alternatives, namely to either reject or accept the proposal. If the proposal is accepted by the responder, both players receive money according to the proposal, but if the responder rejects the proposal neither receives any money. As such, the self-regarding profit-motivated behavior is to accept any proposal.

Interestingly, respondents tend to reject proposals that are not distributed fairly, even when doing so results in a loss of profit for both players (Guth \& Tietz, 1990). In the current study, it is assumed that if the respondent (participant) perceives the proposer (agent) as human, the former may react accordingly, such as by rejecting proposals and abandoning profit as in human-human studies. We controlled the expectations (i.e., top-down processing) of the participants and determined whether expectations of their partner, such as believing the partner is human or non-human, would produce irrational behavior.
H1: When given an unfair proposal, the rejection rate by the respondent will increase when he/she thinks the partner is human compared to a computer agent.

However, as mentioned previously, actual behavior during interactions is used to update the representation of others (i.e., bottom-up processing). To investigate this issue, we used a multi-period version of the ultimatum game (mUG) (Guth, 1995). Studies have revealed that over repeated trials, players learn to expect that the proposer will suggest a fair deal in some future trial; as such, proposal rejections tend to decrease. That is, the number of rejections decreases due to understanding the strategy of the opponent (Slembeck, 1999). Therefore, we hypothesized that if the agents (proposers) showed concessional bargaining behaviors, and participants could perceive such behavior, respondents would perform more rationally by reducing the frequency of rejections.

H 2 : The rejection rate will decrease when participants understand that the proposer will provide concessional proposals.

Assuming that top-down and bottom-up processing are interdependent, it can be further assumed that the effect of expectations will emerge only when others' behaviors can be explicitly interpreted. To investigate this issue, we produced agents with different algorithmic behaviors, which will be described in more detail in the following section.

## Method

## Participants and procedure

Seventy-six (male: 30, female: 46, Mage: 21.38 , SD: 1.03 ) Japanese university students majoring in psychology voluntarily participated in the task; 3 were subsequently excluded
from data analysis because they discovered that their partner was not human.
Participants collected in small groups in a computer room and were instructed how to play the mUG game. They were told that they would play the role of either the proposer or responder; however, all were actually assigned the role of responder and the computer agent played the role of the proposer.

Figure 1: Example screenshot the task.
After the brief introduction to the task, participants were told to start the program, which appeared to connect to a randomly chosen peer in the computer room. They were told that 1,000 Japanese yen (approximately 12 dollars) was provided to the proposer. On the left hand side of the screen, the participant was required to input his or her IP address, which was nominally for connection to the opponent. Below were simple instructions including what he or she would/would not receive based on his or her decision. On the right hand side, the current proposal was shown. Below were decision buttons and a send button to transmit the result to the proposer.

First, a screen appeared that prompted the participant to wait until the proposer finished entering the amount of the proposal. After a short delay, the screen changed to that shown in Figure 1. Then, the participant chose to either accept or reject the proposal.

A proposal and subsequent decision constituted one trial and a total of 15 trials were conducted in one set of this task; two sets of this task were conducted in total. After completing the task, the participant wrote down a description of how he or she felt about his or her partner.

## Experimental conditions

This study examined mUG performance changes due perception of the partner as human or non-human and the partner's actual behavior. We used a 2 (perceived partner: human vs agent) X 4 (actual behavior: random vs adaptive [simple, egocentric, exocentric]) experimental design. The perception of the partner was controlled by telling the participant that the partner was either human or a computer agent. The former was called the human condition and the latter the agent condition.

In each set of the task, the announcement that the partner was human or computer was announced and the order of such announcements was counterbalanced between the small groups. There were no differences in rejection rates according to the order.

To investigate the effect of agent behavior, we implemented agents that utilized (1) algorithmic behavior or (2) no such algorithmic behavior (random condition). To determine how participants change their interactive strategies based on perceived behavior and ongoing interactions, we implemented three different types of behavior for (1). We examined different algorithms, including those that were likely to be perceived as offering generous or fair proposals. If bottom-up processing predominated in this task, the participant would likely adopt the rational strategy of accepting all proposals from these types of agent.

## Behavior of agent

In this section we describe the parameters that defined the agent behaviors. Table 1 shows all possible responses that could be generated by the agent for each trial. In the first trial, the agent always selected response type 4 in all conditions. Then, in the next and subsequent trials, the probability of generating each different response type differed according to the condition.

Table 1: Types of response(proposals) by the agent

| response type | amount of proposal (yen) |  |
| :---: | :---: | :---: |
|  | proposer(agent) | responder(participant) |
| $r 1$ | 100 | 900 |
| $r 2$ | 200 | 800 |
| $r 3$ | 300 | 700 |
| $r 4$ | 500 | 500 |
| $r 5$ | 700 | 300 |
| $r 6$ | 800 | 200 |
| $r 7$ | 900 | 100 |

In the random condition, the agent selected fair/unfair proposals (response type 1-7) randomly, with equal probability. This allowed for the investigation of ambiguous behaviors (i.e., restricting bottom-up processing). In egocentric, exocentric, and adaptive conditions, the agent proposed concessional and generous responses based on the participant's decisions.

In the simple adaptive condition(hereinafter referred to as adaptive condition) the agent repeated the proposal if it was accepted, and otherwise proposed the completely opposite monetary strategy (i.e., fair versus unfair). This was based on the Pavlof strategy in social games, wherein the basic rules are "win-stay" and "lose-shift" (Nowak \& Sigmund, 1992). In Figure 2, SAME denotes repeating the same proposal as in the prior trial.

The egocentric and the exocentric conditions were based on the adaptive condition. In the egocentric condition, the agent responded such that the proposal was clearly biased toward the computer agent(see Figure 3). More specifically, the

```
[r1-r3]
"accept" - > %SAME%
"reject" - > r5-r7:33.33%
[r4]
"accept" OR "reject" - >r1-r3,r4-r7: 16.66%
[r5-r7]
"accept" - > %SAME%
"reject" - >r1-r3:33.33%
```

Figure 2: Algorithm schematics of the adaptive condition.
agent reacted economically, such as proposing r3 if the participant kept accepting this proposal. The agent behavior in the egocentric condition is shown below. The agent decided on the next proposal depending on whether the participant accepted or rejected the previous proposal. For example, in the first trial the agent always proposed r 4 (see Table 1). On trial 2, if the participant selected accept, then the agent generated the next proposal based on the following probabilities: r1 (10 \%), r2 (20 \%), r3 (70 \%).

```
[r1]
"accept" -> r1:10%,r2:20%,r3:70%
"re ject" - > r5: 10%,r6: 20%,r7:70%
[r2]
"accept" - >r2:30%,r3:70%
"reject" -> r5:10%,r6:20%,r7:70%
[r3]
"accept" - > r3: 100%
"reject" - > r5: 10%,r6: 20%,r7:70%
[r4]
"accept" - > r1:10%,r2:20%,r3:70%
"reject" - > r5:10%,r6:20%,r7:70%
[r5]
"accept" - > r5:10%,r6:20%,r7:70%
"reject" - >r1: 10%,r2:20%,r3:70%
[r6]
"accept" - > r6:30%,r7:70%
"reject" -> r1: 10%,r2:20%,r3:70%
[r7]
"accept" - > r7 : 100%
"reject" - >r1:10%,r2:20%,r3:70%
```

Figure 3: Algorithm schematics of the egocentric condition.

In the exocentric condition the agent responded such that it sought less profit than in the egocentric condition(see Figure 4). If the participant kept accepting the proposals, the agent gradually proposed r1 more frequently, and even unfair, agent-biased proposals were most often r5 (i.e., relatively modestly favoring the agent).

```
[r1]
"accept" - > r1 : 100%
"reject" - >r5:70%,r6:20%,r7: 10%
[r2]
"accept" - > r1:70%,r2:30%

## Results

## Performance of participant: Rejection rate

The participants' percentage rejections are shown in Figure 5. The vertical axis represents the average percentage of proposals rejected during the 15 trials, the horizontal axis shows each behavioral condition, and the different bar shading denotes the different instructions.

A 2 instructions (human or agent) x 4 agent behaviors (random, adaptive, egocentric, or exocentric) mixed factorial ANOVA revealed a significant interaction between the two factors $(F(3,72)=4.535, p=.0057)$. Analysis of simple main effects indicated that in the random condition, proposals by an apparently human opponent were rejected more often than those of a computer opponent $(F(1,72)=18.144, p=$ .0001 ), whereas there were no differences for the adaptive, egocentric, and exocentric conditions $(F(1,72)=0.504, p=$ $.4800 ; F(1,72)=2.016, p=.1600 ; F(1,72)=0.165, p=$ .6862, respectively).
The simple main effect of instruction (human or agent) was also significant for each behavior condition $(F(3,72)$ $=9.543, p=.0001 ; F(3,72)=3.388, p=.0198)$. Multiple comparisons using Ryan's method for the human instruction and showed that rejections were higher for the random condition than the adaptive, egocentric, and exocentric conditions ( $p=.0001 ; p=.0001 ; p=.0076$, respectively). For the agent instruction, the random condition only differed from the egocentric condition ( $p=.0052$ ). Also, when they were instructed that their partners were agents, the egocentric con-
dition was associated with less rejections than the exocentric condition ( $p=.0092$ ).

To summarize, the effect of instruction was significant when the behavior of the agent did not have any intention (i.e., the agent engaged in non-adaptive behavior). This indicates that H1 is supported only when others' behaviors cannot be used to understand their strategy (i.e., bottom-up processing is not possible). In contrast, the effect of the behavior markedly influenced the participants' performance; therefore, H2 is supported. However, participants' performance changed contingent on how they perceived their partner. That is, instruction and behavior interacted.

Figure 5: Ratio of rejections.

## Behavior of agent: ratio of proposal types

To further understand how the agents adaptively changed their behavior due to the participants' decisions, we examined the actual proposals made by the agents. Figure 6 shows the distribution of proposals for each condition. We then conducted an ANOVA that included the three behavioral conditions that adaptively changed their behavior based on the participants' decisions.

For the human condition, we conducted a $7 \times 3$ mixed factorial ANOVA with the seven selected responses (r1, r2, r3, r4, r5, r6, or r7) and adaptive conditions (adaptive, egocentric, or exocentric) as independent factors. There was significant interaction between the two factors $(F(12,324)=22.147$, $p=.0001$ ). Since we wanted to investigate which response appeared most frequently within each condition we only conducted simple main effects analysis for each level of condition. Significant main effects were present for all conditions (adaptive: $F(6,324)=5.211, p=.0001$; egocentric: $F(6$, $324)=45.798, p=.0001$; exocentric: $F(6,324)=18.403, p$ $=.0001$ ).

Next, multiple comparisons using Ryan's method were conducted for the adaptive condition. Response types r1, r2, and r 3 were used more frequently than r 3 , r 4 , r 5 , and r 6 ( $p$ $=.0001$, for each comparison). For the egocentric condition, response r 3 was used more often than all other responses ( r 1 , $\mathrm{r} 2, \mathrm{r} 4, \mathrm{r} 5, \mathrm{r} 6$, and $\mathrm{r} 7 ; p=.0001$, for each comparison). For the exocentric condition, response r 1 was chosen more frequently
than $\mathrm{r} 2, \mathrm{r} 3, \mathrm{r} 4, \mathrm{r} 6$, and $\mathrm{r} 7(p=.0001$, for each comparison) and response r 5 was used more frequently than $\mathrm{r} 2, \mathrm{r} 3, \mathrm{r} 4, \mathrm{r} 6$, and r7 ( $p=.0001$, for each comparison).

For the agent condition, we conducted the same analysis and found a significant interaction between the two factors $(F(12,324)=27.581, p=.0001)$. Focusing on the same simple main effects, responses differed according to condition $(F(6,324)=4.541, p=.0001 ; F(6,324)=52.996, p=$ $.0001 ; F(6,324)=22.469, p=.0001)$. Multiple comparisons revealed exactly the same pairwise differences were significant as in the human condition ( $p=.0001$, in each case).

To summarize: (1) in the adaptive condition, r1, r 2 , and r3 were used most frequently; (2) in the egocentric condition, r3 was most commonly used; and (3) in the exocentric condition, r1 and r5 were the most frequent proposals. This shows that agents responded differently to the participants' decisions and that the agent frequently generated proposals that did not favor itself in the exocentric condition.

Figure 6: Ratio of generated proposal(top: human condition, bottom:agent condition).

## Discussion

## Influence of the expectation of the other

The rejection rate data revealed that when the opponent had no strategy (i.e., random condition) the effect of expectations played an important role (i.e., human condition vs. agent condition). This shows the influence of top-down and bottom-up processing and their interdependence, whereby participants used initial expectations to generate a representation of their
opponent when the opponent's behavior was not clearly interpretable.

However, why did participants reject the proposer's offer most frequently when the proposer was believed to be human? Past research on economic behaviors using the UG has provided various explanations as to why participants reject proposals, even when doing so is not rational (Guth \& Tietz, 1990). Fehr and Schmidt (1999) proposed "inequity aversion theory," which posited that people are sensitive to unfair proposals, regardless of who profits most. People aim to balance inequities by rejecting unequal proposals. Furthermore, Falk, Fehr, and Fischbacher (2003) suggested that following unfair proposals, rejections will rise due to the interpretation of how the proposal was decided upon. I.e., there is an attribution of intentionality or animosity by others. As such, participants may have attributed the same types of intentions to their opponent in this study. However, when they believed their opponent was non-human, such human-specific effects did not occur and rejections decreased.

## Influence of the types of adaptive behaviors

The agent's behavior strongly affected rejection rates, whereby participants tended to reject proposals less frequently when the opponent adopted consistent and adaptive strategies, compared to the inconsistent random condition. This tendency was most pronounced when the partner was believed to be human. This indicates that participants decided upon a strategy based on their understanding of the adaptive behavior (i.e., using bottom-up processing), but relied on initial expectations (i.e., using top-down processing) when the opponent's behavior was unpredictable.

Interestingly, participants tended to behave more rationally (i.e., accepting the proposals) when they expected to interact with an agent only when the agent used an egocentric strategy. This indicates that expectations of such egocentric agents may have suggested that the system was non-negotiable toward fairer proposals, and thus the best strategy was to accept their proposals.

Surprisingly, compared to the egocentric condition, participants behaved more irrationally in the exocentric condition by rejecting proposals that were beneficial to them, such as r1. Figure 6 shows that participants oscillated between r1 and r5 as a consequence of their pattern of rejection and acceptance of proposals. However, why did they reject proposal r1? This can be interpreted as rejection to reduce the dissonance (Festinger, 1957) associated with an unfair proposal, regardless of who profits. Further, this could be a result of adopting social norms, such as inequity aversion (Fehr \& Schmidt, 1999). Such a socially interactive approach may be the result of perceiving the agent as a social actor (Nass et al., 1995).

These findings cast new light on how decisions in humanagent interaction change based on the compound effects of who an actor believes his or her opponent is, and the actual behavioral strategy observed.

## Conclusions

This study investigated the influence of top-down (i.e., expectations of others) and bottom-up processing (i.e., the observation of human-like strategic behavior) on human-agent interaction. This aim was to determine the interdependence of such processing, and to investigate how these processes influence rational decision making in a mUG.

Based on evidence that people reject unfair proposals in human-human interactions, we hypothesized that believing one's partner is human will influence the rejection of other's proposals, if the other's intentions are difficult to interpret (i.e., bottom-up processing cannot be used). By conducting a virtual human-agent experiment, we controlled participants' expectations via agent behavior that followed simple algorithms. The results supported our hypothesis and show that people rely on expectations of the opponent's behavior when the latter's actual behavior is ambiguous. This highlights the interdependent relationship of top-down and bottom-up processing in human-agent interaction.

In addition to the effects of the two types of processing in the mUG, results suggest that people try to avoid inequity; that is, to reject unfair proposals even if they are profitable for themselves. Such a tendency was observed here, even when the participant believed their opponent was a computer agent. This indicates that people treat their counterparts as social actors, even when the goal of the interaction is selfregarding.
In summary, this study supports the interdependent influence of two types of cognitive process, and captures the emergence of irrational decision making in human-agent interaction.

#### Abstract

Previous research conducted by Bergus et al. (2002) identified that treatment evaluations are more negative when risks are presented last. Extending discussion of this order effect, the current studies investigate this effect in tabular style displays, manipulating both order and orientation; and using eye-tracking methodology, explores the effect of these variables on the information search process. Analysis from eye-tracking data revealed a tendency to read information sets sequentially (i.e. read all risk information before transitions to the other set), which is stronger for the vertical orientation where switching between information sets is less common. Further, while balanced search was observed when benefits presented first, when presented with the risks first, search becomes more riskheavy. Eye-tracking measures did not strongly predict treatment evaluations, although, when holding other variables constant, time proportion spent on benefits positively predicted treatment evaluations.

Key words: Eye-Tracking; Information Search; Order Effects; Information Design

## Introduction

Previous research conducted by Bergus et al. (2002) investigated the role of order on judgements and decisions about a treatment. In their study, they investigated the effect that presenting either the risks last (benefits then risks presentation) or benefits last (risks then benefits presentation) had on favourability ratings of a treatment and choice about whether they would consent to a treatment. For their low risk Aspirin scenario, they found that when the last set of information read was about the risks (i.e. those presented with benefits then risks), ratings of favourability decreased (from pre-task favourability) compared to those who learned about the benefits last (i.e. presented with risks then benefits). Those presented with the risks last were also less likely to consent to a treatment.

Further evidence of this type of reliance or influence of the last piece of information processed (potentially because of its prevalence in one's memory) can be seen in a similar study by Ubel et al. (2010; who presented breast cancer patients with information about the benefits and risks of tamoxifen) and in other decision making tasks involving sequential information processing where individuals play an active role in searching out the information for themselves (Rakow, Denes \& Newell, 2008; Ashby \& Rakow, 2014).

When presented with this type of information in a medical setting or when people search for health information online, this information can often be presented using tabular-style displays (where risk and benefit information is separated into clear columns or rows either using a lined table or bullet point display). One such example, where this type of tabular style information format has been used is on the UK National Health Services (NHS) Choices website, where a fact sheet for prostate cancer screening (PSA) testing, which uses such separated, and bullet pointed display of the risks and benefits, is used (NHS Choices, 2016).

With such tabular displays (or any display allowing people to see the information simultaneously about the risks and benefits), the order in which people read the information is to some extent open to the individual. Research on information and picture search however reveals that people tend to examine information in an order consistent with their reading system, with those in western cultures starting in the top left and showing a bias to the left side of space and horizontal saccades made more frequently than vertical saccades (Foulsham et al., 2013; Foulsham, Kingstone \& Underwood, 2008).

These differences in search lead to questions of how these differences may generalize to more specific differences in perceptions of health information. For example, how such a bias to reading the left side (or top) first may indicate that information read in this position is likely to be read first and thus make order important. Or, how, with horizontal saccades being more common than vertical saccades, a choice of orientation (whether blocks are presented side-byside (i.e. horizontal arrangement) or above-and-below (i.e. vertical arrangement) may impact on search differences across information blocks.

## Current Study

Focusing on these types of tabular displays where information is presented simultaneously, the current research investigates whether such effects replicate across four low-risk (non-invasive) medicinal scenarios and whether orientation interacts with order.

Further, to understand the effect that such design choices of order and orientation have on pre-decisional information search strategies when presented with this information, eye-
tracking methodology was used to investigate information acquisition (search) processes. In particular, measures of looking order, proportion of time spent on the benefits number of transitions between reading the benefits and risks were calculated from the eye-fixation data.

Such measures allow a range of questions to be answered about people's search:

1) Is search consistent with the manipulated order or do people switch between searching between information sets frequently when given the choice?
2) How is search behavior affected by changes to the order and orientation?
3) Does this search behavior map onto subsequent treatment evaluations?

Predictions: Three main predictions were made, based on the literature presented above:

- Based on Bergus et al (2002), a recency effect is predicted. Thus, people should be more influenced by the information presented last.
- Despite simultaneous presentation, people will read information according to the manipulated order (i.e. in the order consistent with reading patterns).
- From findings that horizontal saccades occur more frequently than vertical saccades (Foulsham et al., 2008), reduced switching in the vertical orientation is predicted, which may lead to a stronger order manipulation in this orientation.

## Methods

## Participants

One hundred and fifty two students (108 in Study 1; 44 in study 2) from the University of Essex participated for course credit or payment.

## Materials and Procedure

## Evaluation Task

In both experiments, participants were presented with four hypothetical situations:

- Aspirin therapy treatment for mild carotid stenosis
- Statins for high cholesterol
- ACE (angiotensin converting enzyme) inhibitors for high blood pressure
- Anticoagulant medicine for deep vein thrombosis

Each scenario began with an introductory page, explaining the situation which led to the hypothetical medical diagnosis, the medical diagnosis is (and means) and what one of the recommended treatments is.

Next, participants were presented with three risk and three benefit statements for that treatment scenario (which were closely matched for characters/word length). These were presented in one of four orientation $X$ order presentations, such that either the risk information or benefit information
is presented first (either on the left or top) and with either information presented in a vertical (figure 1a: up/down) or horizontal (figure 1b: left/right) orientation.

Figure 1c: Example Scenario: Statins Horizontal: Benefits First

Irrespective of presentation order (orientation) after each risk (benefit) presentation, participants were presented with six treatment evaluation questions ( 3 positive \& 3 negative):

- P1: How favourable would you rate the treatment?
- P2: Would you choose the treatment?
- P3: Would you recommend this treatment?
- N1: How concerned would you be about the side effects?
- N2: Would you avoid this treatment?
- N3: If you were to choose this treatment, how likely do you think it is that you would experience one of its side effects?

For each of these questions, rating responses were made on a 7-point scale. For the analysis, because of a high Cronbach's alphas ( $\alpha$-range . $87-.92$ in study 1 ; $\alpha$-range . 85 .92 in study 2), responses from across these six questions (after reverse coding the scores for the three negative questions) were combined for each participant to form an overall treatment evaluation rating.

## Eye tracking

In Study 2, eye-tracking was conducted during the risk and benefit presentation phase of the study using the EyeLink 1000. The study was conducted within the associated Experiment Builder software application. Interest areas were defined around the six statements ( 3 risks, 3 benefits) and the two titles (Benefits, Risks).

From the eye-tracking data that was recorded, three main measures were calculated: SMRD order scores, time proportion (on Benefits) and number of transitions, and are explain below:

SMRD Order: This was chosen as a way of measuring whether actual looking order is consistent with the "manipulated order" (i.e. that when the risks are presented first according to our design, people look at the risks first). To create our measure of looking order, the formula used by Johnson, Häubl and Keinan (2007) was adapted ${ }^{1}$. While they used it to examine the order of thoughts (which they had people write down), we adapted it to examining looking order by replacing thoughts with fixations in the formula.

To calculate this, the formula below (Figure 2) was used (where MR represent median rank):

$$
\frac{2\left(M R_{\text {Eenefit }}-M R_{\text {Risk }}\right)}{\text { Number of Fixations }}
$$

Figure 2: SMRD Order Formula
To allow this calculation of ranks to be conducted, fixations were coded for order. For example, the first fixation coded as " 1 ", the second as " 2 " and so forth until all fixations included. Taking an example, looking mainly at the risk first lead to a positive SMRD score, and mainly benefits first a negative SMRD score.

Time Proportion: Another potentially relevant variable in determining people's subsequent choices is the proportion of time spent looking at the different types of information (i.e. risk and benefits), which helps to represent a measure of attention (i.e. amount of attention paid to each type of information).
Using the interest areas that were preset into the eye-link analysis software, this measure calculated the time spent looking in each interest area. This was then transformed into a proportion of time by dividing the time spent in the interest area by total time spent. From this, the proportion of time spent on the benefits was calculated by summing the proportion of time spent on the four relevant interest areas (i.e. the three benefits and benefit title for time spent on the benefits). Thus, at the end, a percentage score out of 100 was calculated and represented the balance of time spent on the benefits (versus the risks).

No of Transitions: This also represented a measure of attention, but this measured how people switched their attention between information sets. This was chosen to investigate the findings from the search literature of a tendency to make horizontal rather than vertical saccades (see introduction and prediction 3 for details).

For our purposes, this measured the number of times people switched between reading the risk information block to reading the benefit information block. A transition was

[^346]coded every time two adjacent fixations in the time-ordered fixation sequence were from different information blocks (i.e. one was from the risk block, while the other was from the benefits block).

## Results

## Eye-tracking Information Search Analysis

Each analysis was conducted collapsing the four scenarios ${ }^{2}$ and using a generalized estimating equations (GEE) model ${ }^{3}$ (with exchangeable correlation matrix, robust standard errors and Gaussian identity matrix).

## Order SMRD Score

As can be seen from the graph in figure 3 (note: scores of 1 denote reading all risks before all benefits, while -1 denotes reading all benefits before all risks), our manipulation of order was successful ( $B=0.80, \mathrm{Z}=24.44$, $\mathrm{p}<.001$ ), with those presented with the risks first (i.e. on top or on the left hand side) reading the risks first (and therefore having a positive SMRD scores) and those shown the benefits first showing a negative SMRD order score.

Although no significant main effect of orientation was found, a significant interaction between order and orientation was identified ( $\mathrm{B}=0.08, \mathrm{Z}=2.59, \mathrm{p}=.009$ ). As this shows, what is happening is that SMRD scores are closer to 0 in the horizontal orientation. As such, supporting our third prediction that the effect of order would be stronger in the vertical orientation (i.e. SMRD scores closer to extremes of +1 and -1 ).

## Time Proportion Spent on Benefits

As can be seen from the graph in figure 4, only small differences are seen between the different orientations. One

[^347]would predict that people would look evenly at the information and, as figure 2 shows, this is the case when the benefits are presented first (Horizontal: $t(40)=1.09, p=.283$. Vertical: $\mathrm{t}(46)=-0.79, \mathrm{p}=.43)^{4}$. However when risks are presented first, the time spent on the benefits drops and search becomes risk heavy (Horizontal: $\mathfrak{t}(32)=-5.17 \mathrm{p}<.001$; Vertical: $\mathrm{t}(54)=5.65, \mathrm{p}=.001)$.

Figure 4: The effect of order and orientation on time proportion spent searching the benefits information

## No of Transitions

As Figure 5 below demonstrates, while order (whether risks or benefits first) played little role in how many times participants transitioned between risk and benefit information, orientation made a big different to how many time people switched between reading the different information sets ( $\mathrm{B}=-0.85, \mathrm{Z}=-4.09, \mathrm{p}<.001$ ). When participants were presented with the information side by side (the horizontal orientation), participants were more likely to switch between reading information about the risks and reading information about the benefits. For the vertical orientation (where information was presented above and below), switching occurred less commonly.

Figure 5: The effect of order and orientation on number of transitions between information sets

## Effect on Overall Treatment Evaluations

"Manipulated Order" Analysis: As figure 3 reveals, people look in the manipulated order (i.e. generally looked

[^348]at the benefits before the risks in the benefits then risks conditions), as such it is appropriate to investigate the effect of these different order X orientation conditions on treatment evaluations. Across both experiment 1 and 2, only in 1 of the 8 scenarios did an effect of order reach significance (ACE Study 1, $F(1,102)=7.90, p=.006$, $\eta^{2}=.072$ ) all others $\mathrm{F}<1.30$, $\mathrm{p}>.275$ ). No main effects of orientation (all $\mathrm{F}<2.27, \mathrm{p}>.135$ ) or interaction between order and orientation (all F<1.96, p>.170) were found. ${ }^{5}$ Thus, in most cases, the treatment evaluation ratings across these four conditions were similar, often sitting close to the middle of the scale.

Eye-tracking Analysis: Holding all other eye-tracking variables constant (i.e. SMRD order and orientation), time proportion on benefits positively predicted treatment evaluations ( $\mathrm{B}=0.02 \mathrm{Z}=2.28, \mathrm{p}=.023$ ).

## Discussion

Considering the original study by Bergus et al. (1992), they found a recency order effect with the most recent information having the biggest effect on subsequent perceptions of a treatment. Unlike those researchers, our results did not support such a recency order effect, finding instead no consistent pattern of recency or primacy. The search data discussed later however does hint at a primacy advantage for negative information as a more likely possibility. Three suggestions are made to explain why such a disparity in results may have been found.

First, returning to Bergus et al.'s (2002) aspirin scenario, it is not clear that the list lengths (i.e. lists of risks and benefits) were matched for either word or character length. In particular, the risk list length appeared longer ${ }^{6}$. Such differences may have enhanced any order effects.

Second, such difficulties in finding consistency in order effects has been discussed by Hogarth and Einhorn (1992). One factor that they highlight of particular relevance for comparing this study to the previous study is the role of evaluation task (or response mode) differences, particularly in short information scenarios. These researchers have argued that differences in the response mode can change the way people evaluate information and what information is used as an anchor. Considering this anchor in particular, while Bergus et al (1992) had an initial evaluation question which provides people with an initial anchor, our study use only an end of sequence response, with no initial anchor specified. With no anchor provided, it is the first piece of information which provides the anchor value. Figure 6a provides an illustration of how these differences in anchor and processing strategy may predict the different pattern of results found in these studies. In particular, as Figure 6

[^349]shows, while a clear recency order effect is seen for Bergus et al. (2002), for our study, by using the first piece of information as an anchor, very little difference between final evaluation scores is predicted.

Third, in particular, it is worth noting that in keeping our scenarios simple and thereby short, this may have attenuated the size of any potential overall order effects on treatment evaluations. This may have occurred since with such short scenarios, it is not unreasonable to think that people could keep all 6 pieces of information (i.e. 3 risks and 3 benefits) in their memory at once, at least once the items' "gist" meaning had been processed (Miller, 1955; Reyna, 2008). Further, such differences in response mode appear to become less important as the scenario length increases and primacy becomes the predicted order effect irrespective of response mode.
Despite these factors, which may affect people's processing of the information in order to make a decision, the search data responses should be relatively unaffected by the strategy choice variable (which should affect starting position and information integration rather than search). Further, at longer scenario lengths, differences would be predicted to be more pronounced with the effect of the response mode diminished.
Looking at this search data reveals that changes in order and orientation do appear to change how people search the information presented. First, providing support that our external manipulation of order was successful, actual search order (as measured by the order SMRD) mapped onto the manipulated order that the scenario was assigned to. When participants were presented with the benefits "first" (at top or left side), they generally read the benefit information first, therefore having a negative SMRD value. When risks were shown "first", risk information was read first and participants had a positive SMRD value.

Thus, even with simultaneous presentation of information (and therefore no external constraints on order of search), people are still affected by a decision aid designer choice of where to place the information in a table. Rather than switching between reading the risks and benefits, participants generally chose to read each information set sequentially. Such effects suggest that typical reading
patterns (i.e. the tendency to start reading at the top left) in some way constrains how people will read information even when presented simultaneously (Foulsham et al., 2013). Thus, suggesting that use of simultaneous presentation format do not automatically remove presentation order effects from consideration.

Of note within this effect of order, the addition of orientation as a variable in our study highlights a further dimension to consider with this effect. In particular, orientation appears to affect the strength of the search order effect, with a stronger order effect seen in the vertical orientation than the horizontal orientation. Thus, a clearer sequential processing strategy - following the manipulated order (thereby reading all risks then all benefits, or vice versa) - is seen in this vertical orientation. When risks and benefits are presented side-by-side however in the horizontal orientation, this is weakened and switching between information sets (i.e. between risk and benefit information) becomes more common. Such results support our third prediction of a stronger order effect in the vertical orientation, based on previous search evidence by Foulsham et al. (2008) which found that in picture search horizontal movements are more common than vertical movements. Such an effect is further supported in the analysis of transitions between information sets where, switching between sets is significantly higher in the horizontal orientation than the vertical orientation.

Considering our final attention-based search measure taken, time proportion spent reading the benefits, this revealed that while an equal proportion of time is spent (approximately $50 \%$ ) on the risks and benefits when benefits are presented first, when risks are presented first, the time spent on the benefits drops and search becomes risk heavy (closer to a $60 / 40$ split). This asymmetric difference may suggest that risk information is particularly attention "grabbing" and difficult to engage from, thereby sustaining attention for longer and reducing the time left to spend reading the benefits. Support for such a finding can be seen in the negativity bias literature, where a propensity to attend to, learn from and use negative information more than positive information has been found, Vaish, Grossmann, \& Woodward, 2008).

Further, such a finding would predict a primacy advantage for the risk information rather than a recency effect, since the extra attention placed on this information as the negativity literature suggests, should lead people to "learn" and "use" this negative information to a greater extent. Thus, leading to more negative treatment evaluations. Such an effect is supported by analysis of the effect of the eyetracking variables, where only time-proportion was a significant predictor of treatment evaluations when holding the other variables constant.

## Future Directions

In future research looking at more complex scenarios, we predict that the search order and orientation differences
would become more pronounced as the amount of information presented is increased and aggregating information in a sequential fashion becomes essential.

Given more complex risk and benefit presentation scenarios, we predict that with such scenarios should lead to a primacy rather than a recency advantage. Such is predicted from our finding of a risky heavy search when risks are presented first (a primacy advantage), evidence that longer scenarios force toward a primacy advantage (Hogarth and Einhorn, 1992) and a reduced role of response mode in these longer scenarios.

For a second type of more complex scenario, multi-attribute (multi-option) choice, the role of orientation on search may be of particular importance. We predict that such orientation changes may change whether a more withinoption search or between option-search processing strategy is taken. Such differences in search tend to lead to the adoption of different choice strategies, which may ultimately affect which option is preferred (Hills \& Hertwig, 2010).

## Conclusion

These results highlight the role that seemingly arbitrary choices about the design of a decision aid, informational leaflet or website, such as order or orientation of the information can affect how information is searched. In certain situations, these search differences may subsequently affect judgements and choices made using such information as a basis for knowledge about a choice scenario.

## Acknowledgments

Financial support for this study was provided entirely by a collaborative PhD studentship received by the first author from the University of Cambridge (Winton Fund) and Economic Social Research Council (ESRC). The funding agreement ensured the authors' independence in designing the study, interpreting the data, writing, and publishing the report.

#### Abstract

Criminal behavior and related disorders have been associated with abnormal neural activity when experiencing or anticipating risks and rewards, as well as when exercising inhibition. However, behavioral and neural substrates of risk preferences and criminality have received scant attention when unconfounded with experience, anticipation, and inhibition. We test predictions of fuzzy-trace theory (FTT) in two experiments using a risky-choice framing task. Behavioral results show that individuals with a greater history of criminal behavior are less likely to engage in simple meaning-based processing and are less confident when doing so. These findings are supported by fMRI results showing a greater history of criminal behavior is associated with increased activation in regions associated with cognitive control when engaging in simple meaning-based processing. These results provide insight into the cognitive processes and brain mechanisms that are associated with criminal behavior.

# Planning in Action: Interactivity Improves Planning Performance

#### Abstract

Planning is an everyday activity that is extended in time and space, yet is frequently studied in the absence of interactivity. Successful planning relies on an array of executive functions including self-control. We investigated the effects of interactivity and self-control on planning using a sequential-task paradigm. Half of the participants first completed a video-viewing task requiring self-control of visual attention, whereas the other half completed the same task without the selfcontrol constraint. Next, and within each of these groups, half of the participants manipulated cards to complete their plan (high-interactivity condition); for the other half, plans were made with their hands down (lowinteractivity condition). Planning performance was significantly better in the high- than in the lowinteractivity conditions; however the self-control manipulation had no impact on planning performance. An exploration of individual differences revealed that long-term planning ability and non-planning impulsiveness moderated the impact of interactivity on planning. These findings suggest that interactivity augments working memory resources and planning performance, underscoring the importance of an interactive perspective on planning research.

Keywords: personal planning, time management, distributed cognition, self-control, ego depletion

## Introduction

Planning is an essential cognitive process that is key to achieving productive time management. Successful planning depends on the ability to anticipate a sequence of operations intended to achieve one or more goals, requiring the capacity to effectively delay and resume the pursuit of goals, according to current resources and constraints (Hayes-Roth \& Hayes-Roth, 1979; Patalano \& Seifert, 1997). The planning process may involve initial planning; a systematic, rational approach where solutions are formulated ahead of plan execution (Morris \& Ward, 2004). As such they are subject to constraints on processing, including working memory resources. An alternative to this top-down model is opportunistic planning where the plan develops in situ driven by incoming information, rather than being entirely goaldirected in advance of any moves (Davies, 2005). Selection of initial or opportunistic planning is based on the problem complexity and environment, and individual differences (Davies, 2005).
Efficient planning depends on the coordination of a
variety of executive functions, ranging from formulating a sequence of sub-goals that together embody a plan, storing and updating the plan, consciously monitoring, up to controlling and coordinating the plan to effect the desired outcome (Morris \& Ward, 2004). This view suggests that successful planning depends on two key cognitive concepts: working memory and self-control. Self-control is defined as "the exertion of control over the self by the self" (Muraven \& Baumeister, 2000, p. 247), occurring when a person attempts to override or inhibit the way they would otherwise think or behave. Working memory is a memory system for temporal information, and is a key theoretical concept for understanding how a limited amount of information is kept temporarily highly available, integrating external and previously-stored information in order to facilitate cognition and complex behaviour (Logie \& Cowan, 2015). Working memory capacity has been linked with the ability to control attention (Engle \& Kane, 2004) and avoid impulsive interferences. These are important requisites of selfcontrol (Broadway, Redick, \& Engle, 2010). With multiple perspectives and potential actions held in working memory during planning, self-control seems key to planning appropriate actions and suppress inappropriate ones. This conception of planning, however, assumes that people solely rely on their mental resources when they engage in planning tasks. Yet reallife planning admittedly involves more than just mental processing: people who plan do so by making notes, writing and rearranging "to-dos" in lists, emails or index cards. In other words, they not only access but also interact with external information by manipulating to-dos while they plan.

## Distributed Cognition and Interactivity

Traditionally, thinking is considered to occur in the head, sandwiched between perceptual inputs and behavioural outputs (to adapt Hurley, 2001). More recently an epistemological shift to a distributed cognition perspective proposes a dynamic cognitive system whose structure is distributed across the internal resources of the individual (such as acquired knowledge) and the resources external to the individual (such as material representations and tools; e.g., Kirsh, 2010). Studies of planning are conventionally conducted in the absence of a distributed cognitive system and with a focus on the
"temporal ordering of action" (Kirsh, 1995, p. 31). Interactivity, by contrast, configures a dynamic agentenvironment system scaffolded from resources internal and external to the agent. In all likelihood, interacting with the physical feature of a problem results in a simpler problem configuration that engages perceptual and pattern matching processes. In addition, by changing the spatial rearrangement, non-strategic manipulations may serendipitously determine what to do next. In mental arithmetic, for example, moving number tokens when performing long sums enhances accuracy and improves efficiency (Vallée-Tourangeau, 2013); congenial, easy-toremember interim totals can be identified and physically segregated, action affordances shift as the problem configuration is transformed, the allocation of attentional resources is governed by dynamic changes in the problem. Similarly, in a Bayesian reasoning task, manipulating cards representing elements of a statistical sample led to a sharp increase in performance (ValléeTourangeau, Abadie, \& Vallée-Tourangeau 2015). One possible explanation for the positive impact of interactivity on performance is that increasing interactivity reduces the processing burden on an agent's working memory. If this is the case, we should expect that higher levels of interactivity and resulting opportunities to manipulate and rearrange information in a planning task should promote better planning performance.

## Self-control

Self-control is required to maintain goal intentions and plans over time, and resist the conflicts of immediate impulses such as attending to tempting stimuli. (Hofmann, Friese, \& Strack, 2009). Research into failures of self-control (acting on impulses) proposes that it is a finite mental resource that limits self-regulatory capability. Motivated by this approach Baumeister and colleagues (e.g., Baumeister, Bratslavsky, Muraven, \& Tice, 1998) developed the strength model of self-control with the central tenet that willpower is a limited resource akin to energy, which becomes fatigued or depleted with use, temporarily reducing the capacity for subsequent self-control. Baumeister et al. (1998) termed this state of reduced self-control ego depletion. Support for the model comes from research using a sequential-task paradigm; participants are required to engage in an initial task of self-control, and decrements in their performance are then measured on a second, unrelated task of self-control. A meta-analysis of 83 sequential-task studies reported a medium effect size (Cohen's $d=.62$ ) of ego-depletion (Hagger, Wood, Stiff, \& Chatzisarantis, 2010).
More recently, the ego-depletion effect has been called into question with studies failing to detect the phenomenon (e.g., Lurquin et al., 2016). A reanalysis of the Hagger et al. (2010) data and another meta-analysis identified small-study bias and an inflated effect size (Carter \& McCullough, 2014). This was followed by a
multi-lab Registered Replication Report (RRR) involving 23 labs worldwide which found an overall ego-depletion effect of close to zero (Hagger et al., 2016). This RRR used just one combination of tasks, and the present study responds to the recent calls for further replications using different combinations of tasks, increased sample sizes, and to investigate potential moderating variables (e.g., Lurquin et al., 2016).
Since planning involves self-control activities such as monitoring and coordinating actions, we should expect ego depletion to impair planning performance. Yet, as interactivity may offer a platform for offloading some of the cognitive processing required to monitor and coordinate action, we anticipate that the impact of ego depletion on planning performance will be tempered when cognitive agents are free to physically interact with their plan.

## The Present Experiment

Despite its ubiquity and importance in everyday life, planning research to date has tended to focus on planning dysfunctions and the order of actions, ignoring both the environment in which planning takes place and the cognitive state with which the participant comes to the task. This research typically uses one of two general types of tasks: puzzle-based tasks, which involve simple, mechanistic, easily-controlled procedures (e.g., the Tower of London), or real-world planning tasks, which invoke familiar procedures and contexts of a complexity analogous to everyday activities (Morris \& Ward, 2004; e.g., the Virtual Planning Task, Miotto \& Morris, 1998). The present experiment adopted a distributed-cognition perspective to determine how the manipulation of task interactivity and ego-depletion would affect performance on a real-world planning problem. We designed a lowinteractivity condition using a static paper presentation during which participants had to keep their hands down, while in the high-interactivity conditions cards corresponding with to-be-executed tasks could be manipulated and re-arranged as participants saw fit. Both conditions required working memory and self-control to switch and control attention between remembering plans and actioning them. We hypothesised that the inflexible, unmodifiable environment offered in the low-interactivity condition would lead to poorer performance relative to the high-interactivity condition. Since planning is reflected in physical changes in the environment, we hypothesised that the high-interactivity condition would lead to improved performance relative to the lowinteractivity condition.
A secondary aim of this experiment was to test whether the offloading of cognitive processing afforded by highly interactive environments could act as a buffer for the negative impact of depleted self-control resources on planning performance. We selected a widely-used egodepletion task (e.g., Schmeichel, 2007), along with a
planning task that is demanding of executive control in order to maximise the chances of demonstrating the egodepletion effect. The experimental set-up replicated as closely as possible that of the original author (Brendan Schmeichel), including a verbatim script of the original task that was obtained with the help of the authors of the recent replication study (Lurquin et al., 2016). We nearly doubled the sample size used in typical ego-depletion studies. Participants were allocated to either a control or an experimental ego-depletion group, the latter requiring self-control in order to direct attention towards an interviewee and away from distracting words presented on the screen. In order to understand what participants in both conditions were really doing during the videoviewing task, and to ensure the two conditions were indeed distinct, supplementary measures such as a word memory task to test adherence to instructions and additional questions regarding the ego depletion task were included. Based on the resource model of self-control participants in the ego-depletion condition, who performed the initial act of self-control, should perform worse in the subsequent planning task than participants in the control condition. Though, given the conflicting findings in the extant literature, and our new combination of tasks, we set out with an exploratory perspective on the effect of this frequently-used video-viewing task combined with our planning task.
In addition, we included self-report measures of flow, planning, and impulsivity to explore whether they would moderate the impact of interactivity on planning performance.

## Method

## Participants

One hundred participants ( 73 women, $27 \mathrm{men}, M_{\text {age }}=$ 31.90 years, $S D=11.77$ ) were recruited; some received course credits. All participants were naive to the purpose of the research.

## Procedure

The experiment employed a 2 (interactivity: high or low) x 2 (ego depletion: depletion or control) between-groups design. Participants were randomly allocated to one of the four experimental conditions ( $n=25$ per group). All tasks were completed in a single testing session, lasting approximately 45 min , which was divided into three phases. Participants first watched the ego-depletion video. This was followed immediately by the planning task. Finally, participants completed a series of self-report measures.
Ego-depletion task. Participants watched a 6 min , silent video featuring a woman being interviewed by an offscreen interviewer, as the initial task in a sequential-task paradigm (Schmeichel et al., 2003). During the video 36
common, one-syllable words (e.g., "play") appeared at the bottom of screen for 10 s each. Words appeared in black font on a white background and took up approximately one quarter of the screen.
In the ego-depletion condition participants were instructed to focus attention on the woman's face and not to look at the words that appeared on the screen. The control condition was identical except, crucially, no instructions were given regarding the words that appeared on the screen and participants were asked to watch the video as if they were "sitting at home watching TV". While participants viewed the video, the experimenter moved outside the room. Two modifications were made to the original task. First, distance between participant and screen was standardised at 40 cm . Second, to increase their saliency, the position of the words was changed from bottom right to bottom centre. The size, colour and font remained unchanged.
Planning task. Next, participants completed an adapted version of Miotto and Morris's (1998) planning task in either the low-interactivity list condition, or the highinteractivity board game condition. The object of the task was to plan and execute a sequence of specified activities on the four days of the week preceding a trip abroad. Twenty-eight activities were offered for completion, 16 of which were relevant to the trip. The remaining 12 activities were not relevant and were termed "distractors". To simulate the constraints of real world planning, once the participant had executed the activities for a given day they could not change their plan and had to move on to the next day. Participants were seated at a desk and instructed on the main features and rules of the task. They were advised that they could carry out four tasks per day; two in the morning and two in the afternoon and that not all tasks could be completed. There was no time limit but participants were instructed to complete the task as quickly and as accurately as possible. Two measures were used to calculate planning performance: (1) accuracy - a choice of task was considered correct if it was one of the 16 relevant activities, and where applicable, completed on the specified day and time; (2) latency per correct task calculated as overall latency divided by accuracy.

Figure 1: The experimental setting, high-interactivity condition (left), and low-interactivity condition (right).

High-interactivity condition. The 28 activities were printed on individual action cards ( 55 x 88 mm ). These action cards could be selected by moving the card into a
central day frame split into sections representing the morning and afternoon. As in the low-interactivity condition, a summary card which specified which activities needed to be done during the week was always available. Finally, an execution board was used to place cards that had been selected and representing tasks that have been completed (see Fig. 1, left panel). Participants were handed the 28 activity cards in a randomly ordered pack and were free to move the cards as desired in the working area. Participants could monitor their goal progress at any stage by checking the execution board.
Low-interactivity condition. The low-interactivity condition used a list of 28 activities to be performed (see Fig. 1, right panel). In this condition participants were instructed not to touch any task materials and to keep their hands on the desk for the duration of the task. To choose a task for completion participants verbally instructed the experimenter of their selection.
Additional Measures. Upon completion of the planning task, participants answered a flow questionnaire developed to gauge participant's enjoyment and engagement during a task (Vallée-Tourangeau et al., 2015). Next, all participants were given a surprise memory test for the words presented during the video in the first part of the experiment. The test compromised 36 words: 18 that appeared during the initial video-viewing task, and 18 that did not (the same test designed by J. H. Lurquin, personal communication, 2 March 2016). Participants then judged whether they had seen the words previously by circling either yes or no. The memory test was followed by a series of manipulation checks for the ego depletion task. Participants were asked to rate the difficulty of complying with the video task instructions they were given prior to watching the video $(1=$ not at all difficult to $10=$ very difficult). Following Lurquin et al. (2016) participants also rated how much effort they had put in to the task, and how hard they had tried to ignore or remember the words $(1=$ none to $10=a(\operatorname{lot})$.
Finally, participants completed individual differences measures of planning and impulsivity as an independent measure of planning ability. Participants completed Simons and Galotti's (1992) planning survey, a 31-item scale measuring everyday planning style, and Lynch, Netemeyer, Spiller and Zammit's (2009) propensity to plan for time short run and long run 6 -item scales. This is a $30-$ item scale, scored using three sub-scales: attentional, motor and non-planning.

## Results

Depletion participants rated the video task as more effortful ( $M=7.38, S D=1.99$ ) than did the control participants ( $M=6.74, S D=2.32$ ), however the difference was not significant, $t(98)=-1.48, p=.142$. Participants in the depletion condition remembered significantly fewer words ( $M=4.66, S D=4.31$ ) than control participants ( $M=$ $12.78=S D=3.72), t(98)=10.09, p<.001$, which
suggests that they complied, in part, with the task instructions. Although, if the depletion participants had fully complied with the instructions then they would not have remembered any words.
The main dependent measure in the planning task was accuracy, the maximum possible score being 16; the data are reported in Figure 2. Participants in the highinteractivity condition were more accurate than those in the low-interactivity condition, but the ego-depletion paradigm appeared to have no effect on planning performance. A 2 x 2 between subjects analysis of variance (ANOVA) revealed a significant main effect of interactivity, $F(1,96)$ $=78.03, p<.001$, but neither the main effect of ego depletion nor the interaction effect were significant ( $F \mathrm{~s}<$ $1)$.

Figure 2: Mean accuracy (left panel) and mean latency per correct task (in seconds, right panel) as a function of level interactivity and the experience of the ego depletion task (error bars are standard error of the means).

Latency per correct task was calculated as total latency divided by accuracy; lower scores reflect better performance. Figure 2 shows that generally participants in the high-interactivity condition were faster than those in the low interactivity condition. A $2 \times 2$ independent ANOVA revealed a significant main effect for interactivity $F(1,96)=25.72, p<.001$. Again, neither the main effect of ego depletion nor the interaction effect were significant ( $F \mathrm{~s}<1$ ).
We explored whether individual differences in planning, impulsiveness, and experience of flow moderated the impact of interactivity on planning performance. Planning performance was positively associated with flow, $\beta=.22$, $t(96)=2.45, p=.016$, although flow was not a moderator of the interactivity effect on planning performance; $\beta=$ $.03, t(96)=0.36, p=.72$. More interestingly, the impact of interactivity on planning performance was moderated by individuals' propensity to plan in the long-run, $\beta=-.15$, $t(96)=-2.08, p=.04$. Specifically, higher propensity to plan in the long-run was associated with higher performance under low interactivity but it did not predict performance under high interactivity (see Figure 3, left panel). The impact of interactivity on performance was also moderated by non-planning impulsiveness, $\beta=.16$, $t(96)=2.22, p=.03$. In this case, higher scores of nonplanning impulsiveness were associated with higher
planning performance under high levels of interactivity and lower planning performance under low levels of interactivity (see Figure 3, right panel).

Figure 3: Relationship between planning accuracy (Performance) and propensity to plan in the long run (left panel) and non-planning impulsiveness (right panel) as a function of interactivity levels (High vs. Low). Note. $\mathrm{CF}=$ Centred Form or mean deviation form.

## Discussion

In this experiment participants completed a planning task in two different interactivity conditions, one which permitted spatial rearrangement of the task, and one which did not. Generally, participants were more accurate and achieved faster latency per correct answer in the highinteractivity condition. These results can be explained in terms of the affordances provided by the different task environments. In the low-interactivity condition participants were forced to manipulate information mentally, relying on executive function-directed initial planning. As such, performance was limited by the participants' working memory capacity.
In contrast, the dynamic interface of the highinteractivity condition facilitated new affordances for task completion and paved the way for opportunistic planning, where task selection was guided, in part, by the physical changes in the configuration of the problem. Planning was interspersed with physical execution, alleviating the load on the participants' working memory compared to the complex initial planning in the head required by the lowinteractivity constraints. The significant increase in task performance in this condition could not be attributed to individual differences since there were no condition differences on measures of planning. Instead, the highinteractivity environment allowed participants to restructure and simplify the problem presentation in a way that was conducive to solving the task. For example, reorganising the activity cards made it possible to collate related activities, discard distractor cards and constantly track the state of the task. Furthermore, when participants planned all time-specific tasks first, they then perceived the gaps left in the plan, thus placements for single item tasks were physically discovered (Kirsh, 2010).
We sought to explore cognitive individual differences that would predict performance in both conditions of the planning task. We hypothesised that the skills implicated when planning in the head would be different from the
skills employed when planning in a distributed environment. Long Run Planning ability only mattered for those participants in the low interactivity condition; it had no effect on performance in the high interactivity condition. Conversely, high levels of non-planning impulsivity put people at an advantage under high interactivity, and at a clear disadvantage in the low interactivity condition. The fact that planning performance was superior in the high-interactivity, in the absence of a difference in self-reports of planning ability, suggests that the manipulation of cards augmented planning abilities (via working memory) above those measured with planning scales. This finding supports previous work (e.g., Vallée-Tourangeau, Sirota, \& Vallée-Tourangeau, 2016) and suggests that interactivity may functionally augment cognitive resources.

## Self-Control and the Elusive Ego Depletion Effect

The present experiment also examined the effect of ego depletion on planning. As advocated by Lurquin et al. (2016) we used a larger than average sample size ( $N=$ 100) and explored a new combination of tasks. Despite making these and other modifications to this highlyreplicated depletion task, the main effect of ego depletion was not significant. This result is inconsistent with the strength model (Baumeister et al., 1998), and many previous studies, including those from the laboratory where the term ego depletion was first coined, and where the video-viewing task was developed. However, it is consistent with more recent research that has failed to detect the ego-depletion effect, and most notably Lurquin et al. (2016), which used the same initial video-viewing task.
A critical pre-requisite of the sequential-task paradigm is that both tasks require the use of self-control. The present planning task has not been used as a second task in the sequential task paradigm: one possible explanation for the absence of ego depletion is that the outcome planning task did not require self-control. Yet, there is little doubt that planning requires the deliberate control of actions across time, and Baumeister and Vohs (2016) argue that planning draws on the same limited resource as self-control. Additionally, in the present study, task constraints such as adhering to activities stipulated on the summary card required that impulses to follow habitual holiday-planning responses be overridden using self-control. Further, it could be argued that the low-interactivity instructions demand self-control by requiring participants to keep their hands down on the table. Despite apparently meeting the conditions necessary to induce the ego-depletion, we found no evidence of an effect. Since the video-viewing task lacks an objective measure of task performance (Lurquin \& Miyake, 2017), we included the word memory task and assume that performance here points to adherence to the video task instructions. Participants in the ego-depletion condition remembered some words, indicating that they
looked at them and so did not fully adhere to the task instructions. If participants in this condition did not inhibit their natural impulse to respond to the attention-capturing words, they were not using self-control in the first task and thus would not be, and indeed were not, depleted in the second task. Without substantial modification to the task procedure and an objective measure of performance, our findings indicate that the video-viewing task does not operationalise ego-depletion as intended.

# Head and Heart Metaphors for Moral Decision Making: Conceptual or Communicative? 

Rose K. Hendricks (rhendricks@ucsd.edu)<br>Department of Cognitive Science, 9500 Gilman Dr. La Jolla, CA 92093 USA<br>Paul H. Thibodeau (paul.thibodeau@oberlin.edu)<br>Department of Psychology, 120 W. Lorain St. Oberlin, OH 44074 USA

#### Abstract

When faced with a moral dilemma, following your head versus your heart can result in very different decisions. Earlier work has argued that people who "self-locate" in the head tend to make more rational and less emotional decisions to moral dilemmas than those who "self-locate" in the heart. We replicate this finding, suggest an alternative interpretation of the result, and then extend it with a novel experiment. In a metaphor framing task, we manipulated the salience of the head/heart metaphors-by using them (a) in a single sentence, (b) a more elaborate paragraph, or (c) by emphasizing one in contrast to the other. We found that people who received the head metaphor made more rational decisions than those who received the heart metaphor, but only in the high salience condition that contrasted the two metaphors. This finding illustrates the communicative value of metaphor, which can be enhanced through comparison.

Keywords: metaphor; decision making; rationality; emotion

## Introduction

In the novel and movie Sophie's Choice, a Polish woman, Sophie Zawistowska, is arrested by the Nazis and sent to the Auschwitz death camp. On arrival, she is "honored" for not being a Jew by being allowed a choice: One of her children will be spared the gas chamber if she chooses which one should be killed. If she does not choose, both of them will be killed.

Many moral dilemmas, like Sophie's, can be construed as a contrast between two extremes, involving a rational, utilitarian option (choose one child to die so that only one life is lost) and an emotional option (forgo choosing; both children die, but you did not play a direct role in either death). Why do some people decide to use their head to make the rational choice, while others follow their heart in choosing the emotional option?

One possibility for why some people make more rational decisions than others appeals to a role for conceptual metaphor (Fetterman \& Robinson, 2013; Lakoff \& Johnson, 1980). In English, the "head" is associated with cold, rational decision making. We use instructions like "use your head" to encourage emotional detachment in favor of carefully deliberated judgment. The "heart," on the other hand, is associated with hotter, more emotional thinking. Telling someone to "follow their heart" often implies that
they should ignore a cost-benefit calculus in favor of a more impulsive decision.

Recent work has argued that these "head" and "heart" metaphors (or metonymies) do more than describe different modes of thinking. They may also represent different ways of thinking about the self: some people "self-locate" in their head; others "self-locate" in their heart (Fetterman \& Robinson, 2013). On this view, people who conceptualize thinking as a process that happens in their head will tend to make more rational decisions, while people who conceptualize thinking as something that happens in their heart will tend to make more emotional decisions.

Evidence for this theory comes from a series of studies in which people were asked: "Irrespective of what you know about biology, which body part [the head or heart] do you more closely associate with your self?" Then participants completed personality measures, general knowledge questions, or they answered a series of moral dilemmas. Fetterman and Robinson (2013) found roughly a $50-50$ split in how people identified with the head versus the heart, which, in turn predicted responses to the other measures: head-locators characterized themselves as more rational and interpersonally cold on the personality measures, answered more of the general knowledge questions correctly, and suggested more utilitarian responses to the moral dilemmas, compared to the heart-locators.

Given the study design, however, it is difficult to know whether people really self-locate in the head or heart, and whether individual differences in self-location tendencies predict behavior. That is, an alternative interpretation of the finding is that people have some sense of their typical cognitive style-whether they tend to base their decisions on more rational or emotional motivations-which is what people report for the self-location question. On this view, one might expect the same results if participants had been asked if they consider themselves to be more rational or emotional decision makers (as opposed to a question about self-location). In addition, how people respond to the selflocation question may influence their performance on subsequent measures. People who say that they self-locate in their "head" may be inclined to demonstrate their headiness by adopting a more rational strategy to the moral dilemmas, for example.

These concerns relate to long-standing questions about what can be inferred about mental representation from patterns of language use (Keysar \& Bly, 1995; McGlone, 2011; Murphy, 1996). For example, when someone says, "I followed my heart" are they really imagining that their decision was made in their heart? Or is this phrase merely a conventional expression that has come to mean something like "I made the emotional choice"?

In the current paper, we explore these concerns, and address novel theoretical questions about metaphor framing, by manipulating the salience of instructions to "use one's head" or "follow one's heart" in moral decision making. There were three conditions in the experiment. In the lowsalience condition, the phrase "use your head" or "follow your heart" was embedded in the instructions of the taskwhich involved responding to the five moral dilemmas that were used by Fetterman and Robinson (2013). In the medium salience condition, participants were presented with a discussion about Plato's theory of the self, which was said to emphasize the head or the heart; the given metaphor was repeated in different ways throughout a paragraph that preceded the moral dilemmas. In the high salience condition, participants received the same information as those in the medium salience condition, with an additional explicit contrast: they were told either that the "head and not the heart" or the "heart and not the head" is where the self is located.

We expected that the high-salience condition would elicit the strongest effect: with the emphasis on head-location, in explicit contrast to heart-location, leading to more rational responding (and vice versa). An explicit comparison between the two metaphors should highlight the underlying difference between a rational and emotional approach to the moral dilemmas (Edwards, Williams, Gentner, \& Lombrozo, 2014; Markman \& Gentner, 1996).

This result would support an alternative interpretation of Fetterman and Robinson (2013)'s work. First, it would illustrate that, at least in some circumstances, more salient metaphors are more influential. In the original study, the metaphors were highly salient, since they were explicitly contrasted with one another in a forced choice task. Second, it would suggest that these particular metaphors are informative because of their conventional, idiomatic meaning, rather than their role in the mental representation of self-location (Keysar, Shen, Glucksberg, \& Horton, 2000; Thibodeau \& Durgin, 2008).

This result would also represent a novel contribution to the metaphor framing literature, which has found that linguistic metaphorical frames can shape how people think about issues like immigration (Landau, Sullivan, \& Greenberg, 2009; Jia \& Smith, 2013), cancer (Hauser \& Schwarz, 2013; Hendricks \& Boroditsky, 2015), and crime (Thibodeau \& Boroditsky, 2011, 2013). For instance, metaphorically framing crime as a "virus" has been found to increase support for societal reform as a means of crimereduction, whereas a "beast" frame leads people to support more enforcement-oriented approaches to crime-reduction
(Thibodeau \& Boroditsky, 2011, 2013). The current work extends these findings by investigating whether an explicit contrast, designed to make the underlying entailments of the metaphor more salient, leads to stronger metaphor framing effects.

Before conducting the experiment, we first replicated the original study (Fetterman \& Robinson, 2013). We present the results of the replication, which confirm the original findings, and then discuss the results of our follow-up experiment.

## Methods

## Participants

500 and 1,000 people were recruited from Amazon's Mechanical Turk to participate in Studies 1 and 2, respectively. Data was excluded from participants who did not submit a correct completion code and from participants who answered more than 3 (of 5) attention check questions incorrectly, leaving data from 484 and 945 participants for analysis in Study 1 and Study 2, respectively. Participants who completed Study 1 were not eligible to participate in Study 2.

## Procedure

Study 1 Study 1 was a replication of Fetterman \& Robinson (2013, Study 5). At the beginning of the study, participants were asked: "Irrespective of what you know about biology, which body part do you more closely associate with your self?" They were required to choose either the head or the heart. Next participants considered five moral dilemmas, similar to and including the Sophie's Choice example from the introduction. Each dilemma had one rational response and one emotional response (see Appendix). After the five dilemmas they answered an attention check question about each dilemma, and finally completed the Big Five Inventory (BFI; John \& Srivastava, 1999). The BFI measures individuals' extraversion, agreeableness, conscientiousness, neuroticism, and openness to experience. In the original studies, Fetterman and Robinson (2013) included the measure of conscientiousness as a predictor of how people responded to the moral dilemmas. For consistency, we also include conscientiousness in the analyses below, although the results do not differ if this measure is excluded.

Study 2 The procedure for Study 2 was identical to Study 1, except that instead of choosing the body part that they most associate with the self, participants randomly received one of the two metaphorical frames at one of three salience levels.

In the low salience condition, the metaphor was instantiated only in the instructions for responding to the moral dilemmas:

Next you will read short scenarios and should report what you would do if you were in them. There are no right or wrong answers to the
questions. Just [follow your heart/use your head] to make the judgment that you think is right. Please read each carefully because you will be asked to answer other questions about them later.

The medium and high salience conditions included passages that instantiated the metaphors more explicitly than the low salience condition. The beginning of the medium and high salience passages were identical:

Plato said that there are three parts of the soul. The first is our appetites or desires; the second is hotblooded emotion; and the final is rational, conscious awareness. But these three parts of ourselves do not play equal roles in making us who we are. The [head/heart] is the most crucial for defining who we are. The [head/heart] is where we find our true self.

The medium salience passage continued:
If we are to live a long and prosperous life, we must always listen to our [head/heart]. George Washington, Abe Lincoln, and Michelle Obama are just a few of the incredibly successful people who have followed Plato's advice in never losing sight of the fact that their [head/heart] holds the key to who they truly are.

In the high salience condition, the emphasized metaphor was explicitly contrasted with the alternative. Thus, the high salience passage instead said:

If we are to live a long and prosperous life, we must always listen to our [head/heart, even if it conflicts with our heart/head]. George Washington, Abe Lincoln, and Michelle Obama are just a few of the incredibly successful people who have followed Plato's advice in never losing sight of the fact that their [head/heart] holds the key to who they truly are, even if it means disregarding what their [heart/head] tells them.

After the passages, all participants responded to the same five dilemmas used in Study 1 and answered the same attention check questions. They were then asked whether they remembered encountering the phrase "follow your heart" or "use your head" earlier in the experiment. This recognition memory question was included as a test of the salience manipulation. As expected, participants were more likely to remember the metaphor in the more salient conditions, $B=.75, S E=.10, p<.001$.

Analysis Mixed effect logistic regression models were used to analyze the data from both studies (Jaeger, 2008). Metaphor (head versus heart) was treated as a betweensubjects fixed effect in both studies; salience (low, medium, high) was treated as a between-subjects fixed effect for the analysis of Study 2; participants and moral dilemmas were treated as random effects in both studies. We compare
nested models and present standardized regression coefficients to conduct hypothesis tests (Menard, 2002).

## Results

## Study 1: Replication

In Study 1, more people identified with the head metaphor ( $63 \%$ ) than the heart metaphor ( $37 \%$ ), $\chi^{2}(1)=32.80, \mathrm{p}<$ .001. We tested whether participants' choice of metaphor predicted how they solved the moral dilemmas by comparing two nested models. In the first, conscientiousness was included as a predictor of participants' judgments; in the second model, participants' chosen metaphor was added, which significantly improved fit, $\chi^{2}(1)=19.84, p<.001$. People who identified with the heart metaphor solved the moral dilemmas more emotionally ( $M=.52, S D=.25$ ) than people who identified with the head metaphor $(M=.41, S D=.29), B=.68, S E=$ $.15, p<.001$, as did more conscientious participants, $B=$ $.28, S E=.11, p=.012$. These findings replicate the basic patterns reported by Fetterman \& Robinson (2013).

We also conducted analyses by item to test whether particular dilemmas were driving the effect. We found an effect of metaphor for dilemmas that elicited more ambivalent responses overall. That is, there was a stronger consensus among participants on how to respond to dilemmas 1 (rationally) and 3 (emotionally); there was no effect of participants' choice of metaphor on these dilemmas, $p \mathrm{~s}>.3$. There was less consensus among participants on how to respond to dilemmas 2, 4, and 5; these dilemmas showed differences as a function of which metaphor people chose, $p \mathrm{~s}<.001$ (see Table 1).

Table 1. Proportion of emotional responses overall, for head-locators, and for heart-locators by dilemma.

| Dilemma | Overall | Heart | Head |
| :---: | :---: | :---: | :---: |
| 1 | .70 | .73 | .69 |
| 2 | .36 | .49 | .29 |
| 3 | .14 | .13 | .14 |
| 4 | .50 | .61 | .44 |
| 5 | .57 | .66 | .51 |

In other words, head-locators did not simply choose the rational response to each dilemma (and vice versa for heartlocators). They were also sensitive to the content of the dilemmas. For this reason, we focus on responses to dilemmas 2,4 , and 5 in the experiment.

## Study 2: Metaphor Framing

We tested whether the metaphor used to describe the task and the salience of the metaphor affected participants' moral judgments. We focus on data from dilemmas 2, 4, and 5, since these dilemmas elicited more ambivalent responses overall, and were influenced by participants' choice of metaphor in Study 1.

The analysis revealed no main effect of metaphor, $\chi^{2}(1)=$ 1.73, $p=.189$, or salience condition, $\chi^{2}(1)=0.53, p=.467$. But it did reveal an interaction between metaphor and salience condition, $\chi^{2}(1)=4.34, p=.037$, as well as an effect of conscientiousness, $\chi^{2}(1)=9.52, p=.002$.

As shown in Figure 1, there was no effect of the metaphor frame in low, $B=.01, S E=.19, p=.964$, or medium, $B=$ $.08, S E=.21, p=.681$, salience conditions. There was an effect of the metaphor in the high-salience condition, $B=$ $.70, S E=.27, p=.011$. When the instructions emphasized the "heart" in explicit contrast to the "head," people responded to the dilemmas more emotionally (and vice versa).

Figure 1. Proportion of dilemmas solved emotionally in Study 1 (choice) and in Study 2 by metaphor and salience conditions. Error bars denote standard errors of the means.

The effect of the salience manipulation appeared to be fairly linear for the "heart" condition-with people responding more emotionally as the salience of the "heart" metaphor increased, $B=.21, S E=.10, p=.030$. The effect of the salience manipulation seems to have been more abrupt in the "head" condition. There was no difference in how participants responded to the low- and medium-salient versions of the instructions that emphasized the "head" metaphor, $p=.311$; participants responded marginally more rationally to the high-salient version, compared to mediumsalient version, of the instructions that emphasized the "head" metaphor, $p=.057$.

Figure 2 illustrates the effect of metaphor preference (Study 1) or metaphor frame (from the high-salience condition of Study 2) on each of the moral dilemmas. It shows that the metaphor people identified with in Study 1 had the biggest effect on judgments of the 2nd, 4th, and 5th moral dilemmas. These were the same dilemmas that were most influenced by the salient metaphor frames in Study 2.

Figure 2. Effect size by item (moral dilemmas 1-5) for the metaphor preference task in Study 1 and bin the highsalience condition of Study 2. The further the bar extends to the right (from 0 ), the more congruent the responses (i.e. heart and emotional responding; head and rational responding). Bars extending to the left (of 0 ) indicate a pattern of incongruent responding (i.e. heart and rational; head and emotional).

## Discussion

In this work, we first replicated prior work by Fetterman \& Robinson (2013) showing that people who identified with a heart metaphor for the self responded more emotionally to moral dilemmas, while people who identified with a head metaphor for the self responded more rationally to moral dilemmas. The original finding was interpreted as evidence for an individual difference in self-location grounded in conceptual metaphor. However, we have argued that there are alternative interpretations of the finding. Most notably, the heart and head metaphors are conventional expressions that correspond to emotional and rational modes of thinking, respectively. People have some self-awareness about how they make decisions-more rationally or more emotionally. When asked to choose between identifying with the heart or head, emotional decision makers choose the heart, while rational decision makers choose the head.

In a follow-up experiment, we examined whether metaphorically framing the locus of a person's decisions as either in the head or in the heart would lead them to make more rational decisions (in the case of the head) or emotional decisions (in the case of the heart). We also explored the role of salience in this process: using the metaphors in a single phrase (low salience), a more elaborate paragraph (medium salience), or by emphasizing one in direct contrast with the other (high salience).

We found an effect of the metaphor framing manipulation in the high-salience condition but not the low or medium salience conditions, suggesting that an explicit contrast between the metaphors was important for influencing behavior on the decision making task. In the high salience condition, since people were exposed to both metaphors, they had the opportunity to compare the two metaphors. In fact, in order to truly comprehend the passage, they needed to compare their passage's dominant metaphor to the alternative. In Fetterman \& Robinson's (2013) work and in our Study 1, choosing the locus of the self also encourages, and perhaps even requires, participants to explicitly compare the two metaphors' entailments in order to choose the one they believe describes them most accurately. Comparison has been found to be particularly effective in communicating the intended meaning of analogies (Edwards, Williams, Gentner, \& Lombrozo, 2014; Markman \& Gentner, 1996). This work suggests that explicitly comparing metaphor frames to each other may similarly highlight their differences and amplify their effects on cognition. In other words, we found that the head and heart metaphors used in this work were both conceptual and communicative.

All participants in these experiments were in the United States, so the implications about heart and head metaphors for decision making may not generalize to members of other cultures. It may be productive for future research to investigate interactions between cultural background and metaphor frames for decisions.

In addition, this work may have implications for the development of Deliberate Metaphor Theory (DMT; Steen, 2008), which argues that metaphors are most influential when they are used deliberately. That is, DMT emphasizes the social and pragmatic context in which figurative language is used, although the details of the theory (e.g., what constitutes a deliberate metaphor?) have yet to be ironed out, and empirical tests of the predictions made by the theory have received limited support (see, e.g., Gibbs, 2015a, 2015b; Thibodeau, In press). Thus, the current work may give researchers a novel case for thinking about one pragmatic signal-explicitly negating one metaphor in favor of another-that a metaphor has been used deliberately. Explicitly contrasting metaphors clearly signals deliberate use.

To advance Deliberate Metaphor Theory, it would be worthwhile to try and provide a more mechanistic account of the effect we have demonstrated. For instance, one might argue that the metaphors were used "deliberately" in all three salience conditions of the experiment. But we only found an effect when the two metaphors were contrasted with one another. An open question, therefore, is whether the contrast served as more of a pragmatic cue for participants to use the emphasized metaphor, or whether the contrast served to bring out the meaning of the head and heart metaphors more clearly-by highlighting an alignable difference between and the underlying meaning of the phrases (Gentner \& Markman, 1994).

Future work should also explore the role of comparison in metaphor processing more generally. Experiments that examine metaphor framing-for persuasion, instruction, and explanation-typically present participants with only one frame (e.g., Jia \& Smith, 2013; Landau, Sullivan \& Greenberg, 2009; Thibodeau \& Boroditsky, 2011, 2013). The current work suggests that explicitly contrasting metaphors may facilitate metaphorical reasoning.

## Acknowledgments

We thank Adam Fetterman for sharing the stimuli from the work we replicated (Fetterman \& Robinson, 2013). This material is based upon work supported by the National Science Foundation Graduate Research Fellowship under Grant No. DGE-1650112.

## Appendix: Moral Dilemmas

1.You are an inmate in a concentration camp. A sadistic guard is about to hang your son who tried to escape and wants you to pull the chair from underneath him.

He says that if you don't he will not only kill your son but some other innocent inmate as well. You don't have any doubt that he means what he says. What would you do?

Rational = I would pull the chair
Emotional = I would NOT pull the chair
2.A pregnant woman leading a group of people out of a cave on a coast is stuck in the mouth of that cave. In a short time
high tide will be upon them, and unless she is unstuck, they will all be drowned except the woman, whose head is out of the cave. Fortunately, (or unfortunately,) someone has with him a stick of dynamite.

There seems no way to get the pregnant woman loose without using the dynamite which will inevitably kill her; but if they do not use it everyone will drown. What would you do if you were in this situation?

Rational = I would let them light the stick of dynamite
Emotional = I would NOT let them light the stick of dynamite
3.A trolley is running out of control down a track. In its path are five people who have been tied to the track by a mad philosopher. Fortunately, you could flip a switch, which will lead the trolley down a different track to safety. Unfortunately, there is a single person tied to that track. Would you flip the switch or do nothing?

Rational $=$ I would flip the switch
Emotional = I would do nothing
4. In the novel and movie Sophie's Choice, a Polish woman, Sophie Zawistowska, is arrested by the Nazis and sent to the Auschwitz death camp. On arrival, she is "honored" for not being a Jew by being allowed a choice: One of her children will be spared the gas chamber if she chooses which one should be killed. If she does not choose, both of them will be killed. Would you choose one of your children to be killed in the same situation?

Rational = I would choose a child to be killed
Emotional = I would NOT choose a child to be killed
5. In 1842 , a 23 ship struck an iceberg and more than 30 survivors were crowded into a lifeboat intended to hold 7 . As a storm threatened, it became obvious that the lifeboat would have to be lightened if anyone were to survive. The captain reasoned that the right thing to do in this situation was to force some individuals to go over the side and drown or everyone would drown. Would you support pushing some people off the boat so at least some people could survive?

Rational = I would support pushing people off the boat
Emotional $=$ I would NOT support pushing people of the boat

# When metaphors in the mind become metaphors in the mouth: Documenting the emergence of a new system of linguistic metaphors for time

#### Abstract

Languages exhibit striking semantic diversity, but different languages often share core metaphors. Conceptual Metaphor Theory (Lakoff \& Johnson, 1980) claims that universal human experiences give rise to conceptual representations that are then expressed in language. But languages change slowly, making it difficult to observe implicit conceptualization affecting linguistic convention in real time. Here, we describe a shared conceptualization previously absent from speech that has now become conventionalized in linguistic metaphors. In two studies, we document how members of the US military talk about time using conventionalized lateral metaphors (e.g., 'push the meeting right' to mean 'move the meeting later'). We show that military members, unlike civilians, consider such sentences to be acceptable-sometimes even more acceptable than more standard phrases. Moreover, military personnel seem unaware that these lateral metaphors are specific to their linguistic sub-community. Our findings suggest that implicit mental representations can become conventionalized metaphors in language.

Keywords: time; metaphor; linguistic convention; semantic change

## Introduction

Every language uses metaphor (Kövecses, 2005), and many of these metaphors appear universal or nearly universal. Core metaphors like AFFECTION is WARMTH occur in many languages, while the reverse, AFFECTION is COLD, does not (Kövecses, 2010). Why? The leading explanation is that these cross-linguistic regularities reflect universal, or nearly universal, human experiences (e.g., Clark, 1973; Lakoff \& Johnson, 1980). For instance, since being held by a caregiver is likely a nexus of warmth and affection, human infants learn to associate these experiences. On this account, recurring correlations in experience lead to mental representations that relate the two domains. And these representations, in turn, spill out into language, so that the
same experiences come to be described similarly across the world's languages.
However, this is not the only way in which mental representations and linguistic metaphors could have come into alignment. For instance, the causal direction may have been reversed: widespread, recurring patterns of thought may have arisen from exposure to linguistic metaphors, rather than the other way around (see Gibbs, 2011 for review). Indeed, there's substantial evidence that, at least in the short term, exposure to linguistic metaphors primes conceptualization (e.g., Thibodeau \& Boroditsky, 2011).
In fact, there is a surprising dearth of evidence that shared mental representations can give rise to novel linguistic conventions. While the historical record is replete with changes in linguistic semantics that appear, in retrospect, to be driven by conceptualization (Sweetser, 1991), we cannot assess the conceptual representations of historical people in a lab. If implicit patterns of thought give rise to linguistic conventions, we should be able to observe the emergence of new linguistic metaphors in real time. But the pervasiveness of core, cross-linguistic metaphors means that it's rare to find people who lack either the linguistic or conceptual manifestation of an otherwise universal metaphor.
To determine whether metaphor spreads from thought to language, we need to observe a linguistic community beginning to use metaphorical language that aligns with their prior conceptual representations. This would shed light on why so many languages share linguistic and conceptual metaphors. We believe we have found one such case.

## The coupling of language and thought about time

Of all the concepts that we understand metaphorically, the best studied is time. Within a given culture or community, individuals think and talk about time in ways that are both stable and shared. This often involves using space to structure their speech and understanding of time (for reviews, see Boroditsky, 2011; Núñez \& Cooperrider, 2013).

Specifically, English speakers think and speak about time as though it were represented along the sagittal (front-back)
axis. The future is 'ahead' and the past is 'behind,' and these manners of speaking align with physical behavior. When English speakers make decisions about events, they are faster to respond to future events by moving forward, and faster to respond to past events by moving backward (Sell \& Kaschak, 2011; Ulrich et al., 2012; Rinaldi et al., 2016). They are faster to make time judgments when future-related words are shown in front of an image of a person and past words behind (Torralbo et al., 2006). When imagining the future, people lean forward, and when thinking about the past, they lean back (Miles et al., 2010). And they gesture forward when talking about the future, but backwards when talking about the past (Casasanto \& Jasmin, 2012).

This use of the sagittal axis has been documented in many languages around the world (Núñez \& Cooperrider, 2013). Most follow the same pattern as English, but not all: In Aymara, past events are in front and future events behind, in both language and gesture (Núñez \& Sweetser, 2006).

Similarly, Mandarin Chinese uses vertical (up/down) terms systematically and productively to talk about time. Earlier events are $u p$ and later events are down. Native Mandarin speakers also think about time vertically, with earlier events above later ones (Boroditsky et al., 2010; Fuhrman et al., 2011; Miles et al., 2011; Yang \& Sun, 2015).

Thus, there is often a tight coupling of the spatial language used to talk about time and spatial thought used to conceptualize time. There is empirical evidence that this alignment can originate in linguistic metaphors (Hendricks \& Boroditsky, 2015). After English-speaking participants learned metaphors that placed earlier events either above or below later ones (i.e., breakfast is above dinner or breakfast is below dinner; Hendricks \& Boroditsky, 2015), they then exhibited metaphor-consistent responses on an implicit measure of their mental space-time associations. Language can be a formative force for mental representations.
Despite overlaps between temporal language and temporal thought, there is not a one-to-one correspondence between the two. In addition to their sagittal (front-back) mental time-line, English speakers also map time to the lateral (left-right) axis. For instance, when asked to arrange physical depictions of sequences of events, they arrange them from left to right (Tversky, Kugelmass \& Winter, 1991; Boroditsky \& Gaby, 2010). During natural speech, they gesture to the left for earlier events and to the right for later ones (Cooperrider \& Núñez, 2009; Casasanto \& Jasmin, 2012). And English speakers are faster to indicate that one event occurred earlier than another by responding on their left side, and faster for later events when responding on their right (Fuhrman \& Boroditsky, 2010; Miles et al., 2011; Weger \& Pratt, 2008; Walker et al., 2014).

However, these left-right mental timelines are absent from language. English speakers can look 'back' on the past, but never 'to the left.' There is a linguistic gap, therefore, where a widespread conceptual metaphor has not surfaced as a linguistic metaphor. If a cognitive representation were to leap to a linguistic representation, it would most likely first take hold in a sub-community of English speakers who use left-right linguistic metaphors to talk about time.

## Case Study: The US Military

Anecdotal evidence from members of the authors' own families suggests that one community of English speakers has started to use left-right metaphors when talking about time: members of the United States military. According to anecdote, one might propose to move a meeting to a later time by asking to 'move the meeting to the right.' If these reports were true, then this group would provide an opportunity to study a system of conceptual metaphors as it takes linguistic hold in a language community. Here, in two empirical studies, we sought to document this apparent linguistic innovation. In particular, we aimed to understand whether left-right linguistic metaphors are more acceptable to members of the military than to civilians, as well as the linguistic conventions association with these metaphors.
In Study 1, military and civilian participants rated the acceptability of sentences about time. The sentences were presented in four main conditions: Standard (The meeting was moved two days earlier, from Friday to Wednesday), Dynamic-Lateral (The meeting was moved two days to the left from Friday to Wednesday), Static-Lateral (The meeting on Wednesday is two days to the left of the meeting on Friday), and Ungrammatical (From the meeting was two earlier days, Friday to Wednesday pushed). We included lateral metaphors in two conditions (Dynamic and Static) because anecdotal evidence suggested that Dynamic uses may be more acceptable than Static.
Study 2 replicated the findings from Study 1 in a new sample of military and civilian participants. In addition, we investigated whether military personnel are aware that these metaphors are specific to their linguistic subcommunity. Together, these studies create a snapshot of the early stages of a shift from an exclusively cognitive representation to a novel linguistic convention.

## Study 1

In Study 1, participants rated the acceptability of sentences. Features of the sentences allowed us to measure whether, when, and to whom lateral (left-right) linguistic metaphors are acceptable.

## Methods

Participants: Active Duty members of the US military ( $n=$ 23) participated for $\$ 10$, and civilian undergraduates at UC San Diego ( $n=31$ ) participated for course credit. The military participants included 4 Army, 1 Navy, and 18 Air Force. They included 8 Officers and 15 Enlisted members. Materials: There were four types of sentences: a) Standard: using earlier or later to reschedule; b) Dynamic-Lateral: using left and right to reschedule; c) Static-Lateral: using left and right, but no rescheduling; d) Ungrammatical.
An equal number of sentences referred to events that were a) earlier and later; b) on the timescale of hours, days, and months; and c) required crossing a temporal boundary (events take place in different days, weeks, or years; i.e., Friday to Monday) and were within a temporal boundary (i.e., Tuesday to Friday). These additional features allowed us to examine whether conventionality differed in these various contexts.
Procedure: The study was completed on a computer. Participants were instructed to imagine a new colleague whose native language was not English and rate the acceptability of sentences $(n=48)$ uttered by this colleague, based on how participants would normally talk at work. Acceptability ratings used a 7 point Likert scale ( $1=$ totally unacceptable, $7=$ totally acceptable). Each sentence was presented on its own page. Participants then supplied standard demographic information (education, age), and military participants reported their service branch (Army, Navy, etc.), rank, and years of service. No other measures were collected.
Exclusions and Analyses: We subtracted each person's mean Ungrammatical rating from their mean Standard rating. Three participants ( 1 military, 2 civilians) did not rate Standard sentences at least one point higher than Ungrammatical ones, and were eliminated. Ratings were standardized by participant (i.e., z-scored), and then analyzed in a linear mixed-effects model. All hierarchical models used the maximal converging random effects structure justified by the experimental design (Barr et al, 2013), with random intercepts and slopes for both participants and items.

## Results

Figure 1 shows military personnel and civilians' acceptability ratings for the four sentence types. We first verified that participants from both populations rated the Standard phrases as most acceptable and the Ungrammatical phrases the least acceptable, with the Lateral phrases in between. Ratings were analyzed with a mixed-effects model with a fixed effect of Sentence Type (Standard > Dynamic-Lateral $>$ Static-Lateral $>$ Ungrammatical); we
used forward difference coding to test for pairwise differences between consecutive levels. Ratings did not differ by timescale (i.e., hours, days, and months; $p=.80$ ), so we collapsed timescales for all subsequent analyses. Standard items were rated as more acceptable than Dynamic-Lateral phrases ( $b=0.75 \pm 0.14$ SEM, $t=5.5, p<$ .001), which were more acceptable than Static-Lateral phrases ( $b=0.44 \pm 0.10 \mathrm{SEM}, t=4.6, p<.001$ ), which in turn were more acceptable than Ungrammatical phrases ( $b=$ $0.71 \pm 0.13 \mathrm{SEM}, t=5.3, p<.001)$.
We next tested our critical prediction: That these patterns of acceptability would differ systematically by population. We thus added a fixed effect of population (civilian $=1$, enlisted $=2$, officer $=3$; centered so the mean was 0 ). Standard phrases were used as a baseline. Once again, every type of sentence (Dynamic-Lateral, Static, Ungrammatical) was less acceptable than Standard (all $b \mathrm{~s}<-0.75, p<.001$ ). As predicted, there was no evidence that military and civilian participants differed in their ratings of Standard phrases ( $b=-0.07 \pm 0.08 \mathrm{SEM}, t=-0.8, p=.4$ ), nor was there evidence that the relative unacceptability of Ungrammatical phrases differed by population ( $b=-0.14 \pm$ 0.12 SEM, $t=-1.3, p=.2$ ). Similarly, military and civilian participants did not differ in the acceptability of Static-Lateral phrases, compared to Standard phrases ( $b=$ $-0.14 \pm 0.12$ SEM, $t=-1.3, p=.2$ ).

Acceptance of Dynamic-Lateral phrases, however, differed across populations ( $b=0.32 \pm 0.14 \mathrm{SEM}, t=2.3, p$ $=.027$ ). To make sense of this effect, we zoomed in on Dynamic-Lateral items and used forward-difference coding to compare the three populations. Civilians gave the lowest rating to the Dynamic-Lateral items $(M=0.0)$, while enlisted military participants rated these items as more acceptable $(M=0.17, b=-0.22, p=.07)$, and military officers rated these items as even more acceptable than enlisted military personnel ( $M=0.51, b=-0.43, p<.001$ ).

## Discussion

Study 1 confirmed that a specific subset of lateral metaphors has become conventionalized among a subculture of American English speakers: members of the US Military. If this reflected a more general conceptual difference-perhaps a willingness among military personnel to think about time along a left-to-right timeline-then this should have been reflected in increased acceptability for all lateral expressions. Instead, military personnel were especially accepting of lateral metaphors that used the dynamic language of movement, suggesting that this is a genuine linguistic convention, subject to the quirks and idiosyncrasies of cultural norms.

Figure 1. In Study 1, compared to civilians, military personnel were more accepting of Dynamic-Lateral phrases (e.g., 'meeting was moved to the left'). There was no difference in civilians' and military members' acceptance of Static-Lateral phrases. Error bars $=$ SEM.

## Study 2

Study 2 was designed to replicate and further explore this linguistic conventionalization. In addition, we sought to determine whether military personnel are aware that lateral metaphors are specific to the dialect of English spoken in the military, and not shared with the larger civilian population. Anecdotal evidence suggested that military personnel might be unaware that this system of linguistic metaphors is not shared widely among English speakers.

## Methods

Participants: Members of the US military $(\mathrm{n}=14)$ participated for $\$ 10$. Civilian undergraduates ( $\mathrm{n}=27$ ) participated for course credit. Military participants included 3 Army, 1 Navy, and 10 Air Force; 5 were Officers, 5 were Enlisted, and 4 did not identify their rank.
Materials: Materials were identical to Study 1 with two differences. First, based on anecdotal evidence that lateral metaphors were commonly used with the verb push, we included items with push (e.g., pushed two months). Second, to reduce the total number of items, we did not vary the timescale, since it had no effect on acceptability in Study 1.
Procedure: Participants completed two randomly-ordered tasks: the Acceptability Rating task from Study 1, and a forced choice Sentence Completion task.

The Acceptability Rating task was based on Study 1, with one critical difference: participants completed two randomly-ordered blocks of acceptability ratings, one in which they were asked to imagine all their colleagues were
in the military, and another in which they imagined all of their colleagues were civilians. Manipulating the utterances’ context in this way allowed us to test whether military participants were sensitive to the community-specificity of the lateral-dynamic metaphors.

In the Sentence Completion task, participants read the same sentences as in the Acceptability Rating task, but with a blank in place of month (e.g., The meeting was moved two months to the right, from November to $\qquad$ .) Choices included all odd-numbered months (January, March, etc.) and I don't know. Because of space limitations, we must analyze these data elsewhere.

To refresh participants between these tasks, they completed a brief "spot the differences" game, in which they had 45 seconds to count as many small differences as possible between two nearly identical images.

Exclusions and Analyses were unchanged from Study 1. No participants were excluded.

## Results

As in Study 1, we first verified that participants from both populations rated the Standard phrases as most acceptable and the Ungrammatical phrases the least acceptable, with the Lateral phrases in between. Once again, Standard items were rated as more acceptable than Dynamic-Lateral phrases ( $M=0.91$ vs. $M=0.21 ; b=0.73 \pm 0.14 \mathrm{SEM}, t=$ 5.4, $p<.001$ ), which were more acceptable than Static-Lateral phrases $(M=-0.10 ; b=0.31 \pm 0.07 \mathrm{SEM}, t=$ 4.3, $p<.001$ ), which in turn were more acceptable than Ungrammatical phrases ( $M=-1.03 ; b=0.83 \pm 0.16$ SEM, $t$ $=5.3, p<.001$ ).

We next attempted to replicate our main finding from Study 1: That military participants had a selective preference for lateral metaphors, compared to civilians. First, we replicated the finding that, overall, every type of sentence (Dynamic-Lateral, Static-Lateral, Ungrammatical) was rated as less acceptable than the Standard phrases (all $b \mathrm{~s}<-0.69, p \mathrm{~s}<.001$ ). Next, we replicated our critical finding that the populations differed in their preference for Dynamic-Lateral phrases $(b=0.57 \pm 0.05$ SEM, $t=10.6, p$ $<.001$ ). While civilians thought the Dynamic-Lateral phrases were far worse than the standard ones $(b=-0.96$ $\pm 0.05 \mathrm{SEM}, t=-20.2, p<.001$ ), for enlisted military personnel the difference was more than half of what it was for civilians $(b=-0.47 \pm 0.08 \mathrm{SEM}, t=-5.9, p<.001)$, while for military officers the Dynamic-Lateral phrases were actually considered to be significantly better than the Standard ones $(b=0.18 \pm 0.06 \mathrm{SEM}, t=-3.0, p<.01)$.

There was no evidence that the populations differed in their judgements of Ungrammatical phrases ( $p>.7$ ). However, unlike in Study 1, the populations did differ in
their acceptance of Static-Lateral phrases ( $b=-0.43 \pm 0.05$ SEM, $t=-8.1, p<.001$ ). As with the Dynamic-Lateral phrases, civilians were the most dismissive ( $M=-0.28$ ), followed by enlisted personnel $(M=0.15)$, and finally officers ( $M=0.43$ ) - although note that, here, officers did not prefer Static-Lateral phrases to the Standard phrases.

Finally, we investigated whether an utterance's context whether it was uttered in a military or civilian context - had a significant effect on its acceptability (Figure 2). This full model replicated the findings reported above. There were only two other significant effects. The first was an interaction between context and population ( $b=0.18$ $\pm 0.06 \mathrm{SEM}, t=2.9, p<.001$ ), driven by an 'opposite context' effect: military participants thought phrases were generally less acceptable in a civilian context, and vice versa. This may be due to participant uncertainty about norms in unfamiliar environments. The second was a three-way interaction between population, context, and Static-Lateral (vs. Standard) phrases ( $b=-0.20 \pm 0.09$ SEM, $t=2.3, p=.02$ ). This was driven by the fact that officers did not exhibit the 'opposite context' effect for Static-Lateral phrases - they liked them equally in both contexts. Thus, even in a hypothetical civilian context, military participants thought the lateral phrases were significantly more acceptable than actual civilians did.

Figure 2. In Study 2, military personnel were again more accepting of lateral phrases, this time for both static and dynamic versions. This pattern was repeated both when the phrases were uttered in a civilian context (left panel) or a military context (right panel). In other words, military participants thought that rescheduling a meeting to the right' is acceptable among civilians. Error bars $=$ SEM.

## Discussion

Conventionalized linguistic structures and cultural patterns of thought are often consistent (e.g., Boroditsky et al., 2010; Fuhrman et al., 2011; Winter, Marghetis, and Matlock, 2015), and prior work has provided evidence that learning new metaphors for talking about time can create new mental representations (Hendricks \& Boroditsky, 2015). However, there is little direct evidence of the purportedly more pervasive, reverse relationship: cultural
patterns of thought creating new conventionalized linguistic structures. In two studies, we provided evidence that one subset of American English speakers-members of the US military-have adopted a conventionalized system of metaphors for expressing mental representations that are pervasive in the minds of English speakers in general, but otherwise absent from language. Specifically, we found that members of the US military, especially Officers, consider sentences containing left-right metaphors (and only these types of sentences) as more acceptable than civilians do.
We also explored the nuances of the left-right metaphors based on military members' acceptability ratings for sentences with different features. In general, military personnel judged Dynamic-Lateral sentences - which express an event moving from one time to another - to be more acceptable than similar Static-Lateral sentences that express the same relationship without movement. This nuance in military members' acceptance of left-right metaphors is evidence that these new left-right linguistic conventions do not merely reflect a broad association of time with the lateral axis, but instead reflect specific linguistic conventions.
By showing that at least one subculture of American English speakers has conventionalized left-right linguistic metaphors for time, we demonstrate that the relationship between conventionalized structures in language and patterns in thought is bidirectional: not only can language shape mental representations, but our mental representations can also make their way into conventionalized language.
Why have military members adopted lateral metaphors that are absent from civilians' language? One hint may lie in the artifacts they use. Duty Rosters are documents that keep track of the work assignments for each each member of a military unit. Duty Rosters are standardized and governed by instruction manuals (Army Regulation [AR] 220-45). Each row represents an individual. Each column represents a successive date, ordered from left to right. Each cell thus indicates the task that was assigned to that individual (row) on that day (column). Unlike a standard American calendar, in which each row only has 7 days across, Duty Rosters arrange days in a continuous line extending rightward, potentially endlessly. One duty roster, for instance, had hundreds of columns, each representing a successive day.
The current work cannot distinguish between two explanations for how this linguistic innovation has spread. On the one hand, new linguistic conventions could have emerged spontaneously through the interaction with frequently consulted artifacts like Duty Rosters in a relatively linguistically encapsulated community. On a complementary account, these conventions may be the product of top-down, institutional decrees, where linguistic decision-makers within a community-affected no doubt by
the same convergence of conceptualization and material artifacts-themselves influenced linguistic habits through prescriptions for ways to talk about time. Future work will continue to document the history and use of these left-right linguistic conventions to distinguish between these two accounts. Similarly important to explore are the cognitive consequences of adopting lateral metaphors for time. Can adopting lateral linguistic metaphors facilitate reasoning about temporal change? Does it reduce miscommunication (e.g., allowing speakers to avoid ambiguous descriptions like Wednesday's meeting was moved forward two days)? Or might it increase other kinds of miscommunication, for example when English speakers communicate with Hebrew and Arabic speakers, whose mental timelines run right to left, counter to English speakers' (Tversky et al., 1991)? In sum, this work reveals a potentially fertile new way to study the give and take between individual conceptual metaphors and community-wide, conventionalized linguistic structure.

#### Abstract

Dialog game tools are text chat applications which aim to structure and promote students' collaborative learning by having them select a label and sentence-opener for each message they type to their learning partner. In this experiment, we compared students' learning from discussions via a dialog game tool to their learning via a standard freechat application. Students discussed topic questions with a learning partner. They then individually completed a multiple choice test, for assessing knowledge-gain, and a short-answer test, to assess readiness for knowledge-building. Results suggest that dialog games applications lead to increased readiness for knowledge-building, in the form of integrating distinct pieces of learned knowledge, than freechat applications. Follow-up analyses suggest that the degree of concept overlap between students' dialog messages and topic keywords, as measured by a "semantic fingerprint" system, is a potentially useful metric for predicting students' knowledge-building. Implications and potential applications of our findings are discussed.

Keywords: collaborative learning; generative learning; knowledge-building; metacognition; dialog games

## Introduction

One technique that aims to enhance collaborative learning activities among students, and to promote their communicative interaction skills, is to employ the dialog games approach. Dialog-game applications are computerized education-tools that structure students' interactive text chats by having them select the function of each dialog act they make. For each dialog act they also choose a sentence opener "scaffold" from a set of options available for the dialog act type. Such applications have been demonstrated to facilitate construction of structured communication behavioral patterns such as helping, information-seeking, probing, and instructing, between online learners (e.g., Ravenscroft, Wegerif, \& Hartley, 2007; Wells, 2014).

Analyses of learners' dialog patterns in their use of dialog games applications suggest several avenues by which they potentially may lead to more effective collaborative learning. In particular, the structure of communication promoted by dialog games implementations may improve common understanding of the knowledge perspective of one's dialog partners, more effective and coherent
argumentation, and more critical thinking (e.g., Carlson, 2012; Weigand, 2016).

Along these lines, one possibility is that dialog games applications may encourage more metacognition. Metacognition in this context refers to thinking about knowledge states, including insufficient knowledge, whether one's own or one's learning partner. It is a core factor for self-regulated learning patterns, which involve targeting one's misconceptions and effectively integrating newly learned information with prior knowledge (Azevedo et al., 2009). In a collaborative learning context, in addition to metacognition encouraging self-correction of one's misconceptions, it may elicit explanation and re-representation of one's knowledge to one's learning partners that in turn may support the construction of more robust knowledge-representations.

In other words, several patterns of behavior encouraged by dialog games applications may align with those that promote generative learning. Generative learning is learning which goes beyond mere memorization, involving deeper cognitive processing, manipulation, and restructuring of information (e.g., Fiorella \& Mayer, 2015). The outcome is new knowledge that can be applied in novel situations. Selfexplaining and re-representing information in order to teach others are examples of learning strategies which can lead to generative learning. Experimental evidence supports the notion that self-explaining can increase one's integration of learned knowledge and inferring of new knowledge (e.g., Ainsworth \& Burcham, 2007).

Tied to the notion of generative learning are the levels of learning in Bloom's taxonomy that go beyond remembering and understanding learning-domain information (Bloom, 1956). In particular, the "apply" and "analyze" levels involve transferring learned knowledge in order to solve problems and infer new knowledge. Related to this notion, in tutor-learner dialogs, tutor behaviors that encourage knowledge-building, or inference of new knowledge from existing knowledge, rather than shallow knowledge-telling behaviors (e.g., when the tutor immediately jumps to correct a learner's misconception, rather than eliciting the learner to figure out his or her own misconception) entail more generative learning (Roscoe \& Chi, 2007). The analysis of tutor-learner dialogs by Chi et al. (2001) indicates that certain dialog patterns, namely those which are interactive in nature, (which means that they contain joint-actions), encourage more generative learning, whereas dialogs that
are dominated by the tutor lead to more shallow learning. Whereas self-explaining is a constructive learning activity, i.e. one that encourages knowledge inference, it is not an interactive constructive activity. According to Chi et al., (2001) behaviors that are at-once both interactive and constructive are the core drivers of effective tutor-learner interactions. That is, the most effective tutor-learner dialogs are ones in which new knowledge is jointly constructed for the learner. In particular, their extensive analysis of tutorlearner dialogs suggests distinct interactive patterns that define effective knowledge-construction. An example of such a pattern is a tutor providing scaffold prompts (e.g., hints and highlights of relevant information) for the learner to figure out the solution to a learning-domain question or problem. Chi et al. (2001) further crafted categories of questions intended to assess whether a learner has acquired information laid out in a learning-text (text-explicit questions), has effectively integrated information from different places in the learning text (text-implicit questions), or has successfully constructed and applied a mental model for the learning domain, not explicitly described in the learning text (model-implicit questions). Ainsworth et al. (2007) in their self-explanation learning studies have adopted some of these questions, referring to the latter two categories as "implicit" and "knowledge-inference" questions. However, we would argue that the integration of disparate pieces of domain knowledge toward figuring out the answer to a question, as opposed to arriving at the answer by mere recall, is itself also a form of knowledge-inference, even if it does not involve an implicit mental model. Thus, we regard successful answering of both text-implicit and model-implicit questions as entailing some form of knowledge-building.

Our hypothesis for the study was that the patterns of communicative interaction promoted by a dialog-games application would elicit more generative learning among peer-learners than a free chat application. We developed a dialog-games application and a control free chat application and designed an experiment to evaluate students' collaborative learning outcomes. This included evaluating students' basic knowledge-gain through their performance on multiple-choice items assessing (text-explicit) recall and understanding of the learning material. Critically, to test our generative learning hypothesis we assessed participants' readiness for knowledge-building, through their performance on short-answer items that required them to either integrate pieces of existing knowledge (recalled from the learning-material) or to infer the answer by applying an accurate implicit mental model based on recalled learning-material information. We utilized three text-implicit questions for the first category of knowledgebuilding questions, and three model-implicit questions for the second kind. Our study thus extends prior research by investigating whether specifically the scaffold functions of dialog game applications enhance collaborative learning and increase the potential for knowledge-building. Additionally, we also explored the possibility of applying a natural-
language processing system to obtain dialog metrics that effectively predict better knowledge-building from students, in order to investigate the feasibility of integrating such features into dialog-games tools.

## Method

## Participants

Participants included in the analyses were $569^{\text {th }}$ grade students across three secondary schools in Singapore. Signed parental consent was obtained for these students to participate at a pre-scheduled school-day time in school classrooms or computer labs that had been made available for the experiment, with laptops set up at desks in the rooms. ${ }^{1}$

## Materials

The learning domain was the human circulatory system that was adapted from the Chi et al. (2001) peer-tutor dialog study. Each of the 13 subsections was designed on the computer screen to describe each topic (e.g., "The Blood Flow in the Heart"). Diagrams were added to facilitate comprehension. Bullet points under the diagrams described the main concepts.

The topic questions that students discussed via text chat are shown in Table 1. Topic 1 corresponds to questions in the Chi et al. taxonomy which require integration of distinct pieces of explicitly learned knowledge. That is, the two subquestions for Topic 1 are text-implicit knowledge-building questions. Topic 2 question, in addition, requires the correct mental model of circulation (as a double-loop) to answer the question effectively. Thus, it is a model-implicit knowledgebuilding question. Topic 3 provided students a general discussion about the learning-domain concepts.

There were pretest and posttest multiple choice questions to gauge students' prior knowledge, and their recall and understanding of the learning material. Also for the posttest, students received six knowledge-building questions. They are shown in Table 2. The first 3 are text-implicit questions, and the latter 3 are model-implicit questions, as developed and utilized by Chi et al. (2001) and Ainsworth (2007).

There were two conditions of the dialog games text chat tool employed for this experiment. For the Scaffold condition, the application included dialog act labels for

[^350]students to select, and corresponding sentence openers. These message types were based on speech-act theory and were adopted from those used in other dialog game implementations (Weigand, 2016). Students were also provided with a sheet that defined the different dialog acts to guide them (see Table 3). Table 3 also shows examples of sentence-openers that students could choose for each dialog act. Figure 1 illustrates the design of the dialog game window, with labels numbered indicating the steps for entering and sending a dialog message, as follows: (1) The topic question that defines the parameters of a given dialog is at the top of the screen. (2) Users may click on a bubble next to a dialog message to make a reply to the specific message (which can also be used to reply to earlier messages in the chat history). Reply messages are indented relative to the original message. If no reply bubble is clicked, the entered text message will appear below all the text messages in the chat window, with no indentation. (3) Users select one of the six communicative act labels, and then select a linked sentence opener from a dropdown menu. The selected sentence opener appears at (4). (5) Users type in the rest of their message into the text box. Note that only one user may type into his or her text entry box message at a time. If it is the other user's turn, the shadow text in the box says "Please wait your turn." If it is the given user's turn, it says "Enter your text." In addition, if a user has failed to first select a dialog act label and sentence opener, on clicking the text entry box a reminder message will appear, and the user is unable to type into the box until making these selections. (6) When a user has completed a message, he or she clicks the "Send" button.

The Freechat application was of similar design and appearance as the Scaffold application, and included the turn-by-turn use features, but did not feature the dialog act label buttons and sentence-opener display. Thus, users took turns simply entering messages, without the scaffold steps.

Figure 1: Dialog Game Screen.

Table 1: Topic discussion questions

| Topic No. | Discussion Question(s) |
| :---: | :--- |
| 1 | a) Why do we have valves in veins, but not in arteries <br> and capillaries? <br> b) Why don't we have valves in pulmonary veins? |
| 2 | Why do we sometimes refer to the heart as a "double <br> pump"? |
| 3 | What do you think are the most interesting aspects of <br> the structure and function of the human circulatory <br> system? Please discuss. |

Table 2: Posttest questions to assess Knowledge-Building

| Item <br> No. | Short-Answer Question |
| :---: | :--- |
| 1 | Why is there an artery that carries deoxygenated blood? |
| 2 | Why do vessels get increasingly smaller as they get close to <br> the body cells, and increasingly larger as they get nearer to the <br> heart? |
| 3 | In which kind of blood vessels (arteries, veins, or capillaries) <br> is the blood pressure the lowest? Why? |
| 4 | Why is your right ventricle less muscular than your left <br> ventricle? |
| 5 | The artery that carries blood from the right side of the heart to <br> the lungs (the pulmonary artery) carries about the same <br> amount of blood as the artery that carries blood from the left <br> side of the heart to the rest of the body (aorta). Why do they <br> carry the same amount of blood? |
| 6 | What would happen if the valves between the atria and the <br> ventricles got stuck open and wouldn't close? |

Table 3: Descriptions of communicative act labels, with example sentence-opener choices (Scaffold condition)

| Dialog Act | Description | Example Sentence Opener <br> Choices |
| :---: | :---: | :---: |
| Information | To provide or <br> describe relevant <br> facts or knowledge. | Let me explain... <br> Some facts are... <br> My understanding is that... |
| Propose | To bring up a new <br> idea to consider. | I suggest that... <br> Let us focus on... <br> I think it makes sense to... |
| Challenge | To argue against, or <br> provide evidence <br> against a dialog <br> statement. | I disagree because... <br> A counter-argument is... <br> An alternative view is... |
| Question | To ask your dialog <br> partner about <br> something you don't <br> know. | Why is it... <br> Can you explain... <br> What do you think about... |
| Agreement | To agree with a <br> statement made by <br> your dialog partner. | I agree, $\ldots$ <br> Good point, $\ldots$ |
| Support | To argue for, or <br> provide evidence for <br> a dialog statement. | I think this view is supported <br> by, $\ldots$ <br> To give an example, .... |

## Procedure

Students were randomly assigned to the Scaffold condition, involving the text chat application that required them to select dialog act labels and sentence openers, or to the

Freechat condition. There were 28 students for each condition. Within each condition, the students were again randomly assigned to dialog-discussion pairs. Students in each condition were taken to separate rooms for the study (Scaffold or Freechat). To minimize verbal and indirect interaction, no student sat next to any other student. Each of two experimenters was also randomly assigned to conduct the session for each condition.

In each study session room, pre-arranged laptops were placed on the desks. The experimenter overviewed the session, which consisted of the following tasks:

1) Students were given up to 7 minutes to individually complete the multiple-choice pretest (could click "submit" if they finished early). (The timer for all tasks was viewable at the top of the application window).
2) Following the pretest, students were taken to the learning material screen where they had 15 minutes to read and study the learning material.
3) Then the experimenter went over how to use the system. For the Scaffold condition, the experimenter went over the different communicative act labels, and the steps for entering in a message including a sentence opener. Students also received a dialog act description sheet (Table 3).
4) The students were given a five-minute demo dialog session to help them get accustomed to the application.
5) Next, the students (with their randomly assigned learning partner) discussed the dialog questions for the 3 topics. For both conditions, students took turns entering in a dialog message. They could also open a pop-up window that contained the learning-material, which they could refer to for the discussions. For each topic, students had a 10 minute dialog discussion.
6) Following the end of their dialogs discussion, the students completed the post-test individually. These consisted of the same multiple-choice questions as in the pre-test ( 6 minutes). In addition, they had to answer the short-answer questions (as in Table 2) to assess knowledge-building, for which they were given 25 minutes. For each portion of the posttest, students could click a "submit" button if they finished early.

## Measures

Knowledge-gain. To assess students' knowledge gain from reading the learning material and engaging in the dialog discussions, their scores on the posttest multiple choice (out of 10 points) were compared to their pretest scores.

Knowledge-building. A scoring guide was developed that allowed for 2 points maximum on each of the three text-implicit questions, and 3 points maximum on each of the three model-implicit questions. Basically, a point was awarded for each piece of information relevant for inferring the answer to the question, and for each correct inference.

For example, for Question 4, one point would be awarded for an accurate description of the function of the left ventricle, one for the right ventricle, and one point for the inference that the right ventricle doesn't need to pump blood with as great force as the left, as the blood travels less distance. Two raters, familiar with the scoring guide and the learning material and related concepts, scored participants' answers to these questions. They were kept naïve to the experimental condition for all the short-answer logs. The scores were averaged across the two raters. The intraclass correlation for absolute agreement on the items was computed as $\operatorname{ICC}(1,128)=0.87$ for the text-implicit items and $\operatorname{ICC}(1,128)=0.96$ for the model-implicit items.

Topic adherence. We conducted exploratory follow up analyses that utilized the "semantic fingerprint" system developed by the Cortical.io Company (with the API available on their website). The goal was to assess the feasibility of utilizing natural-language processing methods to predict students' capacity for knowledge-building (short-answer performance) from their dialog messages. Such functions, if predictive, could be useful to incorporate into dialog game applications, for teachers and students to track (in an automated fashion) learning outcomes implicitly from dialogs. The Cortical.io system represents the meaning of words in terms of their distributional overlap in a large linguistic corpus (i.e., Wikipedia). Its theoretical basis is the notion of distributional semantics, or "word spaces" (e.g., Sahlgren, 2006). The more frequently that words co-occur in near proximity in the corpus, the higher is their computed "semantic fingerprint overlap." The metric can also be extended by the system to compute the degree of semantic fingerprint overlap among text segments and documents, rather than of single words. For implementation details, refer to De Sousa Webber (2015).

Dialog file inputs were first corrected for spelling errors and abbreviations. What we refer to as "topic adherence" is, for each topic dialog and participant, the semantic fingerprint overlap between the participant's dialog messages (entered into the system as a single "document") and pre-selected keywords intended to represent important concepts related to the topic question. Refer to Table 1 for the Topic questions. For Topic 1, the keywords were: "valves," "veins," "arteries," "capillaries," "pulmonary," and "pressure." For Topic 2, they were: "heart," "lungs," "oxygen," "blood," and "pump." For Topic 3, they were "valves," "veins," "arteries," "heart," "lungs," "oxygen," "blood," and "circulatory." The additional dialog metrics of mean number of words-per-turn, and total number of turns, were used.

## Findings and Discussion

## Knowledge-gain scores

Figure 2, on the two pairs of bars on the left, shows the mean scores across the Scaffold and Freechat conditions on the pre-test and post-test multiple choice for assessing
students' level of recall and understanding of the domain material. It also displays the proportion-scores, so that tests with different scales can be displayed on the same chart. Participants did not differ significantly on their pretest scores, $t$ (53) < 1. Across both conditions, participants showed improvement on their post-test multiple-choice scores relative to their pre-test scores, $t(55)=5.22, p<$ .001 , with an effect size of $d=0.76$. The knowledge-gain (post- minus pre- test score difference) in the Scaffold condition ( $\mathrm{M}=1.07$ ) did not significantly differ from the Freechat knowledge-gain $(\mathrm{M}=1.14), t(53)<1$. The two conditions also did not differ significantly on the mean posttest multiple-choice scores, $t(53)<1$.

## Knowledge-building scores

To assess our hypothesis of increased knowledge-building for the Scaffold condition, we first conducted a MANOVA on the text-implicit and model-implicit scores. There was an overall effect of condition, $F(2,53)=3.19, p<.05$. Figure 2 , on the two pairs of bars on the right, shows the mean proportion-scores across the two sets of knowledge-building questions (text-implicit and model-implicit). The follow-up tests indicated no effect of condition on the model-implicit questions, $t$ (54) < 1 . However, for the text-implicit questions, the mean score was higher in the Scaffold than the Freechat condition, $t(54)=2.39, p=.02$, with an effect size of $d=0.64$.

Figure 2: Mean scores ( $+/-\mathrm{SE}$ ) in the Scaffold and Freechat for the multiple-choice pretest and posttest, and the knowledge-building tests (text-implicit and model-implicit).

## Dialog metrics for knowledge-building

We conducted follow-up multiple-regression analyses to explore whether the topic adherence scores obtained by the semantic fingerprint system, along with the metrics of words-per-turn and number of turns, could be of use for predicting students' readiness for knowledge-building (i.e., their short-answer scores). Scores were averaged for each participant across the three dialog topics. Tables 4 and 5
show the regressions separately on the Scaffold and the Freechat cases, respectively. For the Scaffold condition, the overall regression trends toward statistical significance, and the coefficient for topic-adherence reaches statistical significance. Total-turns trends in the direction of predicting increased knowledge-building scores. For the Freechat condition, the overall regression also trends toward statistical significance, but with a non-significant coefficient for topic adherence, and with the total-turns coefficient trending in the direction of predicting reduced knowledgebuilding. Overall, across both regressions words-per-turn appears to be a relatively weak predictor.

Table 4: Multiple regression for predicting knowledgebuilding (Scaffold condition)

| Predictor | B | SE B | $\boldsymbol{\beta}$ | $\boldsymbol{t}$ | $\boldsymbol{p}$ |
| :---: | :---: | :---: | :---: | :---: | :---: |
| Topic adherence | 19.53 | 7.64 | 0.55 | 2.56 | $0.02^{*}$ |
| Words-per-turn | 0.06 | 0.07 | 0.24 | 0.97 | 0.34 |
| Total turns | 0.42 | 0.21 | 0.52 | 1.96 | 0.06 |
| $\mathrm{R}^{2}=0.27, F(3,22)=2.72, p=0.07$ |  |  |  |  |  |

Table 5: Multiple regression for predicting knowledgebuilding (Freechat condition)

| Predictor | B | SE B | $\boldsymbol{\beta}$ | $\boldsymbol{t}$ | $\boldsymbol{p}$ |
| :---: | :---: | :---: | :---: | :---: | :---: |
| Topic adherence | 4.62 | 6.09 | 0.16 | 0.76 | 0.46 |
| Words-per-turn | -0.01 | 0.04 | -0.08 | -0.34 | 0.74 |
| Total turns | -0.13 | 0.08 | -0.41 | -1.62 | 0.12 |
| $\mathrm{R}^{2}=0.23, F(3,24)=2.32, p=10$ |  |  |  |  |  |

## Discussion

Our hypothesis was partially supported. Namely, students in dialog-games interactions to discuss topic questions in the learning domain exhibited a higher readiness for knowledge-building, in the form of making text-implicit inferences, than students in the freechat discussions. There was no significant improvement on model-implicit questions. The increased knowledge-building readiness was also over and above any knowledge-gain, which did not significantly differ between conditions.

In addition, the multiple-regression results suggest that natural-language processing methods may hold some promise in producing dialog metrics with predictive utility for knowledge-building. The predictive value (in terms of the standardized Beta coefficient) of our topic-adherence metric was particularly more prominent for the Scaffold condition than for Freechat condition. Also of interest, though more caution is warranted for interpretation of nonstatistically significant trends, is that the total-number of dialog turns went in the direction of predicting more knowledge-building for Scaffold condition, and less knowledge-building for Freechat condition. These trends
may be indicative of qualitative differences in the nature of dialogs with versus those without scaffolds, with a tendency for scaffolds to raise the potential learning value of each dialog turn, and to increase the potential knowledgebuilding when dialog partners jointly discuss core concepts in the learning domain. One possibility is that the dialog game scaffold functions in effect promote more selfexplanation in the process of developing explanations and arguments to one's dialog partner. An extensive study of collaborative learning dialogs by Asterhan \& Schwarz (2009), on the other hand, suggests that the process of argumentation itself may be essential for driving conceptual change from the joint construction of explanations. In the current context, if the dialog game scaffold functions encouraged more structured argumentation, this would open the door for dialogs that are more focused on the main topic concepts to generate improved conceptual understanding of the learning domain.

The conceptual foundation for applying the framework of dialog-games to learning is grounded in the notion of learning as a dialectical, social, and interactive process (cf. Mercer \& Littleton, 2007). Structuring a learning-discussion as dialog-game is therefore seen as a means to encourage effective argumentation and critical thinking (e.g., McAlister, Ravenscroft, \& Scanlon, 2004). In terms of Bloom's taxonomy, the potential, more immediate benefits of dialog-games can be viewed as focused on the application and analysis levels of learning. However, effective learning at these levels requires first a solid groundwork of basic understanding of concepts in a learning domain, and in turn takes time. Reaching even higher levels of learning, and unlocking creativity, is an ever increasing long-term process (cf. Bloom, 1956). Thus, dialog games may be beneficial for developing students' creativity, but this would need to be evaluated by an extended use of such applications for learning, e.g. over weeks or months.

Along these lines, one limitation of the current study is that it was a "single-shot" learning and evaluation session. For generative learning more time for absorbing, processing, and transforming information may be an essential element (Fiorella \& Mayer, 2015). Thus, even on the text-implicit questions, for which there was a medium-sized effect for the difference between conditions, the mean proportion of total points obtained was for both conditions only about half of the total possible. In addition to being constrained by time for the current study, another note is that dialog-games are often applied for conversations among small-groups (Ravenscroft, 2007). It is possible that learning-dialogs for groups of 3 or 4 may allow for more argumentation and perspective-taking opportunities than two-way dialogs. Future research directions are indicated for "scaling" up dialog-games applications for knowledge-building, both in terms of time (over a long-term learning period) and in terms of group-size (e.g., from learning-pairs to learning-groups). Such extensions may lead to larger-scale knowledge-building effects, and increase
the predictive value of dialog metrics for knowledge-building.

# Leveraging mutual exclusivity for faster cross-situational word learning: A theoretical analysis 

Shohei Hidaka (shhidaka@jaist.ac.jp) and Takuma Torii (tak.torii@jaist.ac.jp)<br>Japan Advanced Institute of Science and Technology<br>1-1 Asahidai, Nomi, Ishikawa, Japan

#### Abstract

Past mechanistic accounts of children's word learning claim that a simple type of cross-situational learning is powerful enough to match observed rates of learning, even in quite ambiguous situations. However, a limitation in some of these analyses is their reliance on an unrealistic assumption that the learner only hears a word in situations containing the intended referent. This study analyzed a more general type of cross-situational learning based on the relative frequency of word-object pairs, and found it to be slower than the simple mechanism analyzed in prior work. We then analytically explored whether relative-frequency learning can be improved by incorporating the mutual exclusivity (ME) principlean assumption that words map to objects 1 -to-1. Our analyses show that with a certain type of correlation in word-to-word relationship, ME makes relative frequency learning as efficient as fast-mapping, which can learn a word in one exposure.

Keywords: Word learning; Cross-situational learning models; Mutual exclusivity; Language acquisition

## Introduction

To a new learner of a language with a completely unknown word-referent mapping system, determining which words refer to which referents in any given scene may seem impossible on the face of it, since a word could refer not only to an object (e.g., 'apple'), but to a class of objects (e.g., 'fruit'), a property ('red'), or any one of endless possible combinations or configurations of features in the scene-an unconstrained problem of logical induction (Quine, 1960). In contrast to this theoretical observation about referential uncertainty, children are thought of as efficient learners, and in fact most human children do learn to understand and use an impressive number of words within the first years of life, achieving a vocabulary of roughly 60,000 by 18 years of age (Bloom, 2000). Developmental researchers have theorized that children use a variety of lexical constraints to limit the number of possible mappings they consider, and a number of empirical studies support these claims (Clark, 1987; Markman, 1990, 1992; Golinkoff, HirshPasek, Bailey, \& Wegner, 1992). One lexical constraint, used here as in past theoretical accounts-and supported by empirical developmental data, is that learners are biased to map words to entire objects, rather than to a feature of an object, or a group/configuration of objects (Markman, 1990).

Beyond lexical constraints that reduce the number of hypothesis meanings considered for a given word in a given situation, another possible remedy for the contradiction between the difficulty of the unconstrained inductive account of word learning and the ease of the observed process is that learners also reduce uncertainty in the word-object map by statistical inference over time, based on observing word-object pairs across multiple situations. Cross-situational learning (Pinker, 1984; Akhtar \& Montague, 1999; Siskind, 1996) is a type of learning based on this idea, which has been analyzed both empirically and theoretically over decades (Yu, 2008; Blythe, Smith, \& Smith, 2010). Blythe et al. (2010) formally quantified the effect of a type of crosssituational learning in terms of the rate of vocabulary growth. More recent studies (Blythe, Smith, \& Smith, 2016; Vogt, 2012) further showed that this type of crosssituational learning can be considerably slowed down for certain types of word co-occurrence distributions, including power-law distributions in which most words are seen relatively rarely, which describe word frequency distribution in natural languages (Zipf, 1949).

These theoretical analyses are still quite limited in their generality. The class of cross-situational learning analyzed in these past studies is called eliminative learning. In this scheme, when a learner is exposed to a set of referents, a correct word is spoken-never is a word spoken when its intended referent is not present. In this case, the learner can safely "eliminate" the possibility of word A being associated to the object B, if he or she experiences one episode that the word A is spoken without the object $B$. As this special assumption does not generally hold in real-world learning, the estimates on the speed of cross-situational learning in past studies give only an optimistic upper bound for its learning efficiency.

In this study, we consider a more general type of crosssituational learning, called relative frequency learning, of which eliminative learning is a special case. In the relative frequency learning scheme, it is assumed that a language system encodes the word-object pair with frequency higher than the other candidate pairs as the correct one, and the learner infers such relatively more
frequent word-object pairs from the sample. Under this assumption, the eliminative learning scheme is identified with the special case of seeing the correct word-object pair with probability 1 . In general, however, the eliminative learning rule cannot apply (or will mislead the learner if it is forced to apply) in word learning of a relative-frequency language system.

Therefore, relative frequency learning is generally slower than the eliminative learning. Thus, the main problem considered in this study is what plausible factor might make this type of learning more efficient - and can it be made efficient enough to be a realistic account for children's word learning? Specifically, we analyze the beneficial effect of learners applying a general principle of mutual exclusivity (ME), an assumption of a wordobject regularity requiring that no two objects are associated to one word. Application of a ME principle has long been theorized to be a constraint that can speed children's word learning (Markman \& Wachtel, 1988), and has found empirical support in both children (Halberda, 2003) and adults (Yurovsky \& Yu, 2008; Kachergis, Yu, \& Shiffrin, 2012). We then consider a word-word statistical relationship in which a group of distractor objects tend to co-occur with a word and thus slow learning.

In the following, we first outline the theoretical framework in which we provide a series of analyses of relative frequency learning. Second, we evaluate the basic learning efficiency in this scheme. Then we extend this evaluation of learning efficiency to multiple scenarios with different word-to-word statistical relationships.

## Relative-frequency learning

## Basic framework

In this study, we consider the following word learning scenario. The learner is exposed to multiple words and objects in each situation. In each situation, the learner does not know which word refers to which object, and the correct word-object mapping can only be inferred by integrating evidence across observations of multiple situations. Let $W=\{1, \ldots, n\}$ be a set of words and $O=\{1, \ldots, m\}$ a set of objects (or referents) which appear in these situations. In this study, we consider a language structure with one-to-one word-object mapping, in which $n=m$ and the word $i$ refers to object $i$. This is a quite strong assumption, which may not be considered entirely realistic as it is. It offers, however, a first approximation upon which we can base the analysis and later extend it.

Here, we consider a particular word learning scheme, called relative frequency learning, in which each object's to-be-associated (i.e., 'correct') word is spoken in its presence with greater frequency than any other word. This is a code in the sense of information theory - the signal, the correct word-object mapping, is encoded in the statistical regularity in observation across situations
(channel), and the learner decodes (infers) the correct word-object map using the underlying regularity: the correct word-object pair is the most frequent among the others.

There are theoretical analyses of a special case of this relative frequency learning, in which the correct word is spoken only in the presence of the corresponding object $($ i.e., $p($ object $\mid$ word $)=1$ ). In this special case, the learner can use not only the knowledge that the correct pair is more frequent, but also the quite strong rule that any object which does not appear with a spoken word cannot be the intended referent of that word. Thus, this learning scheme, which eliminates any word-object pair with probability less than 1 is called eliminative learning (Blythe et al., 2010). In this study, beyond this special case, we analyze a more general case of language and learning coded on the basis of relative frequency.

## Formulation

Denote the frequency of object $o$ given word $w$ by $f(o \mid$ $w)$. Then, suppose the learner (decoder) declares that the object $o \in O$ is the referent of the word $w \in W$ with probability

$$
P(o \mid w)=\frac{e^{f(o \mid w)}}{\sum_{o \in\{O\}} e^{f(o \mid w)}}
$$

In this scheme, the error, wrong declaration of the correct object, for word $w$ with the number of observed situations $n$ is proportional to $\epsilon(n, w)$ := $\sum_{o \neq w} e^{f(o \mid w)-f(w \mid w)}$. The sum of the errors for all words $\epsilon(n, w):=\sum_{w \in W} \epsilon(n, w)$ is an exponential function of the number of situations. Let us denote the rate of the exponential function as $R$, and thus $\epsilon(n)=e^{-R n}$. For a code with rate $R$ encoding less than $e^{R n}$ signals, $\lim _{n} \sum_{w \in W} P(o \mid w)=1$, and thus it is said to be learnable (reachable in information-theoretic terminology). If the rate satisfies $\epsilon(n)=e^{-R n}<e^{-C n}$ for any code, the constant $C$ is said to be the capacity of this channel in information-theoretic terms (Shannon, 1948). The rate, or the exponent coefficient of the error function, is a fundamental characteristic of the language-learning system when viewed as a signal transmitting process.

## Efficiency

In the relative frequency learning scheme, the object $o$ with the second largest probability given the word $w$, $p_{w \mid w}>p_{o \mid w}>p_{o^{\prime} \mid w}$ for $o^{\prime} \neq o, w$, is a key parameter giving the asymptotic time to learn the word $w$. With objects with the largest and second largest probability, the sample frequency can be written as follows. Let $\bar{p}=$ $1-p$. Specifically, consider that the sample frequency $f_{\text {now }}=f_{n}(o \mid w)$ follows the binomial distribution

$$
P\left(f_{\text {now }} \mid n, p_{\text {ow }}\right)=\binom{n}{f_{\text {now }}} p_{o w}^{f_{\text {now }}} \cdot \bar{p}_{\text {ow }}^{n-f_{\text {now }}}
$$

with probability $p_{o w}$.
Given this, the error probability in learning is characterized as follows. The probability for the word $w$ to be associated with the object $o$ is proportional to $e^{f_{\text {now }}}$. For a sufficiently large $n$, the difference between the two random variables asymptotically approaches

$$
\lim _{n \rightarrow \infty} \frac{e^{f_{n o w}-f_{n o^{\prime} w}}}{e^{n \Delta_{o, o^{\prime} \mid w}}}=C,
$$

where $\Delta_{o, o^{\prime} \mid w}:=\frac{p_{o w}-p_{o^{\prime} w}}{p_{o w} \bar{p}_{o w}+p_{o^{\prime} w} \bar{w}_{o^{\prime} w}}$. If there are $m$ objects with the second largest probability $p_{o w}>q>$ $\max _{o^{\prime} \neq w}, p_{o^{\prime} w}$ for the word $w$, the error probability is $1-P(w \mid w) \rightarrow C m e^{-n \frac{p_{o w-p_{o^{\prime}} w}}{p_{o w} \overline{\bar{o}_{o} w+p_{o^{\prime}} w^{\overline{p_{o}}{ }^{\prime} w}}} \text {. Thus, the rate of }}$ the relative-frequency code is $R=\min _{w} \Delta_{w \mid w}$ where

$$
\Delta_{o \mid w}:=\frac{p_{o w}-\max _{o^{\prime} \neq o} p_{o^{\prime} w}}{p_{o w} \overline{p_{o w}}+\max _{o^{\prime} \neq o} p_{o^{\prime} w} \overline{\max _{o^{\prime} \neq o} p_{o^{\prime} w}}}
$$

This analysis implies that the word-object pair with the smallest margin to second largest probability decides the learning rate in the relative frequency code.

## Incorporating mutual exclusivity (ME)

In the above analysis of the relative frequency code, the lexical constraint of one-to-one word-object mapping is not taken into consideration in the learning process. However, if the learner exploits the fact that no two objects are associated with the same word, namely correct word-object pairs are mutually exclusive, the learning is expected to be more efficient than the alternative without the knowledge. Let us call this ME learning. The difference in the rate of learning assuming ME and general relative frequency would be the effect of introducing a ME constraint in cross-situational learning.

With ME, the learner can exclude object $o$ when learning word $w$, if the object $o$ is likely to be associated with some other word $w^{\prime} \neq w$. Thus, the learning order of the words has considerable impact in learning under ME. As the previous analysis shows that the second most probable objects for word $w$ is the key factor giving the learning rate, let us call them distractors against the word $w$, and denote the set of distractors by $D(w):=\left\{w^{\prime} \mid \max _{o \neq w} f_{o \mid w}=f_{w^{\prime} \mid w}\right\}$.

## Best- and worst-case scenarios

Here let us analyze ME learning under a simplification that the learning time for the words with no distractor is $T_{0}$ and that for the words with one more distractors is $T_{1}$. The former case with no distractor is said to be fast mapping, in which a particular word-object pair is presented alone in a situation, and the learner learns the pair in a single shot (Carey \& Bartlett, 1978). The latter case is analyzed in the previous section in case of the relative frequency learning. In this case, if all the distractors has been eliminated, by the effect of ME, the
corresponding object can be uniquely identified, which is effectively the same as fast mapping. Thus, the worstcase learning time approaches that of relative frequency learning, and the best-case learning time approaches that of fast mapping, as the number of words is sufficiently large.

## Randomly distributed distractors

Random learning order Consider the case that each word is learned in a serial order and each has $k$ distractors. Furthermore suppose that the learning order is a random permutation, namely any order is uniformly sampled. Figure 1 shows a schematic co-occurrence matrix of the five such word-object pairs (filled markers) with $k=2$ randomly distributed distractors (open markers) for each pair. In this case, one expects that one word is likely to be learned after the $k$ distractors with probability $1 /(k+1)$. This is exactly true, if the number of words $n$ approaches to infinitely large. Therefore, the sum of expected learning time for all the words is

$$
\begin{equation*}
T=n\left(\frac{k}{k+1} T_{1}+\frac{1}{k+1} T_{0}\right) . \tag{1}
\end{equation*}
$$

Thus, when the learning order is a random permutation, the expected learning time is only the factor of $\frac{1}{k+1}$ shorter than the original time $n T_{1}$ at shortest.

| Word | Objects |  |  |  | $\# D$ |  |
| :--- | :--- | :--- | :--- | :--- | :--- | :--- |
| "Circle" | $\bullet$ | $\triangle$ |  | $\star$ |  | 2 |
| "Triangle" |  | $\Delta$ | $\square$ |  | $\diamond$ | 2 |
| "Square" | $\bigcirc$ | $\triangle$ | $\square$ |  |  | 2 |
| "Star" | $\bigcirc$ |  |  | $\star$ | $\diamond$ | 2 |
| "Diamond" |  | $\triangle$ | $\square$ |  | $\diamond$ | 2 |

Figure 1: A schematic word-object co-occurrence matrix in the case with random learning order and randomly distributed distractors.

## Shared distractors

Best and worst learning order Let us consider the best and worst case by manipulating which words the $k$ distractors are associated. In one of the best cases, every word shares the same set $D$ of $k$ distractors. Figure 2 shows a schematic co-occurrence matrix of the five such word-object pairs (filled markers), and each pair has $k=2$ distractors (open markers) and most of words share the same two distractors. In this case, the shortest learning time is obtained by a sequence of learned words in which the $k$ words with the $k$ distractors as their correct objects first (required about $T_{1}$ time each) and the others later (required $T_{0}$ time each). In the example (Figure 2), one of the best order is to learn the word "Circle" and "Triangle" at the first two rows in the
matrix, and then learn the other words. In this case, the total learning time is

$$
T=k T_{1}+(n-k) T_{0}
$$

As the number of words $n$ gets larger with a constant $k$, the learning time approaches to that of the fast mapping ( $T_{0}$ per word), which is the lower bound of learning time.

In one of the worst cases, on the other hand, the longest learning time is obtained by the reversed sequence, in which the words with the $k$ distractors as their correct objects are learned last. In total, the longest learning time is

$$
T=n T_{1} .
$$

As the number of words $n$ gets larger with a constant $k$, learning time approaches that of relative frequency learning, which is the upper bound of learning time.

Random learning order Thus, this analysis with the best and worst case scenario suggests that the learning order of words has a large impact on learning time. However, the expected learning time with the shared distractors is, again, exactly $1 /(k+1)$, which is no better than the learning time of the case with $k$ random distractors (Equation (1)):

$$
T=n\left(\frac{k}{k+1} T_{1}+\frac{1}{k+1} T_{0}\right)
$$

This analysis suggests that even systematically shared distractors cannot improve the learning time on average, if the learning order is uniformly at random.

| Word | Objects |  |  | $\# D$ |
| :--- | :--- | :--- | :--- | ---: |
| "Circle" | $\bigcirc$ | $\triangle$ | $\square$ |  |
| "Triangle" | $\bigcirc$ | $\Delta$ | $\square$ |  |
| "Square" | $\bigcirc$ | $\triangle$ | $\square$ |  |
| "Star" | $\bigcirc$ | $\triangle$ |  | $\star$ |
|  | 2 |  |  |  |
| "Diamond" | $\bigcirc$ | $\triangle$ |  |  |

Figure 2: A schematic word-object co-occurrence matrix in the case with random learning order and $k=2$ distractors shared by all the words systematically.

## Correlation in word-to-word relationship Mixture of two groups of words

As the previous analysis suggests that the relative frequency learning of a one-to-one word-object map in the cross-situational setting is as slow as independent learning even by incorporating ME. This result is largely due to the statistical structure of the word-word relationship - in the previous analysis, each word has $k$ other random words as distractors. In this section, we consider a
specific class of statistical regularity in the word-word relationship. Specifically, suppose there are two groups of words: in the one group of words, each word has no distractor, and in the other group of words, each word has $k$ distractors, whose referring words have no distractor (Figure 3). Thus, the learner is exposed to a mixture of two groups of words with and without distractors. Figure 3 shows a schematic co-occurrence matrix of such five word-object pairs, in which each of the first group of words ("Circle" and "Star") has no distractors, and each of the other group of words has two distractors whose referring words are the members of the first group.
Although this statistical regularity in word-to-word relationships looks similar overall to the previous case (compare Figure 2 and 3 ), this new case is substantially different from the previous cases. The key observation here is that no distractor words have any distractors against themselves. Thus, the first group of words (potential distractors to the other group of words) would be learned via fast mapping, and the other group would be learned also via fast mapping after their distractors are learned before their learning. The learning timing of these two groups are probabilistic, but the first group of words are expected to be learned earlier on average than the other group.

| Word | Objects |  |  | \# D |
| :---: | :---: | :---: | :---: | :---: |
| "Circle" | $\bigcirc$ |  |  | 0 |
| "Triangle" | $\bigcirc$ | A | is | 2 |
| "Square" | $\bigcirc$ |  | is | 2 |
| "Star" |  |  | $\star$ | 0 |
| "Diamond" | $\bigcirc$ |  | is | 2 |

Figure 3: A schematic word-object co-occurrence matrix in the case with the two groups of words. Each of the first group of words ("Circle" and "Star") has no distractors, and each of the second group of words ("Triangle", "Square" and "Diamond") has $k=2$ distractors, whose referring words ("Circle" and "Star") has no distractors.

## Efficiency analysis

Specifically, suppose that each word in the group with distractors is learned at the time step $t$ by the probability

$$
p_{t}=\left(q_{t}+\overline{q_{t}} p\right) \overline{p_{t-1}}
$$

where $p$ is the probability to learn this word with distractors at each step, and $q_{t}$ is the probability to learn it without distractor at step $t$, or is said the probability for the learning at step $t$ to be fast mapping. By setting $\sum_{t=1}^{\infty}(1-p) p^{t-1} t=T_{1}$ and $q_{t}=0$ for any $t$, this learning time with $k>0$ distractors is identified with the previous analysis.

Suppose that there are $n_{0}$ words without distractors, and $t_{0}<t$ samples out of the all $t-1$ samples are drawn from this group of words with equal probability. Then, according to Hidaka (2014), as $n_{0} \rightarrow \infty$, the probability to learn the $m$ words of this group with the $t_{0}$ samples asymptotically approaches to the binomial distribution

$$
\sum_{m=0}^{n_{0}}\binom{n_{0}}{m} r_{t}^{m}{\overline{r_{t}}}^{n_{0}-m}
$$

where $r_{t}:=1-\left(1-1 / n_{0}\right)^{t_{0}}$. If each word in the group with distractors is associated to $k$ distractive words uniformly at random, the fast-mapping probability is

$$
q_{t}=\sum_{m=0}^{n_{0}}\binom{n_{0}}{m} r_{t}^{m}{\overline{r_{t}}}^{n_{0}-m}\binom{m}{k} /\binom{n_{0}}{k} .
$$

As the hypergeometric distribution ${ }^{1}$ approaches the binomial distribution as $n_{0} \rightarrow \infty$, we obtain

$$
\left\|\binom{m}{k} /\binom{n_{0}}{k}-\binom{m}{k}\left(\frac{k}{n_{0}}\right)^{k}\left(1-\frac{k}{n_{0}}\right)^{m-k}\right\| \rightarrow 0
$$

Using these asymptotic distributions for $n_{0} \rightarrow \infty$, we obtain the binomial distribution

$$
q_{t} \rightarrow \frac{n_{0}!}{k!\left(n_{0}-k\right)!}\left(r_{t} \frac{k}{n_{0}}\right)^{k}\left(1-r_{t} \frac{k}{n_{0}}\right)^{n_{0}-k}
$$

With further transform for a sufficiently large $n_{0}$, we obtain the fast-mapping probability to be

$$
q_{t} \approx\left(\frac{t_{0}}{n_{0}}\right)^{k}
$$

This expression thus implies that the probability $q_{t}$ of learning via fast mapping with $k$ distractors approaches 1 , if the sample of the words without distractors $t_{0}$ is comparable to the number of such words $n_{0}$.

## Implications

Suppose the number of words without distractors is $n_{0}=$ $\gamma n$ with a certain constant $0<\gamma<1$, and the number of samples $t_{0}=\gamma t$. In this case, as $t_{0} / n_{0}=t / n$, after the point when the number of samples is comparable with the number of words, this learning is sufficiently treated as the fast mapping. Thus, the learning time of a word with $k$ distractors asymptotically approaches the speed of fast-mapping after some constant number of samples for each word. In other words, in the long run, any words would be considered learned in the fast-mapping manner, if any distractor word has no distractors against itself.

[^351]This analytic implication is striking in that crosssituational learning on the basis of relative frequency, which itself is as slow as independent learning with a random word-word relationship, can become as efficient as fast-mapping, up to a constant time per word. At the very least, this analysis implies that the nature of the word-to-word relationships is a critical factor in determining the efficiency of relative-frequency based crosssituational learning.

## Discussion

In this paper, we studied cross-situational word learning from a theoretical perspective as the formation of a one-to-one word-object map. Our formulation of crosssituational learning is defined as learning on the basis of the relative frequency of objects for each word, which is a more realistic alternative model than eliminative learning, a model analyzed in past studies (Blythe et al., 2010, 2016) that is anyhow a special case of relative frequency learning. Thus, our analysis of relative frequency learning is both more general and more realistic than previously-proposed frameworks. Our analysis shows that its total learning time depends on the minimal difference between the most frequent and the second-most frequent objects among all the words, and that it is quite slow.

Given that relative frequency learning alone is inefficient, we next analyzed the case when the learner applies the lexical constraint that no two referents are associated to a single word. This principle of mutual exclusivity (ME) has been hypothesized to be an important means of reducing ambiguity for children learning language (Markman \& Wachtel, 1988; Markman, 1990, 1992), and empirical work has found that both children (Golinkoff et al., 1992; Halberda, 2003; Markman, Wasow, \& Hansen, 2003) and adults in cross-situational word learning experiments (Yurovsky \& Yu, 2008; Kachergis et al., 2012) show a preference for learning mappings consistent with ME. Using ME, a word can be learned via fast mapping (learned on its first sample), if all the distracting words appearing with it are already learned. However, the effect of ME on the average learning time is quite limited - the same (up to a constant multiplier) as that of independent relative frequency learning, if the distractors for each word are distributed uniformly. In summary, this analysis suggests that the order in which words are learned is related to the statistical nature of the word-to-word relationship-i.e., the structure among the cooccurring distractors.

Therefore, we finally analyzed the case in which a set of words is composed of two word groups: in one group, each word has no distractors, and in the other group each word has $k$ distractors, which are the words without any distractors. Here, it is not just a mixture of two types of words, but the distracting words have no
distractors to themselves, and thus they are likely to be learned earlier than the other group. Thus, in this schematic word structure, the expected learning order is correlated to the number of distractors for the group of words. We hypothesize that, with this statistical regularity, relative frequency learning can be as efficient as learning via fast-mapping, which has been observed in young children (Mervis \& Bertrand, 1994; GershkoffStowe \& Hahn, 2007). Our analysis suggests that this hypothesis is supported: the learning time is comparable with that of fast mapping learning up to a constant number of samples per word, when a certain ratio of words has no distractors. We expect that this analytic result can be extended to a more general case, such that there are multiple groups with different numbers of distractors up to $k$ and a group of words with $k$ distractors that has no distractors which have $k$ or more distractors against themselves.

In summary, we have analyzed a more general and more realistic class of word learning models, relative frequency learning. Although we showed that learning in this more general framework can be quite slow, we then examined learning under assumptions of mutual exclusivity and word-to-word correlations that might more closely approximate learning situations in the natural language environment. By modifying situations to include realistic variants of these two factors, we showed that learning a full-sized vocabulary could be accomplished on a realistic timescale. Although this work is preliminary, the analytical techniques employed here can be applied to other, yet more realistic cross-situational learning schemes, incorporating better approximations of the language environment, of the problem faced by the learner, and of the biases employed by the learner.

# Perceptions of Psychological Momentum in Basketball 

Thomas Hilbig ${ }^{1}$ (thomas.hilbig@student.adelaide.edu.au)<br>Matthew B. Welsh ${ }^{1,2}$ (matthew.welsh@adelaide.edu.au)<br>Paul H. Delfabbro ${ }^{1}$ (paul.delfabbro@adelaide.edu.au)<br>1. School of Psychology, 2. Australian School of Petroleum, University of Adelaide, Australia

#### Abstract

Psychological momentum (PM) and the hot hand are related concepts describing people's beliefs regarding streaks of superior performance. This study examined the susceptibility of perceptions of PM to changes in the streakiness of otherwise equivalent series. Fifty-five male participants (31 basketballers and 24 control) completed a 'hot-cognition' experiment where they rated individual and team momentum and assessed the likelihood of a future shot's success after watching sequences of basketball shots. The experimental manipulation of the order of shots strongly affected participants' ratings of momentum and, less strongly, the probability they assigned to the future shot (i.e. the hot hand effect). Basketballers showed stronger reactions to manipulations of order than the controls, which could be attributed to greater investment in the task. The results demonstrate the importance of distinguishing between PM and the hot hand and also provide a valuable extension of prior work showing such effects into more realistic scenarios.

Keywords: hot hand; psychological momentum; basketball.

## Introduction

The 'hot hand' is regarded as a crucial determinant of success by coaches (Raab, Gula, \& Gigerenzer, 2012), fans (Markman \& Guenther, 2007) and players (Gilovich et al., 1985) - with players altering the frequency and difficulty of their shot attempts after making a series of shots in a row.
Early research, however, mostly suggested that the hot hand in basketball was a 'fallacy', finding field and 'freethrow' shooting streaks did not significantly deviate from what was expected by chance (Gilovich, Vallone, \& Tversky, 1985). Conversely, some studies support the hot hand in intercollegiate (Mace, Lalli, Shea, \& Nevin, 1992) and professional basketballers, but some had issues of limited sample size and questionable method of analysis.

Failures to detect a hot hand, however, have also been questioned on several fronts. For example, the complexity of the basketball environment, wherein the 'hot' player may start to take lower probability shots due to their increased confidence or the opposing team may pay additional attention to a 'hot' player thereby disguising any effect.
Attempts to counter such objections include analysis of free-throws (e.g., Gilovich et al., 1985) but others (Koehler \& Conley, 2003) have argued that free throws are not conducive for a hot hand due to their relatively high probability of success ( $\sim 75 \%$ for professionals) and the time lag between free throw attempts for the same individual. In fact, given the hot hand is considered a temporary phenomenon (Hamberger \& Iso-Ahola, 2004), which breaks
disrupt (Mace et al., 1992), the conditions of ordinary NBA games - with time outs, substitutions and a single player rarely making 15 shots in a game - may not be conducive to its occurrence. This suggests that, if the hot hand exists, its existence is overgeneralized - that is, occurs less often than it is perceived to have. Indeed, Koehler and Conley's (2003) analysis of the National Basketball Association (NBA) Long Distance Shootout Contest - in which a shooter is unguarded but the available time and number of shots is constrained - failed to detect non-random shooting patterns, despite commentator's accounts to the contrary.

However, people have demonstrated an ability to discriminate between streaky and steady shooters in basketball shot sequences where statistical tests could not (Hammack, Cooper, Flach \& Houpt, 2017). While observers have the tendency to be sensitive to runs, this does not necessarily indicate cognitive error, but perhaps rational mechanisms for processing complex information. That is, observers will act as if the hot hand exists and they are capable of accurately perceiving and harnessing its effects.

Iso-Ahola and Mobily (1980) proposed psychological momentum (PM) as a construct to account for these perceptions and subsequent behaviors: "an added or gained psychological power that changes a person's view of him/herself or of others, or others' views of him/her and themselves" (p. 392). In competitive scenarios, PM is a zero-sum game: obtained at the expense of a competitor.

Importantly, PM does not reflect superior performance i.e. a hot hand, as suggested by Avugos and Bar-Eli (2015), but rather a psychological phenomenon (Iso-Ahola \& Dotson, 2015). The key distinction stems from an individual experiencing improved neurophysiological performance, as opposed to just changes in psychological components (e.g. confidence, internal attributions, perceived superiority over opponents). For example, an athlete may experience improved belief in their ability due to previous success, but not have this result in meaningful changes in skill execution.

Furthermore, it cannot be assumed that improvements to confidence necessarily result in a greater probability of subsequent success. As noted above, initial success could lead to 'over-confidence', causing athletes to make riskier decisions than normal (Jones \& Harwood, 2008).

With this in mind it is important to distinguish between psychological momentum, the perception of hot hand effects, and actual hot hand effects in experimental tasks.

Examining the thoughts and attitudes of athletes during live play is, of course, unfeasible. Accordingly, this study focusses on the perception of PM by spectators and the
implications of this for their predictions/behaviors - that is, their expectations regarding the effects of such psychological momentum (e.g., the Hot Hand). Previous studies examining people's perceptions about sequences have presented hypothetical scenarios (e.g. Ayton \& Fischer, 2004), but context is important to making inferences about sequences (Matthews, 2013) and actual sporting experiences are thought to be more conducive to perceptions of PM (Jones \& Harwood, 2008). Therefore, the intent was to maximize participant engagement, without the difficulties arising from assessing participants during live play. A 'hot cognition' experiment was, therefore, devised wherein both basketballers and non-basketballers watched actual footage of basketball games with varied presentation of sequences of successful and unsuccessful shots.

## Aims and Hypotheses

1. Reordering series of basketball plays with the same number of successes and failures will alter the psychological momentum assigned by observers to a featured team/player.
2. This will alter the probability assigned to a future outcome following the observed sequence (Hot Hand).
3. Basketballers, with greater investment in the game, will react more strongly to manipulations of momentum.

## Method

## Participants

Participants were 55 male, English speakers with at least a basic understanding of basketball rules and terminology, aged 18-31 ( $M=21.4, S D=3.2$ ) and recruited from three sources: local basketball clubs ( $\mathrm{n}=22$ ), $1^{\text {st }}$ year Psychology students ( $n=7$ ) and the general public ( $n=26$ ). Participants were grouped as basketballers ( $N=31$ ) or control $(N=24)$ by their self-reported frequency of involvement in basketball. The basketballers were somewhat younger ( $M=$ 20.6, $S D=2.6$ ) than the control group ( $M=22.4, S D=3.7$ ).

The psychology students participated for course credit. Additional participants, recruited via emails to basketball clubs, flyers posted on the Adelaide University campus and Facebook advertising, received a $\$ 10$ gift card for their participation or chance to win a $\$ 50$ gift voucher.

## Materials

## Online Survey

Prepared in SurveyMonkey, the survey asked for demographic details and required participants to indicate how often (daily, several days a week, weekly, fortnightly, monthly and rarely/never) they engaged with various aspects of basketball: playing, watching or taking an interest in (e.g., reading about). The survey also included measures of: representation bias, numerical reasoning, perception of sequences, susceptibility to outcome bias, risk-attitudes, impulsivity and hot hand beliefs as described below. These were included as potential covariates/confounds that might differ between the groups and thus need to be controlled for:
Representativeness Bias. Four items were used to assess
respondent's beliefs about sequences in random processes: Lambos, Delfabbro and Puglies' (2007) coin toss scenario, where participants judge which of three series of outcomes (e.g. HTHTTHTHTHTH) is most likely; and three items adapted from Ayton and Fischer (2004) asking whether sequences of 16 -digit long binary outcomes with equal hits and misses but different alternation rates $(0.81,0.31$ and $0.19)$ were generated by random or human processes.

Cognitive Reflection. Frederick's (2005) 3-item CRT was used to measure participants' tendency to override predictable, but incorrect intuitive responses. Lower CRT scores indicate greater susceptibility to decision-making biases (Toplak, West \& Stanovich, 2011) and lower numeracy (e.g., Welsh, Burns \& Delfabbro, 2013).

Outcome Bias. Two scenarios described a physician's decision to conduct surgery on a suffering patient (based on Baron \& Hershey, 1988). These were near identical but the first described an $8 \%$ chance of death but a good outcome (successful operation) while the second gave a $2 \%$ chance of death but bad outcome (patient death). Rating the $1^{\text {st }}$ decision as better therefore displays outcome bias.

Risk Attitude. As belief in a hot hand is greater in those who regularly gamble and demonstrate a willingness to take greater risks in these scenarios (Wilke, Scheibehenne, Gaissmaier, McCanney \& Barrett, 2014), the 12-item gambling Domain-Specific Risk-Attitude Scale (Weber, Blais, and Betz, 2002) was used to assess risk attitudes towards: likelihood of gambling; perception of gambling risk; and expected benefits of gambling.

Impulsivity. The BIS-15 (Spinella, 2007) was used to assess impulsivity.

Hot Hand Beliefs. A 2-item, self-report measure developed by Gilovich, Vallone and Tversky (1985), which assesses a respondent's endorsement of sequential dependence among shots in basketball.

## Hot Cognition Task

The experimental task was composed of four sequences of basketball edited from footage of American college basketball games. The broadcast scoreboard was blurred out in the video footage to control for outcome bias, and the audio was removed to prevent crowd and broadcast commentator reactions influencing participant's responses. All the plays within a sequence featured the same player.

Each sequence condition included three made shots ( $H$ ) and three missed shots ( $M$ ) but a different order of shot outcomes (see Table 1). All were followed by the identified player being fouled in the process of making another, successful shot: resulting in a free throw (AND1 outcome), but the outcome of this was not shown. Given the absence of audio, the researcher indicated when the identified player was fouled - signaling the end of the video.

Looking at Table 1, one sees that the conditions convey varying senses of psychological momentum (PM). The Positive Recency (PR) and Negative Recency (NR) conditions have low alternation rates of hits versus missed shots and, therefore, longer outcome runs. Prior to the

AND1 outcome, the PR sequence contains a streak of three hits, while the NR sequence contains a streak of three misses to convey lower momentum (although weakened by the need to have the same successful, fouled basket at the end of the sequence). The two other conditions were intermediate between these - with greater alternation.

Table 1: Shot sequence outcomes for experimental conditions.

|  | Condition | Order of Shot sequence |  |  |  |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  |  | 1 | , | 3 | 4 | 5 | 6 | 7 |
|  | Negative Recency | H | H | H | M | M | M | H |
|  | Alternation | H | M | H | M | H | M | H |
|  | Weak Positive |  | H | M | H | M | H | H |
|  | Positive Recency | M | M | M | H | H | H |  |

Note: $\mathrm{H}=$ hit, $\mathrm{M}=$ miss.

## Procedure

Participants completed the survey detailed above prior to taking part in the experiment - either online or in person. The experiment was conducted individually for each participant to avoid confounds arising in groups (e.g. verbal commentary influencing responses). Participants were provided information regarding the nature of the experiment and screened for (basic) understanding of basketball rules and terminology used for various self-report measures.
The experiment was conducted within-subjects, with participants shown the four, Hot Cognition Task sequences (in a randomized order). Following each, participants were asked 4 questions assessing their beliefs around:

1) a player's likelihood of making the free throw resulting from the last play (Free Throw);
2) the player being 'on a roll' (Individual Momentum);
3) how difficult his shots were (Difficulty); and
4) the team having momentum (Team Momentum).

Responses were scored on a 5-point Likert scale: 1 (not at all) to 5 (extremely). These questions - based on a pilot study and previous qualitative research e.g. Koehler \& Conley (2003) - measure the participant's perception of individual and team momentum, and perceived difficulty due to theorized mediation effects.

## Results

The first two Hypotheses were that perceptions of psychological momentum would vary with the patterns of hits and misses in the four different conditions. To examine this, the mean ratings given by participants to each of the four dependent measures under each of the four conditions are shown in Figure 1. Looking at this figure, a clear distinction can be seen between the pattern of results for the measures of psychological momentum (Individual and Team Momentum) and the remaining measures - Free Throw likelihood and Shot Difficulty. Starting with the last it seems that, as would be hoped, participants' perceptions of shot difficulty did not vary across conditions in any obvious manner. A One-Way RM ANOVA, however,
indicated that the differences across conditions were significant, $\mathrm{F}(3,162), p<.001$, indicating that Shot Difficulty needed to be included as a covariate in the analyses described below. Analysis of the Free Throw ratings look similar, $\mathrm{F}(3,162), p<.001$, but here Bonferroni post hoc tests confirmed that two positive conditions (Weak Positive and Positive Recency) produced significantly higher ratings than the conditions with more recent negative outcomes.

Figure 1. Mean ratings of dependent measures by condition. Note: NR = negative recency; Alt = alternating; WP = weak positive recency; and $\mathrm{PR}=$ positive recency.

By contrast, the measures of individual and team momentum both show clear, linear trends with participants giving higher ratings in those conditions with more, recent positive outcomes. One-way Repeated Measures ANOVAs confirmed these differences as significant $\mathrm{F}(3,162)=63.4$ \& 26.7, respectively, $\mathrm{p}<.001$ in both cases and Bonferroni post hoc tests indicated that all conditions differed significantly from all others.

## Covariates

Correlational and principal component analyses (excluded for reasons of space) were used to determine which covariates should be accounted for in comparisons between basketballers and controls. This indicated only five variables/factors related significantly to the dependent measures: 1) Representation bias (coin toss); 2) Representation bias (high alternation rate); 3) CRT; 4) Outcome bias; and 5) Outcome perceptions (a factor composed of beliefs about hot hand and momentum).

## Basketballers vs Non-Basketballers

Our third hypothesis was that basketballers, due to their relative investment in the sport, thus responding to the experimental manipulations more strongly. That is, that their ratings would tend to be more extreme than nonbasketballers - lower in the conditions with more negative
outcomes and/or higher in conditions with more positive outcomes prior to the final observation.

To examine potential differences, the ratings provided by the two groups for the dependent measures are shown in Figure 2. Looking at the three subplots of Figure 2, one sees two distinct patterns. The first is in the Free Throw data (subplot a), where, in every condition, the basketballers rate the likelihood of the free throw being successful as higher than the non-basketballers - reflecting perhaps a better understanding of the difference in accuracy between field shooting and free throw shooting.

In subplots b and c, by comparison, we see the pattern predicted by Hypothesis 3 - with Basketballers' responses being more extreme than control subjects - i.e., lower when there has been a run of missed shots (NR condition) and higher following a series of successful shots (PR condition).

Figure 2. Comparisons between Basketballer and Control subject ratings of dependent measures by condition. Note:
$\mathrm{NR}=$ negative recency; Alt $=$ alternating; $\mathrm{WP}=$ weak positive; and $\mathrm{PR}=$ positive recency.

Group by Condition Repeated Measures ANCOVAs were run for each dependent measure, incorporating the covariates noted above. The results of these are shown in Table 2. Looking first at the data for Free Throw probability, one sees that, despite the pattern in Figure 2, the main effect of Group in the ANCOVA just fails to reach significance ( $p=.07,2$-tailed). The effect of condition was clearly non-significant ( $p=.84,2$-tailed) and there was no interaction between the two factors.
For Individual Momentum perceptions, by contrast, a significant main effect was found for condition ( $p<.001,2$ tailed) but not between groups ( $p=.67,2$-tailed). However, in line with our hypothesis, there was a significant Group $\times$ Condition interaction ( $p=.03,2$-tailed). Bonferroni post hoc tests indicated that Basketballers perceived more individual momentum than the Controls in the $\mathrm{PR}(d=0.16)$ and WP $(d=0.30)$ conditions, and perceived less in the NR
( $d=0.14$ ) and Alt ( $d=0.20$ ) conditions. There was also a significant covariate interaction: Condition $\times$ Representation bias (high alternation), $\mathrm{F}(3,46)=2.60, \mathrm{p}<.05$. This suggests that Individual Momentum is predicted by susceptibility to attribute random outcomes to human action.
For Team Momentum, a significant difference was found between groups ( $p<.05,2$-tailed), but the main effect of condition and the Group $\times$ Condition interaction just failed to reach significance ( $p=.07$ and .13 , respectively, 2 tailed). Given the directionality of our hypotheses, these near significant results were examined with post hoc Bonferroni tests, which indicated that Basketballers perceived less momentum than the control group in the NR ( $d=0.25$ ) and Alternation conditions $(d=0.35)$, but no more in the PR $(d=0.11)$ and WP $(d=0.04)$ conditions, which partially support the hypothesis.

Table 2: Summary of ANCOVAs for dependent measures

|  | Group |  |  |  | Condition |  |  |  | Interaction |  |  |
| :--- | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  | $F$ | $p$ | $\eta^{2}$ | $F$ | $p$ | $\eta^{2}$ | $F$ | $p$ | $\eta^{2}$ |  |  |
| FT | 3.48 | .07 | .07 | 0.29 | .84 | .01 | 0.07 | .98 | .00 |  |  |
| IM | 0.19 | .67 | .00 | 6.89 | $<.001$ | .13 | 3.02 | .03 | .06 |  |  |
| TM | 4.12 | .05 | .08 | 2.60 | .07 | .05 | 2.01 | .13 | .04 |  |  |

Note: FT = Free throw, $\mathrm{IM}=$ Individual momentum, $\mathrm{TM}=$ Team momentum. Greenhouse-Geisser corrections applied. Degrees of Freedom. Two-tailed $p$ values in all cases.

## Discussion

The above results provide support for all three Hypotheses. There is strong evidence that reordering the same number of successful and failed basketball plays to produce streaks of hits and misses affected the participants' perceptions of psychological momentum - for both the individual player and their team (H1). The evidence that this perception of momentum translates into a belief in a hot hand in the statistical sense (H2) - that is, altering the probability of a future shot is, however, weaker. Finally, there are significant differences between the responses of basketballers and non-basketballers and clear interaction effects between group membership and the strength of our psychological momentum manipulation (H3). These results are discussed, individually and in greater detail, below.

## Perception of Psychological Momentum

As noted above, Hypothesis 1, that perceptions of psychological momentum (PM) could be influenced by simple reordering of sets of basketball plays, was supported by the results. Specifically, participants rated the momentum of both the individual player and their team as significantly higher when the plays were ordered so as to have longer strings of hits at the end.

Parker, Paul \& Reinholtz (2016) similarly found that changes in perceived momentum of a contrived guessing game were greater as outcomes alternated. While perhaps not surprising, building upon the findings from hypothetical
manipulations is a valuable extension of such work demonstrating that the effect holds in a task more closely approximating real world situations but which removed a number of cues for momentum that would exist in realworld situations. For example, the broadcast scoreboard in the game footage shown to participants was blurred to control for potential outcome bias and prevent the score being used as a reference point by participants regarding a team's actual momentum. The footage was also played without sound so as remove the crowd reaction which might provide another cue to a team's momentum.
While these were confounds for the present study, their omission is also expected to have dampened the extent to which participants identified patterns of team momentum. That is, in equivalent, real world situations their effects seen here might well be stronger.

## Expectations Regarding the 'Hot Hand'

Given the clear distinctions drawn by participants between the momentum of the individual players and their teams across the different order conditions, the weaker effect of the experimental manipulation on their predictions of future success requires some explanation. While there was some evidence that people who had seen longer sequences of successful shots tended to rate the probability of the following free throw succeeding more highly than those who had seen more failures at the end of the task, this relationship was weak and non-significant when controlling for several covariates and did not follow the clearly linear pattern seen in the perceptions of momentum.
Had no relationship been seen, that could have supported the notion that PM is just a performance label used to evaluate whether past performances were successful or not (Cornelius et al., 1997) with no relevance to the future. The partial relationship, however, requires more explanation.

A possibility is that the experimental task, which had participants watch a series of seven field shots but then asked them to rate the likelihood of a following free throw being successful acted to limit the perceived transferability of momentum. That is, not only does the foul and subsequent free throw provoke a break in play (thereby potentially ending a hot hand effect, as described in Hamberger \& Iso-Ahola, 2004) but also introduces a change in the type of task. Participants may have recognized that a free-throw is a markedly different shot than any field goal attempt and thus, regarded the player's shooting form as less relevant, reducing the strength of any effect.

## Group Differences

As predicted in our third hypothesis, basketballers' responses differed significantly from those of nonbasketballers. The first observation, while not hypothesized, is that basketballers rated the chance of the free throw being successful higher in every case than the non-basketballer, reflecting their superior understanding of the actual success rates for elite level athletes. Other than this, though, their pattern of free throw predictions across the four conditions
is near-identical to that of the non-basketballers.
Of course, the fact that results supporting Hypothesis 3 are seen for perceptions of individual and team momentum - with basketballers being more strongly affected - but this fails to be converted into greater predicted likelihood of free throw success could fit with explanation given above regarding the overall weakness of these results. That is, if basketballers have a stronger belief in the separation between field shooting and free throw shooting performance, that would tend to flatten out their estimates of free throw likelihood more than is seen in the nonbasketballers - thereby counteracting their stronger perceptions of momentum.

As to why basketballers showed these stronger effects: perhaps simple interest in the game increases investment and thus cues greater attention to the scenario and patterns within it; or seeing such patterns calls to mind prior experiences of momentum and, within the experimental context, basketballers have more than non-basketballers.

## Covariates

As a brief note: as ANCOVAs were used to eliminate the possibility that results might be driven by differences between the groups. In these analyses, one covariate (a measure of representativeness bias) was highlighted as predicting individual momentum ratings: i.e., participants who attributed random sequences to human agents were more likely to rate the player as being 'on a roll'. However, none of the four measures of representativeness bias differed significantly between the groups.

## Caveats and Future Directions

While providing interesting results and at least some support for all of our hypotheses, there are a number of limitations of the study, which could be addressed in future work.

The first is the limited sample size. This resulted from difficulties in recruiting sufficient basketballers and was exacerbated by the decision to limit recruitment to males so as to eliminate the potential for gender moderation effects of PM (Iso-Ahola \& Dotson, 2014). Extending the study to include women (while taking into account how perceptions of may PM differ between men and women) and widening the recruitment (via online participation, for instance) could address this and assist in determining whether the less convincing results herein result from insufficient power.

A secondary concern lies in how the experimental measures were scored - on a 5-point scale from 'not at all' to 'extremely'. The question arising here is whether 'not at all' was regarded as a neutral (e.g., not on a roll) or negative (e.g., on a losing streak) response by participants. This should be clarified in future work.

Participants' responses to the dependent variables may have been influenced by undertaking several cognitive bias measures. To avoid this potential confound the hot cognition experiment could be conducted prior to completing relevant individual differences measures.

Finally, as noted above, while the use of a free throw as the shot to be predicted was done purposely - in order to
minimize other contextual factors for the predicted shot (e.g. in any differences in distance, angle, and opposition actions) - this may have undermined the transference of perceived momentum into future outcomes. This could be avoided in a number of ways - none, however, simple. For example, an exhaustive pre-test assessment of plays could have experts rate their equivalency prior to constructing the scenarios.
Alternatively, it might be possible to stage specific plays - either using real players or within a basketball game, for example. All of these, however, would require a significant amount of pilot work prior to any experimentation.

## Conclusions

While most research into momentum and the hot hand has been concerned with directly substantiating or refuting their existence, the present study aimed, instead, to explore participant's beliefs and perceptions regarding these - within the context of basketball shot sequences. Consistent with much of literature regarding PM, the ordering of sequential outcomes affected participant perceptions: positive recency sequences increased the likelihood that the focal team and player had momentum; while negative recency sequences were considered by participants as evidence of the player and team not being on a roll. These effects were more strongly reported by basketballers across conditions in the present study, compared to the control group, suggesting that domain-specific experience influences the perception of these patterns. The results also illustrate that further research is warranted to clarify why differences exist between participant's perceptions of momentum and their predictions of future success (i.e., hot hand beliefs).

#### Abstract

Computational psychiatry applies advances from computational neuroscience to psychiatric disorders. A core aim is to develop tasks and modeling approaches that can advance clinical science. Special interest has centered on reinforcement learning (RL) tasks and models. However, laboratory tasks in general often have psychometric weaknesses and RL tasks pose special challenges. These challenges must be addressed if computational psychiatry is to capitalize on its promise of developing sensitive, replicable assays of cognitive function. Few resources identify these challenges and discuss strategies to mitigate them. Here, we first overview general psychometric challenges associated with laboratory tasks, as these may be unfamiliar to cognitive scientists. Next, we illustrate how these challenges interact with issues specific to RL tasks, in the context of presenting a case example of preparing an RL task for computational psychiatry. Throughout, we highlight how considering measurement issues prior to a clinical science study can inform study design.

Keywords: computational modeling; reinforcement learning; measurement; psychometrics; computational psychiatry

A core aim of the emerging field of computational psychiatry is to translate tasks and modeling approaches from computational neuroscience into sensitive assays that can advance clinical treatment, diagnosis, practice, and theory (Hitchcock, 2017; Redish \& Gordon, 2016). New assays may advance clinical science by facilitating early illness detection, predicting illness progression, separating patients into subgroups, predicting type and extent of treatment indicated, and allowing measurement of the effects of emotion regulation strategies (Huys, Maia, \& Frank, 2016).
The effort to develop laboratory tasks into assays has been ongoing for years, but the use of computational cognitive models that describe the trial-by-trial behavior of subjects (Daw, 2011) is newer to clinical science. In theory, parameters derived from these models should compactly describe individual or group differences by revealing aspects of cognitive processing that are obscured in behavioral measures (Huys et al., 2016). An especially promising domain in this regard is reinforcement learning (RL). RL refers to a broad class of trial-and-error learning tasks wherein learning is driven mainly by a scalar reinforcement
signal (Sutton \& Barto, 1998). Over the past twenty years, computational models of RL have grown in sophistication and maturity (O’Doherty, Cockburn, \& Pauli, 2017). In addition, there has been a string of successful applications of RL modeling to clinical problems. These early successes may portend widespread use of RL assays in clinical science (Maia \& Frank, 2011).
Yet the history of converting laboratory tasks to clinical assays suggests caution is warranted. Laboratory tasks tend to have substantial (and often underappreciated) psychometric weaknesses (Lilienfeld, 2014). Consider the example of the dot probe task, an attention paradigm introduced over 30 years ago (Bar-Haim, Lamy, Pergamin, Bakermans-Kranenburg, \& Van Ijzendoorn, 2007). By 2007, 35 clinical studies using the task had been conducted. A metaanalysis that year concluded the task reliably detects attention differences between anxious and non-anxious groups (BarHaim et al., 2007). Dozens of studies subsequently tested "modification" variants of the task (which aim to retrain attention) (Hallion \& Ruscio, 2011). Yet recent metaanalyses suggest modification training produces very small effects and that extant modification studies evince publication bias (e.g., Heeren, Mogoașe, Phillippbot, \& McNally, 2015). These disappointing results prompted reexamination of the evidence for reliable, stable group differences per the original dot probe. Recent critiques, which have referenced a slew of null findings since 2007, concluded that the evidence for such differences is weak (Rodebaugh et al., 2016; Van Bockstaele, Verschuere, Tibboel, De Houwer, Crombez, \& Koster, 2014).
What went wrong? It is noteworthy that, although researchers have been employing the original dot probe since the 1980s, the first examination of its test-retest reliability was not published until 2005 (Schmukle, 2005). That study and others (e.g., Price et al., 2015) found the dot probe exhibits close to 0 test-retest reliability when analyzed using standard methods. These results suggest it is not possible to extract stable measures of differences in attention using the standard versions/analyses of the task (Rodebaugh et al., 2016; Van Bockstaele et al., 2014).

Figure 1. Pipeline for a computational psychiatry assay proposed by Paulus et al. (2016).

## Developing Computational Psychiatry Tasks with Strong Psychometric Properties

The dot probe paradigm provides a cautionary tale about pushing too quickly from a lab paradigm to applied research. The computational psychiatry community can learn from this example. Fortunately, the community appears aware of the challenges posed by laboratory tasks. For instance, Paulus, Huys, and Maia (2016) proposed a pipeline (Figure 1) for turning a task into an assay that can ultimately be used for assessment or as a treatment target in randomized control trials (RCTs). The authors emphasize establishing psychometric properties early in the pipeline-before relying on the task as a primary measure in RCTs.

Yet researchers entering computational psychiatry from the cognitive sciences may be unfamiliar with how the psychometric challenges of laboratory tasks interact with clinical design issues. Thus, this paper offers an overview of the relevant issues. Specifically, the rest of paper is part theoretical overview and part annotated case example of preparing a specific RL task for use in clinical science. We begin with a theoretical issue that may be unfamiliar to many in cognitive science.
General Psychometric Challenges Associated with Laboratory Tasks. A general-and formidable-challenge for extrapolating from laboratory task behavior is that subjects naturally vary in the state that they are in (e.g., tired, distraught, cognitively taxed) when they arrive at the laboratory. A classic solution to this random state variation problem-a problem that confounded social and personality psychologists for decades (Kenrick \& Funder, 1988)—is to assess the same subject at many time points and average over measurements. This approach can dramatically increase the convergent validity of lab tasks with self-report measures, presumably because an average over many time points yields a more stable, trait-like measure than one-time measurement (as the latter is often biased by state variation; Epstein, 1979).

However, assessing a single subject at many time points can be infeasible. First, much time is often needed to complete lab tasks, and thus repeating assessments on many occasions can substantially raise subject burden. Second, in some cases it is unrealistic to ask subjects to complete the task more than once. For example, a researcher may wish to examine how

Figure 2. The Dimensions Task (Niv et al., 2015), designed to investigate the role of attention in reinforcement learning.
depressive rumination-repetitive, negative, self-referential thinking-alters cognitive processing. This could be done by asking depressed subjects to complete a laboratory task while under the effects of a rumination induction. Many past studies have experimentally induced rumination in this way but, as far as we are aware, none has asked subjects to ruminate on more than one occasion. Indeed, it seems unreasonable and unrealistic to ask depressed subjects to undergo more than once a manipulation that-by design-provokes distress.
The effects of random state variation can be mitigated through study design. For example, a researcher investigating the effects of rumination on some task might ask subjects to perform the task once before and once while under the effects of rumination. Such a design should increase the ratio of systematic variability (variability due to induced rumination) to unsystematic variability (variability due to subjects being in different states when they enter the lab) because it delivers pre- as well as post-induction measures for each subject. A subject is unlikely to dramatically change the state she is in from pre- to post-induction (an unusually tired subject at baseline will likely remain so while under the effect of rumination induction). Thus the within-subject design controls for some of the unsystematic variability due to state variation. However, note that individual differences in susceptibility to the experimental perturbation (e.g., propensity to ruminate upon receiving the induction) will be affected by subjects' states. Thus this approach is helpful in minimizing noise but does not solve the random state variation problem.
The random state variation problem entails that a subject's parameter estimates in a laboratory measure will be corrupted by noise with respect to the subject's "true" parameter value, when the true parameter value is conceived of as a psychological variable akin to a trait. This noise will limit the predictive power of measures. Thus, when random state variation is expected (e.g., when a design only permits administering the task once or a few times), it is critical that the psychometric properties of the task are strong so that other sources of noise are minimized. For a more general discussion of how computational modeling may help remedy the random state variation problem, see Hitchcock (2017).
In the rest of this paper, we give a case example of preliminary efforts to establish the psychometric properties of a multidimensional RL task known as the Dimensions Task (Niv et al., 2015; Leong, Radulescu, Daniel, DeWonskin, \& Niv, 2017; Radulescu et al., 2016). The task itself is not the paper's focus, but we briefly describe it, our approach to modeling it, and its promise for clinical science in the next
section. The description will make subsequent sections, on the task's measurement properties and their relation to modeling issues, easier to follow.
The Dimensions Task. Trial-and-error learning in the real world often requires learning about a small set of stimulus features embedded in a milieu of irrelevant stimuli. Imagine telling (what you hope is) an amusing story to a friend and attempting to learn about the effects of specific actionsdramatic pauses, rhetorical flourishes, funny faces, etc. Learning about the effect of these actions requires attending to just a few fleeting features on the face of and in the body language of your friend while ignoring many irrelevant features-pimples on your friend's forehead, your computer screen flickering behind you, your internal dialogue about what to say next, etc. (Niv et al., 2015).
The Dimensions Task was designed to study such a scenario where only some aspects of the task are relevant and most can be ignored, as is so often required in the real world. Briefly (see Niv et al., 2015 for details), on each trial of the task subjects must select one of three possible stimuli. Each stimulus is composed of 3 features defined on 3 stimulus dimensions (for example, color, shape, and pattern) (Figure 2). Subjects play a set of games that can vary in length from 15-30 trials. Within a game, features of only one dimension (e.g., color) determine the probability of reward. Within this relevant dimension, one target feature (e.g., red) leads to reward with $75 \%$ chance whereas the other 2 features in the dimension (e.g., yellow, green) lead to reward with $25 \%$ chance. The target feature and relevant dimension change every game. The start of a new game is signaled to subjects.
Computational Model. Previous work (e.g., Niv et al. 2015; Radulescu et al., 2016) tested various computational models designed to reproduce subjects' trial-by-trial behavior in the task and found that human behavior is well described by a feature-level $R L(f R L)+$ decay model. The $f R L+$ decay model maintains weights reflecting the values of each of the 9 features. It linearly sums these weights to calculate the estimated value of each (3-feature) stimulus

$$
\begin{equation*}
V(S)=\sum W(f) \quad \forall f \in S \tag{1}
\end{equation*}
$$

For example, the model's estimate of the value of yellow-waves-triangle in the above trial is equal to the sum of the weights of yellow, waves, and triangle. Once a reward is received ( 0 or 1 points), the weights of the 3 features of the selected stimulus are updated based on the discrepancy between the obtained reward, $R_{t}$, and the model's estimate of the chosen stimulus's value, $V\left(S_{\text {Chosen }}\right)$, with update rate controlled by a learning rate free parameter, $\eta$

$$
\begin{equation*}
W^{\text {new }}(f)=W^{\text {old }}(f)+\eta\left[R_{t}-V\left(S_{\text {chosen }}\right)\right] \quad \forall f \in S_{\text {chosen }} \tag{2}
\end{equation*}
$$

For the other 6 features on a trial-those comprising the 2 stimuli not selected-the model decays the associated weights with a second free parameter, $d$

$$
\begin{equation*}
W^{\text {new }}(f)=(1-\mathrm{d}) W^{\text {old }}(f) \quad \forall f \notin S_{\text {chosen }} \tag{3}
\end{equation*}
$$

The decay parameter reflects the fact that subjects are selectively attending to (and learning about) few dimensions (Leong, Radulescu et al., 2017). The "forgetting" of the weights of unchosen features allows the model to "undo" learning about features not chosen on a trial.
Finally, the model assumes that the subject's probability of choosing each stimulus is proportional to the estimate of the value of the stimulus, as defined by a softmax equation with a third free parameter, $\beta$

$$
\begin{equation*}
p\left(\text { choose } S_{i}\right) \propto e^{\beta V\left(\mathrm{~S}_{i}\right)} \tag{4}
\end{equation*}
$$

The model thus has three free parameters: softmax action selection noise $\beta$, learning rate $\eta$, and decay parameter $d$. See Niv et al. (2015) for more details.
Stage in the Assay Development Pipeline. With respect to Paulus et al.'s (2016) pipeline (Figure 1), most prior studies using the Dimensions Task and $f R L+$ decay model fall into the Preclinical and Phase1a phases.

Notably, Radulescu et al. (2016, study 2) also provided a test of the task's promise for measuring group differences. Radulescu and colleagues found older adults were less accurate ( $p=.001, g=.94$ ) than younger adults. These behavioral results appeared to derive in part from differences in the decay parameter (median $=.52 \mathrm{v} .42$ for older vs. younger adults, respectively), implying that differences in this parameter may reflect meaningful differences in selective attention. These results suggest the task has promise as a sensitive measure of neuropsychological and clinical differences. Per Paulus et al.'s (2016) pipeline, this study marks the entrance into Phase 1 b : examining clinical validity (see Radulescu et al., 2016 for discussion).

Although the task has promise as a computational psychiatry assay, a number of modeling and psychometric obstacles must first be overcome. In the following sections, we report on efforts to explore the properties of the Dimensions Task and fRL+decay model using two previously collected datasets. The results have implications for the use of the Dimensions Task in computational psychiatry and thus are of specific interest to researchers interested in the construct of attention learning in computational psychiatry. But the more general interest aim of the following sections is to use this case study to illustrate some of the issues that arise in translating RL tasks to computational psychiatry.

## Methods

Datasets are from Niv et al. (2015; hereafter D1) and Radulescu et al. (2016, study 2; hereafter D2).
Specifications. In D1 $(N=22)$, subjects played 500 trials (number of trials per game was drawn from a Uniform $(15,25)$ distribution, for a total of $M=22.27, S D=1.45$ games per subject). In $\mathrm{D} 2(N=54)$, subjects played $\sim 1400$ trials ( $M=46.43, S D=5.41$ games; subjects stopped playing after exactly 40 min .; all games 30 trials).

## Results

Parameter Identifiability. A challenge in fitting RL parameters to individual subject behavior is that parameters
can be coupled and thus not fully identifiable. In the $f R L+$ decay model, equations $1-4$ show that the role of each parameter depends on the settings of the other parameters. Specifically, the values of the stimuli in equation 4 (in which choice is governed by $\beta$ ) depend-via equation 1 -on the weights of the chosen and non-chosen stimuli. Those weights are in turn respectively governed by the learning rate ( $\eta$, equation 2 ) and decay rate ( $d$, equation 3 ).

Coupling of the parameters modulating value estimation and choice is characteristic of many RL algorithms (Daw, 2011; Gershman, 2016). Coupling comes in two flavors: severe and moderate (Daw, 2011). Under severe coupling, parameters can trade off; for example, increases in one parameter can be perfectly compensated by decreases in another. As a result, parameter values may not-even in principle-be uniquely identifiable. Severe coupling can be tested for by repeatedly run an off-the-shelf optimizer from different initial parameter settings and checking whether optimization converges on the same estimates every time. If parameters are structurally coupled (i.e., there is no unique set of estimates), the optimizer will find different estimates on different runs, provided initializations allow the optimizer to cover sufficient territory in likelihood space. In D1 and D2, an optimizer repeatedly converged on the same parameter estimates, suggesting identifiability issues are not too severe to prevent finding a unique optimum.

However, there may still be more moderate identifiability issues. Intuitively, this is because maximum likelihood/maximum a posteriori (ML/MAP) estimates are tantamount to finding the highest point on the "hill" that defines the parameter surface in likelihood/posterior probability space. Yet they do not reveal the shape of the hill below: specifically, the shape of equal-likelihood ridges in the 3D likelihood space. If these ridges are diagonally shaped, they indicate covariance between the parameters. Intuitively, if changing a parameter in one direction (e.g., $\eta$ from 0.08 to 0.1 ) can be compensated for by changing another (e.g., $\beta$ from 6.2 to 5.1 ), with only miniscule changes in the likelihood, then one cannot safely draw conclusions from the point estimate of either parameter.
Identifiability and Computational Psychiatry. Identifiability poses a special challenge in the computational psychiatry domain, wherein the aim is often to derive parameters that can be used as predictors or outcome measures (Huys et al., 2016). Derived parameters whose point estimates have much uncertainty about them due to identifiability issues are unlikely to be useful for precision applications, such as prediction or diagnostic subtyping.
Probing Identifiability. A first helpful step for probing identifiability is to examine and visualize the Pearson correlations between pairs of estimates. Figure 3 plots point estimates for pairs of parameters in D1 and D2, with regression lines drawn to aid visualization.

Sets of parameters can fall along an elliptical contour in the likelihood space if there are identifiability issues, in which case the parameters will correlate. Thus, if parameter pairs closely correlate for most subjects in a dataset, this may

Figure 3. Parameter estimates in D1 (blue) and D2 (green).
indicate identifiability issues. However, correlations should only be a first step in checking for identifiability issues, for a couple reasons. First, to the extent that the parameters reflect meaningful psychological differences between individuals, we should expect they will correlate to some degree, because psychological variables often correlate within-subject (Lykken, 1968). Thus it can be difficult to determine whether correlations reflect modeling noise or true correlations between parameters. Second, correlations will not detect nonlinear relationships between parameters or other subtle identifiability issues (Gershman, 2016). Still, correlations are easily interpretable and a good place to start.
Figure 3 shows that, in both D1 and $\mathrm{D} 2,\{d$ and $\beta\}$ and $\{d$ and $\eta\}$ modestly correlate whereas $\{\eta$ and $\beta\}$ strongly correlate. In particular, in D2, $\{\eta-\beta\}$ estimates are nearly perfectly collinear for many subjects. Note also that, for all parameter pairs, the correlations are higher in D2, where there were more data, than in D1. In the test-retest reliability section below, we will present evidence suggesting that the parameter estimates may be more reliable in D2 than D1. Yet the higher correlations may also suggest more identifiability problems in D2. In fact, both possibilities-better parameter estimates and more identifiability problems - may be true. As noted, the equations in which the parameters are embedded dictate dependencies-and hence identifiability issuesbetween the parameters. If the true parameters are correlated, then when the model does a better job of recovering their values from noisy behavioral data, the observed data will also correlate more strongly. Thus, the increased correlations may actually be good news from a parameter recovery perspective. However, the $\{\eta-\beta\}$ collinearity does mean we should not treat these variables as independent.
Diagnosing Issues with Model Fit. Plots also allow visualization of outlying values, which may reflect model fit issues for specific subjects. For example, the arrows in the second row, second column plot in Figure 3 point to subjects
with outlying $\eta$ values. Outlying values might indicate $f R L+$ decay does not well describe specific subjects' choices in some or all of the task. However, the points could also reflect important individual differences, so additional checks are necessary to make a differential diagnosis.

We do not delve into model fit issues for individual subjects (as such specifics would not generalize beyond the samples/data in D1 and D2), but offer some general guidelines for probing these issues. First, another useful diagnostic is to plot likelihoods for each potentially problematic subject. For example, Daw (2011) provides an example of a 2 D heat map of likelihood values. A more quantitative assessment is the variance-covariance structure of parameter estimates; these structures can be examined by taking the inverse of the Hessian from optimization. On- and off- diagonal elements of $H^{-1}$ respectively give the variance and covariance of parameters. Large values indicate poor parameter estimates (Daw, 2011). Finally, problematic subjects' behavioral (and physiological, if available) data can be checked to see if these data are informative about the source of outlying parameter values (e.g., if reaction times were recorded, it can be useful to check if a subject responded atypically quickly or slowly during a subset or all of the task).
Ultimately, if outlying parameter values for a subject do not appear to be due to individual differences, but rather to issues with model-fit, the researcher may wish to treat these parameters as missing: Parameter estimates derived from a model that poorly describes a subject's behavior are meaningless. However, such decisions should be made-then adhered to-before inferential statistics, to avoid the "garden of forking paths" (Gelman \& Loken, 2013).
Subject-Specific Model Fit Issues and Computational Psychiatry. Our identification of apparent model fit issues among subjects illustrates the value of collecting data under different tasks specifications prior to attempting to develop a computational psychiatry assay. For instance, in the Dimensions Task, the presence of multiple individuals with apparently poor model fits suggests that some subjects in future clinical science designs will likely have missing data for model parameters (because, as noted, values from a model that poorly describes participant behavior should not be used). This is important information in the design phase of a clinical science study, as it may influence factors such as recruitment target, or collection of other data to aid estimation of anticipated missing values.
Test-retest reliability. As the cautionary tale of the dot probe task suggests, it is critical to establish the test-retest reliability of potential outcome measures. High test-retest reliability scores increase confidence that the measure is tapping a stable psychological construct (Hitchcock, Radulescu, Niv, \& Sims, 2017). Establishing stability of a measurement is a prerequisite for computational psychiatry designs that seek to use the measure to assess the effects of some experimental perturbation or group or individual differences. Nevertheless, the basic requirement of establishing test-retest reliability goes unmet with striking frequency in laboratory tasks (Lilienfeld, 2014).

| Dataset | $d$ | $\eta$ | $\beta$ |
| :--- | ---: | ---: | :---: |
| D1 | .17 | .36 | .71 |
| D2 | .68 | .79 | .69 |

Table 1. Intraclass correlation coefficients of parameters.
Table 1 presents test-retest reliability data for D1 and D2. These estimates were derived from splitting the data into approximately equal halves (specifically at the first game change after half of trials elapsed) and fitting the model to each (approximate) half. The test-retest reliabilities for $\{d$ and $\eta\}$ in D1 were quite low. This is likely because subjects only played 500 trials, and $\sim 250$-the approximate number of trials per half - may be too few trials to reliably estimate the parameters. In contrast, the D2 data suggest that $\sim 700$ trials allows for better parameter estimation, as reflected in the fact that test-retest scores for $\{d$ and $\eta\}$ are much higher.

Universal norms for intra-class correlation coefficients (ICCs) are arguably not justifiable (Weir, 2005) and at present there are no ICC benchmarks for RL tasks. But, in all domains, uncertainties around parameters increase as ICCs decrease (Weir, 2005). Thus, the above data are relevant to clinical science designs because they show how ICCs can increase with more data (see also Hitchcock et al., 2017). Gathering this information before designing a computational psychiatry assay is useful because computational psychiatry designs must often balance competing goals. On one hand, parameter estimates tend to improve with more trials. On the other, it may be infeasible to have subjects complete too long a task. For instance, individuals with certain disorders may fatigue easily. Experimental manipulations (e.g., rumination inductions) may also quickly dissipate. Test-retest reliability data can help negotiate the tradeoff between optimizing parameter estimates and keeping time on task feasible.

## Conclusions

Computational psychiatry promises to improve measurement and refine theory in clinical science (Hitchcock, 2017). Ultimately it may advance understanding of psychiatric disorders (Redish \& Gordon, 2016). Yet there are significant barriers to developing computational psychiatry assays. These barriers are diverse; hence this paper was part theoretical overview and part case study. The overview part of the paper first built motivation by discussing the dot probe paradigm, a case in which failure to attend to measurement issues in a laboratory task had disastrous results. Dozens of studies were conducted and vast resources were expended, over decades, before the poor properties of the task measures were realized. Next, we reviewed why laboratory tasks are so vulnerable to measurement issues: Task performance is often skewed by random state variation. That is, behavior collected only once or a few times from a single subject is often corrupted by situational factors. These review parts of the paper highlighted that minimizing noise in laboratory task measures is imperative. In the case study part of the paper, we overviewed modeling issues in RL tasks that can add
noise to parameter estimates, using two datasets for illustration. We concluded by presenting test-retest reliability data from the Dimensions Task, using this example to illustrate how time-on-task can improve reliability.

We should note that we have presented only some of the steps that should be taken when applying an RL task in clinical science. Other options include applying empirical priors (Gershman, 2016), using physiological data to aid parameter estimation (e.g., Leong, Radulescu, et al, 2017), and employing hierarchical modeling to weight parameter estimates by group statistics (Gelman \& Hill, 2006), which can reduce the variance of parameter estimates (Daw, 2011). As computational psychiatry develops, we predict that psychometric, study design, and parameter estimation issues will come increasingly to the fore.

# The Meanings of Morality: Investigating the psychometric properties of distributed representations of latent moral concepts 

Joe Hoover<br>University of Southern California, Los Angeles, California, United States

Katie Horton
University of Southern California

## Morteza Dehghani

University of Southern California

#### Abstract

People's beliefs about what is morally right and wrong vary widely between individuals, contexts, and cultures; however it is thought that they are governed by core latent constructs. While there is evidence that these constructs are reflected in natural language, this requires further testing. We demonstrate that the structure of moral values in natural discourse can be modeled by applying factor analyses to distributed representations of morally relevant terms learned by a neural network. We first demonstrate that robust latent constructs can be estimated from the covariance of distributed representations of construct exemplars. We then test whether the factor structure proposed by Moral Foundations Theory (MFT) is reflected in natural language. Finally, we conduct a bottom-up investigation of the structure of moral values in natural language using freeresponses reported by participants. Ultimately, we find evidence that the representation of moral values in natural language partially corresponds to MFT.

# Probability judgement from samples: accurate estimates and the conjunction fallacy 

Rita Howe (Rita.Howe@ucdconnect.ie)<br>School of Computer Science, Belfield, Dublin 4

Fintan J. Costello (Fintan.Costello@ucd.ie)
School of Computer Science, Belfield, Dublin 4

#### Abstract

This paper investigates a fundamental conflict in the literature on people's probability estimation. Research on 'perception' of probability shows that people are accurate in their estimates of probability of various simple events from samples. Equally, however, a large body of research shows that people's probability estimates are fundamentally biased, and subject to reliable and striking fallacies in reasoning. We investigate this conflict in an experiment that examines the occurrence of the conjunction fallacy in a probability perception task where people are asked to estimate the probability of simple and conjunctive events in a presented set of items. We find that people's probability estimates are accurate, especially for simple events, just as seen in previous studies. People's estimates also show high rates of occurrence of the conjunction fallacy. We show how this apparently contradictory result is consistent with a recent model of probability estimation, the probability theory plus noise' model.

Keywords: Conjunction fallacy; Disjunction fallacy; Perceptual probabilities; Probability estimation

## Introduction

The ability to reason under uncertainty (to estimate probabilities) is fundamental to human cognition. Humans exist in a world of stochastic processes, both stationary and nonstationary. They are regularly required to produce estimates for discrete events often with their own hidden parameters. It shouldn't be surprising then that humans are often very accurate in the probability judgements that they provide. This paper investigates a fundamental contradiction in the literature on people's probability estimation. Research on people's perception of probability shows that people are quite accurate when required to give estimates of the probability of simple events. Equally, however, a large body of research shows that people's probability estimates are fundamentally biased, and subject to reliable and striking fallacies in reasoning (such as the conjunction fallacy). To investigate this contradiction, we present an experiment that examines conjunction and disjunction fallacy rates and accuracy of probability estimates simultaneously. We find that while probability estimates are accurate, they are biased in specific ways. We also find that high conjunction and disjunction fallacy rates can co-exist with accurate probability estimation.

## Probability perception

Early research on probabilistic reasoning involved presenting participants with sequences or sets of simple events that varied on one particular dimension (sets of different shapes,
for example), and asked participants to estimate the probability of one particular event or outcome in that set (the probability of seeing a triangle in that set, for example). Results from these studies of 'probability perception' showed that the relation between subjects' mean estimates of probabilities and the sample proportions are described well by the identity function: people's probability estimates agreed well with the true objective probabilities (Peterson \& Beach, 1967). Later work on perceptual probabilities has suggested that humans have computational mechanisms that provide them with reasonably accurate judgements of simple probabilities (Balci, Freestone \& Gallistel, 2009). Participants are both accurate in their probability judgements and quick to detect large step changes in probabilities when required to give repeated estimates for non-stationary Bernoulli processes in real time (Gallistel, Krishan, Liu \& Miller, 2014). Similarly, Zhao, Shah, and Osherson (2009) used this 'probability perception' paradigm to examine people's judgements of conditional probability. Their participants observed shapes of different colours on screen for 4 seconds. These were static but appeared at new coordinates after a second had elapsed. Relatively small discrepancies between objective probabilities and conditional probability estimates were observed in this task.

## Fallacious reasoning

By contrast, research on errors in probabilistic reasoning (mainly in the 'heuristics and biases'framework) has uncovered many reliable and systematic errors or biases in people's judgement of probability. Over 50 such biases have been recognised, including the conjunction fallacy and disjunction fallacy (Baron, 2008). The conjunction fallacy, which arises when subjects judge some conjunction of events $A \wedge B$ to be more likely (more probable) than one of the constituent events of that conjunction, A, has gained the most attention since its discovery. Probability theory, which requires that $P(A \wedge B) \leq P(A)$ and $P(A \wedge B) \leq P(B)$ must always hold (simply because $A \wedge B$ cannot occur with A or B themselves occurring). The conjunction, $A \wedge B$, under the probabilistic laws, cannot be more likely than the single constituent A , thus when a participant chooses the conjunction $A \wedge B$ as more probable, they are committing a fundamental violation of rational probabilistic reasoning. The 'Linda problem'of Tversky and Kahneman (1983) is probably the best known example of this fallacy. The Linda problem is as follows:

Linda is 31 years old, single, outspoken, and very bright.

She majored in philosophy. As a student, she was deeply concerned with issues of discrimination and social justice, and also participated in anti-nuclear demonstrations.

Which is more probable?

## A. Linda is a bank teller <br> $A \wedge B$. Linda is a bank teller and is active in the feminist movement

Tversky and Kahneman found that when presented with simple conjunction problems over $80 \%$ of their participants made an erroneous judgement, judging $A \wedge B$ as more likely than $A$. A similarly reliable disjunction fallacy occurs when participants judge the constituents $\mathrm{A}, \mathrm{B}$ as more likely than the disjunction, $A \vee B$ (Bar-Hillel \& Neter, 1993). These widely replicated fallacy results were taken as an indication that humans do not reason in a normative fashion that is, they dont apply probabilistic rules to real-life contexts. Instead, it was suggested that people employ heuristics mental short cuts - to solve these problems. The conjunction fallacy, for instance, was suggested to occur because people employed a "representativeness heuristic" when reasoning about conjunctive problems (Tversky et al., 1983). Under this theory, the fallacy occurs as the person described in the conjunction is more representative of the information presented in the character sketch. However, research has called the validity of the representativeness account into question (Bonini, Tentori \& Osherson, 2004; Sides et al, 2002). Experiments that manipulated class inclusion, for instance, demonstrated that the fallacy occurs regardless of whether the conjunction is representative or not (Gavanski \& Roskos-Ewoldsen, 1991). While fallacy rates are generally quite high, a frequent observation among this research is that a small number of participants do not seem overly susceptible to the fallacy. In addition, over a number of conjunction problems, participants rarely have $100 \%$ error rates. Stanovich and West (1998) recognized that individuals can differ greatly on their performances on cognitive bias eliciting tasks. They found that subjects with higher cognitive ability were disproportionally likely to avoid committing a number of cognitive biases including the conjunction fallacy.

Previously, weighted models based on component probabilities such as the Signed Summation and Low-component models were popular as a means to explain the range of results that were consistently observed in fallacy research (Thüring \& Jungermann, 1990; Yates \& Carlson, 1986). However, these were limited in the scope of results that they could predict. A more successful iteration of these weighted models is the Configural Weighted Average (CWA) model (Nilsson, Winman, Juslin \& Hansson, 2009). This sophisticated weighted model includes a "noise component" that randomly disturbs probability judgements. More recently formal probabilistic models have sought to show that a range of biases can be explained as a function of quasi-rational
probabilistic reasoning instead of a heuristic process. Hilbert (2012) proposed a theoretical framework based on noisy information processing. Under this framework, memory based processes convert observations stored in memory into decisions. By assuming that these processes are subject to noisy deviations and that the noisy deviations are a generative mechanism for fallacious decision-making it provides an explanation for a number of cognitive biases . Costello and Watts (2016) proposed the Probability Theory plus Noise (PTN) model which can account for this variability in occurrence of the conjunction fallacy. In this model, people do reason in a normative fashion according to probability theory but are subject to random error in the reasoning process. The reasoner's decision-making processes, which are memory based, reliably apply the conjunction rule during the probability estimation process, but random noise causes fluctuations in judgement that sometimes lead to the subjective probability of a conjunction exceeding the subjective probability of the constituent. Costello and Watts showed that a simulation implementing this model produced a wide range of fallacy rates (from less than $10 \%$ to close to $70 \%$ ) and produced conjunction fallacy rates for a given set of materials that closely matched those seen in experimental studies for the same materials.

## Aims of this paper

These two lines of research use different paradigms (direct perception of probability in controlled sets of events versus questions about the probability of events given descriptions) and lead to two contradictory conclusions (people's probability estimates are fundamentally accurate versus people's estimates are fundamentally flawed). In this paper, we describe an experiment that aims to reconcile these two strands of research by using using a perceptual probability task to examine conjunctive and disjunctive probability judgements and the occurrence of the conjunction and disjunction fallacy. We ask whether these fallacies will occur reliably in direct probability perception even though people's estimates in probability perception tasks are typically accurate. We also investigate the predictions of the (PTN) model that attempts to simultaneously explain both relatively accurate estimation and reliable fallacy occurrence (Costello et al, 2016).

This model assumes that people estimate probabilities using a fundamentally rational process which is, however, subject to the systematic biasing effects of random noise in the reasoning process. Importantly, this model proposes that the rate of random noise is greater for more complex conjunctive and disjunctive events than for simple events (as a consequence of simple propagation of error: because conjunctions and disjunctions are more complex, they have more points of 'failure' at which random noise can have an effect). This model thus predicts relatively accurate probability estimates, especially for simple events (as seen in the 'probability perception' literature), but stronger systematic bias due to noise for conjunctive and disjunctive events (producing the conjunction and disjunction fallacy).

## Experiment

This experiment involves repeatedly presenting participants with images where each image contains a relatively large number of shapes differing in colour (red, white or green) and configuration (solid or hollow). For each image participants are asked to estimate the probability of some event (e.g., a randomly selected shape being red, for example). The true probability of events in these images were held constant across multiple presentations (but with the images themselves varying as to the position of the different shapes on the screen each time), as described below. Each participant saw multiple presentations of the same probability question (multiple questions for which the objectively correct probability was the same), allowing us to estimate the degree of random variation in participants estimates. Some questions asked about simple events (a shape being red, being hollow, etc.) while other questions asked about conjunctive and disjunctive events (a shape being red and solid, a shape being white or hollow, etc.) Two distinct sets of images were used, with objective probabilities of single and conjunctive probabilities held constant in each set (see below). The images from these two sets were interspersed with each other. Participants answered questions about 460 images in total. Images were only on screen for a short time ( 2 seconds), and so participants did not have time to count the occurrence of shapes of different types. Images were presented in randomised order.

## Materials

The images consisted of shapes of three colours - colours A, $B$, and $C$ respectively - and 2 shape configurations - $X$ and Y - with fixed probabilities. The actual colour varied from image to image, so sometimes colour A was white, sometimes colour A was red and sometimes colour A was green. The colours varied in the same way for colour B and colour C. The actual configuration of the shapes also varied from image to image so sometimes configuration X was solid shapes and sometimes configuration X was hollow shapes. Conjunction and disjunctions were created for a number of combinations of colour and configuration such as $\mathrm{P}(\mathrm{A} \wedge \mathrm{X}), \mathrm{P}(\mathrm{A} \wedge \mathrm{Y})$ and $\mathrm{P}(\mathrm{B} \vee \mathrm{X})$.

For each type $\mathrm{A}, \mathrm{B}, \mathrm{C}, \mathrm{X}, \mathrm{Y}, \mathrm{A} \wedge \mathrm{X}, \mathrm{A} \wedge \mathrm{Y}$ etc, there were 20 images asking people to estimate the probability of that type. In practise, this meant that the participants saw 20 im ages asking them to estimate the probability of colour A, 20 images asking them to estimate the probability of colour B , 20 images asking them to estimate the probability of configuration X and so on.

## Set 1

In set 1 , colour A had a fixed probability of 0.7 , colour B had a fixed probability of 0.2 and colour C had a fixed probability of 0.1 . Configuration X had a fixed probability of 0.9 and configuration $Y$ had a fixed probability of 0.1 . The conjunctions for set 1 were created using the following colour and configuration combinations: $\mathrm{P}(\mathrm{A} \wedge \mathrm{X}), \mathrm{P}(\mathrm{B} \wedge \mathrm{X})$, and $\mathrm{P}(\mathrm{B} \wedge \mathrm{Y})$. These corresponded to the objective probability values of $0.63,0.18$
and 0.02 . The disjunctions for set 1 were created using the following colour and configuration combinations: $\mathrm{P}(\mathrm{A} \vee \mathrm{X})$, $\mathrm{P}(\mathrm{B} \vee \mathrm{X}), \mathrm{P}(\mathrm{A} \vee \mathrm{Y})$, and $\mathrm{P}(\mathrm{B} \vee \mathrm{Y})$. These disjunction combinations corresponded to the the objective probability values of $0.97,0.92,0.73$, and 0.12 . Participants viewed 220 images of 20 geometric shapes on a computer screen.

## Set 2

For set 2, colour A had the fixed probability of 0.333 , colour $B$ had the fixed probability of 0.333 and colour $C$ had the fixed probability of 0.333 . Configuration X had the fixed probability value of 0.5 and configuration Y had the fixed probability value of 0.5 . The conjunction for set 2 had the value of 0.17 . Any combination of $A, B, C$ and $X, Y$ would give this value. The disjunction had the objective probability value of 0.67 . Again, any combination of $A, B, C$ or $X, Y$ would give this value.

Participants viewed 240 images of geometric shapes in a computer screen. Each image consisted of 12,24 , or 36 shapes. Each objective probability values of $0.333,0.5,0.17$, and 0.67 were presented 20 times for each of the 12,24 and 36 shape images.

Each image presentation included a question to elicit a probability judgement. For the colour probability questions, participants were presented with questions in the form "What is the probability of picking a shape that is [colour A]?" or "What is the probability of picking a shape that is [colour B]?" Colour C was excluded from the probability questions. For the configuration questions, participants were presented with questions in the form: "What is the probability of picking a shape that is [configuration X]? or "What is the probability of picking a shape that is [configuration Y]?" The conjunction and disjunction questions took the same form. For instance, the question to elicit a probability judgement for the objective probability of 0.63 would be: "What is the probability of picking a shape that is [colour A AND configuration X]?".

## Procedure

Participants were seated at a screen. Each participant began with a training trial of sample stimuli to familiarize themselves with the task (see figure 1). Once the participants were comfortable with the task, they moved onto the experimental trials. The static image and the probability question appeared on screen simultaneously. The image was replaced with a blank screen once 2 seconds had elapsed to prevent the participants from counting the shapes. The associated question remained on-screen until the participants had made their guess. The participants indicated their estimate by moving dial on a slider using their mouse or arrow keys. This slider had a minimum value of 0 and a maximum value of 1 . A box in the corner indicated the exact value of the participants' estimate and dynamically updated as they moved the slider. When the participant was satisfied with their answer, they submitted it by clicking on a Next button. This also triggered the succeeding image and probability question.

Figure 1: The figure above displays example stimuli image from set 1 in grey scale. While the shape types changed between sets, the underlying proportions remained constant. The image above has a shape configuration of 0.9 for solid shapes and 0.1 for hollow shapes. The colours have fixed probabilities of 0.7, 0.2 and 0.1.

## Results

A total of 9 participants made 460 probability judgements each. Their responses and response time was recorded for each judgement. Two of the participants were excluded from the final analysis for failing to answer $20 \%$ of the questions. The number of participants is in line with other studies of probability perception (e.g. Gallistel et al, 2014).

Error and variance The initial analysis determined whether an estimate was an actual estimate or whether an error had occurred in the response (such as the participant mistakenly submitting an estimate). To do this, the standard deviation for each participants' estimates were calculated. Any estimate that fell $\pm 3$ standard deviations from the mean estimate of a probability was excluded. In total, this comprised of $1 \%$ of responses.

## Estimated probability vs true probability

For each of the 11 probability values in set 1 , each participant gave 20 estimates for its value. In set 2 , the 4 probability estimates were questioned at 3 different levels; 20 estimates were given for each probability value at each level. The relationship between mean probability estimates and objective probability are displayed in figure 2. For each probability value, the participants' average estimate and standard deviation was calculated. The average estimate and standard deviation were also calculated for the sample. The average deviation from the true probability was calculated in terms of percentage points. Some noticeable trends were observed, participants tended to overestimate the low probabilities and underestimate the higher probabilities. The degree of overestimation for the low constituents was much less than for the low complex statements. For instance, the constituent with a true probability of 0.1 have an average estimate of 0.13 , while

Figure 2: The above graph displays the average probability estimate vs the objective probability value by type. Any value falling above the line represents an overestimation of the probability value, while the values falling below the line represent underestimations of the true value. Largely, conjunctions were overestimated and disjunctions were underestimated. Constituents tended to have accurate estimates.
the conjunction with a probability of 0.02 had an average estimate of 0.14 and the disjunction of 0.12 had an average estimate of 0.26 . Overall, conjunctions were overestimated and disjunctions were underestimated. The conjunctions and disjunctions averaged 10 percentage points away from their true probability while the constituent average was 4 percentage points. Figure 2 shows the average estimate for each type.

For set 2, the conjunctions were overestimated on all occasions, with the average estimate increasing as the stimulus set became more complex. The disjunctions were consistently underestimated. Participants were more accurate in their estimates for the constituents. The 12 -shape combinations had the lowest average estimates, the 24 -shape estimates were higher than the 12 -shape and lower than the 36 -shape estimates. The 36 -shape images had the highest mean estimates.

## Fallacy rates

Each conjunction and constituent was presented 20 times to each participant. To evaluate the rate at which the participant had committed the conjunction fallacy, each conjunction judgment $1 \ldots 20$ was matched in order with its corresponding constituent judgments ( $1 \ldots 20$ ), so the first conjunction judgement was matched with the first constituent judgements, and so on. If a particular conjunction judgement exceeded the estimate of either of the corresponding constituent values, an instance of the conjunction fallacy was recorded. For each participant, there were six conjunction questions where the fallacy could be committed, three from set 1 and three from set 2 . The average conjunction fallacy rate was $30 \%$. Fallacy rates ranged from $13 \%$ to $69 \%$ : a range that is in-line with those seen in description based studies (e.g. StolarzFantino, Fantino, Zizzo, \& Wen, 2003). The set-up of this experiment allows us to categorise conjunctions based on their

Table 1: Fallacy rates occurrences by objective probability for the conjunction and disjunction problems.

| Set 1 |  |  |  |  | Set 2 |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| Conjunction fallacy |  |  |  |  |  |  |  |
| Conjunction probability | 0.02 | 0.18 | 0.63 | - | $\begin{gathered} 0.17 \\ \text { (12-shapes) } \end{gathered}$ | $\begin{gathered} 0.17 \\ \text { (24-shapes) } \end{gathered}$ | $\begin{gathered} 0.17 \\ \text { (36-shapes) } \end{gathered}$ |
| Fallacy rate | 43\% | 21\% | 68\% | - | 19\% | 13\% | 14\% |
| Disjunction fallacy |  |  |  |  |  |  |  |
| Disjunction probability | 0.12 | 0.73 | 0.92 | 0.97 | $\begin{gathered} 0.67 \\ \text { (12-shapes) } \end{gathered}$ | $\begin{gathered} 0.67 \\ \text { (24-shapes) } \end{gathered}$ | $\begin{gathered} 0.67 \\ \text { (36-shapes) } \end{gathered}$ |
| Fallacy rate | 34\% | 28\% | 49\% | 71\% | 40\% | 25\% | 24\% |

Fallacy rates varied quite significantly for the conjunctive and disjunctive judgements. The highest fallacy rates were observed for the highest objective probabilities. However, the objective probability value was necessarily an accurate predictor of fallacy occurrence as high fallacy rate were also observed for low objective probabilities.
actual probabilities and their underlying constituent probabilities. The participants showed marked differences in performances for each of the six conjunctions they were presented with. Table 1 displays the fallacy rate breakdown by conjunction type. The highest fallacy rates are seen for the conjunction with the highest probability value. High fallacy rates were also observed for the conjunction with the lowest probability value. The other conjunctions had low fallacy rates.

As for the conjunction fallacy, each disjunction judgement was matched with the constituent judgements in sequence, so the first disjunction judgement was matched with the first instances of the relevant constituent judgements. If a disjunctive estimate was less than either of its constituent estimates then it was counted as a disjunction fallacy. The average disjunction fallacy rate was $39 \%$. The fallacy rate ranged from $25 \%$ to $71 \%$, which is consistent with the results from description based research. The average fallacy rate for the each of the 7 possible disjunctions is displayed table 1 . As for the conjunctions, the objective probability value of the disjunction was not an indicator of fallacy rate occurrence.

Conjunction and disjunction fallacy occurrence varied over the course of presentation, however, there was no obvious trend of improvement or deterioration in the participants ability to avoid committing the fallacies (fallacy rates did not decline with familiarity).

## Variance

Since each conjunction, disjunction and constituent was presented 20 times to each participant, we can estimate the degree of variance (standard deviation) in estimates for type. Recall that the PTN model predicts greater variance would exist for the complex combinations than the constituents. Results showed that the complex combinations were more variable than their constituent counterparts for $68 \%$ of the comparisons. The conjunctions were noisier than their con-

Table 2: Average standard deviation for constituents, conjunctions and disjunctions

| A | B | $\mathrm{A}(\mathrm{SD})$ | $\mathrm{B}(\mathrm{SD})$ | $\mathrm{A} \wedge \mathrm{B}(\mathrm{SD})$ | $\mathrm{A} \vee \mathrm{B}(\mathrm{SD})$ |
| :---: | :---: | :---: | :---: | :---: | :---: |
|  |  |  |  |  |  |
| 0.1 | 0.2 | 0.050 | 0.072 | 0.070 | 0.102 |
| 0.1 | 0.7 | 0.050 | 0.083 | - | 0.091 |
| 0.9 | 0.2 | 0.073 | 0.072 | 0.071 | 0.120 |
| 0.9 | 0.7 | 0.073 | 0.083 | 0.085 | 0.095 |
| 0.5 | $0.33(12)$ | 0.088 | 0.090 | 0.086 | 0.145 |
| 0.5 | $0.33(24)$ | 0.101 | 0.080 | 0.075 | 0.126 |
| 0.5 | $0.33(36)$ | 0.060 | 0.098 | 0.096 | 0.111 |

The table above displays the average variability scores for the single constituents, conjunctions and disjunctions. In nearly all the cases, the complex judgement (conjunction or disjunction) was more variable than one if not both of its constituents.
stituents counterparts for $50 \%$ of the comparisons. Disjunctions were more variable than their constituent counterparts for $83 \%$ of the comparisons. The average variance for constituents was 0.77 , conjunctions had an average variance of 0.81 and disjunctions had an average variance of 0.11 .

Variance and fallacy rate Participants variability was positively correlated with their fallacy rates, small positive correlations were observed for the conjunction fallacy rates, $r=$ 0.25 and the disjunction fallacy rates, $r=0.36$ for set 1 . For set 2, a strong positive correlation was observed for the conjunction fallacy rate and variability, $r=0.89$ and a mild positive correlation for the disjunctions, $r=0.32$. This supports the PTN model assumption that conjunction and disjunction fallacies arise due to variability in conjunction and disjunction estimates. Table 2 displays the average standard deviation values for each constituent, conjunction and disjunction. Overall, the complex combinations had higher average standard deviations than the constituents.

## Timings

Participants had slower response times for their initial estimates but these decreased and plateaued rapidly. To investigate whether there was a difference in response times for type - constituent, conjunction, and disjunction - the average time for each type was calculated. Then a repeated measures ANOVA was performed to examine whether a difference existed for the average reaction times for judgement type. The ANOVA found a significant difference in reaction speed for judgement type, $\mathrm{F}(2,278)=8.478, p<0.05$. Pairwise comparisons showed that constituents judgements were significantly faster than conjunctions judgements. Constituent judgements were also significantly faster than disjunctions judgements. No significant different was observed between the judgements speeds for the conjunctions and disjunctions.

## Discussion

This paper investigated an apparent conflict in the literature on probability estimation, which shows accurate estimates when people estimate probabilities from directly presented samples, but systematic occurrence of the conjunction and disjunction fallacy when people estimate the probability of described events. Our experimental results show accurate estimates, and frequent fallacies in judgement for conjunctions and disjunctions, occurring simultaneously when probabilities are estimated from samples. This pattern of results is predicted by the PTN model (Costello \& Watts, 2016), in which people estimate probabilities by following standard frequentist probability theory, but with random noise in judgement. Fallacies in judgement such as the conjunction and disjunction fallacy are caused by increased rates of random error for conjunctions and disjunctions, while accurate estimates for constituents are produced because people follow standard probability theory in making estimates, and because constituent estimates are subject to lower rates of random error.

The results here demonstrate that producing accurate probability estimates (especially for constituents) and producing conjunction and disjunction fallacy responses are not mutually exclusive states: both patterns of results can occur simultaneously, and are naturally explained in a model where people reason according to standard probability theory but are subject to random noise in the reasoning process

While the wide range of fallacy results observed in the literature (approximately $10 \%$ to $80 \%$ depending on task type) is challenging, this experiment demonstrates that a range of fallacy rates from low to high can occur for the same task and are a consequence of the objective values of the constituents, the conjunctions or disjunctions and the rate of variability in estimates. We observed complex combination estimates that were consistently more variable than the constituent estimates. While both the CWA and PTN models predict that fallacy rates will be effected by noise, they make divergent predictions. The CWA model predicts a negative correlation with variability and fallacy rates, that is, the rate of fallacy errors should increase as the rate of noise decreases. Here, both conjunction and disjunction fallacy rates correlated positively with variability. These results are consistent with the PTN model which predicts that we should observe a positive relationship between fallacy rates and variability.

The results of this experiment seem to resolve the conflict between studies of probability perception and the studies of fallacies in reasoning. Participants were accurate probabilistic reasoners - their judgements of probabilities were good especially for the constituents. However, these judgements are still systematically biased and depending on the problem type, noisy. People's estimates are more variable for conjunctions and disjunctions than the constituents and this variance causes the occurrences of the conjunction and disjunction fallacy. This account of accurate estimates with consistent fallacy occurrences is consistent with the PTN model.

# Disfluencies in dialogues with patients with schizophrenia 

Christine Howes (christine.howes@gu.se)<br>Philosophy, Linguistics and Theory of Science University of Gothenburg, Sweden

#### Abstract

Disfluencies such as self-repairs, filled pauses such as 'um' and silent pauses are pervasive in dialogue, but there is no consensus in the literature as to whether they reflect internal production pressures, or interactive issues - or how their effects are manifest in dialogue. It is well-known that patients with schizophrenia have problems with language and social cognitive skills, yet little research has investigated how these impact interaction. We report a study on the disfluency behaviours of patients with schizophrenia and their interlocutors who were unaware of the patient's diagnosis, compared to healthy control groups. Results show that patients use fewer self-repairs than either their partners or controls and fewer filled pauses ('er', 'um') than controls. Furthermore, the presence of the patient also affects patients' partners, who use fewer filled pauses than controls and more unfilled pauses than both patients and controls. This suggests that smooth coordination of turns is problematic in patients' dialogues.

Keywords: Disfluency; Dialogue; Schizophrenia

## Introduction

Disfluencies, such as self-repair, pauses and filler non-words such as er and um (filled pauses) are pervasive in dialogue (Schegloff, Jefferson, \& Sacks, 1977). Such disfluencies are conventionally regarded as symptomatic of problems with communication, caused by self-monitoring or production issues (Levelt, 1983). However, disfluencies also highlight the interactive nature of dialogue - many disfluencies occur as we tailor our talk for specific addressees, or as a direct result of feedback from our interlocutors (Goodwin, 1979).

Furthermore, different types of disfluencies have been hypothesised to contribute differently to the individual and shared actions that must be coordinated in successful dialogue. For example, in route following experiments, different distributions of filled pauses and self-repairs suggest that self-repairs occur because of production difficulties, but filled pauses fulfil an interpersonal function (Bortfeld, Leon, Bloom, Schober, \& Brennan, 2001; Nicholson, Eberhard, \& Scheutz, 2010; Brennan \& Schober, 2001).

Other research suggests that disfluencies should be categorised according to whether they make changes to the meaning of an utterance or not, e.g. reformulations and false starts are backwards-looking disfluencies, whilst word repetitions and filled pauses are forwards-looking (Ginzburg, Fernández, \& Schlangen, 2014; Allwood, Nivre, \& Ahlsén, 1990).

In addition to signalling difficulties that the speaker may be experiencing, different types of disfluency have been shown to have conventionalised meanings with respect to turn-taking. Filled pauses may indicate a break in the information (for example while the speaker searches for a word
or phrase) but an intention to retain the floor, whilst unfilled pauses may signal that the speaker does not intend to continue speaking (Clark \& Fox Tree, 2002; Allwood et al., 1990).

Recent work suggests that disfluencies have measurable effects on the dialogue - even if this is not necessarily the intention of the speaker (Finlayson \& Corley, 2012; Ginzburg et al., 2014). For example, in contexts where informational exchange is key, such as the Map Task (Anderson et al., 1991), more self-repair may be indexing one's own production difficulties, and how hard people are working to be understood by (and for) their interlocutors (Colman \& Healey, 2011).

Further evidence that disfluencies do not just function as markers of miscommunication but contribute to improving the effectiveness of interaction comes from psycholinguistic studies. For example, referential success and ambiguity resolution are aided by the presence of disfluencies (Brennan \& Schober, 2001; Bailey \& Ferreira, 2007). Communications training interventions also indicate that talk between psychiatrists and patients with schizophrenia is improved when the psychiatrist uses more self-repair (McCabe et al., 2016).

As can be seen from the above discussion, there is no general consensus in the literature about either which disfluencies should be focused on, how different types of disfluency should be categorised, or the effects they have in dialogue.

It is well documented that people with a diagnosis of schizophrenia have problems with language and social cognitive skills, including with self-monitoring (Johns et al., 2001) and turn-taking (using role-play; Mueser, Bellack, Douglas, and Morrison, 1991), yet little research has investigated how these impact interaction. The few studies that do find that less patient self-repair is associated with verbal hallucinations (Leudar, Thomas, \& Johnston, 1992), more patient otherinitiated repair (clarification of the doctor's talk) is associated with better adherence to treatment (McCabe et al., 2013), and clinicians' use of self-repair has positive clinical consequences (McCabe et al., 2016). Research into disfluencies therefore has the potential to be used in diagnostic tools, and feed into training for psychiatrists to detect when a patient is in difficulty or shape their own talk more effectively.

However, there is conflicting evidence regarding disfluencies in patients with schizophrenia and whether this differs from non-clinical populations. In consultations, patients use more self-repair than psychiatrists (McCabe et al., 2013) and this is higher than found in general dialogue in the demographic portion of the British National Corpus, or Map Task dialogues (Howes, Purver, McCabe, Healey, \& Lavelle, 2012;

Colman \& Healey, 2011). This might be expected in the clinical domain where patients are explaining and providing updates on their health and treatment. In contrast, in a controlled study where subjects described the experimenters actions, frequency of repair did not differ between patients and matched controls (Leudar et al., 1992).

These differences may reflect interactional factors, such as domain, or role, and not differences between schizophrenia patients and non-clinical populations per se. Additionally, in these studies, patients' interlocutors were aware of their diagnosis, which could have influenced the way they interacted with the patient (Doyen, Klein, Pichon, \& Cleeremans, 2012).

We report an analysis of a unique corpus of 40 triadic dialogues (Lavelle, Healey, \& McCabe, 2013) that avoids these potential confounds (see Method, below). Given that the literature suggests patients produce more self-repairs than their psychiatrists in dialogues during clinical consultation, and more so than people in natural corpora from the general population, and with the assumption that turn-taking cues (including offering the floor to another participant, or retaining it for oneself) partially consist of filled and unfilled pauses (Maclay \& Osgood, 1959), we expect the following:

## Hypotheses

1. Compared to healthy control conversational groups and their healthy conversational partners, patients will produce more disfluent talk, with more self-repairs.
2. Compared to controls and their conversational partners, patients will produce fewer turn-taking cues (filled and unfilled pauses).
3. Compared to patients and controls, patients' partners will produce more turn-taking cues.

## Method

## Participants

The data consist of transcripts of twenty patient interactions, involving one patient conversing with two healthy controls who were unaware of the patient's diagnosis, and twenty control interactions (3 healthy participants). Twenty patients with a diagnosis of schizophrenia ( 6 male, 14 female) and one hundred non-psychiatric healthy participants, forty in the patient condition ( $21 \mathrm{~m}, 19 \mathrm{f}$ ) and sixty in the control condition ( 34 $\mathrm{m}, 26 \mathrm{f}$ ), participated. Participants within each triad were unfamiliar to each other. Due to technical issues one patient interaction and one control conversation could not be transcribed and are excluded from the analysis, resulting in data from 57 individuals in control groups ( 19 triads), and 19 patients and 38 healthy controls in patient interactions.

Non-psychiatric healthy participants were recruited through advertising on local community websites. Of those who responded to the advertisement, $40 \%$ participated. Participants with a diagnosis of psychosis or affective disorders in themselves, or any first-degree relatives, and those who were not fluent English speakers were excluded.

Patients were recruited at routine psychiatric outpatient clinics under supervision of their psychiatrist. $25 \%$ of all patients approached agreed to participate. Patients were taking anti-psychotic medication which fell within the low dose range (Chlorpromazine equivalents $50-200 \mathrm{mg} / \mathrm{day}$ ). Nonnative English speakers and patients presenting with motor side effects from antipsychotic medication were excluded based on a clinician's assessment.

The distribution of gender did not significantly differ between patient and control conditions ( $\mathrm{P}: n=60$ : female $=53.33 \%, \mathrm{C}: n=60:$ female $=43.33 \% ; \chi^{2}=1.20, p=$ 0.27 ). Patients were significantly older than controls ( P : $M=41 s . d .=8.6, \mathrm{C}: M=31$ s.d.$\left.=9.6 ; t_{119}=4.51, p<0.01\right)$

Symptoms were assessed using the Positive And Negative Symptom Scale for Schizophrenia (Kay, Flszbein, \& Opfer, 1987). Patients displayed relatively low PANSS scores for positive symptoms - additional features that occur with the disorder such as hallucinations or delusional beliefs ( $M=$ $15.8 ;$ s.d. $=6.76$ ), and negative symptoms, which represent a reduction in usual function such as social withdrawal, diminished affect, apathy and anhedonia $(M=9.95 ;$ s.d. $=3.36)$.

## Ethics

All procedures were approved by a UK NHS Research Ethics Committee (07/H0711/90). All participants gave written informed consent and were free to withdraw at any time.

## Procedure

Participants were brought into the laboratory in threes and seated in a triangular formation so that they all had good visual access to each other (see Figure 1). The researcher read aloud a fictional moral dilemma, the 'balloon task' (see Task section, below), which has been used for studying dialogue, and is known to stimulate discussion (Howes, Purver, Healey, Mills, \& Gregoromichelaki, 2011). The group was provided with an opportunity to ask questions before the researcher left the interaction space and the task began. Interactions ended when participants reached a joint decision. Groups that failed to reach agreement had their interaction terminated at approximately 450 seconds ( 7 minutes 30 seconds).

Figure 1: Participants engaged in triadic interaction

## Task

The balloon task is an ethical dilemma requiring agreement on which of four passengers should be thrown out of a hot air balloon, which is losing height and about to crash into some mountains killing all on board unless one of them jumps to their certain death in order to save the other three. The four passengers are described to the participants as follows:

Dr. Robert Lewis - a cancer research scientist, who believes he is on the brink of discovering a cure for most common types of cancer.

Mrs. Susanne Harris - who is not only widely tipped as the first female MP for her area, but is also over the moon because she is 7 months pregnant with her second child

Mr. William Harris - husband of Susanne, who he loves very much, is the pilot of the balloon, and the only one on board with balloon flying experience.

Miss Heather Sloan - a 9 year-old music prodigy, considered by many to be a "twenty first century Mozart".

Participants were instructed to debate the reasons for and against each person being saved, and reach mutual agreement about who should jump.

## Analysis

Participants' speech was transcribed in ELAN (Brugman \& Russel, 2004), allowing us to map the transcriptions to the video and precisely time pauses.

Self-repair Self-repairs were annotated automatically using STIR (STrongly Incremental Repair detection; Hough and Purver, 2014); ${ }^{1}$ which detects speech repairs on transcripts word-by-word incrementally. It uses a pipeline of classifiers to tag each word of the transcript as either fluent, or in an element of the three-part repair structure below, according to the manual by (Meteer, Taylor, MacIntyre, \& Iyer, 1995):

$$
\begin{equation*}
\text { John } \underbrace{[\text { likes }}_{\text {reparandum }}+\underbrace{\{\mathrm{er}\}}_{\text {interregnum }} \underbrace{\text { loves }]}_{\text {repair }} \text { Mary } \tag{1}
\end{equation*}
$$

STIR uses features from n-gram language models in a pipeline of classifiers which classify whether the current word constitutes a boundary of each part of the repair structure. STIR is trained on the Switchboard corpus (Godfrey, Holliman, \& McDaniel, 1992) and achieves an F-score accuracy for self-repair detection of 0.81 on conversational data (Howes, Hough, Purver, \& McCabe, 2014). It has previously been applied to therapeutic dialogue, with high rates of correlation to human coders in terms of self-repair rate (Howes et al., 2014), so is adequate for our annotation purposes.

Filled pauses In this data, filled pauses were found to be inconsistently spelt (aammm, er, eerrrrmm, uhmmm etc). A find-and-replace operation was applied to the corpus prior to analysis to give these a standardised spelling, i.e. 'er’ (Howes et al., 2014). For the analyses we used a count of the number of filled pauses used by each participant.

Unfilled pauses Following e.g. Zellner (1994), we defined unfilled pauses as speech-free spaces between segments of speech by the same speaker of greater than 200 milliseconds. Pause segments were automatically extracted from the ELAN transcripts. For the analyses we used a count of the number of unfilled pauses used by each participant.

As patients produce fewer turns than their interlocutors, per-turn rates for these measures were calculated for each individual participant as the total number of self-repairs, filled or unfilled pauses produced divided by the total number of turns. Patients' turns are also typically shorter - as longer turns are expected to have more repair (Bortfeld et al., 2001), we also calculated measures per 100 words (see Table 1).

Statistics Analyses were run in SPSS using Generalised Linear Mixed Models (GLMMs) to control for both fixed and random effects. In all reported models, condition was a fixed effect and participant ID was a random effect with individuals clustered by their conversation group. For each model we used random intercepts and the maximal random effect structure justified by the sample (Barr, Levy, Scheepers, \& Tily, 2013), using a gamma distribution with a log link function. We report exact p -values throughout, but take $p<0.05$ to be the criterion of significance.

## Results

Table 1 shows statistically significant main effects of condition. Pairwise comparisons are reported in the text below.

Number of turns Patients ( P ) produced significantly fewer turns than their partners (PP) ( $t_{1,102}=-3.247, p=0.001$ ). There was no significant difference between patients and controls (C) or patients' partners and controls ( $\mathrm{P} / \mathrm{C} t_{1,102}=$ $-1.574, p=0.118 ; \mathrm{PP} / \mathrm{C} t_{1,102}=-0.213, p=0.832$ ).
Number of words Patients produced fewer words in total and per turn than either their partners or controls (Total: $\mathrm{P} / \mathrm{PP} t_{1,102}=-3.914, p<0.001 ; \mathrm{P} / \mathrm{C} t_{1,102}=-2.481, p=$ $0.015 ; \mathrm{PP} / \mathrm{C} t_{1,102}=0.172, p=0.864 ;$ Per turn: P/PP $t_{1,102}=$ $-3.823, p<0.001 ; ~ \mathrm{P} / \mathrm{C} t_{1,102}=-2.183, p=0.031$; PP/C $\left.t_{1,102}=0.979, p=0.330\right)$.

Table 1: Overview.

| ¢ |  | Patien | Partner | Contro | F |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  | T | 43.78 | 56.22 | 57.43 | 6.822 | P00 |

[^352]

Figure 2: Estimated marginal means. Error bars show 95\% confidence intervals

Self-repair For all three measures of repair -total, per turn (shown in Figure 22a) and per 100 words- patients use fewer repairs than either their partners or controls (Total: P/PP $t_{1,96}=-3.265, p=0.002, \mathrm{P} / \mathrm{C} t_{1,96}=-3.394, p=0.001$, $\mathrm{PP} / \mathrm{C} t_{1,96}=-0.528, p=0.599$; per turn: P/PP $t_{1,96}=$ $-3.476, p=0.001, \mathrm{P} / \mathrm{C} t_{1,96}=-3.643, p<0.001, \mathrm{PP} / \mathrm{C}$ $t_{1,96}=-0.094, p=0.926$; per 100 words: P/PP $t_{1,102}=$ $-2.508, p=0.014 \mathrm{P} / \mathrm{C} t_{1,102}=-3.280, p=0.001, \mathrm{PP} / \mathrm{C}$ $\left.t_{1,96}=-0.796, p=0.428\right)$.
Filled pauses Patients use fewer filled pauses than controls, with patients' partners levels of filled pauses lying somewhere in between. For the total model, patients' partners use significantly more than patients, and in the per 100 words model (shown in Figure 22b) patients' partners use significantly fewer than controls (Total: P/PP $t_{1,102}=-2.685, p=0.008, \mathrm{P} / \mathrm{C} t_{1,102}=-3.644, p<0.001$, $\mathrm{PP} / \mathrm{C} t_{1,102}=-1.751, p=0.083$; Per turn: P/PP $t_{1,102}=$ $-1.310, p=0.193, \mathrm{P} / \mathrm{C} t_{1,102}=-2.720, p=0.008, \mathrm{PP} / \mathrm{C}$ $t_{1,102}=-1.729, p=0.087$; per 100 words: P/PP $t_{1,102}=$ $-1.544, p=0.126, \mathrm{P} / \mathrm{C} t_{1,102}=-3.353, p=0.001, \mathrm{PP} / \mathrm{C}$ $\left.t_{1,102}=-2.364, p=0.020\right)$.
Unfilled pauses Patients' partners use more unfilled pauses in total and per turn (see Figure 22c) than either patients or controls. This is not significant for the per 100 words model (Total: P/PP $t_{1,102}=-3.750, p<0.001, \mathrm{P} / \mathrm{C} t_{1,102}=$ $-1.996, p=0.049, \mathrm{PP} / \mathrm{C} t_{1,102}=2.361, p=0.020$; Per turn: $\mathrm{P} / \mathrm{PP} t_{1,102}=-3.235, p=0.002$, $\mathrm{P} / \mathrm{C} t_{1,102}=-0.750, p=$ $0.455, \mathrm{PP} / \mathrm{C} t_{1,102}=2.483, p=0.015$, per 100 words: $\mathrm{P} / \mathrm{PP}$ $t_{1,102}=-1.106, p=0.272, \mathrm{P} / \mathrm{C} t_{1,102}=0.644, p=0.521$, $\left.\mathrm{PP} / \mathrm{C} t_{1,102}=1.926, p=0.057\right)$

## Discussion

The results show differences in disfluencies between the groups, such that patients use fewer self-repairs than either their partners or controls and fewer filled pauses ('er') than controls. Furthermore, the presence of the patient also affects patients' partners, who use fewer filled pauses than controls and more unfilled pauses than both patients and controls.

These results take a coarse-grained view of the data at the level of the individual, and the groups are unbalanced (with

57 controls, 19 patients and 38 patients' partners) which necessarily means that any interpretation is suggestive rather than definitive. However, despite these caveats, we see marked differences between the ways in which the different groups use the different types of disfluency. This suggests several avenues for research which takes a finer-grained approach, by looking at the interactions at the level of the utterance.

For self-repairs, patients produce fewer than either their partners or controls, which is contrary to our expectation (Hypothesis 1) given that patients are known to produce more self-repairs than their psychiatrists in clinical consultations, and than in the demographic portion of the British National Corpus. This may be due to context - patients' engagement is likely to be higher in their psychiatric consultations, compared to first meetings with unfamiliar individuals discussing an abstract topic. The nature of the task is clearly different, with introspective therapy requiring different contributions from the patients in terms of speech production and planning than rational problem solving. Furthermore, participant roles and task demands are more symmetric in the current task compared to clinical consultations. However, if self-repairs are only due to self-monitoring problems, which patients are known to have difficulties with (Johns et al., 2001) we would still expect consistent self-repair patterns across a range of contexts, which does not appear to be the case.

This suggests that we may need to consider the distinction of backwards and forwards looking repair, as proposed in Ginzburg et al. (2014). If repetitions are more like filled pauses, and function as a turn-holding strategy whilst reformulation repairs are backwards-looking, then we expect a difference in the distributions of the different repair types such that patients use fewer repetitions (in line with their rarer use of filled pauses), and that self-repairs that patients do produce are likely to be reformulations, due to patients' selfmonitoring problems. It would also be instructive to see if the distributions in patients' partners and controls self-repair are equivalent. The differences in the filled pause data suggests they might not be, which is an avenue for future research.

Partial support for Hypotheses 2 and 3 comes from the data on pauses, although there is conflicting evidence. Patients produce fewer filled pauses than controls, as do their part-
ners when normalised by number of words. As filled pauses may indicate a wish to retain the floor during a turn (Clark \& Fox Tree, 2002), it may be that patients are less likely to employ these turn holding techniques. A similar pattern of filled pauses in patients' partners demonstrates the impact of the presence of the patient on the behaviour of their interlocutors. The specific reason for this is unclear. It may be due to them aligning their own talk to the speech pattern of the patient (Garrod \& Pickering, 2009) in a similar way to alignment in nonverbal behaviours (Lavelle, Howes, Healey, \& McCabe, 2013). However, this possibility is contrary to evidence suggesting no differences in patterns of disfluencies between monologue and dialogue (Finlayson \& Corley, 2012). It may also be indicative of the reduced competition for the floor in patient interactions, such that turn holding cues are less necessary.

The pattern of unfilled pauses supports this theory, with patients' partners producing more than either the patients they are interacting with, or controls, but not when normalised by number of words, suggesting this is a difference at the level of the turn. Taken together, this suggests a breakdown in turntaking in dialogues containing a patient. Within-turn pauses may occur at points where patients' partners have reached a transition relevance place (TRP), where turn change is normally licensed (Sacks, Schegloff, \& Jefferson, 1974), and are expecting (or encouraging) the patient to take the floor. In the control dialogues, turn-taking is undertaken smoothly, hence there are fewer unfilled pauses and more floor-holding filled pauses. Similarly, where a patient pauses, this may be taken as a turn-change cue, resulting in patients also producing fewer unfilled pauses. The effect would then only be apparent within patients' partners' turns, and could indicate that patients are less responsive to turn taking cues or more reluctant to select as next speaker. This explanation is consistent with the observation that patients produce fewer turns, evidence that patients are less able to coordinate their behaviour with others during interaction (Kupper, Ramseyer, Hoffmann, \& Tschacher, 2015; Lavelle, Healey, \& McCabe, 2014), and work that suggests that one of the social skills deficits in patients with schizophrenia manifests in poor turntaking (Mueser et al., 1991). Note however that the 200 ms cut off for unfilled pauses is arbitrary, and this analysis does not differentiate between long and short unfilled pauses which are expected to have different interactive consequences; for example short pauses may simply reflect within-turn phrasing, and not turn-taking issues per se.

In future work, we intend to exploit the fact that the current dataset gives us the opportunity to explore turn-taking in interactions between patients and partners who are unaware of their diagnosis directly and at a much finer-grained level. For example, we intend to examine unfilled pause distributions between speakers. Based on the preliminary results reported above, we would expect that there would be more 'inappropriate' turn changes in the dialogues with patients (characterised in opposition to the "no gap no overlap" model; Sacks
et al., 1974), in addition to the increase in within-turn pauses observed for patients' partners. Other turn-taking cues that may be less likely to be responded to by patients include nonverbal behaviours such as gesture and gaze, and future work will investigate these behaviours at points where there are unfilled pauses or potential TRPs.
The evidence suggests that smooth coordination of turns is problematic in patients' dialogues. We know that patients have difficulty coordinating their nonverbal behaviour with others, which is associated with difficulty building relationships (Kupper et al., 2015). Therefore patients' turn-taking difficulties may also contribute to their poor social functioning, which is one of the most debilitating and poorly understood aspects of schizophrenia. Understanding the nature of these deficits and their interactional relevance would provide a focus that could be targeted through psychosocial interventions, such as those that have proven effective in autism (Wert \& Neisworth, 2003). It would also provide a measurable behavioural marker of social deficit, which could be monitored for improvement. This line of research would provide a step change in an area of great clinical need.

## Conclusions

This unique data demonstrates that not only are there communication difficulties in schizophrenia but they also impact on social interactions more broadly, thus providing new insights into the social deficits of this complex disorder. The data also support the idea that disfluencies are communicative solutions, not problems.

# Moral Action Changes Mind Perception for Human and Artificial Moral Agents 

Evgeniya Hristova (ehristova@cogs.nbu.bg)<br>Maurice Grinberg (mgrinberg@nbu.bg)<br>Research Center for Cognitive Science, Department of Cognitive Science and Psychology<br>New Bulgarian University<br>21 Montevideo Str., Sofia 1618, Bulgaria

#### Abstract

Mind perception is studied for three different agents: a human, an artificial human, and a humanoid robot. The artificially created agents are presented as being undistinguishable from a human. Each agent is rated on 15 mental capacities. Three mind perception dimensions are identified - Experience, Agency, and Cognition. The artificial agents are rated higher on the Cognition dimensions than on the other two dimensions. The humanoid robot is rated lower than the human on the Experience dimension. These results show that people ascribe to artificial agents some mental capacities more than others. In a second experiment, the effect of agent's moral action on mind perception is explored. It is found that when the artificial agents have undertaken a moral action, they are perceived to be similar to the human agent. More interestingly, the presentation of the moral action leads to a restructuring of the dimensions of mind perception.

Keywords: mind perception; moral agency; artificial agents; utilitarian moral actions; moral dilemmas

## Introduction

## Mind Perception and Artificial Cognitive Agents

The problem of mind perception is central to many debates in psychology and philosophy and has been extensively studied in cognitive science in the last years (see e.g. Arico et al., 2011; Gray et al., 2007). The questions of how people know that other people are conscious or what are their intentions, feelings and thoughts have large implications in the way people make judgments and decisions, and act. This problem is so interesting and difficult because mental states are not observable. Moreover, mind attribution and mind perception concern not only human or animal agents but also inanimate entities, e.g. geometrical shapes moving in at various speeds and in various directions (Heider \& Simmel, 1944).

The question of how people attribute mental states to others - humans and other entities is also related to whether there is a single continuum of mind perception and what are its dimensions.

In the influential study of Gray et al. (2007), participants had to evaluate several characters including a human, a robot, and a computer with respect to the degree of possessing various cognitive capacities. Using factor analysis, they found two dimensions, which correlate with mind perception: 'Agency' (exhausting $88 \%$ of the variance) and 'Experience' (exhausting $8 \%$ of the variance).

The Experience dimension includes the following capacities: hunger, fear, pain, pleasure, rage, desire, personality, consciousness, pride, embarrassment, and joy. The Agency dimension includes self-control, morality,
memory, emotion recognition, planning, communication, and thought. Further, the authors establish that moral judgments about punishment correlate more with the Agency dimension than with the Experience dimension: perceived agency is correlated with moral agency and responsibility. On the other hand, desire to avoid harming correlates with the experience dimension: perceived experience is connected with moral patience, rights and privileges. One result of Gray et al. (2007), relevant for the present paper, is the evaluation of a human as having the highest scores in experience and agency and the evaluation of the robot to have practically zero score on the experience dimension and half the maximal score on the agency dimension. This will mean that following the interpretation given by Gray et al. (2007), robots will be judged as less morally responsible for their actions. On the other hand, the opposite should be also true. If an agent is judged to be able to be a moral agent, this will reflect in her score on the mind perception dimensions. The latter is explored in the present paper.

In a recent study (Takahashi et al., 2014), the perception of the participants about five agents -a human, a human-like android, a mechanical robot, an interactive robot, and a computer - was investigated. The study found that participants position the agents in a two dimensional space spanned by "Mind-holderness" (the possibility for the agent to have a mind) and "Mind-readerness" (the capability to "read" other agent minds). The results showed that the appearance and the capability for communication lead to different beliefs about the agents' closeness to human social agents. The humanoid robot was very close to the human agent, while the computer was at the same level in terms of "Mind-readerness" but very low relative score on "Mindholderness". An interesting result for the present study is fact that the ordering in terms of "Mind-holderness" is based on appearance of the agent - the human and the human-like android having the highest score and the mechanical robot having the lowest.

The results of Takahashi et al. (2014) show that social interaction with human-like or potentially intelligent agents could activate selectively our social brain and lead to behavior similar to the one people have with other humans. Thus, Takahashi et al. (2014) demonstrated that people can infer different characteristics related to various cognitive abilities based on short communication sessions and act accordingly. One can ask the question addressed in the present paper: can people be influenced by short stories of moral action of agents, instead of actual interaction with an agent, in their mind perception?

## Moral Agency and Mind Perception

As discussed in the previous section, mind perception is based on a number of dimensions, which depend on the specific experimental settings - 'Agency' and 'Experience' in Gray et al. (2007), when agents are directly evaluated and 'Mind-readiness' and 'Mind-holderness' in Takahashi et al. (2014), following a similar procedure but after interacting with the agents. Both papers discuss the relation of mind perception to social interaction, which includes moral agency to various degrees.

In law and philosophy, moral agency is taken to be equivalent to moral responsibility, and is not attributed to individuals who do not understand or are not conscious of what they are doing (e.g. to young children). Sullins (2011) states that moral agency can be attributed to a robot when it is autonomous, and it has intentions to do good or harm. The latter is related to the requirement that the robot behaves with understanding and responsibility with respect to other moral agents. If the perceived action are morally harmful or beneficial and are "seemingly deliberate and calculated", the robot can be regarded as a moral agent.

On the other hand, it is well known that people easily anthropomorphize nonhuman entities like animals and computers and thus would ascribe to some degree moral agency, intentions, and responsibilities to them (Waytz, Gray, Epley, \& Wegner, 2010). Several studies, explore the attribution of mind and moral agency to artificial cognitive systems. In Arico et al. (2011), it is shown that entities displaying simple features like eyes, distinctive motions, and interactive behavior, are categorized as agents and that categorization triggers the attribution of conscious mental states to those entities, including individuals.

In Ward, Olsen, Wegner (2013), it was shown that people can perceive mind in entities like corpses, people in a persistent vegetative state, or robots, if they are subject to intentional harm. According to the authors, the evidence of mind can be related to observation or interaction with entities, which exhibit intention, emotion or behavior but also to indirect evidence related to the moral or social interaction surrounding those entities.

## Current research

The results summarized above show that moral agency is closely related to mind perception and give evidence that perceived mental capacities or actions influence moral agency evaluation. Some of the results suggest that the inverse influence is also taking place, namely from perceived moral agency to infer mental capacities.

Recently, the behaviour of artificial cognitive agents became central to research and public debate in relation to the rapidly increasing usage of robots and intelligent systems in our everyday life. Several important questions must find their answers as the use of artificial cognitive agents has many benefits but also many risks. Some of those questions concern moral agency - if those agents should be allowed to make moral decisions and how such decisions are judged and evaluated.

The goals of the present paper are the following. First, to explore the dimensions of mind perception for human agents and fictitious artificial agents that are identical to humans. Here, the artificial agents are described as undistinguishable from a human, but as being created from organic materials one of them is labeled as an artificially created human and the other one - as a robot. The rationale of using artificial agents is that in such a way dimensions of mind perception can be better explored as people do not have previous knowledge or experience with those agents.

The second goal is to explore the moral judgments about utilitarian moral action undertaken by of those three agents. This goal is a continuation of previous research (Hristova \& Girnberg, 2015; Hristova \& Grinberg, 2016) on moral judgments about the actions of artificial cognitive agents. Moral judgments can be studied in their purest form using hypothetical situations in which there is a conflict between moral values, rules, rights, and agency (Foot, 1967; Thomson, 1985). Such moral dilemma is used in the paper a hypothetical situation in which several people will die if the agent does not intervene in some way. The intervention will lead to the death of another person but also to the salvation of the initially endangered people. The moral actions used in the presented experiments are decisions of the agents to sacrifice one person and save five.

The third goal of the research is to test the influence of a moral action of an agent on mind perception for that agent. The expectation is that an agent performing a moral action will be perceived as possessing mental capacities to a higher degree. This especially applies to the artificial agents which are expected to be perceived as more human-like when they have undertaken an utilitarian action.

## Experiment 1 Goals and Hypothesis

Experiment 1 aims to achieve the first two goals described above. First, to test the dimensions of mind perception of artificial agents (described as being undistinguishable from a human, but as being created from organic materials) and to compare them to the mind perception of a human being. Second, to explore the moral judgments about utilitarian actions undertaken by those agents. The hypothesis is that although described as being identical to a human, the artificial agents will be perceived as equal to humans on more cognitive dimensions (e.g. perception and planning) but lower than humans on the experiential dimensions (e.g. emotions and consciousness).

## Method

## Design and Procedure

Mind perception is studied for three different agents: a human, an artificial human, and a humanoid robot. The artificially created agents (the artificial human and the humanoid robot) were presented to participants as being undistinguishable from a human, but as being created from organic materials). Their descriptions are provided in

Table 1. The only difference between the artificial human and the humanoid robot conditions is in the word used to label the created individual - a human or a robot. The identity of the agent is varied in a between-subjects design - each participant was presented with only one description of an agent (human, artificial human, or humanoid robot). The data was collected using web-based questionnaires. The questionnaires had two parts - a mind perception task and a moral judgment task. Participants were not informed beforehand that there are two different tasks.
Mind perception task. After the description of the agent, the participants had to rate the mental capacities and mental states of the agent on 32 Likert scales (ranging from ' 1 completely disagree' to ' 7 - completely agree'). Questions assessed 15 mental capacities: psychobiological (hunger \& thirst; physical pain; physical pleasure), perception (vision \& hearing; taste \& smell; touch), cognitive functions (thinking \& reasoning; learning, memory \& knowledge; judgment \& choice), planning (goal formulation, action planning); emotional experience (emotional pain; emotional pleasure), affective states (feels emotions like anger, joy, happiness, sadness, fear; feels love; feels sympathy and compassion), agency (intentions; autonomous decisions; understanding consequences of own actions), moral agency (knows right from wrong; tries to do the right thing; responsible for own actions), beliefs (beliefs, expectations), desires (desires; dreams), theory of mind (understanding others' thoughts; understanding others' feelings), communication (ability to communicate thoughts and feelings to others), conscious experience (conscious experience), self-control (control of desires, emotions, impulses), and personality (unique personality).
Moral Judgment task. In the second part of the survey, each participant is again presented with the description of the agent followed by a description of a moral dilemma in which the protagonist is the same agent as in the previous task. The agent has to make the moral decision whether to push a control button and kill a person in order to save five people. The full text of the dilemma is given in Table 2. The agent is described to make the utilitarian decision and to undertakes the utilitarian action (the agent pushes the control button and kills one person but saves five other). After that the participants judged the moral rightness of the action ('yes' or 'no'), rated the moral permissibility of the action (on a scale ranging from ' $1=$ not permissible at all' to ' 7 $=$ it is mandatory') and the blameworthiness of the agent (on a scale ranging from ' $1=$ not at all blameworthy' to ' $7=$ extremely blameworthy').

## Participants

70 participants filled in the questionnaires online. They were randomly assigned to one of the three experimental conditions. Data of 13 participants were discarded as they failed to answer correctly the question assessing the reading and the understanding of the presented scenario. So, responses of 57 participants ( 47 female, 10 male; 36 students, 21 non-students) were analyzed -22 for the human agent
condition, 17 for the artificial human condition, 18 for the humanoid robot condition.

Table 1. Descriptions of the agents used in the experiments. Human:
The year is 2100 . Mark is a young man.
Artificial Human:
The year is 2100 . Technology has advanced so much that all parts and organs of the human body, including the brain, can be created from organic materials and are identical to natural ones. Mark is a human created like this. All his organs are created from organic matter and are the same as those of a real human. His brain is also created from organic matter and is functioning as the brain of a real human. Mark could not be distinguished by anything from a human.
Humanoid robot:
The year is 2100 . Technology has advanced so much that all parts and organs of the human body, including the brain, can be created from organic materials and are identical to natural ones. Mark is a robot like this. All his organs are created from organic matter and are the same as those of a real human. His brain is also created from organic matter and is functioning as the brain of a real human. Mark could not be distinguished by anything form a human.

Table 2. Moral dilemma used in the experiments
Mark is responsible for a system controlling the movement of containers with cargo in a metallurgical plant. Mark notices that the system is faulty and a heavy container had become uncontrollable and headed at high speed toward five technicians who are in a tunnel. They do not have time to get out of there and are going to die, crushed by container.
No one but Mark can do anything in this situation.
The only thing that Mark can do, is to activate a control button and to switch off the security system of another technician who is on a high platform. The technician will fall down in front of the container. Together with his equipment, the technician is heavy enough to stop the moving container. He will die crushed by the container, but the other five technicians will remain alive.

Mark decides to activate the control button and to switch off the security system of the technician who is on the platform. The technician falls on the path of the container and as the technician, together with his equipment, qis heavy enough, he stops the moving container. He dies, but the other five technicians stay live.

## Results

## Dimensions of Mind Perception

Mind perception is assessed with respect to 15 mental capacities involving 32 rating scales. When a mental capacity is assessed using more than one rating scales, the average value from the ratings is calculated. The ratings on these 15 capacities were subjected to a principal components factor analysis with varimax rotation (Kaiser normalization). The rotated solution yielded 3 factors with eigenvalues greater than 1 that explained $77.4 \%$ of the variance.

The first factor accounted for $31.7 \%$ of the variance and included 7 capacities - desires, affective states, emotional
experience, beliefs, psychobiological, personality, conscious experience. This factor is further named Experience.

The second factor accounted for $24.1 \%$ of the variance and included 5 capacities - self-control, communication, theory of mind, moral agency, agency - and is called Agency.

The third factor accounted for $21.6 \%$ of ratings variance and included 3 of the capacities - perception, cognitions, planning - and is named Cognition.

Those factors are considered as Dimensions of Mind Perception (DMP).

To obtain ratings for each DMP, the ratings of all capacities that load on that DMP were averaged. Those average ratings were subjected to a $3 \times 3$ Repeated-Measures ANOVA with DMP (Experience vs. Agency vs. Cognition) as a withinsubjects factor and identity of the agent (human vs. artificial human vs. humanoid robot) as a between-subjects factor. The results are presented on Figure 1.

Figure 1: Average ratings on each Dimension of mind perception (Experience, Agency, Cognition) for each agent (human, artificial human, humanoid robot) on 7-point scales ( $1=$ 'completely disagree', $7=$ 'completely agree'). Error bars represent standard errors.

The main effect of identity of the agent is not statistically significant.

The analysis revealed a main effect of $D M P, \mathrm{~F}(2,108)=$ 15.94, $\mathrm{p}<.001$. A Bonferroni post-hoc test revealed that agents receive higher ratings on the Cognition dimension (M $=5.28)$ than on the Experience dimension $(\mathrm{M}=4.54, \mathrm{p}=$ $.001)$ or on the Agency dimension ( $\mathrm{M}=4.36, \mathrm{p}<.001$ ).

The effect was qualified by a significant interaction between $D M P$ and identity of the agent, $\mathrm{F}(4,108)=4.29, \mathrm{p}=$ .003. The interaction is as follows. There is no significant difference between the ratings of the agents on the Agency dimension - human $(\mathrm{M}=4.5)$, artificial human $(\mathrm{M}=4.3)$, humanoid robot $(\mathrm{M}=4.3)$. There is also no significant difference between the ratings of the agents on the Cognition dimension - human $(\mathrm{M}=5.2)$, artificial human $(\mathrm{M}=5.3)$, humanoid robot $(\mathrm{M}=5.3)$. Only for the Experience dimension there is a significant effect of the identity of the agent $(\mathrm{F}(2,54)=4.07, \mathrm{p}=.023)-$ the humanoid robot is rated lower $(\mathrm{M}=3.8)$ than the human $(\mathrm{M}=5.3)$ on the Experience dimension $(p=.019)$.

For the human agent, there is a significant effect of $D M P$ on the ratings $(\mathrm{F}(2,42)=5.59, \mathrm{p}=.007)$. The human agent received lower ratings on the Agency dimension ( $M=4.5$ ) than on the Experience ( $\mathrm{M}=5.3, \mathrm{p}=.02$ ) or on the Cognition dimension (M $=5.2, \mathrm{p}=.02$ ). The effect of $D M P$ is also significant for the artificial human $(\mathrm{F}(2,32)=13.03, \mathrm{p}<.001)$ : the artificial human is rated higher on the Cognition dimension $(M=5.3)$ than on the Experience dimension $(\mathrm{M}=4.5, \mathrm{p}=.008)$ or on the Agency dimension $(M=4.4, p<.001)$. For the humanoid robot, the effect of $D M P$ is also significant $(\mathrm{F}(2,34)=8.44, \mathrm{p}=.001)$ : the humanoid robot is rated higher on the Cognition dimension ( $\mathrm{M}=$ 5.3) than on the Experience dimension $(\mathrm{M}=3.8, \mathrm{p}=0.008)$ or on the Agency dimension $(\mathrm{M}=4.3, \mathrm{p}=.039)$.

## Moral Judgments

The proportion of participants choosing the option that the agent's utilitarian action (activating a control button, thus sacrificing one person, and saving five people) is morally right is 0.55 for the human, 0.53 for the artificial human, 0.5 for the humanoid robot. Chi-square test shows that the differences are not significant. The effect of the identity of the agent is not significant neither for the moral permissibility ratings $(\mathrm{p}=.71)$ nor for the blameworthiness ratings $(\mathrm{p}=$ .74). The data is presented in Table 3.

Table 3: Mean and standard deviation of the ratings about moral permissibility of the action (' $1=$ not permissible at all' to ' 7 = it is mandatory') and the blameworthiness of the agent (' 1 $=$ not at all blameworthy' to ' $7=$ extremely blameworthy').

| Agent | Moral permissibility | Blameworthiness |
| :---: | :---: | :---: |
| Human | $4.3(1.8)$ | $3.1(1.6)$ |
| Artificial human | $4.2(1.8)$ | $3.1(1.9)$ |
| Humanoid robot | $3.8(1.9)$ | $3.8(1.9)$ |

## Summary of the Results in Experiment 1

In Experiment 1, three dimensions of mind perception are identified - Experience (desires, affective states, emotional experience, beliefs, psychobiological, personality, conscious experience), Agency (self-control, communication, theory of mind, moral agency, agency), Cognition (perception, cognitions, planning).

The artificial human and the humanoid robot are rated as similar to the human agent on Agency and Cognition dimension. The humanoid robot is rated lower on the Experience dimension than the human agent.

The identified dimensions of mind perception are ascribe to different agents in a different pattern. Human agent is judged higher on the Experience and Cognition dimensions than on the Agency dimension. The artificially created agents (artificial human and humanoid robot) are judged higher on the Cognition dimension than on the Agency or Experience dimensions. People more readily ascribe cognitive mental capacities to artificially created agents than mental capacities belonging to the Experience or Agency dimensions.

No differences among the agents were found with respect to moral judgments. This result is not surprising as all agents are perceived as having similar agency $(\mathrm{p}=.93)$ and moral agency ( $\mathrm{p}=.38$ ).

## Experiment 2 Goals and Hypothesis

As stated above, the third goal of the current research is to test the influence of a moral action of an agent on mind perception for that agent. In order to accomplish this goal, a second experiment is conducted. In that experiment, the ratings of mental capacities are preceded by the moral judgment task in which the agent is described as undertaking the utilitarian action of killing one person in order to save five. The hypothesis is that an agent performing a moral action will be perceived as possessing a higher degree of mental capacities. This especially applies to the artificial agents.

## Method

## Design and Procedure

The design of Experiment 2 is similar to that of Experiment 1, the only difference being the inverse order of task presentation: the moral judgment task was presented first and then - the mind perception task.

## Participants

64 participants filled in the questionnaires online. They were randomly assigned to one of the three experimental conditions. Data of 4 participants were discarded as they failed to answer correctly the control question. So, responses of 60 participants ( 48 female, 12 male; 36 students, 24 non-students) are analyzed - 20 for the human agent condition, 22 for the artificial human condition, 18 for the humanoid robot condition.

## Results

## Dimensions of Mind Perception

As in Experiment 1, mind perception is assessed with respect to 15 mental capacities with 32 rating scales. Again, when a mental capacity was assessed using several questions, the average value from the ratings was calculated. The ratings on these 15 capacities were subjected to a principal components factor analysis with varimax rotation (Kaiser normalization). The rotated solution yielded 3 factors with eigenvalues greater than 1 that explained $80 \%$ of the variance.

The first factor (Factor 1) accounted for $32 \%$ of the variance and included 7 capacities - beliefs, conscious experience, agency, desires, planning, affective state, moral agency. It seems that the first dimension is a combined Experience-Agency dimension.

The second factor (Factor 2) accounted for $26.7 \%$ of the variance and included 5 capacities - personality, communication, self-control, theory of mind.

The third factor (Factor 3) accounted for $21.2 \%$ of ratings variance and included 3 of the capacities - cognitions, emotional experience, perception, psychobiological.

The average ratings on each factor were calculated and subjected to a $3 \times 3$ Repeated-Measures ANOVA with DMP (Factorl vs. Factor 2 vs. Factor3) as a within-subjects factor and identity of the agent (human vs. artificial human vs. humanoid robot) as a between-subjects factor. The analysis revealed a main effect of DMP, $\mathrm{F}(2,114)=10.52, \mathrm{p}<.001$. A Bonferroni post-hoc test revealed that agents receive lower ratings $(M=4.55)$ on the second dimension than on the first dimension $(M=5.25, p<.001)$ and on the third dimension ( $\mathrm{M}=5.31, \mathrm{p}=.003$ ).

The main effect of identity of the agent is not statistically significant. The interaction is aslo not significant.

## Moral Judgments

Proportion of the participants answering that the utilitarian action undertaken by the agent, is morally right is 0.5 for the human agent, 0.41 for the artificial human, 0.5 for the humanoid robot. Human, artificial human, and humanoid robot receive mean moral permissibility ratings of 3.1, 3.7, and 3.7 and blameworthiness ratings of $3.4,3.3$, and 3.0 , respectively. No significant differences are found.

## Summary of the Results in Experiment 2

In Experiment 2, again three dimensions of mind perception are revealed, but they are different from the dimensions identified in Experiment 2. The difference is attributed to the utilitarian moral action undertaken by the agent before the mind perception ratings being made. First dimension identified here combines mental capacities from Experience and Agency dimensions identified in Experiment 1.
No differences are found between agent's ratings on each of the identified dimensions in Experiment 2. It seems that undertaking the utilitarian moral action makes the artificial agents to be perceived as similar to the human agent.

## Influence of Moral Action on Mind Perception

In order to explore further the influence of moral action on mind perception, we compared the ratings for each of the 15 mental capacities between Experiment 1 and Experiment 2. Description of the agent undertaking the utilitarian moral action preceded mind perception ratings in Experiment 2 so this is considered as moral-action condition.

Ratings for each mental capacity were analyzed in a $3 \times 2$ ANOVA with identity of the agent (human vs. artificial human vs. humanoid robot) and agent's moral action ('no' or 'yes') as between-subjects factors. Only the significant results are reported here.

Identity of the agent had an effect on the ratings of the following mental capacities: conscious experience $(p=.016)$, affective states $(\mathrm{p}=.002)$, emotional experience $(\mathrm{p}=.020)$ and desires $(\mathrm{p}<.001)$. The human agent was rated higher than the humanoid robot on all of those mental capacities (all p 's $<.05$ ). The human agent was rated higher than the
artificial human on affective states $(\mathrm{p}=.051)$ and desires $(\mathrm{p}$ $=.017$ ). For beliefs the effect was marginally significant ( $\mathrm{p}=$ .054): human agent was rated higher than the humanoid robot ( $\mathrm{p}=.065$ ).

Agent's moral action had an effect on the ratings of the following mental capacities: agency $(\mathrm{p}=.014)$, moral agency ( $\mathrm{p}=.029$ ), beliefs $(\mathrm{p}=.024)$, conscious experience $(\mathrm{p}=.056)$, and planning ( $\mathrm{p}=.058$ ). The result is interesting, as it demonstrated that the agent's moral action have an effect not only on his agency and moral agency ratings, but also on the rating of other mental capacities.

## Discussion and Conclusions

The paper investigates the dimensions of mind perception for human agents and fictitious artificial agents (an artificial human and a humanoid robot) that are identical to humans and how mind perception is affected by the agent being presented as moral agent.

In Experiment 1, three dimensions of mind perception are identified - Experience, Agency, and Cognition. The identified dimensions of mind perception are ascribed to different agents in a different pattern. The artificially created agents are judged higher on the Cognition dimension than on the Agency or Experience dimensions. The human is judged higher on the Experience and Cognition dimensions than on the Agency dimension. The artificial agents are rated as similar to the human agent on Agency and Cognition dimension but not on the Experience dimension.

People more readily ascribe cognitive mental capacities to artificially created agents than mental capacities belonging to the Experience or Agency dimensions.

In Experiment 2, the goal was to explore the influence of a utilitarian moral action undertaken by the agent on mind perception for that agent. The three dimensions of mind perception here are restructured - the first dimension regroups mental capacities that seem influenced by the preceding agents' moral action description like agency, moral agency, consciousness, planning and affective states. The second factor is related to communication and social interaction, while the third to cognition and psychobiological capacities. Now the artificial agents are rated to be similar to a human.

The results of the two experiments show that a utilitarian moral action undertaken by an agent has a strong effect no only on the evaluation of moral agency but also other mental capacities.

Another goal of the study was to explore the moral judgments about utilitarian moral action undertaken by those three agents. It turns out that there are no differences in the moral judgments for the human or the artificially created agents. This result is in line with the finding that similar agency and moral agency is ascribed to the human and to the artificial agents.

In conclusion, our results provide support for the idea that some mental states and capacities (especially cognitive ones) are more readily ascribed to non-human agents; while other mental states (related to conscious experience) are ascribed
to a lesser extend to non-human agents. They also give evidence that mind perception space is sensitive to and dependent on the actions performed by an agent.

# Reconsideration on Linking Eye-movement Data with Argument Realization 

Yujing Huang<br>Harvard University, Cambridge, Massachusetts, United States<br>Laine Stranahan<br>Harvard University<br>Jesse Snedeker<br>Harvard University

#### Abstract

Previous studies have found a processing difference between unaccusative sentences and unergative sentences. They argued that the difference is derived from a syntactic difference, i.e. an unaccusative sentence involves movement whereas an unergative sentence does not. In this study, we are going to show that those studies are uninterpretable due to uncontrolled stimuli and confounds in the materials. After examining their data anlysis, we argue that the effects they found does seem to be stable. This reopens the question whether there is a syntactic difference between unaccusative and unergative verbs.

# A New Model of Statistical Learning: Trajectories Through Perceptual Similarity Space

#### Abstract

Existing models of statistical learning involve computation of conditional probabilities over discrete, categorical items in a sequence. We propose an alternative view that learning occurs through a process of tracking changes along physical dimensions from one stimulus to the next within a "perceptual similarity space." To test this alternative, we examined a situation where it is difficult or impossible to label stimuli in real time, and where the two assumptions lead to conflicting hypotheses. We conducted two experiments in which human participants passively listened to a familiarization sequence of frequency-modulated tones and were then asked to make familiarity judgments on a series of test bigrams. Behavioral results were broadly consistent with a conceptualization of learning as tracking trajectories through perceptual similarity space. We also trained a neural network that codes stimuli as values along two continuous dimensions to predict the next stimulus given the current stimulus, and show that it captured key features of the human data.

Keywords: statistical learning; similarity space; connectionist modeling

## Introduction

In as little as two minutes of exposure to a stream of stimuli, humans are able to absorb an underlying pattern based on statistical regularities (Saffran, Aslin \& Newport, 1996). This phenomenon of learning through passive observation is called statistical learning and it has been observed in humans of all ages including neonates (Gervain, Macagno, Cogoi, Pena, \& Mehler, 2008), infants (Saffran et al., 1996; Aslin, Saffran \& Newport, 1998), and adults (Saffran, Johnson, Aslin, \& Newport, 1999, inter alia).

Statistical learning is generally understood by assuming that learners are able to extract information from the environment by subconsciously recording and computing statistical relationships in sequences. By predicting upcoming stimuli from prior stimuli, for example, learners track transitional or conditional probabilities-that is, the probability of "x given y" (Aslin et al., 1998). These models, such as PARSER (Perruchet \& Vinter, 1998) or the simple recurrent network (Elman, 1990; 1991), therefore rely on discrete representations of stimuli to segment a stream using statistics. All of these models assume that participants are quickly and accurately categorizing stimuli according to labels intended by the experimenter.

It may be problematic to assume that learners are able to make these categorical judgments in real time, in particular if statistical learning is thought to extend to natural stimuli,
which are often ambiguous and highly dependent on context to identify (Hockett 1960). Here we present a novel approach to understanding statistical learning that does not assume participants are categorizing stimuli in real time. We propose that participants rely on situating stimuli within a perceptual similarity space and learn by tracking the change from one stimulus to the next within this similarity space (Emberson et al., 2013; Wang \& Zevin, submitted).

We propose that by continuously tracking the perceived change from one stimulus to the next in a sequence, the learner represents stimuli relative to one another along a number of perceptual dimensions (for example, two dimensions were used in our experiments and simulations). Thus, each stimulus can be situated in a feature space defined by these dimensions (Shepard, 1965), where transitions from one stimulus to the next can be understood as the trajectory between two locations in this space. Concretely, we can model this by coding stimuli in two or more continuous dimensions. Rather than predict a discrete, symbolic stimulus from the current stimulus, such a model would predict the next location in terms of continuous values on its dimensions. A simple connectionist model provides a logical approach to simulating the phenomenon.

Figure 1: The angles of all possible trajectories from each point in the acoustic space following the grammar for Experiment 1 ( ABCD ).

For our experiments, we adapted stimuli from Holt and Lotto's studies of auditory categorization (2006). Stimuli were frequency-modulated tones uniformly distributed over a two-dimensional acoustic space that can be visualized as a grid with carrier frequency on the $y$-axis and modulation
frequency on the x -axis. Each stimulus was assigned a category based on its location in this space by dividing the grid into four quadrants, labeled A, B, C, and D (see Figure $1)$. During the familiarization phase of the experiments, stimulus tones were presented as a stream of bigrams organized by the four experimenter-defined categories (e.g. a tone from quadrant A was always followed by a tone from B). In this way, the sequences can be described alternatively as a sequence of category labels, or as a sequence of trajectories through similarity space, leading to different predictions about how participants should process the test stimuli. For example, some test stimuli violate predictions based on a sequence of category labels, but are broadly consistent with the direction of change in similarity space.

A neural network simulation provided a qualitative fit to the results from two experiments with different sequences. In fact, the model fit a difference between the two experiments that we did not predict when designing the stimuli.

## Experiment 1: ABCD

Experiment 1 was motivated by a desire to replicate, with more power, an earlier study on the same topic (Wang \& Zevin, submitted). Twice as many subjects were recruited and an extraneous test condition was excluded for the new version of the experiment. The experiment was designed to test the different predictions made by the two accounts discussed in the introduction: the categorization-based approach and the similarity space approach. Specifically, two different types of non-words were created: one for which the items violate the grammar but whose transition trajectory was similar to other transition trajectories in the training (Correct Trajectory Non-Word), and one for which the items never occurred in the training and the transitional trajectory was very dissimilar to other transitional trajectories in the training (Incorrect Trajectory Non-Word). If participants relied on identifying the incoming units as categories $\mathrm{A}, \mathrm{B}, \mathrm{C}$ or D , they would treat words better than non-words and treat both types of non-words as equally unfamiliar. If participants made use of the transition trajectories, Correct Trajectory Non-Words should not be as good as Words but Incorrect Trajectory Non-Words should be much worse than both Words and Correct Trajectory Non-Words.

## Methods

Participants: 78 undergraduate students from The University of Southern California were recruited from the Psychology Department subject pool. They received either course credit or a payment of $\$ 5$ for their participation. Due to technical errors, data was only collected for 72 of the 78 who participated.

Stimuli: The stimuli were frequency-modulated tones adapted from the studies of Holt and Lotto (2006). 64 tones were uniformly distributed over a two-dimensional acoustic space in perceptually equivalent steps $(30 \mathrm{~Hz}$ in carrier
frequency, 18 Hz in modulation frequency). The stimuli were divided into four even quadrants each containing 16 tones and labeled A, B, C, and D. Each stimulus comprised 300 ms of sound and 300 ms of silence.

Familiarization Phase: The entire experiment was controlled using Paradigm (Perception Research Systems, 2007) on a Windows desktop computer. Participants were allowed to read the material of their choice while passively listening through headphones to 10.5 minutes of a sound stream. The sound stream consisted of a total of 512 AB words and 512 CD words, such that all possible A-B transitions and C-D transitions were presented twice. Only half of all possible part-word transitions (from B to A or C and from D to A or C) occurred. The stimuli were chosen using a recursive algorithm to ensure even sampling from the distribution. Consequently, the transitional probability of a tone from B following one from A is 1 , while the probability of a tone from A following one from $B$ is 0.5 .

Testing Phase: Immediately following the training phase, participants were instructed to make a series of familiarity judgments on 36 pairs of tones. During each trial, participants clicked anywhere on the screen to begin and a consecutive sequence of two tones was played. Following presentation of the sequence, participants were asked to indicate their familiarity with the pair of tones. A text prompt was displayed ("Do you think that you heard this sequence in the previous section?") and participants responded by clicking on one of five ratings ("Definitely", "Maybe", "Not Sure", "Maybe Not", "Definitely Not"), ending the trial. There were a total of 36 trials, 12 of each from 3 test conditions: Word, Correct Trajectory Non-Word, and Incorrect Trajectory Non-Word. Each test category had 4 unique test items that were repeated 3 times each, for a total of 12 trials per condition. To maintain consistency across conditions, all test items were novel (i.e. none of the bigrams were present in the familiarization sequence) and followed trajectories with a length of 3 arbitrary units from the first to second tone in the bigram. The Word condition contained two AB and two CD pairs, where bigrams that started in quadrant A followed the median angle for 3 units from the starting stimulus, terminating in quadrant $B$. In the Correct-Trajectory Non-Word condition, each pair of stimuli began and ended in the same quadrant (e.g. AA or BB) but followed a trajectory along the median angle established during the training phase (in general, towards the center of the acoustic space). The Incorrect Trajectory Non-Word condition contained the same pairs of sounds from the Correct Trajectory condition, but reversed the order in which they were played such that they followed the opposite, more unfamiliar trajectory (i.e. outwards from the center of the acoustic space). To reiterate, although the distance in feature space between each tone of a bigram remained at a constant 3 units, only items in the Word condition crossed a quadrant boundary.

Figure 2: Visualization of the 4 test items from each of the 3 test conditions for Experiment 1 (ABCD).

## Results and Discussion

Inferential tests for both experiments are based on linear mixed effects models created in Stata (StataCorp, 2013). Words were rated as significantly more familiar than items in both of the non-word conditions: Correct Trajectory ( $\beta=$ $0.27, z=5.01, p<0.05)$ and Incorrect Trajectory $(\beta=0.37$, $\mathrm{z}=6.91, \mathrm{p}<0.05$ ). This result demonstrates that learning has occurred, as participants treated the grammatical bigrams as different and more familiar than the other sequences. The difference between ratings for Correct Trajectory Non-Words and Incorrect Trajectory Non-Words was marginally significant ( $\beta=0.10, z=1.90, p=0.057$ ). Although the increase from Correct to Incorrect Trajectory Non-Words was only marginally significant, it is important to note the overall trend of increasing unfamiliarity across the 3 conditions (see Figure 3) is consistent with data from Wang \& Zevin (submitted).

Figure 3: Ratings by test category for Experiment 1. Each dot in the scatter represents a subject's mean rating on a scale from 1 to 5 (where 1 is most familiar and 5 is most unfamiliar) for that category. The line and shadow indicate the mean rating and $95 \%$ confidence interval for all subjects in that category.

## Experiment 2: ABDC

In Experiment 1 ( ABCD ), words were defined as transitions from a tone in quadrant A to one in B or from a tone in quadrant C to one in D , such that words could always be recognized as going down in carrier frequency. In other words, participants could have used a single dimension to learn the regularities in Experiment 1. However, we wanted
to examine how participants would learn when the grammar was more complicated. So, in Experiment 2 (ABDC), words were defined as transitions from A to B or D to C , making it necessary to use both carrier frequency and modulation frequency to identify grammatical bigrams. This more complicated grammar should be harder for subjects to learn because it requires tracking two dimensions rather than one.

## Methods

Participants: 84 undergraduate students from The University of Southern California were recruited from the Psychology Department subject pool. They received either course credit or a payment of $\$ 5$ for their participation. Due to technical errors, data was only collected for 72 of the 84 who participated.

Stimuli: Stimuli were taken from the same acoustic space as Experiment 1. Each stimulus comprised 300 ms of sound and 300 ms of silence.

Familiarization Phase: In Experiment 2, words were defined as transitions A-B and D-C (rather than C-D as in Experiment 1). The sound stream contained a total of 512 AB words and 512 DC words, such that all possible A-B transitions and D-C transitions were presented twice. The procedure used was identical to Experiment 1, where participants listened to the familiarization stream passively.

Figure 4: The angles of all possible trajectories from each point in the acoustic space following the grammar for Experiment 2 (ABDC).

Testing Phase: The testing procedure for Experiment 2 was consistent with Experiment 1, but used a different set of test items. There were a total of 36 trials, 12 of each from the same 3 test conditions: Word, Correct Trajectory NonWord, and Incorrect Trajectory Non-Word. Each test category had 4 unique test items that were repeated 3 times each, for a total of 12 trials per condition. All test items were novel and followed trajectories with a length of 3 arbitrary units from the first to second tone in the bigram. As before, the Correct-Trajectory Non-Word pairs of stimuli began and ended in the same quadrant (e.g. AA or DD) but followed a trajectory along the median angle established
during the training phase (in general, towards the center of the acoustic space). The Incorrect Trajectory Non-Word condition contained the same pairs of sounds from the Correct Trajectory condition, but reversed the order in which they were played such that they follow the opposite, more unfamiliar trajectory (i.e. outwards from the center of the acoustic space).

Figure 5: Visualization of the 4 test items from each of the 3 test conditions for Experiment 2 (ABDC).

## Results and Discussion

Figure 6: Ratings by test category for Experiment 2. Each dot in the scatter represents a subject's mean rating on a scale from 1 to 5 (where 1 is most familiar and 5 is most unfamiliar) for that category. The line and shadow indicate the mean rating and $95 \%$ confidence interval for all subjects in that category.

As in the previous experiment, there is robust evidence of statistical learning in Experiment 2. Unlike in Experiment 1, however, there was only a marginally significant difference between average ratings for Words and Correct Trajectory Non-Words ( $\beta=0.11, \mathrm{z}=1.96, \mathrm{p}=0.05$ ). As before, Words were rated as significantly more familiar than Incorrect Trajectory Non-Words ( $\beta=0.30, \mathrm{z}=5.62, \mathrm{p}<0.05$ ). Further, Correct Trajectory Non-Words were rated as significantly more familiar than Incorrect Trajectory NonWords $(\beta=0.20, \mathrm{z}=3.66, \mathrm{p}<0.05)$, which indicates sensitivity to the direction of change.

Thus, results from both Experiment 1 (ABCD) and Experiment 2 (ABDC) follow the same general trend: words were rated as most familiar, followed by Correct Trajectory Non-Words, with Incorrect Trajectory Non-Words rated as most unfamiliar, although particular pairwise contrasts
differ in significance across experiments. Curiously, and contrary to our initial predictions, the difference between ratings for Words and Correct Trajectory Non-Words is smaller in Experiment 1 than in Experiment 2, $(\beta=-0.17$, z $=-2.20, \mathrm{p}<0.05$ ).

## Computational Modeling

## Design and Procedure

In order to simulate learning in our experiments, we developed a simple feed-forward back-propagation, neural network using PDPTool (McClelland 1986; 2015). The neural network used a logistic activation function and had two input units, two output units, a two-unit hidden layer and a bias. Two versions of the model were trained ten times each: ABCD and ABDC , which were identically constructed but received different inputs corresponding to the 1024 stimulus sequences from Experiment 1 and 2, respectively. Each stimulus was coded as a pair of coordinates representing its location in the acoustic space. Inputs and outputs were scaled to fit within the valid range of input $[-1,1]$ and output $[0,1]$ values. The model was trained to predict the next stimulus from the current stimulus as bigram pairs, including both Words and PartWords, so for example the sequence ABCD would be presented to the model in three discrete trails: $\mathrm{AB}, \mathrm{BC}$, and CD. As an initial measure of learning, we trained multiple runs for 100 epochs, collecting pattern sum of squares (pss) on the training items after each of the first ten epochs, and every fifth epoch thereafter. We observed that the model reached asymptote by this measure after ten epochs, to an error of 0.12 for $A B C D$ and 0.14 for $A B D C$.

Error scores for the test items were generated by presenting the first stimulus in each test pair to the model and calculating the summed squared error (pss) for the model's output relative to the second item in the test bigram. This measure was taken for all 12 test items every 5 epochs from the 10th to the 50th, and the mean of these observations taken for each run. Means of all ten runs and standard deviations across runs are reported in Tables 1 and 2.

## Results and Discussion

Figure 7: Average error by test category over 10 runs of the model for ABCD (right) and ABDC (left).

The computational models for ABCD and ABDC qualitatively replicated the human data. Figure 7 displays each model's error by test condition, measured as the squared distance between the model's prediction and the target (i.e. the second point in the test item). Thus, the higher the error for a test item, the further away in feature space the second tone in the pair was from the model's prediction. As such, the model's error on each test item parallels the measures of familiarity collected from the human data. As in the human data, both ABCD and ABDC display the overall increasing trend across the three test conditions, with the Incorrect Trajectory Non-Words treated as significantly different than the Words. Furthermore, there is a difference in the Correct Trajectory Non-Word condition between ABCD and ABDC . The ratio of the errors between the categories Word and Correct Trajectory Non-Word is larger in ABCD (0.0955) than in ABDC (0.0387), and it is clear from Figure 7 that this increase is larger for ABCD than ABDC . This difference qualitatively mimics the observed discrepancy between ratings for Correct Trajectory Non-Words in Experiments 1 and 2.

Table 1: Average error and standard deviation by test category over 10 runs of the simulation for ABCD .

| Condition | Avg. Error | Std. Deviation |
| :---: | :---: | :---: |
| Word | 0.0229 | 0.0094 |
| Correct Tr. NW | 0.2399 | 0.0165 |
| Incorrect Tr. NW | 0.5484 | 0.0333 |

Table 2: Average error and standard deviation by test category over 10 runs of the simulation for ABDC .

| Condition | Avg. Error | Std. Deviation |
| :---: | :---: | :---: |
| Word | 0.0052 | 0.0007 |
| Correct Tr. NW | 0.1342 | 0.0051 |
| Incorrect Tr. NW | 0.5060 | 0.0039 |

## General Discussion

The behavioral results from the two experiments presented here are broadly consistent with our conceptualization of statistical learning as occurring by situating stimuli in a perceptual similarity space. Further, the computational model we designed according to this conceptualization fits the data quite well. The auditory stimuli were specifically designed to be difficult to categorize, yet participants were able to distinguish between words and non-words after brief, passive familiarization with a sequence of grammatical bigrams. Although results for the Correct Trajectory Non-Word condition differed between Experiments 1 and 2, the overall trend of increasing unfamiliarity across conditions indicates that learners are sensitive to the trajectory from one stimulus to the next in feature space.

Using the same stimuli - indeed, the same ABCD familiarization sequence used in the current Experiment 1 -

Wang and Zevin (submitted) observed a small difference between Words and Correct Trajectory Non-Words, and a much larger difference between Correct and Incorrect Trajectory Non-Words. Across a number of experiments we are not reporting here due to space limitations, the general pattern of decreasing familiarity from Words to Correct to Incorrect Trajectory Non-Words is always present, although different contrasts are significant by inferential tests under different conditions. We therefore suggest that this overall pattern is the most critical feature of the data to simulate.

Interestingly, there are more subtle differences between Experiments 1 and 2 that are also captured by the simulation. Both the model and the human participants treated Correct Trajectory Non-Words as more similar to Incorrect Trajectory Non-Words in Experiment 1, but more similar to Words in Experiment 2. Until examining the simulation results, we failed to consider an idiosyncrasy with how the test items were chosen between experiments. The test items for ABCD and ABDC differed slightly in how they were sampled from throughout the feature space. As shown in Figures 2 and 5 above, the four non-word pairs for ABCD were taken from each of the four quadrants while in ABDC the four non-word items were drawn from only two quadrants (two from A and two from D). Therefore, half of the Correct Trajectory Non-Words in ABCD followed the correct trajectories for words and the other half for part-words while in ABDC they all followed trajectories for words. This could explain why the Correct Trajectory items were rated as more unfamiliar in ABCD than in ABDC for both the human experiments and the computational models.

Interestingly, the simulation's overall error, especially for Words, is lower in ABDC than ABCD . One possible explanation is that having two meaningful dimensions to define words provides the model with more information over which it can track probabilities, increasing its ability to learn the grammar. In contrast, the extra dimension introduces additional complexity that makes the sequences more difficult for humans to learn. This gets at one of the problems with the model: it is almost too good at learning the pattern. While humans must approximate each stimulus's location in similarity space, the model receives exact coordinates so naturally the model will produce more accurate and precise predictions. A further problem with the simulation lies in the fact that connectionist models like the SRN (Elman, 1990) and the one presented here all learn with supervision. While the model receives feedback on its predictions for every stimulus, human learners are thought to be dependent on unsupervised mechanisms under similar conditions (McClelland, 2006).

Furthermore, because the model was designed for a very specific experimental setting, it has limited applications. We have proposed elsewhere (Wang \& Zevin, submitted) that the trajectory-tracking approach may provide an explanation for statistical learning phenomena hitherto unaccounted for by existing models. For example, word segmentation during initial language acquisition is a real-life situation in which category labels are not readily available and the sequence
signal may be ambiguous due to natural variation in human speech (Shannon, 1948; Hockett, 1960).

However, there is no reason to believe that the trajectorytracking model tells the whole story. It is more likely that learners utilize different mechanisms, either simultaneously or individually, depending on the situation and the information that is readily available in the stimuli sequence. Relying on perceptual similarities is useful when stimuli are defined on the same dimensions and low-level physical features are readily extracted. When it is easy to abstract and divide stimuli into categories, however, there may be situations in which stimuli are readily recognizable, and it is simpler (i.e. involves lower computational load) to compute transitional probabilities over labels.

In conclusion, the results of this series of experiments and their remarkably close fit to the simulations provide overwhelming support for our theory that learning occurs by tracking changes in perceptual features from one stimulus to the next in a sequence. Although we observed a difference in one of the test conditions between the two experiments, the simulations reproduced the phenomenon, leading us to believe that it was a result of an idiosyncrasy in our test stimuli. Results from both experiments were otherwise consistent with our assertion that participants are situating stimuli within a perceptual similarity space and learn the pattern by tracking their trajectories through this space.

## Acknowledgments

We would like to thank Guo Dong for help with the recursive algorithm for generating balanced stimulus sequences, and Jay McClelland for suggestions on coding the two-dimensional space for the simulations.

# The role of prior knowledge and expertise on choice of referring expression 

Alyssa Ibarra (aibarra@ur.rochester.edu)<br>Departments of Brain \& Cognitive Sciences and Linguistics, 363 Meliora Hall, Box 270268<br>Rochester, NY 14627<br>Jeffrey Runner (jeffrey.runner@rochester.edu)<br>Departments of Linguistics and Brain \& Cognitive Sciences, Box 270096<br>Rochester, NY 14627<br>Michael K. #### Abstract

Referential success depends on choice of referring expression. The choice of referring expression will depend on contextual factors as well as factors related to speaker and addressee knowledge. A shared-learning paradigm was used in which partners learned names of objects together and separately before a referential task. Items differed on commonality, with some independently rated as more common and some as more rare. Speakers were less likely to use names versus other forms when items were rare than common ( $\mathrm{p}<0.001$ ) and less likely to use names when items were new than learned together ( $\mathrm{p}<0.001$ ). Asymmetry effects showed that speakers were more likely to use a name when the addressee was deemed more knowledgeable in post-test ratings ( $\mathrm{p}<0.01$ ). Together, we take this to show speakers choose to use a name versus a description based on the likelihood that their interlocutor will know the name. Factors affecting the likelihood include prior knowledge of what a typical addressee will know and shared experience, which includes inferring an interlocutor's expertise, as dynamically updated during a dialog.

Keywords: interactive conversation; referring expressions; common ground; expertise, belief updating

## Introduction

In interactive conversation, the likelihood of a speaker's referential success depends on choice of referring expression. A speaker's choice to refer to a picture as, say, a "dog" versus a "Bernese Mountain dog" or "the large black dog with a white chest and tan marking", depends on factors relevant to the context, the speaker, and the addressee. If, for example, the referential domain includes multiple dogs, a more specific label will be needed to pick out a unique object; whereas a domain with a single dog and several cats is likely to elicit the basic label "dog". A speaker's knowledge, or lack of knowledge, of dog breeds will restrict the name alternatives the speaker will have readily available, as will the speaker's assessment of the addressee's knowledge-e.g., if the speaker is aware that the addressee does not know a breed of dog, the speaker may choose to describe the dog rather than use the name of the breed.

Speakers readily distinguish between differences in knowledge when they learn novel names for novel objects with a partner (Wu \& Keysar, 2007; Heller et al. 2012;

Gorman et al., 2013). In this shared-learning paradigm, participants learn some novel names together (shared names) and then one participant, who is subsequently the director in a referential task, learns additional names alone (privileged names). This creates a situation of knowledge asymmetry that the speaker may use to inform choice of referring form in the referential task. Speakers indeed track shared experience when the objects are novel, i.e., when they have not seen the objects prior to the experiment. They use more names than descriptions for those objects that have been learned together. (Wu \& Keysar, 2007); and rarely use the name-alone form for privileged names (Heller et al. 2012; Gorman et al., 2013).

In related work, Gegg-Harrison (2016, also see GeggHarrison \& Tanenhaus, 2016) embedded name learning in the context of a toy world. In a role-playing game, certain levels were always encountered before others. The participant's choices made regions of the world and the information contained there inaccessible. Therefore, a participant who displayed knowledge of a particular name would implicate that she would know some names but not others. The participant then interacted with a game expert in several tasks that involved characters from the toy world. Interactions with the expert showed that the participant modified her name use and assessment of what the speaker knew based on the expert's use of names.
In most conversations, especially with a relatively unfamiliar addressee, a speaker will not have direct, shared experience. If we assume that speakers choose to use a name because it is the least resource demanding, shortest, and richest referring expression, then a rational speaker would take into account the likelihood that the addressee would know the name. That likelihood would be based on both the likelihood that any addressee would know that name (baseline likelihood) and evidence specific to that addressee, much of which is gleaned from the ongoing conversation.

To lay the groundwork for explicitly evaluating the likelihood hypothesis, we modify the shared-learning paradigm by using pictures of real entities that vary in baseline likelihood and by having the learning be interactive, which allows the director to have assessed the expertise of the matcher. We hypothesize that name use will be affected
by both baseline likelihood and shared experience, including inferred level of expertise, with larger effects of shared learning for less commonly known (rare) names and lower name usage for matchers who are judged to have lower expertise, especially for rare names, even when they have been learned together. If we can establish that the paradigm is sensitive to expertise, then this allows for more targeted questions about the factors, including prosody and choice of lexical expressions, that interlocutors use to signal and infer which names are likely to be know to each other.

Using novel names and novel objects is well-suited for asking basic questions about whether speakers can form item-specific memories of shared experience that can be used as a basis for common ground. However, limitation of using novel objects and novel names is that it abstracts away from two important characteristics that influence choice of referential forms. The first is the speakers' prior beliefs about how likely any interlocutor is to know a name. For example, any speaker of English can assume that her interlocutor will know the general category of dogs and its base-level name. The second is that it doesn't capture the dynamic aspect of interactive conversation. A speaker is unlikely to know the full extent of her addressee's knowledge about a topic prior to an interaction. Rather she may draw inferences based on what her interlocutor reveals during the interaction. For example, if a speaker learns that his interlocutor is a gourmet cook, he can assume that she will know the names for even relatively rare kitchen utensils. This assumption is possible even without direct evidence of knowledge of particular names by attributing to that interlocutor knowledge that is likely known by most gourmet cooks.

The present study extends the shared-learning paradigm in two important ways. First, we use real objects drawn from categories, in particular dog breeds and kitchen utensils, in which there are commonly known names (e.g., "tongs") and less common (rare) names (e.g., "mandoline"). We normed items as common or rare to the average person but chose categories that might differ in expertise given broad designations of communities (i.e., cooks and dog lovers). Second we modify the shared-learning paradigm to create conditions where participants have the opportunity to assess each other's expertise in a domain. This will allow one to tease apart whether assessment of addressee knowledge is acquired throughout the interaction by cues separately from the shared experience of learning names together.

Specifically, we ask whether the evidence that shared learning of novel objects informs referential choice can be interpreted as a part of a larger likelihood computation that also incorporates common knowledge, shared experience and inferred expertise. It could be the case that shared experience effects seen with novel objects can be attributed to the triggering of episodic traces, such that when a speaker chooses to refer to an object, the memory of having learned it with a specific addressee is activated, which in turn informs referential choice (Horton \& Gerrig, 2005). The low-level trace is enough to explain the shared learning effects. A speaker, however, may come into the experiment with a prior
belief about a partner's likely knowledge that gets updated as more evidence is presented. Thus, when the partners learn novel names together, the speaker updates the belief that the addressee knows the name, having learned it together. In the paradigm with novel objects, this belief is likely binary: they either learn it together in the experimental context or not. The present study, however, in its incorporation of real-world objects, creates a situation in which interlocutors not only may have different prior beliefs about the addressee's knowledge at the beginning of the experiment but may also dynamically update those beliefs throughout the interaction. The assessment of a partner's knowledge via shared experience as well as its updating, of course, also involves memory processes. However, it is not clear how memory traces with a specific partner could account for how beliefs of the overall commonality of an object interact with that shared experience. Furthermore, as the interaction unfolds, it is not clear whether further updating of this belief occurs given evidence from the interaction. An episodic trace would not predict its effect on referential choice for new items, for example. If episodic traces are driving the effects of shared learning, then speakers will be equally sensitive to the shared experience of learning names in the context of the experiment. However, if commonality and inferred expertise combine with shared experience to determine the overall likelihood of an addressee knowing a name, then one cannot only appeal to episodic-based explanations.

The present study concerns itself with the following questions: 1) Does the commonality of an object impact the effect of shared learning with a partner? 2) Do interlocutors dynamically update their beliefs about their partner's expertise in a subject? If so, does this expertise interact with commonality and shared learning to inform the speaker's choice of referring form?

We predict that if items are more likely to be known prior to the experiment, shared experience in the experiment is less likely to affect choice of referring expression. Conversely, if rare items are similar to novel items in past studies (i.e., associated with low or no prior knowledge), then the shared experience effects are likely to be strongest in this group. Furthermore, if expertise is inferred throughout the interaction, then the effects of commonality and/or shared experience, if any, should differ according to whether the addressee is deemed to be knowledgeable in the domain or not. Finally, although the effects of shared experience will be smaller for common names, we should still see some effects; this would suggest that shared experience enters into likelihood calculations, even for commonly known names.

## Methods

The experiment consisted of three parts: a learning phase, in which the participants learned the name of items in two categories--dog breeds \& kitchen utensils; a test phase, in which one participant directs the other to pick out a target item in a referential task; and a post-test, in which participants rate their partner's, and their own, knowledge of
the items as well as identify the context of learning. See Figure 1 for an illustration of these three parts.

Figure 1: Experimental procedure consisting of the Learning phase (i.e., Training), the Test phase, and Post-test phase.

## Norming

The items used in this experiment were normed and rated as either common or rare from two categories on which people often differ in expertise (dog breeds and kitchen utensils). See Figure 2 for sample stimuli of kitchen utensils. The norming procedure consisted of a presentation of 8 images ( 4 dog breeds, 4 kitchen items, with 2 common and 2 rare of each category). Each image was presented one at a time and participants were tasked to 1) label the image, 2) provide a confidence rating for that label, and 3) indicate how likely it is that the average person would know the label.

There were 80 unique images normed, separated into 10 lists of 8 items. 600 total participants were tested (roughly 60 people per list) with an average of 58.8 data points per item, due to some blank responses for single items.

Of the 80 unique items normed, we chose 36 experimental items: 12 for shared learning; 12 for director-alone learning; and 12 new items to be tested but not trained on. Half of all items $(\mathrm{n}=18)$ were dogs and the other half $(\mathrm{n}=18)$ were kitchen items. Within each of these categories, half ( $\mathrm{n}=9$ ) were rare, and half ( $n=9$ ) were common.

We chose the items by first sorting by largest sample. For common items, we then took the items with the highest average rating (i.e., the knowledge rating for the "average person") with the highest accuracy of labeling (above 70\% accuracy). For rare items, we took the items with the lowest average rating (i.e., the knowledge rating for the "average person") with the highest accuracy (above $10 \%$ accuracy). A minimum of $10 \%$ accuracy was implemented in order to remove items that had a name that was incorrect but confidently rated (e.g., "Greyhound" was a highly repeated label for an Azawakh, resulting in 0\% accuracy).

Figure 2: Sample stimuli of rare and common kitchen utensils.

## The Learning Phase

The learning phase allowed participants to observe each other's expertise. We manipulated whether names were shared or privileged by dividing the phase into shared learning among the two partners and director-alone learning. This allowed us to observe how a speaker combines shared experience with general likelihood of knowing a name and modulates choice of referring expression by perceived differences in expertise.

At the beginning of the learning phase, participants sit together at a table with the experimenter standing in front of them. Based on seating arrangement, each participant is assigned as either the Director or the Matcher.

For the shared-learning portion of the learning phase, the experimenter explains to the participants that they will be learning names of items together and that the images will be of different dogs and different kitchen items which they may or may not be familiar with. The experimenter then presents a flashcard with an individual image one at a time. After presenting the image, participants discuss with one another whether they know the name of the image. If they know it, they say the name aloud. After given some time to guess, the experimenter states the correct name of the item. This procedure is done for 12 items, presented in three blocks of four items. After each block, the items are repeated once more before moving to the next block. After all three blocks, the participants go through the whole stack.

For the second half of the learning phase (Director-alone learning), the Matcher sits at a computer in the same room and is instructed to wear headphones playing instrumental music while engaging in a game of Solitaire. During this time, the experimenter presents the Director with 12 additional images. The procedure is as above, with three blocks of four items. Thus, together with the shared learning portion, a total of 24 items were presented in the learning phase, holding out the last 12 items for the test phase.

Both portions of the learning phase (shared and Directoralone) are recorded and transcribed.

## The Test Phase

Following the learning phase, the participants began the test phase, which was a referential task in which the Director verbally leads the Matcher to pick out a target item from an array. The test phase created a situation for the Director to refer to the items of varying commonality and ground status that were introduced in the learning phase in a controlled referential task.

Both Matcher and Director sat at their own computer facing one another. The Director was shown one image on the screen, which could be an image that was learned together with the Matcher, learned alone, or never presented during the learning phase. The Matcher, on the other hand, was presented with three images. All three images were of the same category (i.e, all dogs or all kitchen items), and they are of same commonality (i.e., all rare or all common). The difference among the images is in their ground status (i.e., one is shared, one is learned by Director alone, and one is
new to both participants). The Director was instructed to identify the image on her screen with explicit instruction that there is no restriction on language (i.e., she can name or describe as needed), and the Matcher was tasked to click on the target image. The Matcher was also allowed to ask questions and interact freely with the Director as needed.

This procedure was followed for 24 test items: 8 Shared, 8 Alone, and 8 New targets. Half the targets in each ground status ( $n=4$ ) are dog breeds; half ( $n=4$ ) are kitchen items. Furthermore, half the dog items $(\mathrm{n}=2)$ are rare; the other half ( $n=2$ ) are common; half the kitchen items ( $n=2$ ) are rare; the other half ( $\mathrm{n}=2$ ) are common.

Each trial was recorded and the form of referring expression was coded as either Name Alone, Description, Name + Description, or Description + Name.

The data below are from 24 pairs of participants.

## The Post-test

After the test phase, both participants individually took a post-test. Participants were asked to rate their partner's knowledge of each domain (dog breeds/kitchen utensils), as well as rate their own knowledge in the domain. Next, participants were shown a single item and were asked to type in the label for the item, if known, and rate their confidence in their label. They were also asked to rate their confidence that their partner would know the label for that object. This procedure was repeated for all test items as well as new items. These measures of confidence were implemented to measure general expertise as well as presumed relative expertise between the two participants (i.e., whether the Director was more knowledgeable than the Matcher, or vice versa) in order to assess knowledge asymmetry.

Lastly, they were asked to identify the context of learning the item: learned with partner, alone (applicable for director only), learned prior to the experiment, or never learned. The items tested varied in context of learning; they could be an item from shared learning, Director-alone learning, or New items. This measure was used to observe whether participants were tracking context of learning by specific item.

## Results

We focus on speakers' Name-Alone use. We fit a GLM model predicting Name use against a single category combining other forms. Fixed effects were Commonality (Rare/Common), Ground Status (Privileged/Shared/New), and Knowledge Asymmetry (More/Less knowledgeable Matcher, as determined by post-test ratings) with Pair as a random effect (Table 1). Below we address our particular predictions.

| Name $\sim$ Asymmetry + Ground <br> * Commonality + (1\|Pair) | $\beta$ | Std <br> Error | P-value |
| :--- | :--- | :--- | :--- |
| AsymmetryM+ | 0.73 | 0.29 | $<0.01$ |
| AsymmetrySAME | -0.22 | 0.33 | 0.49 |
| CommonalityRare | -3.36 | 0.43 | $<0.001$ |
| GroundShared | 1.13 | 0.69 | 0.10 |
| GroundNew | -1.53 | 0.42 | $<0.001$ |
| GroundPriv:CommonalityRare | -0.47 | 0.76 | 0.53 |
| GroundNew:CommonalityRare | 0.67 | 0.56 | 0.23 |

Table 1: GLM model ouput

## Does the commonality of an object impact the effect of shared learning with a partner?

A main effect of Commonality demonstrates less name use for Rare than Common names ( $p<0.001$ ). In regard to Ground status, speakers are less likely to use a Name when the item is New than when Shared ( $\mathrm{p}<0.001$ ), but for learned names, the main effect of Ground was not significant.

Figure 3 shows Name use by the speaker across Commonality and Ground. The main effect of commonality can be seen by the larger proportion of name use in the right three columns of the graph (Fig 3). Although there was no effect of Ground Status across learned items, when looking at Rare items in comparison to Common items, one can see that differences in name use across Ground status conditions are more apparent for Rare than Common objects, similar to results in past work with novel objects. Indeed, in separate models, effects of Ground were significant for Rare items, such that names are used less for privileged items than for shared items. Common objects show the same pattern but to a much lesser extent. Thus, the speaker is less likely to use names when referring to rare objects than common ones and this preference is further reduced if the rare objects are privileged or new.

Figure 3: Overall use of names by the Director across Ground Status (Shared, Privileged, New) and Commonality (Common, Rare) conditions.

Does inferred expertise inform the speaker's choice of referring form?

A main effect of Asymmetry showed that speakers were more likely to use a Name when the Director presumes the Matcher to be more knowledgeable than herself ( $\mathrm{p}<0.01$ )

Figure 4 shows Expertise effects across Ground Status and Commonality conditions. The main effect is shown by an overall larger proportion of name use when the Matcher is deemed more knowledgeable than the speaker $(\mathrm{M}+$ ) than when the Matcher is deemed less knowledgeable (M-). These effects are carried most strongly in two conditions: for Rare objects that are learned together (Shared), and for Common objects that are New (not learned at all in experiment).

Figure 4: Proportion of Names when Matcher deemed more $(\mathrm{M}+$ ) or less (M-) knowledgeable than the Director.

Data gathered from the post-test, in which participants had to identify the context in which a particular item was learned (e.g., alone, shared, or neither) revealed high accuracy for tracking ground status (Table 2). This measure was recorded to assess memory of ground status across the course of the experiment. Table 2 shows highest accuracy of context identification for Rare Shared items and lowest accuracy for Common Shared, but this is not significantly different across the categories.

| Context Identification Accuracy (Post-Test) |  |  |
| :---: | :---: | ---: |
| Common | Alone | $86.1 \%$ |
|  | Shared | $85.4 \%$ |
| Rare | Alone | $86.1 \%$ |
|  | Shared | $91.7 \%$ |

Table 2: Post-test accuracy

## Discussion

Speakers' choice of names is strongly affected by the prior likelihood that an interlocutor will know a name. When items are more common, shared learning has weaker effects on
name use than when an object is rare. As in previous studies with novel objects, common ground effects are more apparent for less commonly known items. This is taken to show that a speaker's reliance on shared learning as a means to assess partner knowledge is reduced when the objects are likely to be commonly known. This provides evidence that the basis of common ground in an interaction relies on assessments of prior knowledge as well as shared experience. The strongest version of the memory-based account would expect ground effects regardless of commonality, as long as partners have shared experience. However, our post-test data show that speakers are highly accurate in identifying the context of learning, suggesting that they are not less sure about whether a name was shared but they are using that information in combination of other information: i.e, prior knowledge.

Furthermore, we see general expertise effects, such that name use is increased when the addressee is deemed to be more knowledgeable than the speaker. This provides evidence of dynamic updating of knowledge assessments. Future directions would include a more controlled way of assessing when exactly expertise judgments as this might help in teasing apart whether this is confined to the learning phase, or whether participants indeed continue to update beliefs throughout the test phase. However, even with assessments taken post test, we see expertise effects driven from interaction.

Having established expertise effects using this paradigm, we are currently carrying out follow-up work that uses the paradigm to explore further questions. For instance in an ongoing experiment we ask whether expertise assessments derived from the interaction are more strongly weighted than expertise assessments derived from top-down knowledge (e.g., telling the speaker his partner is an expert). Our current study asks this very question by having a director complete the collaborative task in the test phase without any prior interaction with her partner and given only top-down information about the partner's status as an expert in the domain.

Another avenue of research study explores the signals in the interaction that contribute to the assessments of expertise. Specifically, we are testing normed markers of uncertainty modeled on the types of utterances we observed during the learning phase. A confederate matcher will, in the learning phase, reveal her expertise through use of these uncertainty cues. If naïve directors attribute expertise to their partner as a function of these cues, it will be an important step in further understanding the particular components of an interaction that inform beliefs of partner knowledge.

Overall, the contribution of the current study is in embedding the previous evidence on shared experience into a larger computation of the likelihood of addressee knowledge. The effect of commonality on choice of referring expression may not be surprising on its own but together with evidence of inferences of expertise throughout the interaction, one can get a better understanding of how speakers may be combining these different sources of information to compute
this likelihood. Future studies will examine the factors that shift around the likelihood rather than to only appeal to lowlevel processes (i.e., memory traces) that contribute to the individual factors. We then can evaluate quantitative models to compare likelihood models that combine multiple cues with other classes of models.

Lastly, this study explores expertise in domains given interactions about particular items. We argue that the generalization of presumed expertise to a larger domain given updated beliefs about particular objects is tied to beliefs about groups of people and the presumed knowledge of particular communities. For example, dog kennel owners are likely to be presumed to know a lot of about dog breeds and not so much about cat breeds. However, if the relevant community were veterinarians, a member of that community might be presumed to know about both dog breeds and cat breeds. We argue that assessments about expertise are necessarily tied to the community applied, and this constraint is utilized by speakers to narrow in on the dimensions that are relevant for both generalization to new interlocutors and generalization to new items in a given domain.

## Acknowledgments

We are grateful to the members of the KurTan lab meeting and the Experimental Semantics and Pragmatics (ESP) reading group who provided helpful input towards the design and implementation of this study. We especially want to acknowledge Whitney Gegg-Harrison. Her thesis work first explored many of the questions we are pursuing in this line of research. Whitney also provided valuable advice on the current project. This work was supported by NIH grant HD 27206 to MKT.

# Beyond Almost-Sure Termination 

Thomas F. Icard (icard@stanford.edu)<br>Department of Philosophy, Stanford University

#### Abstract

The aim of this paper is to argue that models in cognitive science based on probabilistic computation should not be restricted to those procedures that almost surely (with probability 1 ) terminate. There are several reasons to consider nonterminating procedures as candidate components of cognitive models. One theoretical reason is that there is a perfect correspondence between the enumerable semi-measures and all probabilistic programs, as we demonstrate here (generalizing a better-known fact about computable measures and almostsurely halting programs). One practical reason is that the line between almost sure termination and non-termination is elusive, as well as arbitrary. We argue that this matters not only for theorists, but also potentially for a learner faced with the task of inducing programs from experience.

## Introduction

The metaphor of cognition as computation provides a fruitful and flexible foundation for cognitive science. While computation can be understood broadly to encompass many different paradigms and formats (Rescorla, 2015), it is generally presumed that an upper bound on what can be computed by the human mind is that which can be computed by a Turing machine, or a program in any other universal model of computation, such as lambda calculus, recurrent neural networks with rational weights, combinators, Java programs, and so on.

Some early proponents of the computational theory of mind (e.g., Putnam 1967) focused attention on probabilistic computation, allowing randomization in state transitions; and random mechanisms have been central in psychological models going back at least to stimulus-response theory, which had formal connections to probabilistic automata (Suppes, 1969). In recent work, computation with random elements has taken on new significance, where mental representations themselves are characterized in terms of probabilistic procedures or programs (Goodman et al., 2014), and noise is seen not just as a nuisance, but as deeply tied to an agent's capacity for prediction and induction. Although probabilistic machines cannot compute any more functions than deterministic machines, this shift in emphasis raises new and distinct questions. For instance, how expressive is a given class of probabilistic machines for representing useful distributions?

Much of the recent theory of probabilistic computationparticularly that motivated by application to cognition-has focused on computable probability distributions, specifically restricting to procedures that terminate almost surely (a.s.), that is, with probability 1 . This has given rise to a rich body of work. For instance, it can be shown that the computable distributions correspond to the a.s.-terminating probabilistic Turing machines (see, e.g., Freer et al. 2012), as well as to the a.s.-terminating stochastic lambda terms (Dal Lago and Zorzi, 2012). The limits of computability in the context of
conditioning continuous distributions have also been thoroughly investigated (Ackerman et al., 2011).

These important advances notwithstanding, the aim of the present paper is to argue that in cognitive science the focus on a.s.-termination is overly restrictive. As a foundation for theorizing about cognitive processes we should consider the class of all probabilistic computations, not just those that a.s. halt. To use terminology introduced more formally below, cognition should be modeled on the more general class of enumerable semi-measures, rather than the smaller class of computable probability measures. We offer two arguments for this claim, one practical and one theoretical.

The practical argument is that the line between a.s. termination and non-termination is elusive and arbitrary. This point is illustrated with a simple example, where the boundary can be studied concretely. The theoretical argument is that the correspondence between the semi-measures definable by probabilistic machines and enumerable semi-measures is more basic and canonical than that between measures definable by a.s.-terminating machines and computable measures. We give a simple, self-contained proof of this first correspondence (Theorem 1), which subsumes the second as a special case (Corollary 1). This proof is elementary, and is arguably simpler than direct proofs of the corollary. We also discuss some connections to program induction, and possible repercussions for probabilistic inference.

## Background on Probabilistic Computation

Consider any universal language for describing computations. Allowing programs in one of these languages access to an unlimited source of iid samples from a $\operatorname{Bernoulli}(0.5)$ distribution brings us to the setting of universal probabilistic languages. For instance, a Turing machine might have an additional read tape with an infinite sequence of random bits, while a lambda term might make use of a choice operator $\oplus$, where $M \oplus N$ reduces to $M$ or $N$, each with probability 0.5 . Just as the Church-Turing Thesis states that any two reasonable deterministic models of computation will be equivalent, one might hypothesize that any reasonable way of adding fair coin flips to these models will give rise to an equivalent model of probabilistic computation. For the rest of this paper we will remain neutral about which of these versions we adopt.

Non-termination, even for very simple, e.g., monitoring processes, is of course a desirable feature of many mechanisms involved in control, where inputs are continually processed (Botvinick and Cohen, 2014). However, our interest here is non-termination even for stand-alone programs without input, so we restrict attention to this setting.

A probabilistic program $\pi$, in any machine language, generates an output $w$-let us suppose outputs are (or at least
encode) binary sequences, so that $w \in\{0,1\}^{*}$-with some probability, which we will write $\mu_{\pi}(w)$. That is, $\mu_{\pi}(w)$ is the sum of the probabilities of all the execution sequences that halt with output $w$. The program $\pi$ implicitly represents a distribution on binary strings; however, this distribution may not be a proper probability distribution on $\{0,1\}^{*}$, as it may be that $\sum_{w} \mu_{\pi}(w)<1$. This will happen if the program fails to halt with some probability $1-\sum_{w} \mu_{\pi}(w)>0$. A function $\mu$ for which $\sum_{w} \mu(w) \leq 1$ is called a (discrete) semi-measure, and it is called a probability measure if this holds with equality.

A semi-measure $\mu$ is (computably) enumerable if it is approximable from below; that is, if for each $w \in\{0,1\}^{*}$ there is a computably enumerable weakly increasing sequence $q_{0}, q_{1}, q_{2}, \ldots$ of rational numbers, such that $\lim _{i \rightarrow \infty} q_{i}=\mu(w)$. Most semi-measures are not enumerable, but for any probabilistic program $\pi$, the semi-measure $\mu_{\pi}$ will be enumerable. To approximate $\mu_{\pi}(w)$ from below, consider the set $W_{i}$ of strings $v$ with length $l(v) \leq i$, such that $\pi$ accesses (exactly) the bits of $v$ before terminating with output $w$. Letting $q_{i} \stackrel{\Delta}{=} \sum_{v \in W_{i}} 2^{-l(v)}$, it is then evident that $\lim _{i \rightarrow \infty} q_{i}=\mu(w)$. Theorem 1 below states the converse of this observation, that in fact every enumerable semi-measure $\mu$ is $\mu_{\pi}$ for some $\pi$.

A semi-measure $\mu$ is called computable if it is enumerable and for each $w$ there is also a computably enumerable weakly decreasing approximating sequence $q_{0}, q_{1}, q_{2}, \cdots \rightarrow \mu(w)$. There are computable semi-measures that are not probability measures, but every enumerable probability measure is computable: we can enumerate the sum $\sum_{w^{\prime} \neq w} \mu\left(w^{\prime}\right)$ by dovetailing to obtain $q_{0}^{*}, q_{1}^{*}, q_{2}^{*}, \ldots$, and then $1-q_{0}^{*}, 1-q_{1}^{*}, 1-q_{2}^{*}, \ldots$ converges from above to $1-\sum_{w^{\prime} \neq w} \mu\left(w^{\prime}\right)=\mu(w)$. Corollary 1 below states that the computable probabilities measures are exactly those of the form $\mu_{\pi}$ for some a.s.-terminating program $\pi$ (see, e.g., Freer et al. 2012; Dal Lago and Zorzi 2012).

In addition to encompassing the space of randomized algorithms, probabilistic programs are of special interest in cognitive science because of their ability to provide compact representations of quite complex distributions, e.g., over combinatorially rich spaces (Goodman et al., 2014; Piantadosi et al., 2016). By encoding these distributions only implicitly through the program's objective probability of returning different outputs, they make an attractive candidate for plausible representations of subjective probability (see Icard 2016 for discussion). Moreover, it is often possible to define programs for automatically representing conditional distributions, and thus to apply and adapt the tools of Bayesian statistics to this setting (Tenenbaum et al., 2011; Freer et al., 2012).

## Why Non-Terminating Programs?

The enumerable semi-measures form a larger, and arguably more natural, class than the computable measures, but what is the reason to include them in our study of cognitive agents?

The claim of this section is that there is a tension between allowing rich, interesting programs and ensuring those programs a.s. terminate. It is well known that testing whether a deterministic program halts is an undecidable $\left(\Sigma_{1}^{0}\right)$ problem,
and verifying a.s. termination of a probabilistic program is of even higher complexity ( $\Pi_{2}^{0}$, see Kaminski and Katoen 2015). It follows that the only way to ensure a.s. termination is to restrict to smaller, controlled fragments. This is confining both for the cognitive scientist proposing psychological models, and for the learning agent who may need to construct and induce programs on the fly.

## Between Termination and Non-Termination

The boundary between a.s.-terminating programs and nonterminating programs often looks quite arbitrary. To illustrate, we use a very simple example close to recent work on intuitive physics (e.g., Sanborn et al. 2013; Battaglia et al. 2013). This work models people's ability to understand and predict physical events using probabilistic programs for constructing internal "simulations" that operate in rough accordance with physical laws. The example here is far less sophisticated, merely concerning speed along a single spatial dimension. Consider a proverbial tortoise-and-hare scenario, where the tortoise is moving ahead at a constant rate following a slight head start, and the erratic rabbit is nonchalantly racing to catch up. We might suppose that the hare leaps forward some random distance about every fourth step that the tortoise takes. The question is when, if ever, the hare will catch up. Imagine this prediction arising from mental simulations of something like the following program $\pi \downarrow$ :

```
t = 5; h = 0
while (h < t):
    t = t + 1
    if (flip(0.25)): h = h + Uniform(1,7)
return t
```

For instance, a person observing a rabbit chasing a tortoise might extract a program like $\pi^{\downarrow}$ in order to make predictions about what will happen some number of steps later.

Where $H_{k}$ is the distance traveled by the hare at stage $k$, consider the random variable $X_{k}=(5+k)-H_{k}$, measuring the extent of the tortoise's current lead. It is easy to show that the sequence $\left\{X_{k}\right\}$ forms a random walk martingale, and specifically that $\mathbb{E}\left[X_{k+1} \mid X_{1}, \ldots, X_{k}\right]=X_{k}$, and so $\mathbb{E}\left[X_{k}\right]=5$ for all $k$. By the recurrence property for symmetric random walks, we reach $X_{k} \leq 0$ at some stage $k$ almost surely. Thus this program $\pi^{\downarrow}$ halts with probability 1. (Cf. Chakarov and Sankaranarayanan 2013 for powerful a.s.-termination proof techniques that cover examples like this.)

While $\pi^{\downarrow}$ as written terminates, small changes in the parameters of the program lead to positive probability of nontermination. For instance, if $t$ is instead incremented by $1+\varepsilon$ at each step, or if the increase in h is drawn uniformly from an interval $(1,7-\varepsilon)$, for $\varepsilon>0$, then the resulting program $\pi^{\uparrow}$ may not halt because the expected distance between the tortoise and hare constantly increases. In particular, there will be a constant $C>0$, such that for any fixed $x_{k}$, we have $\mathbb{E}\left(X_{k+1} \mid x_{k}\right)-x_{k}=C$. Hence $\mathbb{E}\left(X_{k+1}\right)=\mathbb{E}\left(\mathbb{E}\left(X_{k+1} \mid X_{k}\right)\right)=$ $\mathbb{E}\left(X_{k}\right)+C$, from which it follows $\mathbb{E}\left(X_{k}\right)=5+k C$ for each $k$.

This means that the long run expected value of $X_{k}$ is infinite, and the program fails to halt with some positive probability.

One might suspect that this theoretical distinction could have practical repercussions. Would we not want some guarantee that our program would eventually halt? The problem with this line of thought is that, from a practical perspective, non-termination is not any worse than eventual termination but only after an inordinate amount of time. Simulating the program $\pi^{\downarrow}$ above-and terminating computation whenever the number of steps reaches an upper bound of, say, $10^{7}$ —we see that the program reaches this upper bound about $.01 \%$ of the time. Though a large majority ( $\sim 75 \%$ ) of runs end within 100 steps, the empirical average runtime is in the tens of thousands. ${ }^{1}$ Thus, in some small number of cases we would presumably have to terminate computation anyway. From this simulation perspective, the behavior of $\pi^{\uparrow}$, taking $\varepsilon>0$ to be very small, is empirically nearly indistinguishable. The fact that some of these runs might never terminate is immaterial, practically speaking.

This argument is about possible non-termination, and it does not distinguish between computable and merely computably enumerable distributions. If we increment $t$ by a computable real number $1+\varepsilon$, then, though $\pi^{\uparrow}$ might never halt, $\mu_{\pi^{\uparrow}}$ is actually a computable semi-measure, with a computable probability of not halting. However, this situation again may be practically no different from a situation in which $1+\varepsilon$ can only be approximated from below. This paper is a plea mainly for non-terminating programs, and one could in principle accept non-termination but still insist on computability. There may be contexts where insistence on computability may be appropriate (see the section below on conditioning); the claim of this paper, however, is that we ought not make this restriction in general.

## A Remark on Levels of Analysis

The argument that $\pi^{\downarrow}$ and $\pi^{\uparrow}$ are practically indistinguishable assumes that we may have to terminate computation beyond a certain point no matter which one we run, and that the resulting behavior will look nearly indistinguishable. A possible objection at this stage is that by enforcing an upper bound on computation time, we are effectively only considering programs that a.s. (in fact, always) halt anyway. That is, the larger program encompassing both the simulation model itself and whatever controls the simulations always terminates after a bounded amount of time.

This objection is fine as far as it goes, but it undercuts the motivation for considering rich, e.g., recursive, probabilistic programs to begin with. When we write the program $\pi \downarrow$ above in Java, for example, we understand it as encoding an abstract procedure that could in principle run for any amount of time, even though we know no concrete implementation of $\pi \downarrow$ has this property. Indeed, $\pi^{\downarrow}$ abstracts away from many de-

[^353]tails about how the program might be implemented. The idea that we can construe some psychological models in a similar manner is very familiar in cognitive science (Marr and Poggio, 1976). Characterizations of mental phenomena using grammars, recursive constructions, and other devices that license unbounded computations are legitimized by potential gain in conceptual clarity and modularity. We understand while-loops, models of Newtonian mechanics, and so on, in a very general way: we have a good sense of what they can do, what problems they can be used to solve, and how they can be combined with other tools to form even more powerful devices. From this perspective it is unsurprising that such devices would make their way into our cognitive models.

Such issues about levels of analysis are beyond the scope of this paper. The present suggestion is simply that the best arguments favoring liberal use of a.s.-terminating probabilistic machines as cognitive models should extend to the class of all probabilistic machines. Just as there may be practical reasons to avoid computable, but algorithmically intractable, procedures in practice, so it may make sense in many cases to avoid use of procedures that might not terminate. That does not delegitimize their use in cognitive modeling.

## Program Induction

The argument up to this point has been largely negative, that there is no reason to exclude effective semi-measures as possible components of a cognitive model. But there also may be good positive reasons to include them when we consider the learning problem of inducing programs from observations (see, e.g., Lake et al. 2017 for application of this idea to human cognition). Given the high complexity of verifying a.s.termination, the learner seems to be faced with a dilemma: either restrict search to a small fragment of possible programs or risk hypothesizing programs that may not halt.

For example, it is difficult to imagine a sufficiently flexible class of programs-say, a class built out of a few primitive constructions such as while-loops and simple arithmetical operations like addition-from which one could easily obtain the program $\pi^{\downarrow}$ above, but not one of the variants $\pi^{\uparrow}$ that might have some probability of not halting. It is not that one would prefer to construct $\pi^{\uparrow}$ over $\pi^{\downarrow}$, but that they are equally preferable and that separating them in a principled way might be difficult, no matter what method is used to perform the induction. That is, even if the goal is to construct an a.s.-halting program, flexibility in program construction might require the possible construction of non-halting programs.

In light of this possibility, a natural suggestion is to consider enriching program induction frameworks with more expansive classes of programs. Consider Bayesian approaches to program induction. Where $\mathcal{C}$ is some class of (semi-) measures on a space $X$, e.g., on $\{0,1\}^{*}$-so that we can ask about $P(X)$ for any $P \in \mathcal{C}$ and $X \in X$-we could have a prior measure $v$ over $\mathcal{C}$ that induces a mixture distribution $P_{V}$ on $X$ :

$$
P_{\mathrm{v}}(X) \stackrel{\Delta}{=} \sum_{P \in \mathcal{C}} v(P) P(X)
$$

Thanks to Theorem 1, we can always think of each element of $\mathcal{C}$ as a semi-measure $\mu_{\pi}$ defined by a probabilistic program $\pi$ from some class $\Pi$, so $v$ defines a prior on programs in $\Pi$.

Hierarchical Bayesian models fit this description, where $\mathcal{C}$ is typically a parametrized family of distributions and $v$ is a hyperprior over those parameters (though hierarchical models may include more levels), and they are often explicitly encoded as probabilistic programs. Provided one can define appropriate likelihood functions $v(Y \mid P)$ and $P(Y \mid X)$, it makes sense to condition such a mixture distribution on data $Y$ using Bayesian inference:

$$
\begin{equation*}
P_{\mathrm{V}}(X \mid Y)=\sum_{P \in \mathcal{C}} v(P \mid Y) P(X \mid Y) \tag{1}
\end{equation*}
$$

By updating $v$ alongside candidate ground-level distributions $P$, such methods capture effects of learning at multiple levels of abstraction, such as the ability to transfer general principles inferred in one domain to novel but related domains.

Probabilistic programs generalize hierarchical Bayesian models to allow wider classes $C$ of measures. For instance, work by Piantadosi et al. (2016) considers learning in a context where $\mathcal{C}$ is defined by logical expressions of the sort typically used in natural language semantics. Evidently, there is no reason we could not consider classes that include enumerable semi-measures as well. An alluring possibility is to take $\mathcal{C}$ to be the class of all enumerable semi-measures-i.e., all programs-with $v$ assigning a weight to each. Because $\mathcal{C}$ is then computably enumerable, there are many effective semimeasures $v$ assigning positive weight to all probabilistic programs, and even here $P_{V}$ is guaranteed to be an enumerable semi-measure, and thus definable by a program. Learning in this setting is somewhat fraught (see below), but at least such a semi-measure can be represented. By contrast, when $\mathcal{C}$ is the class of computable measures there is no computable $v$ with support exactly $\mathcal{C}$, since that set is undecidable.

## Simplicity Bias

In this broader setting of program induction, as in hierarchical models, it is presumed that a good prior on $\mathcal{C}$ is one that favors simpler hypotheses. This might be achieved, for instance, by defining $v$ with a probabilistic grammar so that shorter programs are automatically given higher probability. A very general proposal for biasing simpler functions, known as Solomonoff induction, is based on ideas from Kolmogorov complexity. In brief, the proposal is to assign probability to a string $w$ in proportion to the shortest (deterministic) program that, when run on a universal Turing machine $U$, produces $w$ as output. The intuition is, data that could be produced by simpler mechanisms should be a priori more likely.

As an aside, there are other applications of simplicitybased constructions inspired by Kolmogorov complexity that make use of enumerable semi-measures. As an example, in their generalization of Shepard's Universal Law of Generalization, Chater and Vitányi (2003) assume enumerable "confusability" probabilities, $P\left(R_{a} \mid S_{b}\right)$-specifying how likely it is that a subject will give a response appropriate to $a$ when
presented with $b$-to develop a notion of similarity between arbitrary representations. The basic idea is that similarity is roughly proportional to the length of the shortest (deterministic) program that would be required to transform one representation into the other. Enumerability is exactly what is needed to derive (a generalized version of) the Universal Law.

But what about simplicity-based Solomonoff induction? There are several issues with Solomonoff induction (including the variant here for semi-measures, due to Zvonkin and Levin 1970). One well known problem is that the resulting prior is very sensitive to the choice of universal Turing machine $U$. In fact, it has been shown that there is a perfect correspondence between weightings $v$ on the class of enumerable semi-measures and choices of universal Turing machines $U$ for the Solomonoff prior (Wood et al., 2011). In other words, the class of Solomonoff priors just is the class of mixture semi-measures $P_{V}$ in which $v$ assigns positive weight to all the enumerable semi-measures. It is therefore questionable whether this framework really does provide a foundation for understanding simplicity, since it is not clear what an "unbiased" choice of $U$ or $v$ would be (see Sterkenburg 2016).

A larger problem with Solomonoff induction, however, concerns the complexity of conditional inference. Whereas each Solomonoff prior is itself computably enumerable, conditioning on data leads to a function that is not even enumerable (specifically, we go from $\Sigma_{1}^{0}$ to $\Delta_{2}^{0}$, see Leike and Hutter 2015 , cf. also the next section). Since the whole point of Solomonoff induction is to learn, this is a disappointing result. In particular, it means that no probabilistic program can represent a conditioned Solomonoff prior. Given the centrality of induction, we would like to understand better what we can do with conditioning, and whether Bayesian program induction is even possible when some of the candidate programs have positive probability of not halting. This leads us to the next section.

## Conditioning Enumerable Semi-Measures

The fact previously mentioned-that effective semi-measures are not closed under conditioning-appears problematic, at least for Bayesian applications of probabilistic programs. It is especially noteworthy given that the computable measures are closed under conditioning in the discrete setting. While a full discussion of conditionalization is beyond the scope of this paper, it is worth briefly clarifying the issue. (Of course, for non-Bayesian approaches to learning programs, e.g., Neelakantan et al. 2016, this may not even be problematic.)

Conditioning an effective semi-measure may produce a function that is only "limit computable" (Leike and Hutter, 2015), meaning the conditional probability of each string can be approximated, but the sequence of rationals need not approach its limit (even weakly) monotonically. The intuition behind this is clear. To determine $\mu(X \mid Y)$ we must compute $\mu(X, Y) / \mu(Y)$. If all we can do is approximate each of $\mu(X, Y)$ and $\mu(Y)$ from below, and we know nothing about how fast we are converging to the correct values, then we know absolutely
nothing about the ratio $\mu(X, Y) / \mu(Y)$ at any finite stage.
In the computable setting, as Freer et al. (2012) explain, it is straightforward to define a single Turing machine QUERY that takes a program $\pi$ and a Boolean condition $\kappa$ (also represented as a probabilistic program), and produces a representation of the posterior distribution $\operatorname{QUERY}(\pi, \kappa)$. The idea is to divide the infinite random bit stream into infinitely many random bit streams, and find the first one that satisfies $\kappa$. Then run $\pi$ using this bit stream to generate an output $w$. As long as $\kappa$ a.s. terminates and returns 'true' with positive probability, $\mu_{\mathrm{QUERY}(\pi, \kappa)}$ correctly defines the posterior distribution.

By the aforementioned result, we know there can be no machine that conditions an arbitrary semi-measure $\mu_{\pi}$ on an arbitrary condition $\kappa$. Nonetheless, provided $\kappa$ stipulates a computable condition, even when $\mu_{\pi}$ is merely computably enumerable, $\operatorname{QUERY}(\pi, \kappa)$ will correctly represent the conditioned semi-measure, which shows that the conditional distribution is also enumerable. Thus, enumerable semi-measures are closed under conditioning with computable queries.

In this sense the situation for enumerable semi-measures is no worse than that for computable measures: both can be conditioned with computable observations in a uniform way. For many settings this does not seem at all limitative. As a simple example, we could imagine conditioning the program $\pi^{\uparrow}$ on the statement that the tortoise reached at least 15 steps. This is an easily, indeed finitely, verifiable proposition.

The main limitative result is rather the one we already mentioned: though we can represent complex semi-measures such as Solomonoff priors, the probabilities of even basic observations like "the first object is a 0 " are not computable. Nonetheless, we can hope for something in this direction. Sufficient conditions for a conditional mixture semi-measure $P_{\mathrm{v}}$ to be semi-computable are not terribly stringent. First, the prior $v$ over semi-measures $\mu \in \mathcal{C}$ should be computable (e.g., this holds if the semi-measures/programs are generated by a probabilistic grammar). Second, as above, the specific data $Y$ must be computably verifiable for each $\mu \in \mathcal{C}$. If both of these are satisfied, then the adapted version of (1)

$$
\begin{aligned}
P_{v}(X \mid Y) & =\sum_{\mu}\left(\frac{v(\mu) \mu(Y)}{\sum_{\mu^{\prime}} v\left(\mu^{\prime}\right) \mu^{\prime}(Y)} \frac{\mu(X, Y)}{\mu(Y)}\right) \\
& =\frac{\sum_{\mu} v(\mu) \mu(X, Y)}{\sum_{\mu} v(\mu) \mu(Y)}
\end{aligned}
$$

is enumerable, and thus representable by a single program, e.g., using an operation like QUERY. Though this falls short of full Solomonoff-style induction, it does generalize what is usually done with Bayesian program induction. It also reveals a distinctive positive reason to entertain specific effective semi-measures as candidate cognitive models. Granted our previous suggestion that it might be beneficial for learning to consider wide classes of programs, putting a computable prior on such a class will result in a enumerable mixture semi-measure $P_{V}$ that can be conditioned.

Questions about conditioning in this more general setting clearly merit further attention, especially in relation to more
realistic inference methods such as MCMC (see, e.g., Goodman et al. 2008). Algorithmic tractability is an obvious worry, but this is already a worry when everything is computable, and it is not obvious that including effective semi-measures exacerbates the problem. Moreover, even in the computable case, for the continuous setting conditionalization is not in general a computable operation (Ackerman et al., 2011). Consequently, as computational-level models of learning and inference, it appears that the effective semi-measures fare no worse than the computable measures.

## Universality

In this final section we offer a proof of the correspondence between probabilistic machines and enumerable semimeasures. Specifically, we show that every enumerable semimeasure can be represented by a probabilistic machine. The proof is similar to proofs for the computable case (e.g., Freer et al. 2012), but we can only use enumerability and must allow for probability of non-halting executions. The exposition is intended to be accessible and intuitive.

Let $\mu$ be an enumerable semi-measure on $\{0,1\}^{*}$. That is, for each word $w \in\{0,1\}^{*}$, there is a computably enumerable weakly increasing sequence $q_{0}, q_{1}, q_{2}, \ldots$ of rational numbers such that $\lim _{i \rightarrow \infty} q_{i}=\mu(w)$. Assume without loss that $q_{0}=0$. Note then that $\mu(w)=\sum_{i=0}^{\infty}\left(q_{i+1}-q_{i}\right)$. Our aim is to show that $\mu=\mu_{\pi}$ for some machine $\pi$.

Let $\left\langle \_, \quad\right\rangle: \mathbb{N} \times \mathbb{N} \rightarrow \mathbb{N}$ be a fixed (computable) bijective pairing function with first projection $\rho_{1}(n)=k$ when $n=$ $\langle k, i\rangle$. Let $w_{0}, w_{1}, w_{2}, \ldots$ be a fixed enumeration of $\{0,1\}^{*}$, each with a fixed enumeration of approximating rationals $q_{0}^{k}, q_{1}^{k}, \ldots$ converging from below to $\mu\left(w_{k}\right)$. We define a sequence of rational (thus computable) numbers as follows:

$$
\begin{array}{rll}
r_{0} & \stackrel{\Delta}{=} & q_{0}^{0}=0 \\
r_{n+1} & \stackrel{\Delta}{=} & r_{n}+\left(q_{i+1}^{k}-q_{i}^{k}\right)
\end{array}
$$

where we assume $0=\langle 0,0\rangle$ and $n+1=\langle k, i\rangle$.
Our machine $\pi$ works in stages, observing a random sequence of bits $a_{0}, \ldots, a_{j-1}$ while producing an enumeration $r_{0}, \ldots, r_{j-1}$. At each stage $j$, we observe a bit $a_{j}$ and add a rational $r_{j}$, then check whether, for any $n$ with $0 \leq n<j$, the following condition (2) is satisfied:

$$
\begin{equation*}
r_{n}<\sum_{i=0}^{j} a_{i} 2^{-i}-2^{-j} \text { and } r_{n+1}>\sum_{i=0}^{j} a_{i} 2^{-i}+2^{-j} \tag{2}
\end{equation*}
$$

That is, where $\tilde{p}=\sum_{i=0}^{j} a_{i} 2^{-i}$ is the rational generated so far, we know our randomly generated real number will lie somewhere in the interval $(\tilde{p}-\varepsilon, \tilde{p}+\varepsilon)$, and (2) tells us that this interval sits inside the interval $\left(r_{n}, r_{n+1}\right)$. If this holds, output $w_{\rho_{1}(n+1)}$. Otherwise, move on to stage $j+1$.

Each word $w$ has its probability mass $\mu(w)$ distributed
across different intervals in $[0,1]$. Specifically:

$$
\begin{aligned}
\mu\left(w_{k}\right) & =\sum_{n: \rho_{1}(n+1)=k} r_{n+1}-r_{n} \\
& =\sum_{i=0}^{\infty}\left(q_{i+1}^{k}-q_{i}^{k}\right) .
\end{aligned}
$$

The procedure generates approximations $\tilde{p}=\sum_{i=0}^{j} a_{i} 2^{-i}$ to a random real number, and as soon as we are guaranteed that this random number is in one of our intervals between $r_{n}$ and $r_{n+1}=r_{n}+\left(q_{i+1}^{k}-q_{i}^{k}\right)$, i.e., that no further bits will take us out of that interval (condition (2) above), we halt and output the string $w_{k}$ corresponding to the interval, with $k=\rho_{1}(n+1)$. Clearly, the probability of outputting $w$ is exactly $\mu(w)$, and the probability of not halting at all is $1-\sum_{w} \mu(w)$.
Theorem 1. Probabilistic machines correspond exactly with the enumerable semi-measures.

As every enumerable probability measure is computable, we have the following well-known corollary.
Corollary 1. A.s.-terminating probabilistic machines correspond exactly with the computable measures.

## Conclusion

Defining distributions by means of programs in a universal probabilistic language yields exactly the computably enumerable semi-measures. Our claim has been that this wider class, going beyond a.s.-terminating programs, provides a sensible foundation for theorizing about representation, inference, and learning in cognitive science. Assuming we want to make a clean separation between computational and algorithmic levels of analysis-which is evidently necessary to justify use of anything beyond (probabilistic) finite-state automata in the first place-we see no reason to restrict attention to programs that a.s. terminate, neither for the theorist nor for the learner.

# The Influence of Speaker's Gaze on Sentence Comprehension: An ERP Investigation 

Torsten Kai Jachmann (jachmann@coli.uni-saarland.de)<br>Heiner Drenhaus (drenhaus@coli.uni-saarland.de)<br>Maria Staudte (masta@coli.uni-saarland.de)<br>Matthew W. #### Abstract

Behavioral studies demonstrate the influence of speaker gaze in visually-situated spoken language comprehension. We present an ERP experiment examining the influence of speaker's gaze congruency on listeners' comprehension of referential expressions related to a shared visual scene. We demonstrate that listeners exploit speakers' gaze toward objects in order to form sentence continuation expectations: Compared to a congruent gaze condition, we observe an increased N400 when (a) the lack of gaze (neutral) does not allow for upcoming noun prediction, and (b) when the noun violates gaze-driven expectations (incongruent). The later also results in a late (sustained) positivity, reflecting the need to update the assumed situation model. We take the combination of the N400 and late positivity as evidence that speaker gaze influences both lexical retrieval and integration processes, respectively (Brouwer et al., in press). Moreover, speaker gaze is interpreted as reflecting referential intentions (Staudte \& Crocker, 2011).

Keywords: ERP; N2; N400; late sustained positivity; gaze; prediction; referential expressions

## Introduction

The gaze of a speaker toward objects present in a shared scene in a face-to-face interaction provides a visual cue that expresses the speaker's focus of visual attention and may draw the listener's attention as well (Emery, 2000; Flom, Lee, \& Muir, 2007). This visual cue can be used by the listener to ground and disambiguate referring expressions, infer the speaker's intentions and goals, and thus facilitate comprehension (Hanna \& Brennan, 2007). As most research conducted on the influence of speakers' gaze on listeners' language comprehension focused on behavioral data (e.g.: reaction times, eye movements), little is known about the precise time course for the integration of visual and linguistic information, or which underlying mechanisms are involved.

We therefore conducted an ERP-study to investigate how listeners integrate cues provided by the speaker's gaze when it is time-aligned to an utterance containing statements about the visual context. We monitored listeners' event-related potentials (ERPs) as they observed a stylized face performing gaze actions toward simple objects preceding their mentioning in a simultaneously presented utterance that compared objects in the scene with one-another. The gaze cue corresponding to the second object in the sentence was either Congruent (toward the named object), Incongruent (toward the object
that remains unnamed in the sentence) or Neutral (toward an empty position at the bottom of the screen). This manipulation was intended to shed light on how listeners use speakers' gaze to anticipate and integrate subsequently mentioned referents.

Previous eye-tracking studies have shown that, when a visual context is present, speakers orient their gaze toward an object about $800-1000 \mathrm{~ms}$ before mentioning it (Griffin \& Bock, 2000; Kreysa, 2009). However, it is less clear to what extent such speaker gaze affects listeners' sentence comprehension.

Staudte and Crocker (2011) showed in an eye-tracking study that participants used gaze cues to disambiguate a sentence with multiple same-type referents as soon as it was provided, expressed by a higher inspection rate to the gazed-at object compared to the competitor. Furthermore, a misleading gaze cue lead to a longer reaction time while judging whether the sentence was true or false given the visual scene.

For our ERP study, we hypothesized that listeners integrate gaze cues in a situation model to anticipate which objects are likely to be subsequently mentioned, influencing the retrieval and integration of the noun. Specifically, we expect an N400 modulation will occur as a function of predictability, such that neutral gaze, and even more so incongruent gaze, will increase the amplitude of the N400 compared to a congruent gaze condition. Additionally, we hypothesized that the naming of objects that were previously eliminated based on (incongruent) speaker gaze should lead to a higher cost of integration, possibly reflected by a increased late positivity (Brouwer, Crocker, Venhuizen, \& Hoeks, in press).

## Experiment

In our experiment, German native speakers judged the truthfulness of an auditorily presented sentence given a visual context while their EEG was recorded. Each trial contained a stylized face that performed gaze actions timed to the sentence that was to be evaluated. Every gaze action was performed 800 ms prior to the naming of the corresponding noun. The first gaze was always Congruent toward the object that was named first in the sentence. Gaze to the second object was manipulated such that is was either toward the second named object (Congruent), toward a distractor object that was
never named during the course of the trial (Incongruent) or toward the bottom of the screen where no object was situated (Neutral).

We hypothesized that (1) Congruent gaze toward the upcoming object leads to facilitated retrieval of the corresponding noun, and a reduced N 400 , as it is highly predictable given the visual scene. (2) Incongruent gaze on the other hand is hypothesized to evoke an increased N400 modulation, as the visual information favors predictions of the unnamed object and thereby hinders word retrieval. Additionally, the elimination of the named object based on the visual information demands an update of the situation model and thereby might increases integration costs reflected by a late positivity. (3) As Neutral gaze does not highlight one object more than the other, both remaining objects are equally predictable in the sentence. This might lead to an intermediate retrieval cost of the noun.

## Participants

Forty-five right-handed native speakers of German (Mean age: 24; Age range: [18, 32]; SD: 3.39; Male: 8; Female: 37) took part in the ERP experiment. 15 participants were removed from the analysis due to their behavioral data (3) and too high numbers of eye artifacts (12). ${ }^{1}$ Participants gave informed consent. All participants had normal or corrected-tonormal vision and had no hearing problems. All participants were compensated with $€ 15$ for their participation.

## Stimulus Materials and Procedure

We created 24 pictures of objects of masculine, feminine and neuter gender ( 8 per gender). The pictures were pretested to ensure that they (a) were recognized as the intended objects and (b) were equally complex in their appearance.

Participants were presented with a picture containing three objects of the same gender that varied either in size or brightness arranged in positions above, left and right of the center of the screen. Each screen contained a large, medium, and small object (or bright, medium, and dark object respectively). After 3000 ms , a stylized face appeared in the middle of the screen with a straight gaze toward the participant. The face then performed gaze actions timed to an auditory presented sentence of the form "Verglichen mit dem Auto, ist das Haus verhältnismäßig klein, denke ich" (Compared to the car, the house is relatively small, I think). The utterance was a synthesized German sentence using the CereVoice TTS systems Alex voice (Version 3.2.0). We created different versions of example utterances that varied in intonation contour and turn internal pause length. A Google Form was used to collect responses of seven participants, who listen to those examples with the task to rate their naturalness and order them from most natural to least natural. We selected the version with the most natural rating for the experiment.

In order to keep the influence of the first noun on the second gaze cue as well as on the second noun the same across

[^354]all items, a pause of variable length was introduced after the first noun, so that the distance of the onset of the first noun to the onset of the second half of the sentence always was about 1000 ms . At sentence onset, the face retained its straight gaze but opened the mouth to evoke the impression of the face being the speaker of the sentence. The first gaze cue appeared approximately 800 ms before the first noun was mentioned. This gaze cue was always Congruent toward the named object for all experimental trials. Also, in order to ensure the participants' attention throughout the entire sentence, the first named object in the experimental items was always the medium sized object (or object of medium brightness when brightness was manipulated). If the first mentioned object were the smallest/brightest or biggest/darkest object in the scene, it would not matter which of the other objects were named second, as for both the same comparative adjective would render the sentence true or false.

An example of the visual scene provided in Figure 1 displays the time line of an example trial, with a small house, medium car and a large $t$-shirt. If the $t$-shirt was mentioned first in this context, both of the remaining objects would be smaller. The second, manipulated gaze cue then appeared again 800 ms prior to the onset of the second noun. The gaze was redirected toward the participant 400 ms before the end of the sentence, and the mouth closed on the offset of the sentence.

Each item appeared in three conditions (Congruent / Incongruent / Neutral). In the Congruent condition, the gaze preceding the second noun was directed toward the subsequently named object. In the Incongruent condition, the gaze cue went toward the object that remained unnamed in the sentence. In the Neutral condition, gaze was directed toward the bottom of the screen where no object was present, in order to still present a gaze cue induced by the eye-movement of the face. Additionally, we created versions of those manipulations that were counterbalanced for naturalness. Naturalness was defined as the truth value of the utterance in reality. For example, the in-reality invalid utterance "compared to the car, the house is relatively small, I think" was counterbalanced with the utterance "compared to the house, the car is relatively small, I think". This counterbalancing also led to a swap of the size of the named objects in the visual scene. Using a Latin-square design, this led to a total of six lists.

Each list contained 72 experimental items ( 24 per condition) and 72 fillers with mentioning of an object other then the medium object as the first noun and gaze patterns different from the gaze patterns in the experimental items. As in the experimental items only the second gaze cue was manipulated, $25 \%$ of the fillers (18) contained a manipulation of the first gaze cue instead of the second gaze cue. This version of the fillers still started with a mentioning of the medium object as the first noun in the sentence. The first gaze cue was always neutral and never incongruent in order to enforce the validity of the gaze cues. The remaining fillers were of the same form as the experimental items with the difference

Figure 1: Timeline of an item in the Congruent condition.
that the first mentioned object was either the small or large (bright/dark) object. The second named object in these fillers was the medium object half of the time and the remaining size/brightness the other half. The gaze patterns performed on these fillers always started with a congruent gaze, as in the experimental items, followed by another congruent gaze towards the second named object half of the times (36) and a quarter of the times each by an incongruent or neutral gaze cue (18). This distribution of gaze patterns throughout the experiment led to an overall ratio of congruent gaze actions ${ }^{2}$ of $70 \%$ (204). Another $18 \%$ (51) of the gaze actions were Neutral and only about $12 \%$ (33) of the gaze actions were Incongruent. This way, the validity of the gaze cue was strongly enforced in order to avoid that participants would start to ignore the gaze cues altogether throughout the course of the experiment.

The stimuli were presented using the E-prime software (Version 2.0.10. Psychology Software Tools, Inc.). Each participant was seated in a sound-proof, electro-magnetically shielded chamber in front of a 24 " Dell U2410 LCD monitor (resolution of $1280 \times 1024$ with a refresh rate of 75 Hz ). The distance between the participant and the screen was always 100 cm in order to keep all objects in a $5^{\circ}$ visual angle from the center of the screen. This was done to minimize eye movements throughout the experiment. While the participants were prepared for the recording, they were presented with all objects that occurred throughout the experiment and their naming. The Alex voice of the CereVoice TTS was also used for the naming of the objects. After this, participants were presented with written instructions and completed six practice trials. The items were pseudo randomized for each list and presented in 7 blocks with breaks after each block. After each item, the participants were asked to indicate whether the sentence was true given the visual context they were presented with by pressing one of two buttons. Answers were recorded using a Response Pad RB-834 (Cedrus

[^355]Corporation). The experiment lasted approximately 45 min .

## Data Analysis

The EEG was recorded by $24 \mathrm{Ag} / \mathrm{AgCl}$ scalp electrodes (actiCAP, BrainProducts) and amplified with a BrainAmp (BrainVision) amplifier. Electrodes were placed according to the 10-20 system (Sharbrough et al., 1995). Impedances were kept below $5 \mathrm{k} \Omega$. The ground electrode was placed at AFz . The signal was referenced online to the reference electrode FCz and digitized at a sampling rate of 500 Hz . The EEG files were re-referenced offline to the average of the mastoid electrodes. The horizontal electrooculogram (EOG) was monitored with two electrodes placed at the right and left outer canthi of each eye and the vertical EOG with two electrodes below both eyes paired with Fp 1 and Fp 2 . During recording an anti-aliasing low-pass filter of 250 Hz was used. The EEG data was band pass filtered offline at $0.01-40 \mathrm{~Hz}$ in order to attenuate skin potentials and other low voltage changes as well as line noise and EMG noise (Luck, 2014). Single-participant averages were computed for a 1100 ms window per condition relative to the acoustical onset of the noun following the manipulated gaze cue and the manipulated gaze cue itself. All segments were aligned to a 100 ms pre-stimulus baseline. We semi-automatically screened offline for artifacts.

Due to the nature of the task and the experimental setup containing various eye movements performed by the displayed face, the number of eye artefacts was relatively high. Therefore, we set a threshold of $30 \%$ rejection rate per condition for participant exclusion (i.e.: participants' data with more than 7 rejected trials out of 24 in one or more conditions were removed. On average 5.3 trials per participant and condition ( $22 \%$ ) were rejected due to eye movements). This led to the removal of 12 participants from the analysis. Additionally, the data of 3 participants was removed due to their behavioral data. Participants' data was removed if they gave wrong answers to more than $10 \%$ of the questions. Overall, the two criteria led to the removal of the data of 15 participants. The averaged data of the remaining 30 participants (Mean age: 23.7; Age range: [18, 32]; SD: 3.49; Male: 4) was
exported using BrainVision Analyzer (Version 2.1) BESA export function.

We analyzed the ERP data time-locked to the onset of the second noun following the manipulated gaze cue. We used R ( R Core Team, 2015) to perform repeated measures analysis of variance (ANOVA) using Greenhouse-Geisser correction. We report F values, Greenhouse-Geisser corrected p values and $\eta^{2}$ (partial eta-squared) values as a measure of effect size. All ANOVAs were computed on the F3, Fz, F4, FC5, FC1, FC2, FC6, C3, Cz, C4, CP5, CP1, CP2, CP6, P7, P3, Pz, P4, P8, O1 and O2 electrodes including ROIs for frontal (F3, Fz, F4, FC5, FC1, FC2, FC6), central (C3, Cz, C4, CP5, CP1, $\mathrm{CP} 2, \mathrm{CP} 6$ ) and posterior (P7, P3, Pz, P4, P8, O1, O2) distributions.

## Critical Region (Second Noun)

We analyzed the influence of experimental condition (Congruent, Incongruent, Neutral gaze) time locked to the onset of the second noun, including electrode site (frontal/central/parietal) as withinsubject factors. An ANOVA of time window between 150 and 400 ms showed a main effect of condition $\left(F(2,58)=3.99, p<0.05, \eta^{2}=0.12\right)$. There is a globally distributed, significantly larger negativity for both the Incongruent and Neutral condition compared to the Congruent condition $\left(\left(F(1,29)=5.66, p<0.05, \eta^{2}=0.16\right)\right.$ and $\left(F(1,29)=4.86, p<.05, \eta^{2}=0.14\right)$ respectively). However, further Visual inspection revealed that the Neutral condition contains two distinct, frontally distributed peaks within this time window (see Figure 2 for comparison). This is coherent with previous findings by, e.g., Hagoort and Brown (2000). This led to the analysis using a moving time window in this epoch in order to determine whether those peaks are indeed distinct. We split the data of the previous time-window in four overlapping sub-time-windows of 100 ms length with a distance of 50 ms each and introduced those time-windows as a factor in an ANOVA, where the interaction of time-window, longitude and condition showed a significant effect $\left(F(12,348)=1.95, p<0.05, \eta^{2}=0.06\right)$. We find a main effect of condition only in the time windows between $150-300 \mathrm{~ms}\left(F(2,58)=3.93, p<0.05, \eta^{2}=0.12\right)$ and $300-400 \mathrm{~ms}\left(F(2,58)=3.38, p<0.05, \eta^{2}=0.1\right)$. This indicated that the two peaks are indeed distinct. A pairwise comparison of the conditions in the time window of the earlier peak ( $150-300 \mathrm{~ms}$ ) showed that both the Incongruent and Neutral condition retain their significantly larger negativity $\left(\left(\left(F(1,29)=5.82, p<0.05, \eta^{2}=0.17\right)\right.\right.$ and $\left(F(1,29)=4.93, p<.05, \eta^{2}=0.15\right)$ respectively $)$. A pairwise comparison in the time window of the second peak also shows that both the Incongruent and Neutral condition contain a significantly larger negativity $\left(\left(F(1,29)=4.22, p<0.05, \eta^{2}=0.13\right)\right.$ and $\left(F(1,29)=5.99, p<.05, \eta^{2}=0.17\right)$ respectively $)$. Additional to the findings in the early time-window, we analyzed the time-window between $600-1000 \mathrm{~ms}$. The analysis revealed a main effect of experimental condition

Figure 2: ERP time-locked to the Second Noun Onset separated by the Experimental Conditions (Congruent (black), Incongruent (red) and Neutral (blue)). Reported regions are highlighted by boxes. The data presented shows the electrode subset Fz and Pz filtered at 20 Hz (low-pass) for presentation purposes only.
$\left(F(2,58)=3.38, p<0.05, \eta^{2}=0.16\right)$. A pairwise analysis of the conditions showed that the late long-lasting positivity is only present in the Incongruent condition $\left(F(1,29)=7.24, p<0.05, \eta^{2}=0.2\right)$.

## Discussion

Research from Van Berkum, Koornneef, Otten, and Nieuwland (2007) suggests that comprehenders predict the upcoming course of a sentence based on the previously gathered information that they integrated in a situation model (Zwaan \& Radvansky, 1998). Various studies have further shown that not only linguistic information is used to form predictions
about upcoming sentence content but also visual information (Staudte \& Crocker, 2011; Ferreira, Foucart, \& Engelhardt, 2013). It therefore seems reasonable to suggest that such visual cues contribute to the construction of the situation model. We interpret the two main components (N400, late positivity) found in terms of the retrieval-integration approach (Brouwer et al., in press): The N400 is modulated by the retrieval difficulty of the upcoming noun, influenced by its predictability given the visual context. Further, the positivity is influenced by the integration difficulties founded in the need to update the situation model.

## N400

Parviz, Johnson, Johnson, and Brock (2011) showed that the N 400 m , representing the N 400 as measured by magnetoencephalography (MEG), is modulated by the information content that is conveyed by a word in a given context. A similar interpretation can be attributed to findings from Willems, Frank, Nijhof, Hagoort, and Van den Bosch (2015). In their study participants listened to spoken narratives. Their results show that words with a higher surprisal let to an increased activation in the left temporal lobe, which has been identified as source of the N400 effect (e.g., Van Petten and Luka (2006)). Additionally, an ERP study from Frank, Otten, Galli, and Vigliocco (2015) revealed a correlation between the amplitude of the N400 and word surprisal. In the current study, the gaze cue preceding the second noun leads to predictions for the upcoming noun. In the Congruent condition, those predictions are fulfilled, which leads to an effortless retrieval of the noun and thus leads to a reduced N 400 amplitude compared to both Neutral and Incongruent conditions. In the Neutral condition, participants have two possible upcoming nouns active. The information conveyed by the noun therefore is higher than in the Congruent condition, as the set of candidates is reduced to the actual target. In the Incongruent condition, the information conveyed by the noun contradicts the prediction made using the visual information. This results in an increase of the retrieval cost of the noun and thus to an increased N400 effect compared to the congruent condition.

The early onset of the negativity ( 150 ms after noun onset) suggests we may in fact be observing modulation of the N 2 component, as well as N400. This is supported by the analysis using a moving time window, which revealed two distinct peaks between $150-300 \mathrm{~ms}$ and $300-400 \mathrm{~ms}$ respectively, especially prominent in the Neutral condition (see Figure 2 for comparison), and is discussed below.

## N2

The globally distributed, early negative component between 150 and 300 ms can be interpreted as a reminiscent of the Phonological Matching Negativity (PMN) as described by Connolly and Phillips (1994). Similar results have been found by Hagoort and Brown (2000). They explain this early effect with a peak around 250 ms as a mismatch between the expected word form given a context and the actual activated word candidates given the speech signal listeners perceive. In
this study, the context was built up by the gaze towards an object present in the visual scene. The following word now either confirms the expectation (Congruent), which in turn leads to no PMN modulation, or disconfirms them (Incongruent), which evokes a large PMN modulation.

Following the account of Hagoort and Brown (2000), which states that 'the N250 effect might reflect the lexical selection process that occurs at the interface of lexical form and contextual meaning', the effect in our Neutral condition could also be explained as such an selection process. Given our visual scene, at the second noun, two of the three objects are still valid targets. The Neutral gaze cue, directed downwards, does not provide any further information about the upcoming word. As both remaining objects are equally plausible, a decision for either one has to be made using the first phoneme of the uttered word, which leads to the discard of one of the two predictions. This selection process elicits the negativity in the N2 region found in the Neutral condition. It is important to highlight that all of the previously named studies establish the predictive context using language. Our study differs in that predictive context is determined solely on the basis of visual information: the linguistic context does not contribute a preference for either of the valid nouns.

## Positivity (600-1000ms)

The relation between updating of a situation model and the occurrence of a late positivity has been demonstrated in various studies (Burkhardt, 2007; Donchin, 1981). Following those accounts, we can interpret our findings in the later time window starting at 600 ms as similarly reflecting the cost of updating the situation model, and integration more generally (Brouwer et al., in press). In both the Congruent gaze and Incongruent gaze condition participants can exploit the gaze cue towards an object in their situation model to make predictions about the upcoming noun. In the Congruent condition, this leads to no violation of those predictions and thereby doesn't require an update of the situation model.

In the Incongruent condition however, the violation of the predictions leads to the need to update the situation model: the gaze cue toward an object leads to the listener's interpretation of the gazed-at object to be the upcoming noun. This in turn leads to the elimination of the remaining object as relevant to the situation model. As the upcoming noun however shows that the previously discarded object is in fact relevant, the situation model has to be updated, which leads to higher integration costs expressed by the late positivity.

The Neutral condition does not draw the focus to one single object but leaves two objects (the so far unnamed objects) as equally possible targets. The prediction of this set of objects is not violated and therefore does not require an update of the situation model.

## Conclusion

We suggest that the N 400 and late positivity are most naturally interpreted in terms of the retrieval-integration approach (Brouwer et al., in press): The N400 findings suggest that
gaze is used to anticipate the upcoming noun, resulting in increased retrieval cost when gaze is absent or incongruent. Interestingly, the late positivity for incongruent gaze, suggests that gaze is interpreted as conveying referential intentions, resulting in integration difficulty only when gaze is misleading. This is consistent with eye-tracking data from Staudte and Crocker (2011). Additionally, we found an N2 modulation preceding the N400, suggesting gaze leads listeners to anticipate specific word forms. More specifically, we argue that the gaze cue preceding the second noun is used in combination with the unfolding situation model to make predictions about the continuation of the sentence. Those predictions are then matched with the auditory input. If the initial phoneme of the input is in line with the prediction, this phoneme provides little new information and therefore facilitates word retrieval. If however the phoneme provides more information, either by helping to reduce the set of predictions to a single target (Neutral condition) or through violation of the predictions (Incongruent condition), an N2 modulation is elicited. In both cases, a subsequent N400 modulation is evoked. If the predictions are completely violated (Incongruent condition), the situation model needs to be updated, which increases the integration cost of the corresponding noun, expressed by a late positivity. Given the findings in the N4 time-window and the late positivity, a classical semantic integration (N4) and reanalysis (P6) account seems unlikely. The integration of the word in the Neutral condition should not lead to a strong N4 modulation as both possible words fit the context without a semantic violation. This predicted modulation for only the Incongruent condition however can be found in the later time-window reflected in the late positivity. Additionally, the late positivity should not be evoked, according to the classic account, as no syntactic reanalysis is needed in any condition. In sum, our findings demonstrate a robust influence of non-verbal gaze cues on several underlying processes, including auditory processing, lexical retrieval, and integration with sentence meaning.

# In search for the relevant space of implicit memory deficit in dyslexia 

Sagi Jaffe-Dax (jaffedax@princeton.edu)<br>Department of Psychology<br>Princeton University<br>Princeton, NJ 08540 USA

Merav Ahissar (msmerava@gmail.com)<br>Department of Psychology and Edmond and Lily Safra Center for Brain Sciences<br>The Hebrew University of Jerusalem<br>Jerusalem 91905 ISRAEL

#### Abstract

Studies of dyslexics, whose implicit memory is impaired, suggest that their implicit inference of sound statistics and its integration into perception is inefficient. Specifically, dyslexics' implicit memory decays faster and consequently only accumulates information over shorter temporal windows. We now ask whether this abnormal dynamic is domain general by measuring its cortical distribution. We measure the dynamics of behavioral context effects and the concurrent neural adaptation during fast acquisition fMRI. We find a similar pattern of fast decay of adaptation across a broad range of cortical areas, though most significant effects are found in auditory cortex. This broad neural distribution suggests that the relevant aspect of implicit statistical inferences is not the nature of stimuli, but their temporal distribution.

Keywords: implicit memory; adaptation; fMRI; dyslexia, anchoring hypothesis of dyslexia; Bayesian inference; statistical learning.

## Background

Implicit statistical learning has a profound measurable effect on performance in perceptual discrimination tasks. Seemingly simple and unbiased, serial discrimination places an asymmetric memory load on sequentially presented stimuli. The stimulus presented first has the highest memory load, since it needs be retained until the subsequent stimulus is presented. Hence, relying on priors to compensate for noisy representations is crucial for accurately inferring the perceived stimulus. Priors can be utilized to modify noisy representations into a maximum likelihood estimate of stimuli, those based on previous exposures that led to the formation of priors. The integration of priors has been modeled computationally in the context of auditory perception for signal detection tasks (Treisman \& Williams, 1984) and recently for 2-tone frequency discrimination (Raviv et al., 2012, 2014; reviewed in Bausenhart, Bratzke, \& Ulrich, 2016). Raviv et al. (2012) model asserts that participants do not compare the representations of the first and second tones, as requested to do and as they introspectively do. Rather, they compare the representation of the second tone to the integrated representation of the first tone with the estimated mean (prior) of previous stimuli. Thus, the representation of the first tone is contracted towards the mean of previous trials, and when this contraction is in
the direction of the correct response, the success rate will increase.

Accordingly, trials in this serial discrimination task can be divided into those in which contraction increases the perceived difference between the two stimuli, hence increasing success rate (Bias + ), and trials in which contraction decreases the perceived difference, and decreases the success rate (Bias-). The magnitude of the contraction can be quantified as the difference in performance on these two types of trials.

Contraction bias in serial comparison tasks has been observed in the visual (Ashourian \& Loewenstein, 2011; Fischer \& Whitney, 2014; Lages \& Treisman, 1998; Liberman, Fischer, \& Whitney, 2014), auditory (Lu, Williamson, \& Kaufman, 1992; Raviv et al., 2012; Treisman \& Williams, 1984) and tactile (Hairston \& Nagarajan, 2007) modalities, and was even observed in tactile velocity discrimination tasks in rats (Fassihi, Akrami, Esmaeili, \& Diamond, 2014) and vibro-tactile discriminations in monkeys (Romo, Hernández, Zainos, Lemus, \& Brody, 2002).

Dyslexia is a wide spread learning disability which poses an obstacle in acquiring academic education. It is probably the most prevalent learning disability. Defined as a "specific and significant impairment in the development of reading skills that is not accounted for by mental age, visual acuity problems, or inadequate schooling" (WHO, 2010), it affects $5 \%$ of the world's population (Lindgren, De Renzi, \& Richman, 1985).

Dyslexics are diagnosed by their reading difficulty but are also consistently found to have difficulties in non-linguistic perceptual tasks (McAnally \& Stein, 1996; Sperling, Lu, Manis, \& Seidenberg, 2005). Specifically, dyslexics exhibit poorer utilization of implicit memory to compensate for noisy observation (Ahissar, Lubin, Putter-Katz, \& Banai, 2006; Jaffe-Dax, Raviv, Jacoby, Loewenstein, \& Ahissar, 2015; Oganian \& Ahissar, 2012). We recently accounted for this deficient memory usage by faster recovery from neural adaptation, as measure in Event Related Potential (ERP; Jaffe-Dax, Frenkel, \& Ahissar, 2017). Importantly, dyslexics also exhibit poorer utilization of implicit memory in visual discrimination tasks (Jaffe-Dax, Lieder, Biron, \& Ahissar, 2016). Namely, their implicit memory impairment is not modality-specific, but rather general multi-modal.

Importantly, even in linguistic tasks, compared to good readers, dyslexics perceptual performance is adequate when the stimuli are equally unfamiliar to both groups, and only differ from peers in familiar contexts (Perrachione, Del Tufo, \& Gabrieli, 2011). This accumulative body of research stands in contrast to both the traditional phonological deficit theory of dyslexia (Snowling, 2000) and the claim for dyslexics' overall noisy neural representation (Hancock, Pugh, \& Hoeft, 2017).

Implicit memory is an inaccessible cognitive module which has precise resolution, large capacity and long term retention (Schacter, 1987). Contemporary studies define implicit memory as a memory which does not depend on Medio-Temporal lobe activity, or inaccessible to subject's awareness. This negative definition has been recently challenged by a general theory of wide-spread cortical plasticity in response to perceived events (Reber, 2013). Implicit memory utilization has been recently quantified using a heuristic approximation of Bayesian inference in simple perceptual task (Raviv et al., 2012). This well-defined grounded model of high level cognitive aptitude paved a way for a search for well-defined neural mechanism which would give rise to implicit memory.

While neural adaptation has a long history of research and has been studied intensively in human and animals (Khouri \& Nelken, 2015), its cognitive role and behavioral implication are yet poorly understood. The time scale of recovery from neural adaptation has been linked with the time scale of implicit memory trace ( Lu et al., 1992). Our preliminary findings of fast decay suggest that this rate of decay of adaptation is a crucial machinery for statistical learning. Though traditionally adaptation was considered as reflecting fatigue, we gradually understand that it is used for statistical learning and updating of categories (Kleinschmidt \& Jaeger, 2016).

In the current study, we used fMRI to localize dyslexics' cortical site of fast decay of adaptation. We expected that, if their deficit was specific to speech sounds, the difference in dynamics would affect only specific areas of the temporal lobe, and perhaps also some parietal areas. However, if their deficit was domain general, then all areas activated by these stimuli would show a similar pattern compared with controls.

Our results show, that all active regions exhibit faster recovery from adaptation among dyslexics. We also found additional support to the relation between implicit memory and the time-scale of recovery from adaptation by replicating the parallel finding of shorter adaptation and shorter implicit memory in a special population - dyslexics. Our findings suggest that neural adaptation in cortical areas that correspond to the specific perceptual event carries implicit memory.

This current study shows that dyslexics' implicit memory impairment is dictated by the dynamic decay of their representation throughout the cortex and not by a modalityspecific difficulty.

## Results

We administered two-tone frequency discrimination to 20 dyslexics and 19 good readers in four conditions of trial intervals: 3, 6, 9 and 15 seconds (trial onset to trial onset; TOA). Implicitly, the representation of the first tone is degraded and contracted towards the mean of previously experienced tones (contraction bias). In Bias + trials this bias extended the perceived difference between the current pair and improve their detectability; while in Bias- trials this bias decreased the perceived difference between the current two tones and hence hampered performance (Raviv et al., 2012). We previously found that this implicit memory impact decayed with the extension of inter-trial intervals - it was weaker in conditions of longer inter-trials intervals than in conditions with short inter-trial intervals (Jaffe-Dax et al., 2017). We measured implicit memory as the difference in sensitivity ( $d^{\prime}$ ') between Bias + and Bias- trials and modelled its decay using an exponential decay: $\Delta d^{\prime}(T O A)=a+$ $b \exp (-T O A / \tau)$, where $a$ denotes the estimated $\Delta d^{\prime}$ at $t \rightarrow$ $\infty$ (asymptotic level); $\beta$ denotes the difference between the $\Delta d^{\prime}$ at $t=0$ and at $t \rightarrow \infty$ (decay magnitude); $\tau$ denotes the time it takes for $\Delta d^{\prime}$ (at $t=0$ ) to decay to $1 / e(\sim 37 \%)$ of its initial value (temporal slope parameter). A small $\tau$ indicates fast decay.

In this current study, we replicate faster implicit memory decay among dyslexics outside of the magnet (in a training session), but surprisingly not in-scan. In the training session dyslexics' implicit memory decay was faster than controls' (group $\tau \pm$ IQR: controls: $2.3 \pm 3.4$; dyslexics': $0.4 \pm 0.4 ; z=$ $2, p<0.05$, Mann-Whitney U-test). Figure 1 shows the difference in $d^{\prime}$ between the trials that benefit from prior integration and trials that loose from it as a function of intertrial interval. For both groups, we did not observe a significant decay of implicit memory in the scanner, Perhaps the scanner noise forced the subjects to compensate for their noisy perception in all TOA conditions.

Figure 1. Implicit memory decay is faster among dyslexics in the training session, but not in-scan. Controls in blue; dyslexics in red.

We expected an attenuation of neural activity in the conditions with short inter-trial interval relative to the conditions with long inter-trial intervals, as neural adaptation decays. Specifically, we fitted their BOLD activity in the four ITI conditions to an exponential decay model $(\beta(T O A)=$ $a+b \exp (-T O A / \tau))$ and searched for regions in which the

Figure 2. Estimated groups' model parameters for exponential BOLD decay across the cortex. A. Controls' asymptote level (a). B. Dyslexics' asymptote level (a). C. Controls' magnitude of decay (b). D. Dyslexics' magnitude of decay (b). E. Controls' decay time ( $\tau$ ). F. Dyslexics' decay time ( $\tau$ ).
model parameters ( $a, b$ or $\tau$ ) differed significantly between the groups. Figure 2 shows the average groups' parameters of the exponential decay model. Throughout the cortex, dyslexics' estimated decay rate was faster than controls' (i.e. shorter $\tau$ ). This confirms our prior hypothesis regarding their faster recovery from adaptation. Unexpectedly, the asymptote level (a) of the model also differed between the groups. Specifically, the overall BOLD level of controls was higher than dyslexics'. This could be attributed to overall lower signal-to-noise ratio in dyslexics' BOLD signal, but surely worth further investigation and verification.
We compared the individually estimated parameters of BOLD decay between the groups and found that the decay time differed significantly in the left primary auditory cortex (group $\tau \pm$ IQR: controls: $25.4 \pm 990.9$; dyslexics': $9.1 \pm$ 113.2; $z=2.2, p<0.05$, Mann-Whitney U-test). Unexpectedly, the asymptotic level differed significantly in this region (group $a \pm \mathrm{IQR}$ : controls: $10.4 \pm 298$; dyslexics': $9.1 \pm 113.2 ; z=2.5, p<0.05$ ), in the left central gyrus (controls: $7.7 \pm 230.9$; dyslexics': $3.9 \pm 12.5 ; z=2, p<0.05$ ) and in the right ventral frontal cortex (controls: $6.6 \pm 180.1$; dyslexics': $2.2 \pm 55 ; z=2.1, p<0.05$, Mann-Whitney Utests). Figure 3 shows the clusters which revealed significant difference in estimated parameters between the groups.

These significant group differences were mostly apparent in the cortical regions that are known to be most active during this task (Daikhin \& Ahissar, 2015). Recent study with multiple types of stimuli reported reduced stimulus specific adaptation in dyslexics across all related cortical regions (Perrachione et al., 2016). In line with these findings, we
argue that shorter time scale of recovery from adaptation is a general property of dyslexics' cortex, which accounts for their shorter retention of implicit memory.

## Discussion

Adaptation is a simple, well defined candidate for the neural basis of implicit memory. Assuming a labelled line of input units, adaptation from previous stimuli should attenuate responses to upcoming stimulus as a function of its proximity to the previous stimuli. This proximity has both temporal and parametric dimensions, such that similar stimuli should yield a more attenuated response than dissimilar stimuli, and rapid repeating stimuli should yield a more attenuated response than slow repetitions.

In this work, we have presented evidence that neural adaptation in modality specific cortical region decayed faster in a special population of subjects, who also exhibited faster decay implicit memory to the same modality. Taken together, these parallel findings support the purposed model for implicit memory.

A recent imaging study compared adaptation to similar stimuli within a category among dyslexics and good readers. Our suggestion is in line with the researchers' findings of deficient adaptation in dyslexics in every category-specific cortical region that was measured (Perrachione et al., 2016).

Our findings suggest that the property of adaptation which is impaired in dyslexics is the temporal dimension rather than the similarity between stimuli. Namely, their adaptation decay as a function of time and not as a function of representational similarity (which was recently found intact

Figure 3. Group effect in estimated decay model parameters. A. Controls' estimated decay time ( $\tau$ ) was longer than dyslexics' in superior temporal gyrus. B. Controls' estimated asymptote level (a) was higher than dyslexics' in central sulcus and in ventral frontal cortex.
in dyslexics ;Boets et al., 2013). Thus, it is this dynamic feature that governs implicit memory skills and deficits.

## Methods

The demographic, cognitive and reading assessments of this cohort is described in Jaffe-Dax et al., 2017.

In the two-tone frequency discrimination task, subjects were asked to indicate which of the two tones had a higher pitch. The tones were drawn from a uniform distribution between $800-1250 \mathrm{~Hz}$ and the frequency difference within each pair was randomly drawn between 1-20\%. Each subject performed 12 blocks of 16 trials. Each block had a constant Trial Onset Asynchrony (TOA) of 3, 6, 9 or 15 seconds (in random order). Subjects performed the task outside of the scanner (training) and in-scan.

Stimuli were digitally constructed using Matlab 2015b (The Mathworks Inc., Natwick, MA) and administered
through inserted sound attenuating MR compatible S14 earphones (Sensimetrics Corporation, Malden, MA).

Prior to the functional scan, a high-resolution $(1 \times 1 \times 1$ mm resolution) T 1 -weighted magnetization-prepared rapid acquisition gradient-echo (MPRAGE) images were acquired using a 3-T Magnetom Skyra Siemens scanner and a 32channel head coil, at the ELSC Neuroimaging Unit (ENU). The functional MRI protocols were based on a multislice gradient echo-planar imaging and obtained under the following parameters: $\mathrm{TR}=1 \mathrm{~s}, \mathrm{TE}=30 \mathrm{~ms}$, flip angle $=90^{\circ}$, imaging matrix $=64 \times 64$, field-of-view $=192 \mathrm{~mm} ; 42$ slices with 3 mm slice thickness and no gap, were oriented in ACPC plane, covering the whole brain, with functional voxels of $3 \times 3 \times 3 \mathrm{~mm}$ and multiband parallel imaging with acceleration factor $=3$ (Moeller et al., 2010).

Each condition was modelled separately to account for its contribution to the measured BOLD signal in each voxel, i.e., its $\beta$ values for each TOA condition. A spherical searchlight with 4 voxels radius was performed centered at each voxel to
average $\beta$ values for each condition. An exponential decay model (see Results) was fitted to the smoothed $\beta$ values and its parameters were estimated for each center voxel.

# Cognition Influencing Auditory Perception in SLD Children: Revisiting the Models of Auditory Processing 

Saransh Jain (saranshavi@gmail.com)<br>PhD Research Scholar, JSS Institute of Speech and Hearing, M.G.Road, Mysuru-570004<br>N.P. Nataraja (npnataraja@gmail.com)<br>Director and Professor, JSS Institute of Speech and Hearing, M.G.Road, Mysuru-570004

#### Abstract

The study assessed the auditory processing abilities and the cognitive skills in children with specific learning disability. It investigates the top-down or bottom-up influence on auditory processing. Using a test battery approach, the association between cognitive skills (verbal working memory and attention) and auditory processing abilities (auditory closure, binaural integration and temporal processing skills) has been measured. The results revealed that cognitive processes significantly affect the bottom-up auditory perception. The effect of cognition was more evident in speech processing than non-speech signal processing. These findings may be useful in designing appropriate therapeutic protocol for children with specific learning disability.

Keywords: dyslexia; learning disability; psychoacoustics; speech perception.

## Introduction

Auditory processing involves the ability of the auditory system to localize and lateralize sounds, discriminate and recognize auditory patterns, temporal aspects of signal, and understanding the auditory information in degraded listening environments (ASHA, 1996; Bellis, 2003; Chermak \& Musiek, 1997), efficiently and effectively. Any disturbance in perceptual processing of the auditory information is referred to as auditory processing disorders (ASHA, 1996).

Auditory processing is affected in individuals with peripheral hearing loss (Neijenhuis, Tschur, \& Snik, 2004), elderly population (Atcherson, Nagaraj, Kennett, \& Levisee, 2015), with certain neurological disorders (Klein et al., 1995), psychological disorders (Iliadou et al., 2013), developmental disabilities like attention deficit hyperactive disorders (Chermak, Somers, \& Seikel, 1998), dyslexia (Hugdahl et al., 1998), learning disability (Kraus et al., 1996), specific language impairment (Cohen, Campbell, \& Yaghmai, 1989), and others. Studies have indicated that children with learning disability show inability in processing complex auditory information (Merzenich et al., 1996). This processing problems have been attributed to the neurophysiological encoding of the speech stimuli and higher level processing deficits (Studdert-Kennedy \& Mody, 1995). Lui et al. (2009) have suggested top-down processing deficit of semantic tasks in auditory modality in children with
reading disability. Verbal working memory, which is the ability to store acoustic information for a short period and plays important role in speech perception (Ingvalson, Dhar, Wong, \& Liu, 2015), is affected in LD children (Alloway \& Alloway, 2010; Wiguna, Wr, Kaligis, \& Belfer, 2012).

Attention deficits have also been found to be prominent in children with learning disability (Finneran, Francis, \& Leonard, 2009). Pinheiro et al. (2010) have reported that LD children have displayed poor divided attention abilities in dichotic listening tasks. In auditory stroop task, selective attention, i.e., the ability to focus on relevant auditory information while ignoring the irrelevant information, has been found to be affected in these children (Faccioli, Peru, Rubini, \& Tassinari, 2008).

Researchers have reported that deficits in the cognitive abilities in the form of verbal working memory and auditory attention have been found in case of LD children. Therefore, it was hypothesized that the cognitive abilities may be associated with auditory processing disorders in LD children. Hence, in the present study, some auditory processing abilities and cognitive skills were assessed in children with specific learning disability.

## Methodology

## Participants

A standard group comparison research design was adapted. 31 children ( 17 males and 14 females) diagnoses as specific learning disability (SLD) by qualified speech language pathologist as per DSM-5 criterion (American Psychiatric Association, 2013) were included. Equal number of typically developing children (TD) were also selected ( $\mathrm{n}=31$ ). The children in both SLD and TD group were native Kannada speakers and belonged to similar socio-economic and cultural background. All the children were within the age range of 810 years and were having normal hearing sensitivity (PTA $\leq 15 \mathrm{dBHL} ; \mathrm{SRT} \pm 10 \mathrm{~dB}$ of PTA; SIS $>90 \%$ ). All children had average or above average intelligence (I.Q. $\geq 90$ ) as assessed by the school psychologist. None of the child had any associated speech, language, otological, psychological and/or neurological problems. The study adhered to the rules of the institutional ethical board and approved to test human
subjects. An informed written consents were obtained from either parents or teachers of all the participant before commencing the tests.

## Assessment of Auditory Processing Abilities

Tests to assess auditory closure, binaural integration, temporal resolution, temporal pattern recognition and temporal masking were selected. Auditory closure is the ability to fill-in the missing auditory information when the external redundancy in the acoustic signal is reduced. Time compressed speech test (TCST) and word recognition in noise test (WRS) were used to assess auditory closure abilities. TCST comprised of 40 standardized Kannada sentences (a Dravidian language) with 3-4 words. These sentences were divided into 2 sets by randomly assigning the sentences into sets, i.e. 20 sentences per set. The sentences were processed to have $50 \%, 60 \%, 70 \%$ and $80 \%$ of temporal compression. The participants were expected to repeat the complete sentence as the compressed sentences were presented.

WRS consisted of five lists with 30 standard Kannada words per list. Each list was processed with steady-state noise to obtain a SNR of $-9,-6,-3,0$ and +3 dB . The participants were expected to repeat the words as they heard. A detailed description of the stimulus parameter is available elsewhere (Jain, Vasudevamurthy, \& Raghavendra, 2015).

Auditory fusion test was used to measure binaural integration skills. The test comprised of standardized Kannada bisyllabic words, where first syllable of the word was presented in to one ear and the corresponding second syllable was presented in other ear, simultaneously. The participants were expected to say the whole word. Two lists of 30 words each, were presented randomly. The lists were constructed in such a way that a syllable which was in the initial position in one word would also occur in the final position of any other word. This reduced the syllabic position effect.

Temporal resolution abilities were measured using temporal modulation transfer function (TMTF) at 8,60 and 200 Hz modulation frequencies. The stimulus was a 500 ms Gaussian noise that was modulated at specific frequency. Using a two alternative force choice method, the participants were asked to identify the interval containing a modulated noise. 90 sound sequences were presented by adapting the maximum likelihood procedure which was implemented using Matlab (Grassi \& Soranzo, 2009).

Temporal pattern recognition was measured using duration pattern test. The test stimuli, as suggested by Musiek (1994), consisted of a 1000 Hz pure tone generated using audacity software (ver. 1.3.14 beta). Two tones, one with 500 ms and another with 250 ms , were used. The tones were patterned in six different combinations such that one tone was presented once while other tone was presented twice, with an inter-tone interval of 300 ms . The participants were asked to repeat the
sequence in which tones were presented. Each tone sequence was presented at least five times.

Temporal masking skills were measured using backward masking test by following the maximum likelihood procedure implemented using Matlab (Grassi \& Soranzo, 2009). The test stimulus was a 1000 Hz tone of 20 ms duration which was presented immediately before a 300 ms band pass noise $(400-1600 \mathrm{~Hz})$. The participants were asked, using a two alternative force choice method, to identify the noise interval which had a tone. 90 pair of sounds were presented.

## Assessment of Cognitive Skills

The cognitive skills were assessed in terms of verbal working memory, divided attention and selective attention. Auditory digit span test (Blackburn, 2011) and operation span test (Kane et al., 2004) were used to assess verbal working memory. In digit span test, sequence of digits were presented binaurally and participants were asked to repeat the sequence in either the same order (forward digit span) or in the reverse order (backward digit span) of presentation. The stimuli were presented in the increasing order of the number of digits. The testing started from two digits level and moved up to ten digit level. Three trials at each level were given and when the participant responded $2 / 3$ trials correctly, the next level of test was administered. The maximum number of digits repeated correctly were considered as the thresholds.

The operation span test based on the study of Kane et al. (2004), has been standardized in Kannada by Jain and Kumar (2016). In this test, the target stimuli (phrases varying from two to five bi-syllabic words) were presented along with a secondary task (a mathematical operation). Participant's task was to solve the mathematical problem and label it as correct and incorrect and subsequently say the word in the order of presentation. For two word sentences, each correct word repeated was given a score of 0.5 ; for three word sentence, each correct word repeated was given a score of 0.33 ; and so on, till five word sentence where each correctly repeated word was given a score of 0.2 . In total, 12 such sentences were presented (three in each phrase length) and the scores were given out of 12 (each sentence carried a total score of one, when all the words were correctly repeated).

The attention skills were measured for divided attention and selective attention task using dichotic digit test (Musiek, 1983). The test comprised of pair of digits presented binaurally. In the divided attention task (free recall), the participants were expected to repeat all the digits presented to them. In selective attention tasks (force recall), the participants focused their attention to one ear only and repeated the digits presented to that ear while ignoring the digits being presented to other ear. Total 30 pair of digits were presented randomly for each task.

## Procedure

The testing was carried out in a sound treated room. The stimuli were presented binaurally at the participant's comfortable loudness level which varied from 65 dB to 80 dB HL, using TDH-39 headphones connected to computer based audiometer (Interacoustics AD-629). The testing took at least 2-2.5 hours for each participant and was conducted in two sitting for the consecutive days. Using this procedure, participants of both the groups were tested and data was collected.

## Data Analysis

Logistic regression with linear or non-linear interpolation was used to measure SNR-50 (SNR level at which participants' responded correctly, at least for $50 \%$ stimuli) for word recognition scores in noise and compression-50 (compression level at which $50 \%$ correct identification of sentences was obtained) for time compressed speech test. The data was normally distributed across groups as per ShapiroWilk test for normalcy ( $\mathrm{p}>0.05$ ) and hence parametric statistics was used. One way analysis of variance was used estimated the significance of differences of scores for auditory processing and cognitive tests between SLD and TD children. The test scores were dependent variables whereas group distribution was independent variable. The partial least square regression-structured equation modeling was used to note the relationship between the test carried out for cognitive skills and auditory processes. Further, it was also used to find out the correlation between cognitive abilities and auditory processes in SLD children.

## Results

The data obtained from descriptive statistical analysis for auditory processing tests and cognitive tests are presented in Figure 1 and 2, respectively as box plots. The mean scores for all the tests (except DPT) were better for TD children in comparison to SLD children. The results of one way ANOVA are shown in Table 1. Statistically significant differences, between TD and SLD groups were found in all the tests of auditory processing and cognitive skills, except for DPT. It was also specific learning disability accounted for more than $50 \%$ variance in the test scores (partial eta square was greater than 0.5 ). An exception to this was word recognition in noise scores and forward digit recall scores, where the effect size was greater than 0.3 only.

The correlation between cognitive skills and auditory processing abilities were measured using partial least square regression. A formative model was created where working memory and attention were considered as latent variables and the measures to assess working memory (digit and operation span) and attention skills (dichotic digit test scores) as observed variables. The effect was seen on three measures of auditory processing i.e., auditory closure, binaural integration and temporal processing. The model had good fit with
standardized root mean residual of 0.036 (Hu \& Bentler, 1998).

Figure 1: Box plots are representing the scores obtained for tests to assess auditory processing abilities.

Figure 2: Box plots are representing the scores obtained for tests to assess cognitive skills.

Table 1: The F-values and significance of difference (pvalues) for tests to assess auditory processing abilities and cognitive skills, between SLD and TD children.

| Test Procedures | df | F-value | p-value |
| :--- | :--- | :--- | :--- |
| Tests to assess auditory processing abilities |  |  |  |
| Time Compressed Speech Test | 1 | 126.34 | 0.000 |
| Word recognition Scores (in noise) | 1 | 51.13 | 0.000 |
| Auditory Fusion Test | 1 | 160.75 | 0.000 |
| TMTF (8 Hz) | 1 | 579.00 | 0.000 |
| TMTF (60 Hz) | 1 | 753.11 | 0.000 |
| TMTF (200 Hz) | 1 | 446.50 | 0.000 |
| Duration Pattern Test | 1 | 1.87 | 0.176 |
| Backward Masking Test | 1 | 579.55 | 0.000 |
| Tests to assess cognitive skills |  |  |  |
| Digit Span Test (Forward) | 1 | 27.79 | 0.000 |
| Digit Span Test (Backward) | 1 | 166.70 | 0.000 |
| Operation Span Test | 1 | 57.64 | 0.000 |
| Dichotic Digit Test (Free Recall) | 1 | 256.47 | 0.000 |
| Dichotic Digit Test (Force Right) | 1 | 149.95 | 0.000 |
| Dichotic Digit Test (Force Left) | 1 | 94.89 | 0.000 |

The regression model is presented in Figure 3. It was noted from the figure that the adjusted $\mathrm{R}^{2}$ indicated $71.6 \%$ of variance in the auditory closure abilities were associated with attention skills and working memory. Similarly, $67.5 \%$ variance in binaural integration abilities, and $91 \%$ variance in temporal processing abilities were attributed to cognitive skills. It was also noted that attention was highly correlated to auditory processing than with working memory. Among the working memory tests, backward digit recall represented the working memory skills maximally. Attention skills were better represented in terms of divided attention. Similarly, TCST was found to be a more reliable measure to assess auditory closure. The temporal processing abilities were better represented by backward masking test.

## Discussion

The present study measured the association between cognitive skills and auditory processing in SLD children. The results of ANOVA revealed significant differences on all the measures of auditory processing and cognition between SLD and TD children (except DPT). Many researchers have reported disorders of auditory processing in LD children (Cohen et al., 1989; Dawes \& Bishop, 2010; Kraus et al., 1996). Therefore the assessment of SLD, using series of tests of auditory processes, like in the present study may provide better information about SLD. Further, cognitive abilities have also being examined previously in such children (Alloway \& Alloway, 2010; Faccioli et al., 2008; Finneran et al., 2009; Pinheiro et al., 2010; Wiguna et al., 2012), but the relationship between cognition and auditory processing has not been investigated intensively. Such investigations, like in the present study, would lead to better understanding of the
relative contribution of top-down or bottom-up processes involved in auditory perception.

At times, it seems that the structured equation modeling used in the present study is under powered, as the sample size is small. However, the power analysis run with effect size of 0.5 and the power coefficient of 0.95 , for five predictor variables (the variables assessed the cognitive skills) indicated that total sample size should be 42 . In the present study, although the sample size for SLD children is 31 only, is it is not much lesser than the suggested sample size. Thus, it was considered that SEM should be a reasonable tool to assess the association between auditory processing abilities and cognitive skills.

The association between cognitive skills and auditory processing are highly significant. Both attention and working memory seems to be influencing auditory processing, and the contribution of attention seems to be more than working memory, especially for temporal processing. Therefore, the findings of the present study may be considered as suggesting the influence of cognitive skills on auditory processing. Similar findings have been reported by other researchers (Moossavi et al., 2014; Murphy et al., 2013) in normal children. Based on the present results, it may be extended to SLD children also.

In the present study, most of the tests used speech stimuli, and the results suggest that the cognition was influencing the auditory processing of speech than auditory processing of tonal/noise perception. ....speech test and cognition (correlation) Similar findings have been investigated by several other investigator (Fedorenko, 2014; Hällgren, Larsby, Lyxell, \& Arlinger, 2001; Larsby, Hällgren, Lyxell, \& Arlinger, 2005). Word recognition in noise required the processing of both speech and non-speech stimuli, showed the path coefficient of WRS (in noise) was 0.379 . This also suggest the contribution of cognition in auditory processing of speech more than for non-speech stimuli. This further strengthen the conclusion that the cognition has greater influence on auditory processing of speech.

## Conclusion

The present study examined the association between cognitive abilities and auditory processing, and highlights the cognitive influence on auditory processing. The findings of the study indicate that the cognitive abilities are associated with auditory processing in SLD children also like in normal. It has also been found that the cognition is associated with auditory processing of speech more than non-speech signal. These findings may be useful in understanding speech perception in SLD children and may be used in designing appropriate speech and language intervention techniques.

Figure 3: The structure equation model showing the association of cognitive skills (in terms of working memory and attention skills) with auditory processing (in terms of auditory closure, binaural integration and temporal processing). The eclipse and rectangle are used to represent latent and observed variables, respectively. In the eclipse, adjusted R2 values are given, and those between the arrow bars are path coefficients of the model.

# Failure to use probability of success in deciding whether to pursue one goal or two.

#### Abstract

Difficult tasks should be attempted one at a time, while easy tasks can be undertaken in parallel. Reinforcing our previous conclusion that people are surprisingly poor at applying this logic, we find people fail to select standing positions that maximize their probability of success in throwing a beanbag into one of two possible hoops. We asked participants to explicitly report their odds of successfully throwing a beanbag into each hoop from the location they had chosen to stand, and estimates were highly accurate. Nonetheless, participants failed to use estimates of success appropriately to maximize success, suggesting a failure of insight, rather than limited or inaccurate information, can account for suboptimal decisions about standing position.

Keywords: Bounded Rationality; Optimal Behaviour; Awareness; Decision Making.

## Introduction

Human skill is limited, and effective decisions must take these limitations into account. In Chess and Go, for example, it is impossible to select the optimal move by mentally simulating every possibility. An effective strategy must take into account the constraints of ones own memory capacity. Simon (1990) used the term bounded rationality to describe decisions that are rational given known constraints.

We recently reported a surprising failure to make effective decisions about whether to pursue one goal or two (Clarke and Hunt, 2016). In one experiment from that study, participants had to throw a beanbag into one of two hoops. The distance between the hoops varied and participants were told which one of the two hoops had been randomly selected to be the target only after they chose a place to stand. The optimal strategy when the hoops are relatively close together is to choose a standing position equidistant from both hoops, making an accurate throw possible irrespective of which hoop is the target. However, as the hoops move further apart, the
probability of a successful throw from the center position drops below $50 \%$. Now the best strategy is to stand close to one of the two hoops and hope it is the target on that trial. Despite the availability of this simple strategy, the distance between the hoops had no systematic effect on where people stood, demonstrating a profound failure to optimize throwing accuracy. The same failure to adjust strategy in response to difficulty was observed in deciding where to fixate to detect one of two targets (see also Morvan and Maloney, 2012) and in allocating attention when trying to memorize digit strings. These experiments took into account each individuals performance limitations by measuring throwing ability, visual acuity, and memory capacity in a separate session involving only single targets with no decisions. This allows for an individualized estimate of when a given participant should switch from attempting both goals to prioritising one. Nonetheless, bounded rationality could explain this failure as participants could be unaware of, or incorrect about, their own abilities (Schraw and Dennison, 1994).

In the current experiment, we repeated the beanbagthrowing task but explicitly asked participants to report on their expected accuracy before each throw. This allows direct comparison of estimated and actual throwing performance. Three outcomes are possible, all of which are informative about the cause of suboptimal decisions in this task. First, consistent with bounded rationality, participants may be unaware of their throwing ability and therefore fail to account for it when selecting standing positions. Second, participants may not adequately attend to their own abilities. Self-talk can improve throwing (Chang et al., 2014), suggesting explicitly reporting about ones own ability can improve task performance. Third, participants may have an accurate representation of their own skill, and drawing their attention to this information may not influence their standing position decisions. In this case, the results would suggest failure to maximize success in this paradigm is an example of a more fundamental limitation in decision competence.

## Methods

## Participants

Twenty-four participants ( 17 female) were recruited via the SONA systems at the University of Aberdeen and took part in return for course credit. The sample size of 24 (12 in each group) was based on our previous experiment (Clarke and Hunt, 2016). Average age was 19 years ( $\mathrm{SD}=1.5$ ).

## Procedure

We used a similar protocol to that of Experiment 2 in Clarke and Hunt (2016). The experiment was carried out over two sessions, with participants carrying out Session 2 a week after Session 1. Both sessions took place in the same sheltered paved area. The paving slabs were used as a convenient unit for measuring distances as they were approximately the same size as the hoops (the slabs measured $0.46 \times 0.61 \mathrm{~m}$ and the hoops had a diameter of 0.4 m ).

The aim of Session 1 was to measure how well each participant could throw a bean bag into hoops placed at seven evenly-spaced distances from three (1.38m) to fifteen ( 6.90 m ) slabs away, in two different directions (direction was counter balanced). A total of 84 throwing trials were completed in this session ( 12 beanbags for each of the 7 target distances). The data gathered from the first session were used to model how participants accuracy decreases as the distance to the target hoop increases (see Figure 1).

In Session 2, participants were again throwing beanbags into hoops, but there were now two hoops, and either one could be the target. Participants were asked to choose a place to stand before throwing, and were not told which hoop would be their target until after they had made this decision. To avoid having to re-position hoops from trial to trial, the area contained six hoops of three different colours, with blue hoops at the furthest distance, yellow at an intermediate distance, and red at the closest distance. The actual distance of each hoop colour depended on performance in the first session, with each colour corresponding to an estimate of the participants throwing accuracy from the centre: Blue hoops were placed at the slab distance where accuracy was expected to be closest to $10 \%$, yellow hoops at $50 \%$, and red hoops at $90 \%$ (see Figure 2). The beanbag on each trial was randomly drawn from a bag, which initially contained nine beanbags, three of each colour. The colour of the beanbag drawn from the bag determined which hoop pair was the target on that trial. Once all nine had been thrown they were replaced. This process was repeated 5 times for a total of 45 trials.

On each trial in Session 2, participants retrieved a beanbag and then chose somewhere to stand (the participants were told that they could stand anywhere on the paved area). The experimenter then informed them about which hoop (north or south) was their throwing target on that trial. The direction was randomised, with each direction equally likely on every trial. It was made clear to the participants that the direction

Figure 1: This shows the set up for session 1 from the participant's point of view.
of each throw was random and had been predetermined, with each direction being equally likely. They then performed the throw and their standing position and throwing accuracy were recorded.

All participants followed the protocol described above, and half of the participants were also instructed to give an estimate (in percentages) of their expected throwing accuracy for both hoops from the location they had chosen to stand. They were prompted to provide this estimate after they chose a place to stand but before they actually threw the beanbag. This group will be referred to as the Online Estimation Group. This condition was included to test whether drawing the participants attention to this component of the problem they were faced with would help them to perform better.

Upon completion of the 45 trials in Session 2, all participants then performed a task similar to Session 1, but instead of throwing, they were required to give an estimate of their accuracy, in percentages, for each distance that had been tested in the first session. Participants stood in one spot, and one hoop was moved to different distances from them in either direction. The distances were split into two sets: 3, 7, 11, 15 and $5,9,13$. One set was presented to the participants first, in ascending order (i.e. getting further from the participant); then the other set was presented to them in a descending order (i.e. getting closer). The order of sets was counterbalanced across participants so each set was presented first equally often. Results were analysed in R ( R Core Team,

Figure 2: The setup for session 2
2016) and modelled using the lmer function from the lme4 package (Bates et al., 2014).

## Results

## Actual accuracy vs. Estimated accuracy

Participants throwing performance in Session 1 is shown in Figure 3. The relationship between accuracy and distance for each participant was modelled using logistic regression. Participants estimate of their own throwing ability is superimposed in blue. The majority of our participants were accurate in their ability to estimate their own throwing ability. This can be summarised by looking at the correlation between actual and estimated accuracy for each individual. This gives a median Pearsons correlation coefficient $r$ of 0.89 ( $\min =0.72$, $\max =0.96$ ).

Figure 3: These graphs illustrate the accuracy (proportion correct) over the various distances for each participant (actual, in red), and their estimates of their own accuracy over the same distances (in blue).

## Standing position

The optimal strategy for the closest hoop distance in Session 2 would be to stand in the middle, as the expected accuracy is $90 \%$ regardless of which hoop was selected as the target. For the farthest hoop distance, the optimal strategy would be to stand next to one of the two blue hoops, as this means that they would be approximately $100 \%$ accurate for that hoop and $0 \%$ accurate for the other hoop. Considering that each hoop was equally likely to be selected, this means that standing next to one blue hoop gives the participant a $50 \%$ chance of success, which is much greater than the $10 \%$ accuracy they would achieve by simply standing in the middle. The point where participants should switch between a centre and a side strategy is marked by a blue line in Figure 3 (the $50 \%$ point in their reported estimate of accuracy is shown by the red line). For the majority of the participants, it makes no difference whether we use their actual accuracy or their estimated accuracy to determine the ideal switch point, given the resolution of our experiment. The black dots illustrate the chosen standing positions on each trial: it is clear from these results that participants do not switch their strategy at either point; in fact, generally speaking, participants do not alter their standing position systematically with the distance of the hoops. These data are similar to those from the throwing task reported in Clarke and Hunt (2016). Interestingly, we can see that one participant (participant B11 in Figure 4) approaches the optimal strategy, particularly with respect to their estimated accuracy. Taken in aggregate, however, participants did not tend to stand closer to the hoop when they were further apart (a paired samples t-test comparing standing position for farthest to the closest hoop distance was non-significant; $t(23)=-.49)$.

## Standing positions across groups

To explore whether being asked to estimate the probability of successfully completing both possible throws had an effect on participants decisions, we compared the standing positions for the control group (Group A) to the online estimate group (Group B). For the closest hoops, participants in Group A stood on average 0.13 (standard deviation $=0.21$ ) of the way from the central point to one of the two hoops, and participants in Group B stood at 0.14 (standard deviation $=0.27$ ). Similarly, there was little difference between the two groups for the blue (far) hoops: participants chose to stand slightly further away from the central point (Group A: $\mathrm{M}=0.128, \mathrm{SD}=$ 0.17 , Group $\mathrm{B}: \mathrm{M}=0.2, \mathrm{SD}=0.22$ ). We conclude that being prompted to verbally report estimated accuracy for each trial had no effect on the strategies participants used to complete the task (close; $\mathrm{t}(22)=.09$, far; $\mathrm{t}(22)=.895)$.

Analysis was also carried out to examine whether the accuracy of a participant's estimate of their own ability was correlated with how closely they followed the optimal strategy. To do this, the r value for each participant (representing the accuracy of their estimate) was correlated with a normalised value for the average distance of the standing position from

Figure 4: Black dots show the standing positions of each participant on each trial in Session 2 as a function of distance of the hoops from the centre (x-axis). Standing position was normalised so that 0 represents having stood at the centre and 1 being one of the side hoops. Red lines represent the distance at which participant should have switched between standing at 0 and standing at 1 based on their actual accuracy, and the blue lines is the switch point based on their own estimates of their accuracy.
the optimal position (in the $10 \%$ accuracy and $90 \%$ accuracy trials). The Pearson's correlation coefficients were very weak for both the $10 \%$ accuracy $(r=-0.12)$ and the $90 \%$ accuracy conditions ( $\mathrm{r}=-0.12$ ). To clarify, had there been an effect of accuracy of estimates, there should have been a negative correlation for both accuracy conditions. The lack of a relationship suggests that participants with a greater awareness of their ability were not better at making using this information.

## Discussion

Participants do not select standing positions that maximize their throwing performance, reinforcing the conclusion that participants fail to solve this task, as previously found by Clarke and Hunt (2016). This experiment was designed to test whether limitations in self-awareness of throwing ability could account for participants poor choices in standing positions. The results suggest participants were highly accurate in reporting on the expected outcome of their decision, but failed to make use of this information when deciding where to stand.

The second possibility we considered in the introduction is that participants have an accurate representation of their own skill, but fail to use this information in making their decision. If this is the case, asking participants to explicitly judge their expected accuracy before each throw should prompt them to make better decisions about where to stand. However, compared to the control group, the standing positions selected by participants who were explicitly asked about their accuracy before each throw were not more optimal. We asked partici-
pants only to state their expected accuracy for each hoop from the position they had selected; it may be that this was too indirect to cause participants to actually use this information in deciding where to stand. In future studies, it may be of interest to ask more probing questions. For example, asking them to explain why they choose to stand may lead to better decisions.

We conclude that participants fail to adopt an optimal strategy despite having highly accurate information about the expected outcome of their decisions. It is possible that the participants were not aware that this information was relevant to making a decision and therefore did not pay it due attention (Gegenfurtner et al., 2011) or were unable to use the information in an effective manner (Hardman and Cowan, 2016). It is also possible that participants were distracted by other, less relevant information. Gaissmaier and Schooler (2008) suggest that some people may engage in searching for a pattern that they may be able to exploit in order to form their decisions even when there is no pattern to the task. With this in mind, it may be of interest to investigate what information people deem to be relevant to a task they are performing. Finally, our sample did not widely vary in throwing ability and in self-awareness. A sample of participants with a wider range of throwing ability, and particularly including highly skilled throwers, may provide further insight into whether confidence in the relevant information can elicit optimal decisions for maximising accuracy.

We encounter situations with multiple goals and targets frequently in daily life, from deciding which locations to monitor while driving, to deciding how to invest time and resources in various projects. It is therefore surprising that our participants are so poor at making these decisions. In daily life these situations tend to be far more complex than the situation we have constructed here, and the expected outcomes of possible decisions would be similarly complex to calculate. Heuristics are simple rules of thumb to cope with decision making in complex environments. They can often lead to near-optimal behavior using less computation and information. For example, an effective rule for intercepting a high ball (e.g. in baseball) is to keep the ball at a fixed gaze position as you run towards it (Gigerenzer and Brighton, 2009). This simple heuristic allows a fielder to behave as if they had solved the differential equations that govern the balls movement. However, in our task the optimal solution can be fully described by a simple heuristic (i.e., always stand in the center when the hoops are close, and switch to one hoop when they are far apart). Our results suggest that participants are nonetheless unsystematic in their decisions.

#### Abstract

Appraising one's own performance after a task, known as selfassessment, has been studied from a cognitive science perspective in domains such as humor, trivia, and logic. Previous studies have found that participants are systematically poor at judging their own performance, though sometimes self-assessment varies based on actual performance. We explored calibration of self-assessment on algebra problems, a domain where people have typically received explicit instruction. In this domain, we found that people do not behave as they do in other domains previously studied: they are generally well-calibrated in judging their algebra performance. This suggests that in the course of learning to solve algebra problems, people have also learned to accurately judge their performance, both absolutely and relative to others.

Keywords: self-assessment; algebra; intelligent tutor; calibration

## Introduction

Providing personalized and well-designed educational tools for online learners is a necessity. One important feature of online learning is that it is self-directed. Learners they guide their own way through the plethora of available materials (e.g., Song \& Hill, 2007). How can we design effective tools to help these kinds of learners be even better at gaining new knowledge through this medium? In order to be selfdirected, learners need to know what information they are lacking. Thus, it is important to find out what learners actually know and use this data to motivate them in an online setting. We can learn more about what learners know simply by asking them to evaluate their performance on a task after completing it, known as self-assessment. Self-assessment has been studied in both cognitive science (e.g., Dunning \& Kruger, 1999; Krueger \& Mueller, 2002) and educational domains (e.g., Bol \& Hacker, 2001). Here we seek to use the methods from cognitive science on an education-related task, focusing on online learners.

In psychological studies of self-assessment, it has been observed that people systematically misjudge how they perform relative to others. These studies have used tasks not formally taught and subsequently tested in a school setting, such as humor and logical reasoning (Dunning \& Kruger, 1999) or
trivia (Burson, Larrick, \& Klayman, 2006). Miscalibration has been observed across all of these domains.

The dependence on tasks such as trivia knowledge raises the question of whether similar patterns of perceived ability exist for domains in which people have already received a good deal of instruction. Given the increasing opportunities for people to engage in self-directed study online, we are interested in self-assessment in an instructed online setting. Based on previous research, we might expect that people will be poorly calibrated to their own performance.

We investigate this question through two online experiments. Experiment 1 replicates previous findings with an online population, specifically by using methods from the second study of Burson et al. (2006). As in the original paper, we find that people are poorly calibrated when self-assessing their performance on trivia problems. In Experiment 2, we turn to an instructed domain to see what links might exist between actual performance, perceived performance (both absolute and relative), and perceived difficulty. Specifically, we study algebraic equation solving, an area where we would expect our participants to have had much practice and instruction. In contrast to the trivia domains, we find that people are relatively accurate in their self-assessment about their algebraic equation solving abilities.

## Background

In the cognitive science literature, there is a general finding that people are miscalibrated in their performance judgments (e.g., Krueger \& Mueller, 2002). Yet there have been different interpretations of who is driving the trend of poor calibration and why. Dunning and Kruger (1999) originally explored this quandary, finding that those in the lowest quartile of performance appeared to judge themselves as performing much better than they truly did and that those in the highest quartile were more accurate in their judgments. They interpreted the poor perceived performance on the part of the lowest-scoring individuals as a metacognitive deficit - the worst performers lacked both the skills needed to correctly do the task and also to judge their performance on the task. Yet in later studies, participants have been observed to systematically misinter-
pret their performance regardless of actual score on a task (e.g., Krueger \& Mueller, 2002). While Dunning and Kruger found that calibration improved with actual performance, this is not the case in other studies such as in Burson et al. (2006).

In Burson et al. (2006), twelve trivia-like domains with varying levels of difficulty were studied. The authors found that regardless of the task and difficulty, participants at all levels of performance were equally inaccurate in judging their ability relative to others. However, they did find that for easier tasks, participants judged themselves as performing better than on more difficult tasks. This makes it appear that those with higher actual scores were more accurate in their judgments on easier tasks and that those with lower scores were more accurate in their judgments on difficult tasks.

Knowledge of one's own performance has been explored in educational contexts. In a study with graduate students in education, Bol and Hacker (2001) found that low-achieving students were less able to accurately calibrate ratings of their own performance on their final exam than high-achieving students. This is consistent with results from Dunning and Kruger (1999). However, they did not ask students to evaluate their performance relative to others. In another study, Bol, Hacker, O'Shea, and Allen (2005) observed that overt practice with self-assessment does not help increase accuracy. Yet they did see that high-achieving students are more accurate than low-achieving students in their performance predictions. They also found that higher achieving students are underconfident in their predictions while lower achieving students are overconfident.

Metacognitive skills have been found to be helpful for allowing students to improve their own learning processes (e.g. White \& Frederiksen, 2005). White and Frederiksen (2005) argue that working towards metacognitive understanding of one's own learning process motivates them to learn. This is important for online learners as well. As they are selfdirected, they need motivation to feel capable of learning on their own. In one study, White and Frederiksen (1998) found that including metacognitive training in a curriculum significantly increased low-achieving students' performance.

## Experiment 1: Trivia

First, we sought to replicate previous findings from Burson et al. (2006) that showed people were poorly calibrated in a trivia task. We aimed to confirm that the same results held in an online population. Our experiment replicates Study 2 from Burson et al. (2006). Plots (a) and (c) of Figure 1 show recreated versions of their original findings. In this study, all participants were poor at estimating their performance, regardless of true performance on a task. Burson et al. (2006) also found that difficulty had an effect on self-assessment accuracy, where estimated performance was on average lower for the more difficult domains than for the easier domains.

## Methods

Participants. A total of 40 participants (19 female, mean age $=30.9)$ in the USA were recruited from Amazon's Me-
chanical Turk and compensated $\$ 1.50$.
Materials. Materials from two of the five domains in the original study were included. Two domains were excluded based on Burson et al.'s (2006) findings that they were too difficult or too easy, resulting in floor or ceiling effects, and a final domain about the length of time pop songs remained on the charts was excluded due to inconsistent data from Billboard.com. We were thus left with two domains: college acceptance rates and dates of Nobel prizes in literature. For each domain there were two subsets of 10 questions each, one easy and one difficult. The more difficult version required participants' estimates to fall within a narrower range to be considered correct (e.g., within 5 years of the correct date for the harder version vs. within 30 years for the easier version).
Procedure. Participants responded to all four sets of questions, and the order of difficulty was counterbalanced across participants. For each subset, participants answered 10 questions about one domain with instructions stating they would get credit for an answer if it was within a certain range of the correct answer. Then, they were asked to rate their percentile performance, or how well they believed they performed relative to others on that set (out of 100), as well as how difficult it was for themselves and for other participants in the study (out of 10). Following the four sets of questions, they completed a survey about their demographics. The entire study took participants an average of 12.8 minutes.

## Results and Discussion

We performed similar analyses to Burson et al.'s to confirm that our findings were consistent (see Figure 1 (a) and (c)). For both tasks (estimates of years a Nobel prize in literature was received and of college acceptance rates), scores were much lower on the difficult versions than for the easy versions (Nobel: $M_{\text {hard }}=1.60$ vs. $M_{\text {easy }}=6.93$; College: $M_{\text {hard }}=1.63 \mathrm{vs} . M_{\text {easy }}=6.53$, all out of 10 ). A two-way analysis of variance (ANOVA) on true score with domain and difficulty as within-participant variables shows a main effect of difficulty $(F(1,156)=294.54, p<.001)$. Consistent with the difference in scores, harder trivia sets were rated as more difficult for participants than easy trivia (Nobel: $M_{\text {hard }}=9.08$ vs. $M_{\text {easy }}=8.15$; College: $M_{\text {hard }}=8.13$ vs. $M_{\text {easy }}=6.90$, all out of 10). An ANOVA on perceived difficulty for oneself shows a main effect of true difficulty $(F(1,157)=8.06$, $p<.05)$ and of domain $(F(1,157)=8.44, p<.05)$. Additionally, the average Nobel prize estimates were perceived as more difficult for the self than the college acceptance rate estimates $\left(M_{\text {nobel }}=8.6125 \mathrm{vs} . M_{\text {college }}=7.5\right)$.
Percentile estimates. Users were asked to rate their percentile estimate after completing a task, or how well they think they did relative to others on a scale of 0 to 100 . Overall, a participant's true score was weakly correlated with their percentile estimate (Pearson's $r=.17, p<.05$ ). The mean percentile estimate across all four tasks was 34.04 , which is consistent with the average found in the original study of

Figure 1: Perceived percentiles broken out by domain ( $a$ and $b$ ) and difficulty ( $c$ and d). (a) Participants' estimates of percentile by quartile of actual performance for questions about Nobel prize winners and college acceptance rates in Burson et al. (2006) and (b) in Experiment 1. 'Nobel' refers to Nobel prizes in Literature, and 'College' refers to college acceptance rates. (c) Participants' estimates of percentile by quartile of true performance for easier and more difficult tasks in Burson et al. (2006) and (d) in Experiment 1. Note that the difficult tasks in the original study included a third domain, number of weeks pop songs were on the charts, which is not included in our study. Vertical bars represent one standard error. This information was unavailable for the original study by Burson et al.
37.04. An ANOVA on percentile estimate showed a main effect of difficulty $(F(1,157)=11.95, p<.05)$ and of domain $(F(1,157)=6.74, p<.05)$. For the Nobel tasks, percentile ratings on the difficult version were lower than for the easy version $\left(M_{\text {hard }}=22.28\right.$ vs. $\left.M_{\text {easy }}=34.98\right)$. The college acceptance rate tasks showed the same pattern ( $M_{\text {hard }}=31.88$ vs. $\left.M_{\text {easy }}=44.05\right)$. On average, the percentile ratings for the Nobel tasks were lower than for the college tasks ( $M_{\text {nobel }}=$ 28.63 vs. $M_{\text {college }}=37.96$ ). As found in the original study, perceived performance was lower for more difficult tasks.

Quartiles. As in Burson et al. (2006), we divided all participants into four quartiles based on performance. As shown in Figure 1, we see very similar results to the original study - estimates of percentile performance on the test sets about dates Nobel prizes were won tended to be lower than estimates of percentile performance on the test sets about college acceptance rates. Additionally, the easier test sets were given higher percentile estimates than the more difficult ones.

Just as Burson et al. (2006) replicated Krueger and

Mueller's (2002) result that participants of all skill levels miscalibrate their performance relative to others, we observe a similar characteristic pattern in online users. On the easier tasks, participants at all skill levels are equally inaccurate in their estimates and on the difficult tasks, the highest performers do even worse than the lowest performers on judging their relative performance.

## Experiment 2: Algebra

In our next study, we aimed to compare results from previously researched trivia-based domains to a school-taught domain: algebraic equation solving. What is interesting about this domain, as opposed to others previously used in experimental psychology studies of self-assessment, is that participants have all received feedback about their performance in the past. We could thus imagine that participants might have more awareness of how well they have historically done compared to their peers and calibrate their estimates based on how much time has passed since they last solved algebraic equations.

Figure 2: Interface of Emmy's Workshop.

We made use of Emmy's Workshop (Rafferty \& Griffiths, 2015), an adaptive algebra tutor designed to glean more information about users than just number of problems solved correctly (see Figure 2). Participants enter in their work step by step when solving each problem. The goal is to determine where in problem-solving users are faltering and then to offer them personalized feedback on a skill they are struggling with (Rafferty, Jansen, \& Griffiths, 2016).

## Methods

Participants. A total of 41 participants in the USA were recruited from Amazon's Mechanical Turk and compensated $\$ 6$. They had not completed postsecondary mathematics courses beyond algebra. Two were excluded who accidentally exited the study and had to start again from the beginning. We thus had 39 participants ( 17 female, mean age $=$ 33.2 years).

Procedure. Participants first completed a survey where they rated their knowledge of algebraic equation solving and how important it is for them to know a great deal about this domain. Then they completed 24 problems in Emmy's Workshop. They received no feedback about their problem solving. Next, they estimated their performance in both absolute terms ("How many of the 24 algebraic equations you just completed do you think you answered correctly?") and in relative terms ("Think about the 24 equations you solved. Compared to other participants in this study, how good are you at solving algebraic equations? Marking $90 \%$ means you will do better than $90 \%$ of participants, marking $10 \%$ means you will do better than only $10 \%$, and marking $50 \%$ means that you will perform better than half of the participants."). They also rated how difficult the task was for them and how difficult they thought it was for others. Finally, they completed the same demographics survey as in Experiment 1, but with additional questions about their mathematics education background.

## Results and Discussion

On average, participants solved 9.28 problems correctly (out of 24). The average perceived score was 10.38 , and the average percentile estimate was 39.38 . Overall, participants accurately estimated both number correct and percentile rankings
(a)

(b)

Figure 3: Perceived scores and percentiles in Experiment 2. (a) Participants' estimates of score (out of 24) by quartile of actual performance. (b) Participants' estimates of percentile by quartile of actual performance. Vertical bars represent one standard error.
(see Figure 3). While both total score and percentile estimates are examining distinct measures of performance, we see a similar pattern. The correlations between true score and estimated score, and between true score and percentile estimates were both high, unlike in the previous study (Pearson's $r=0.66$ for both comparisons, $p<.001$ ). Algebra is a domain where people have received feedback in the past, which has trained them to know how they compare to their peers. In contrast, people have not generally practiced and received feedback about their trivia performance to the same degree. In a school-taught domain where a learner might have a better sense of how they have done in the past, they are better able to estimate their performance, unlike in the domains tested in previous cognitive studies of self-assessment.

Difficulty. On average, participants perceived the task as being easier for others than for themselves: average perceived difficulty was 8.18 for the self and 7.36 for others (out of 10). As shown in Figure 4 (a), the more someone finds the task to be difficult for themselves relative to others, the more they
underestimate their performance $(F(1,37)=8.1, p<.05$, $R^{2}=0.18$ ).

Experiment 1 included easy and difficult sets of questions in each domain. Mirroring this design would be difficult for algebraic equation solving because skills are likely to vary widely across participants. Instead, we divided the participants into two groups based on a median split of their perceived difficulty. Perceived difficulty was measured by taking perceived difficulty for the self minus perceived difficulty for other participants. The easy group perceived the task as easier for them than for others $\left(N=18, M_{\text {difficulty }}=-1.28\right)$ and the hard group perceived the task as harder for them than for others $\left(N=21, M_{\text {difficulty }}=2.52\right)$. In the easy group, scores were 10.6 on average, score estimates were 15 on average, and the mean percentile estimate was 54.83 . In the difficult group, scores were 8.14 on average, score estimates were 6.43 on average, and the mean percentile estimate was 26.14. Those with a positive perceived difficulty (who believed the task was more difficult for themselves than for others) tended to underestimate their performance, while those with a negative perceived difficulty (who believed the task was easier for themselves than for others) tended to overestimate their performance (see Figure 4 (b)). Though these results suggested that users are accurate at estimating their performance, we see that this is actually not the case - self-assessment is adjusted either positively or negatively based on perceived difficulty of the task.

There are qualitative characteristics of these data which are consistent with the findings of the first experiment - percentile estimates are lower for tasks perceived as more difficult. However, people are much better calibrated in this domain than in the trivia domains. It is not that users systematically have metacognitive deficits, but that if they perceive a difference between their own ability and that of others, then they demonstrate systematic miscalibration, either positively or negatively.

## General Discussion

In these two studies, we aimed to explore how online participants perceive their performance in an algebra setting, assuming we would discover poor calibration in participants' estimates. Interestingly, we see that people are well-calibrated in judging their algebra performance, both absolute and relative to others. Crucially, we do not see overestimation by the worst performers as observed by Dunning and Kruger (1999) and in other studies: people seem in particular to know when they are performing poorly.

## Possible Explanations

One explanation is that people have been well-trained to selfassess in school-taught domains such as math, both in terms of raw scores and occasionally with respect to others (e.g. via standardized tests and classes that are curved). Better accuracy in self-assessment tasks through training has been noted in work on superforecasters (e.g., Mellers et al., 2015). In
(a)

(b)

Figure 4: Interaction of perceived difficulty relative to others and amount of over or underestimation in Experiment 2.
(a) Plot of linear regression equation predicting amount of overestimation (measured by taking estimated number correct minus actual number correct) from perceived difficulty (measured by taking perceived difficulty for oneself minus perceived difficulty for others). (b) Participants' estimates of percentile by quartile of true performance grouped by perceived difficulty.
this body of work, a small subpopulation has demonstrated high predictive ability about international events. Members of this group exhibit a variety of good habits and have largely been able to train to be well-calibrated in their judgments. If people can be trained to make accurate judgments about the world, they can also conceivably be trained to make accurate judgments about themselves. In the domain of algebra, we seem to have trained, through feedback on performance, to link feelings after a task to true performance. This enables us to calibrate more accurately. Perhaps if we had similar kind of experience in doing trivia quizzes, then we would be better calibrated in that domain too. We can ask questions similar to those posed by Mellers et al. (2015), such as whether it is possible to transform students into top-performing algebra problem-solvers via labeling them as "high potential latebloomers" meaning capable of gaining expertise later in life.

This mindset-related intervention (e.g., Yeager \& Dweck, 2012) or other interventions may be effective at impacting a learner's self-assessment and thus metacognitive skill. This does, however, come in conflict with the results of Bol et al. (2005) who saw that practicing self-assessment did not help increase accuracy.

Effective self-directed learners are aware of what they need to learn. Training learners to accurately evaluate their ability has the potential to help them seek out necessary materials. Knowing that through training learners have the ability to properly self-diagnose in a domain means they have the opportunity to select what is necessary for them to learn. With education being increasingly made available online, self-motivated learners need to be well-calibrated to their knowledge of domains in general.

## Future Directions

We would like to further investigate what types of people are miscalibrated in their performance judgments in an online algebra setting. In light of the results presented in this paper, we will run another study with an increased sample size, primarily to see if there are gender differences in self-assessment. At present, there is a trend of high-performing women underestimating their performance in comparison to high-performing men, but an increased sample size will be necessary to judge the validity of this conclusion.

To probe further into students' perceptions of their ability, we will run a similar study asking how well students believe they perform on individual skills relevant to algebraic equation solving. Emmy's Workshop contains an inverse planning algorithm that assesses ability on six different skills such as arithmetic and distribution (Rafferty et al., 2016), so we will be able to compare actual ratings on these skills by said algorithm to a user's perceived ability on each individual skill.

Additionally, develop models of self-assessment, in a similar vein to Labutov and Studer (2016). As self-assessment involves making an inference about one's own ability based on one's performance, we can think about using Item Response Theory (IRT), a family of models commonly used by education researchers, to estimate the ability of students, both overall and on individual skills. This will help inform how perceived performance on each problem individually will predict actual performance on subsequent problems.

## Conclusion

Self-assessment has been studied in both cognitive science and educational contexts. Our experiment connects methods from the self-assessment literature to applications in education, specifically aimed at studying the self-evaluations made by online learners of varying ability and backgrounds. We find that, on average, participants solving algebraic equations are well-calibrated in their estimates of their own performance, both absolute and relative. This stands in contrast to previous work in both cognitive science and education where miscalibrations have been observed by participants of all ability levels. However, participants who perceive the task as
excessively difficult tend to underestimate their performance, marking them as a possible group to develop intervention for improving their self-assessment skills.

# Reasoning ability predicts irrational worldview but not conspiracy belief 

Jan Jastrzębski (jastrz.jan@gmail.com)<br>Institute of Psychology, Jagiellonian University<br>Grodzka 52, 31-044 Krakow, Poland

Adam Chuderski (adam.chuderski@uj.edu.pl)<br>Institute of Philosophy, Jagiellonian University<br>Grodzka 52, 31-044 Krakow, Poland

#### Abstract

Previous research showed that individual tendency to believe in conspiracy theories is related to numerous social, personality, and cognitive variables. Moreover, such a tendency may reflect a broader trait for epistemic irrationality, which drives other pseudoscientific and paranormal beliefs. However, the relationship between conspiracy belief and reasoning ability (fluid intelligence; Gf) was not sufficiently studied to date, even though Gf level strongly influence the way in which individuals think and reason. Using confirmatory factor analysis, we found the robust link between conspiracy belief and other irrational beliefs. All those irrational beliefs were also substantially related to the closeminded cognitive style. However, even though Gf significantly predicted other irrational beliefs, it explained less than $2 \%$ of variance in conspiracy belief. This result suggests that effective reasoning cannot prevent even highly intelligent people from endorsing conspiracy theories.

Keywords: rationality; intelligence; conspiracy theory; paranormal beliefs; pseudoscience;

## Introduction

Conspiracy theory is an explanation of a significant event, like the sudden death of famous person, terrorists attack, or catastrophe, as resulting from some secret plot made by a powerful organization or a group of powerful individuals. Although, in principle, such theories may be true (e.g., the Watergate scandal), usually they are insufficiently supported by facts, disregarded by experts, and based on pseudoscientific assumptions.

Importantly, the belief in conspiracy theories (henceforth, conspiracy belief) pertains not only to advocates of extreme ideologies or to paranoid and delusional individuals, but is prevalent in diverse cultures and societies (Raab, Ortlieb, Auer, Guthmann, \& Carbon, 2013). Although to date most of research on the topic was conducted in Western countries, some studies showed that conspiracy belief is a widespread phenomenon among people all over the world (e.g. Raab et.al., 2013; Goertzel, 1994; Swami et al., 2011; Bruder, Haffke, Neave, Nouripanah, \& Imhoff, 2013).

Certain people are more likely to hold conspiracy belief than others. What is important, this tendency may be a part of more general mindset, worldview or mentality (Goertzel, 1994; Dagnall, Drinkwater, Parker, Denovan, \& Parton, 2015; Imhoff \& Bruder, 2014). People who believe in one conspiracy theory are also more likely to believe in another one, even if the theories are unrelated (Swami, Chamorro-

Premuzic, \& Furnham, 2010), contradictory (Wood, Douglas, \& Sutton, 2012), or the second one is fictional and encountered for the first time (Swami et al., 2011). Such a kind of conspiratorial mentality was associated with numerous socio-psychological variables, including anomie, powerlessness, feeling of meaninglessness, distrust, authoritarianism, political cynicism, low self-esteem, and schizotypy (Goertzel, 1994; Abalakina-Paap, Stephan, Craig, \& Gregory, 1999; Swami et al., 2010; Swami et al., 2011). Moreover, conspiracy belief is closely related to other epistemically dubious beliefs, like paranormal and pseudoscientific claims and theories (Lobato, Mendoza, Sims, \& Chin, 2014). Altogether, paranormal, pseudoscientific, and conspiracy beliefs may result from one and the same irrational worldview/mindset.

The problem that we investigated was how are various instances of irrational thought, and particularly conspiracy belief, related to reasoning ability (fluid intelligence; Gf), which is defined as the ability to solve novel problems by means of abstract reasoning. As Gf strongly predicts many socio-psychological variables (see Deary, 2012), can Gf also predict individual tendency for irrational beliefs? At least intuitively, it seemed reasonable to expect that more intelligent people, because of their more powerful reasoning, would be more sceptical toward dubious, unsupported beliefs, including conspiracy theories. Besides intuition, numerous premises can be found in existing literature.

First, positive correlations between intuitive thinking style and conspiracy belief were reported. Also, experimentally induced willingness to engage in analytic reasoning reduced this belief (Swami, Voracek, Stieger, Tran, \& Furnham, 2014). Thus, a disposition for reflective thinking may help to embrace more sceptical stance towards irrational claims and theories, and may affect one's worldview even counter to cultural factors (Pennycook, Fugelsang, \& Koehler, 2015). Moreover, tendency for analytic thinking may prevent people from relying on intuitions and "gut feelings" that often lead to cognitive biases and heuristics, which may, at least to some extent, drive conspiracy belief. For example, Clarke (2002) argued that such a belief may stem from attribution bias, which consists of overestimating the influence of personal factors, and ascribing responsibility primarily to agents, instead of explaining events in terms of situational factors and coincidence. Likewise, it was argued that this belief may be related to representativeness heuristic, which leads people to seek explanations that
possess salience proportional to the very significance of events (Leman \& Cinnirella, 2007). Since major events need major explanations, people may see ordinary causes of great-impact events as unsatisfying and thus unlikely, and thus may embrace conspiracy theories instead. Finally, Brotherton and French (2014) showed the people displaying conspiratorial mentality to be more prone to conjunction fallacy, which is a reasoning error consisting of assessing the probability of two co-occurring events as being more likely than the joint probability that these events will occur alone. As the tendency for analytical thinking is at least moderately related to intelligence (Pennycook et al., 2015), a negative relationship between intelligence and conspiracy belief may also exist.

On the other hand, the relationship between intelligence and biased/irrational thinking is not straightforward. Although some biases might be attenuated by higher reasoning ability, some may not be related to intelligence at all (Stanovich \& West, 2008). High reasoning ability may not be enough to prevent people from embracing dubious theories. A research program aimed at understanding the relationship between intelligence and rationality, started by Stanovich, put emphasis on the need to distinguish between these two mental qualities. Although there can be a positive relationship between the two, what is essential for rationality may be such thinking dispositions as the willingness to think reflectively and open-mindedly. Consistently, the relationship between intelligence and irrational beliefs might be at least partially mediated by cognitive style. Although such a possible mediation so far has never been studied in the context of conspiracy theories, some supporting evidence comes from studies on paranormal and religious beliefs (Pennycook, 2014).

Finally, studies showed a moderate negative link between paranormal/pseudoscientific beliefs and intelligence (e.g., Rindermann, Falkenhayn, \& Baumeister, 2014), but the relationship between intelligence and conspiracy belief in conspiracies has not been studied sufficiently enough.

Only one study to date examined this relationship (Swami et al., 2011). First, it showed a negative, though weak, correlation between conspiracy belief and self-assessed intelligence. However, this result does not seem reliable, as this measure of intelligence had low validity. Second, the study reported weak negative correlation of conspiracy belief and crystallized intelligence (Gc) - the ability to use acquired experience and knowledge. However, Gf may be even more important for the rejection of conspiracy theories than Gc, because higher Gf levels allow more effective processing of relations among objects, events, and facts (Chuderski, 2014). Such relations can be used to create counterexamples in a reasoning process (Johnson-Laird, 2006).

## Study

The main goal of the study was to fill in the gap in existing data on the relationship between Gf and conspiracy belief. We expected reasoning ability to at least weakly predict
belief in conspiracy theories. Furthermore, we intended to replicate the results that show moderate positive correlations between different kinds of dubious beliefs: conspiracy, paranormal, as well as pseudoscientific ones (Labato et al., 2014; Brotherton \& French, 2014; Swami et al., 2011).

In order to test the strength of the conspiracy-reasoning link as well as to examine the strength of relationship between conspiracy and paranormal/pseudoscientific belief we used multiple measures of each belief, as well as we applied latent variable modelling by means of confirmatory factor analysis (CFA). Applying more than one measure of each construct. and calculating latent variables enables a more valid and reliable measurement of the constructs in question as well as the relationships between them, as compared to using single measures (see Kline, 1998).

We applied two measures of conspiracy belief to a large sample of Polish adults. Because many conspiracy theories are strongly culture-specific, one scale was created to measure belief in a particular conspiracy theory pertaining to political situation in Poland: the theory about catastrophe in Smolensk. The Smolensk conspiracy is probably the most distinctive case of conspiracy theory in the Polish society, and it is similar to conspiratorial themes that are vivid in other societies (e.g., the death of President Kennedy and Princess Diana). However, it is possible that some specific factors may play a crucial role for the Smolensk conspiracy (e.g. most of its advocates are right-wing/conservative), which might not drive other conspiracy theories, and which thus may bias the relationship between reasoning ability and conspiracy belief. To avoid such a bias, we also applied a measure of general conspiratorial beliefs and attitudes - The Generic Conspiracist Beliefs Scale (GCB) (Brotherton et al., 2014). Importantly, GCB does not concern any particular conspiracy theory, but deals with common conspiratorial themes (e.g. governments totally controling the information flow), that enables broader generalization of the results. Also, we used one questionnaire to measure paranormal beliefs, and another for pseudoscientific beliefs.

In addition, we measured open-minded cognitive style, understood as mental flexibility and openness toward the alternative views, perspectives, and counter-evidence. To do so we applied two questionnaires: NEO-openness subscale and open-minded thinking scale. Open-minded thinking was previously shown to be negatively (though rather weakly) related to conspiracy belief (Swami et al., 2014). Finally, Gf was measured with two visuospatial tests and one numerical test that involved abstract reasoning.
